The most studied monitoring device in clinical practice is the **ICP monitor**.
Monitoring is accomplished by inserting a catheter-transducer either into the cerebral ventricle or into brain parenchyma (i.e., externalized ventricular drain and parenchymal transducer, respectively). ICP-directed therapies are standard of care in traumatic brain injury (TBI) and are used in other conditions, such as intracranial hemorrhage, some cases of encephalopathy, meningitis, and encephalitis. Other devices being used include catheters that measure brain tissue oxygen concentration, external probes that noninvasively assess brain oxygenation by absorbance of near-infrared light (i.e., near-infrared spectroscopy), monitors of brain electrical activity (continuous electroencephalography [EEG] or somatosensory, visual, or auditory evoked potentials), and CBF monitors (transcranial Doppler, xenon CT, perfusion MRI, or tissue probes). In the severe TBI guidelines, brain tissue oxygen concentration monitoring received level III support and thus may be considered.

**Traumatic Brain Injury**

**Etiology and Epidemiology**

Mechanisms of TBI include motor vehicle crashes, falls, assaults, and abusive head trauma. Most TBIs in children are from closed-head injuries (Fig. 85.4). TBI is an important pediatric public health problem, with approximately 37,000 cases resulting in the death of >7,000 children annually in the United States.
Pathology

Epidural, subdural, and parenchymal intracranial hemorrhages can result. Injury to gray or white matter is also commonly seen and includes focal cerebral contusions, diffuse cerebral swelling, axonal injury, and injury to the cerebellum or brainstem. Patients with severe TBI often have multiple findings; diffuse and potentially delayed cerebral swelling is common.

Pathogenesis

TBI results in primary and secondary injury. Primary injury from the impact produces irreversible tissue disruption. In contrast, 2 types of secondary injury are targets of neurointensive care. First, some of the ultimate damage seen in the injured brain evolves over hours or days, and the underlying mechanisms involved (e.g., edema, apoptosis, secondary axotomy) are therapeutic targets. Second, the injured brain is vulnerable to additional insults because injury disrupts normal autoregulatory defense mechanisms; disruption of autoregulation of CBF can lead to ischemia from hypotension that would otherwise be tolerated by the uninjured brain.

Clinical Manifestations

The hallmark of severe TBI is coma (GCS score 3-8). Often, coma is seen immediately after the injury and is sustained. In some cases, such as with an epidural hematoma, a child may be alert on presentation but may deteriorate after a period of hours. A similar picture can be seen in children with diffuse swelling, in whom a “talk-and-die” scenario has been described. Clinicians
should also not be lulled into underappreciating the potential for deterioration of a child with **moderate TBI (GCS score 9-12)** with a significant contusion, because progressive swelling can potentially lead to devastating complications. In the comatose child with severe TBI, the second key clinical manifestation is the development of *intracranial hypertension*. The development of increased ICP with impending herniation may be heralded by new-onset or worsening headache, depressed level of consciousness, vital sign changes (hypertension, bradycardia, irregular respirations), and signs of 6th (lateral rectus palsy) or 3rd (anisocoria [dilated pupil], ptosis, down-and-out position of globe as a result of rectus muscle palsies) cranial nerve compression. Increased ICP is managed with continuous ICP monitoring, as well as monitoring for clinical signs of increased ICP or impending herniation. The development of brain swelling is progressive. Significantly raised ICP (>20 mm Hg) can occur early after severe TBI, but peak ICP generally is seen at 48-72 hr. Need for ICP-directed therapy may persist for longer than a week. A few children have coma without increased ICP, resulting from axonal injury or brainstem injury. *In addition to head trauma, it is critical to identify potential cervical spine injury* (see Chapter 83).

**Laboratory Findings**

Cranial CT should be obtained immediately after resuscitation and cardiopulmonary stabilization (Figs. 85.5 to 85.11). In some cases, MRI can be diagnostic (Fig. 85.12). Generally, other laboratory findings are normal in isolated TBI, although occasionally coagulopathy or the development of the syndrome of inappropriate antidiuretic hormone (SIADH) secretion or, rarely, cerebral salt wasting (CSW) is seen. In the setting of TBI with polytrauma, other injuries can result in laboratory and radiographic abnormalities, and a **full trauma survey** is important in all patients with severe TBI (see Chapter 82).
FIG. 85.5  Skull fracture. Mildly displaced skull fracture seen on CT imaging (bone window view) in a 4 yr old child who fell and hit her head on a curb.
FIG. 85.6 Epidural hematoma. Left frontal epidural hematoma observed on CT imaging in a 12 yr old child who fell off his bike onto concrete surface.
FIG. 85.7 Subdural hematoma. Left subdural hematoma observed on CT imaging in a 10 yr old child after motor vehicle crash. Note effacement of the left lateral ventricle and midline shift (see dotted line for midline reference).

FIG. 85.8 Subdural hematoma. Hyperacute right frontal subdural hematoma observed on CT imaging in a 5 yr old child after motor vehicle crash. Note that the hyperacute aspect of the subdural hematoma is dark on CT imaging in the early stage after injury. Also, there is marked midline shift of intracranial contents, with both lateral ventricles displaced into the left side of the skull (dotted line for midline reference).
FIG. 85.9  Subdural hematoma. A, in a 3 mo old child who suffered from abusive head trauma, initial CT imaging demonstrates chronic subdural hematoma bilaterally. B, Three days after hospitalization, the subdural hematomas are slightly larger, but infarctions are noted in the posterior areas of brain parenchyma (arrows ).
FIG. 85.10 Hemorrhage and edema. In a 16 yr old child who fell from his dirt bike, CT imaging demonstrates intraparenchymal hemorrhage and significant surrounding edema (arrow).
An 11 yr old child was hit in the head by a horse, and CT imaging demonstrates multiple, comminuted skull fractures with fragments of bone within the brain parenchyma, multifocal areas of intraparenchymal hemorrhage, and obliteration of the left lateral ventricle.
Diagnosis and Differential Diagnosis

In severe TBI the diagnosis is generally obvious from the history and clinical presentation. Occasionally, TBI severity can be overestimated because of concurrent alcohol or drug intoxication. The diagnosis of TBI can be problematic in cases of abusive head trauma or following an anoxic event such as drowning or smoke inhalation.

Treatment

Infants and children with severe or moderate TBI (GCS score 3-8 or 9-12, respectively) receive intensive care unit (ICU) monitoring. Evidence-based guidelines for management of severe TBI have been published (Fig. 85.13). This approach to ICP-directed therapy is also reasonable for other conditions in which ICP is monitored. Care involves a multidisciplinary team comprising pediatric caregivers from neurologic surgery, critical care medicine, surgery, and rehabilitation and is directed at preventing secondary insults and managing increased ICP. Initial stabilization of infants and children with severe TBI
includes rapid sequence tracheal intubation with spine precautions along with maintenance of normal extracerebral hemodynamics, including blood gas values (Pao₂, Paco₂), MAP, and temperature. Intravenous (IV) fluid boluses may be required to treat hypotension. Euvolemia is the target, and hypotonic fluids must be rigorously avoided; *normal saline is the fluid of choice*. Vasopressors may be needed as guided by monitoring of central venous pressure, with avoidance of both fluid overload and exacerbation of brain edema. A trauma survey should be performed. Once stabilized, the patient should be taken for CT scanning to rule out the need for emergency neurosurgical intervention. If surgery is not required, an ICP monitor should be inserted to guide the treatment of intracranial hypertension.

During stabilization or at any time during the treatment course, patients can present with signs and symptoms of cerebral herniation (pupillary dilation,
systemic hypertension, bradycardia, extensor posturing). Because herniation and its devastating consequences can sometimes be reversed if promptly addressed, it should be treated as a medical emergency, with use of hyperventilation, with a fraction of inspired oxygen of 1.0, and intubating doses of either thiopental or pentobarbital and either mannitol (0.25-1.0 g/kg IV) or hypertonic saline (3% solution, 5-10 mL/kg IV).

Intracranial pressure should be maintained at <20 mm Hg. Age-dependent cerebral perfusion pressure targets are approximately 50 mm Hg for children 2-6 yr old; 55 mm Hg for those 7-10 yr old; and 65 mm Hg for those 11-16 yr old. First-tier therapy includes elevation of the head of the bed, ensuring midline positioning of the head, controlled mechanical ventilation, and analgesia and sedation (i.e., narcotics and benzodiazepines). If neuromuscular blockade is needed, it may be desirable to monitor EEG continuously because status epilepticus can occur; this complication will not be recognized in a paralyzed patient and is associated with increased ICP and unfavorable outcome. If a ventricular rather than parenchymal catheter is used to monitor ICP, therapeutic CSF drainage is available and can be provided either continuously (often targeting an ICP >5 mm Hg) or intermittently in response to ICP spikes, generally >20 mm Hg. Other first-tier therapies include the osmolar agents hypertonic saline (often given as a continuous infusion of 3% saline at 0.1-1.0 mL/kg/hr) and mannitol (0.25-1.0 g/kg IV over 20 min), given in response to ICP spikes >20 mm Hg or with a fixed (every 4-6 hr) dosing interval. Use of hypertonic saline is more common and has stronger literature support than mannitol, although both are used; these 2 agents can be used concurrently. It is recommended to avoid serum osmolality >320 mOsm/L. A Foley urinary catheter should be placed to monitor urine output.

If increased ICP remains refractory to treatment, careful reassessment of the patient is needed to rule out unrecognized hypercarbia, hypoxemia, fever, hypotension, hypoglycemia, pain, and seizures. Repeat imaging should be considered to rule out a surgical lesion. Guidelines-based second-tier therapies for refractory raised ICP are available, but evidence favoring a given second-tier therapy is limited. In some centers, surgical decompressive craniectomy is used for refractory traumatic intracranial hypertension. Others use a pentobarbital infusion, with a loading dose of 5-10 mg/kg over 30 min followed by 5 mg/kg every hour for 3 doses and then maintenance with an infusion of 1 mg/kg/hr. Careful blood pressure monitoring is required because of the possibility of drug-induced hypotension and the frequent need for support with fluids and pressors.
Mild hypothermia (32-34°C [89.6-93.2°F]) in an attempt to control refractory ICP may be induced and maintained by means of surface cooling. Hypothermia for increased ICP after traumatic brain injury remains controversial for pediatric and adult patients. Hyperthermia must be avoided and if present should be treated aggressively. Sedation and neuromuscular blockade are used to prevent shivering, and rewarming should be slow, no faster than 1°C (1.8°F) every 4-6 hr. Hypotension should be prevented during rewarming. Refractory raised ICP can also be treated with hyperventilation (Paco₂ 25-30 mm Hg). Combinations of these second-tier therapies are often required.

**Supportive Care**

Euvolemia should be maintained, and isotonic fluids are recommended throughout the ICU stay. SIADH and CSW can develop and are important to differentiate, because management of SIADH is fluid restriction and that of CSW is sodium replacement. Severe hyperglycemia (blood glucose level >200 mg/dL) should be avoided and treated. The blood glucose level should be monitored frequently. Early nutrition with enteral feedings is advocated. Corticosteroids should generally not be used unless adrenal insufficiency is documented. Tracheal suctioning can exacerbate raised ICP. Timing of the use of analgesics or sedatives around suctioning events and use of tracheal or IV lidocaine can be helpful. Seizures are common after severe acute TBI. Early posttraumatic seizures (within 1 wk) will complicate management of TBI and are often difficult to treat. Anticonvulsant prophylaxis with fosphenytoin, carbamazepine, or levetiracetam is a common treatment option. Late posttraumatic seizures (≥7 days after TBI) and, if recurrent, late posttraumatic epilepsy are not prevented by prophylactic anticonvulsants, whereas early posttraumatic seizures are prevented by initiating anticonvulsants soon after TBI. Antifibrinolytic agents (tranexamic acid) reduce hemorrhage size, as well as the development of new focal ischemic cerebral lesions, and improve survival in adults with severe TBI.

**Prognosis**

Mortality rates for children with severe TBI who reach the pediatric ICU range between 10% and 30%. Ability to control ICP is related to patient survival, and the extent of cranial and systemic injuries correlates with quality of life. Motor
and cognitive sequelae resulting from severe TBI generally benefit from rehabilitation to minimize long-term disabilities. Recovery from TBI may take months to achieve. Physical therapy, and in some centers methylphenidate or amantadine, helps with motor and behavioral recovery. Pituitary insufficiency may be an uncommon but significant complication of severe TBI.

Welch TP, Wallendorf MJ, Kharasch ED, et al. Fentanyl and
Brain death is the irreversible cessation of all functions of the entire brain, including the brainstem. It is also known as death by neurologic criteria and is legally accepted as death in the United States.

**Epidemiology**

In children, brain death usually develops after traumatic brain injury (TBI, including brain injury from nonaccidental trauma) or asphyxial injury. Pathogenesis is multifactorial, with the end result being irreversible loss of brain and brainstem function.

**Clinical Manifestations and Diagnosis**

Current guidelines do not apply to preterm infants <37 wk gestational age (Fig. 86.1).
Brain death is determined by clinical assessment. Although ancillary tests
such as electroencephalography (EEG) and cerebral blood flow (CBF) studies are sometimes used to assist in making the diagnosis, repeated clinical examination is the standard for diagnosis. The 3 components for determining brain death are demonstration of coexisting irreversible coma with a known cause, absence of brainstem reflexes, and apnea.

Before a determination of brain death may be made, it is of utmost importance that the cause of the coma be determined using the history, any radiology, and laboratory data, to rule out a reversible condition. Potentially reversible causes of coma include metabolic disorders, toxins, sedative drugs, paralytic agents, hypothermia, hypoxia, hypotension/shock, recent cardiopulmonary resuscitation (CPR), hypo-/hyperglycemia, hypo-/hypernatremia, hypercalcemia, hypermagnesemia, nonconvulsive status epilepticus, hypothyroidism, hypocortisolism, hypercarbia, liver or renal failure, sepsis, meningitis, encephalitis, subarachnoid hemorrhage, and surgically remediable brainstem lesions. Confounding factors must be corrected before initiation of brain death assessment.

Coma

The state of coma requires that the patient be unresponsive, even to noxious stimuli. Any purposeful motor response, such as localization, does not constitute coma. Likewise, any posturing (decerebrate or decorticate) is not consistent with coma, and therefore not consistent with brain death. The presence of spinal cord reflexes—even complex reflexes—does not preclude the diagnosis of brain death.

Brainstem Reflexes

Brainstem reflexes must be absent. Table 86.1 lists the brainstem reflexes to be tested, the brainstem location of each reflex, and the result of each test that is consistent with a diagnosis of brain death.

Table 86.1
Brainstem Reflex Testing to Determine Brain Death

<table>

<td>Midposition (4-6 mm) or fully dilated pupils</td>
</tr>
</tbody>
</table>
reflex | nerves (CNs) II and III, midbrain | while closely observing pupillary size. | that are not reactive to light are consistent with brain death. Pinpoint pupils, even if nonreactive, suggest intact function of the Edinger-Westphal nucleus in the midbrain and are therefore not consistent with brain death.

| Oculocephalic reflex (doll's eyes reflex) | CNs III, VI, and VIII; midbrain; pons | Manually rotate the patient's head side to side and closely watch the position of the eyes. Should not be performed in a patient with a cervical spine injury. | In the intact patient, the eyes remain fixed on a distant spot, as if maintaining eye contact with that spot. In an exam consistent with brain death, the eyes move in concert with the patient's head movement.

| Corneal reflex | CNs III, V, and VII; pons | Touch the patient's cornea with a cotton swab. | In the intact patient, the touch results in eyelid closure, and the eye may rotate upward. In an exam consistent with brain death, there is no response.

| Oculovestibular reflex | CNs III, IV, VI, and VIII; pons; midbrain | Irrigate the tympanic membrane with iced water or saline and look for eye movement. | Absence of eye movement is consistent with brain death.

| Gag and cough reflex | CNs IX and X, medulla | Touch the posterior pharynx with a tongue depressor or a cotton-tipped swab to stimulate a gag. Advance a suction catheter through the endotracheal tube to the carina to stimulate a cough. | Absence of both a cough and a gag is consistent with brain death.

---

**Apnea**

Apnea is the absence of respiratory effort in response to an adequate stimulus. An arterial partial pressure of carbon dioxide ($\text{PacO}_2$) value $\geq 60$ mm Hg and $>20$ mm Hg above baseline is a sufficient stimulus. Apnea is clinically confirmed through the apnea test. Because the apnea test has the potential to destabilize the patient, it is performed only if the 1st 2 criteria for brain death (irreversible coma and absence of brainstem reflexes) are already confirmed.

The [apnea test](#) assesses the function of the medulla in driving ventilation. It is performed by first ensuring appropriate hemodynamics and temperature (>35°C) and the absence of apnea-producing drug effects or significant metabolic derangements. The patient is then preoxygenated with 100% oxygen for approximately 10 min, and ventilation is adjusted to achieve a $\text{PacO}_2$ of approximately 40 mm Hg. A baseline arterial blood gas (ABG) result documents
the starting values. During the test, oxygenation can be maintained with 100% oxygen via a T -piece attached to the endotracheal tube or via a resuscitation bag such as a Mapleson device. Throughout the test, the child's hemodynamics and pulse oximetry oxygen-hemoglobin saturation (Spo₂) are monitored while the physician observes for respiratory efforts. An ABG sample is obtained approximately 10 min into the test and every 5 min thereafter until the target Paco₂ is surpassed; ventilatory support is resumed at that time. If at any point during the test the patient becomes hypoxic (Spo₂ <85%) or hypotensive, the test is aborted and ventilatory support resumed. Absence of respiratory efforts with a Paco₂ ≥60 mm Hg and >20 mm Hg above baseline is consistent with brain death.

**Observation Periods**

To determine brain death in the United States, the findings must remain consistent for 2 examinations performed by different attending physicians (apnea testing may be performed by the same physician) separated by an observation period. The 1st exam determines that the child has met the criteria for brain death, whereas the 2nd exam confirms brain death based on an unchanged and irreversible condition. Recommended observation periods are 24 hr for neonates from 37 wk gestation to term infants 30 days old, and 12 hr for infants and children >30 days old. An observation period of 24-48 hr before initiation of brain death assessment is recommended after CPR or severe acute brain injury.

**Ancillary Studies**

Ancillary studies are not required for the diagnosis of brain death unless the clinical examination including the apnea test cannot be safely or reliably completed. Examples include cervical spinal cord injury, presence of high therapeutic or supratherapeutic levels of sedative medications, or hemodynamic instability or Spo₂ desaturation during an apnea test. Ancillary studies may also be used to shorten the recommended observation period. In this case, 2 complete clinical examinations, including apnea test, should be carried out and documented along with the ancillary study. Ancillary studies are no substitute for the neurologic examination.
The 2 most widely used ancillary tests are EEG and radionuclide CBF studies. A valid **electroencephalogram** to support suspected brain death must be performed according to the American EEG Society standards and technical requirements, under conditions of normothermia and appropriate hemodynamics, and in the absence of drug levels sufficient to suppress the EEG response. An EEG that demonstrates **electrocerebral silence** over a 30 min recording time under these conditions supports the diagnosis of brain death. Advantages of this study are its wide availability and low risk. Disadvantages include potential confounders, such as artifact in the tracing and the presence of suppressing levels of drugs such as barbiturates.

A **radionuclide cerebral blood flow study** consists of intravenous (IV) injection of a radiopharmaceutical agent followed by imaging of the brain to look for cerebral uptake. As with EEG, nuclear medicine scans are widely available and low risk. Unlike EEG, radionuclide CBF studies are not affected by drug levels. A study that shows absence of uptake in the brain demonstrates absence of CBF and is supportive of brain death. Four-vessel intracranial contrast angiography was previously used as the definitive ancillary test, but practical technical difficulties and risks have led to the use of nuclear medicine scans instead.

Interpretation of both EEG and radionuclide CBF studies should be done by appropriately trained and qualified individuals. If the studies show electrical activity or presence of CBF, brain death cannot be declared. A 24 hr waiting period is recommended before repeating the clinical examination or ancillary study.

**Documentation**

Documentation is an important aspect of diagnosing brain death. Complete documentation should include statements of the following:

1. Etiology and irreversibility of the coma.
2. Absence of confounding factors: hypothermia, hypotension, hypoxia, significant metabolic derangement, and significant drug levels.
3. Absence of motor response to noxious stimulation.
4. Absence of brainstem reflexes: pupillary light reflex, oculocephalic/oculovestibular reflex, corneal reflex, cough reflex, and
5. Absence of respiratory effort in response to an adequate stimulus; ABG values should be documented at the start and end of the apnea test.

**Supportive Care**

Following a diagnosis of brain death, supportive care may continue for hours to days as the family makes decisions about potential organ donation and comes to terms with the diagnosis. A diagnosis of brain death may not be accepted by the family for personal, religious, or cultural reasons. It is important for care providers to be patient and supportive of the family dealing with this difficult situation.

**Objections to the Idea of Brain Death**

Although the concept of brain death is widely accepted and very useful in facilitating organ transplantation, it is not accepted by all. Several countries do not recognize brain death, and some individuals, both medical personnel and laypeople, object to the idea of brain death.

It has been pointed out that some patients who meet brain death criteria continue to show evidence of integrative functioning, such as control over free-water homeostasis (absence of diabetes insipidus), control of temperature regulation, capacity for growth and wound healing, and variability of heart rate and blood pressure in response to stimulus. Along with scientific arguments, there are also philosophical arguments about what constitutes death and whether a person who lacks function of the brain, but not of the body, is truly dead.

**Bibliography**

2011;128:e720–e740.
Syncope is defined as a sudden transient loss of consciousness with inability to maintain postural tone. The most common cause of syncope in the normal pediatric population is neurocardiogenic syncope (vasovagal syncope, fainting). Vasovagal syncope is classically associated with a prodrome that includes diaphoresis, warmth, pallor, or feeling lightheaded and is often triggered by a specific event or situation such as pain, medical procedures, or emotional distress (Table 87.1). This type of syncope is characterized by hypotension and bradycardia. Approximately 30–50% of children will have had a fainting episode before 18 yr of age.

Most patients with a vasovagal syncope episode will have prodromal features followed by loss of motor tone. Once in a horizontal position, consciousness returns rapidly, in 1-2 min; some patients may have 30 sec of tonic-clonic motor activities, which should not be confused with a seizure (Table 87.2). Syncope must also be distinguished from vertigo and ataxia (Table 87.3).

</table>

Although this type of syncope is very common in adolescence and has an excellent prognosis, other causes for loss of consciousness are more dangerous; thus syncope may be the first sign of more serious conditions (Table 87.4 ). Indeed, the occurrence of syncope may well be the pediatrician’s best opportunity to diagnose a life-threatening condition before the patient subsequently succumbs. The task of the clinician, therefore, is not only to counsel the family and the patient concerning the common form, but also to rule out a number of important life-threatening cardiac problems.

#### Table 87.4

**Life-Threatening Cardiac Causes as Risk With Syncope**

- Long QT syndromes (congenital and drug induced)
- Short QT syndromes
- Cardiomyopathies
  - Hypertrophic cardiomyopathy
  - Dilated cardiomyopathy
  - Arrhythmogenic right ventricular dysplasia
- Brugada syndrome
Catecholaminergic polymorphic ventricular tachycardia
Myocarditis
Lyme myocarditis
Chagas disease
Wolff-Parkinson-White syndrome
Coronary artery anomalies
Late postoperative arrhythmias
Adult congenital heart patients
Congenital or acquired complete atrioventricular block
Aortic, mitral, or pulmonic valve stenosis
Primary pulmonary hypertension
Eisenmenger syndrome
Dissecting aortic aneurysm (Marfan syndrome)
Cardiac tumor
Pacemaker malfunction
Takotsubo cardiomyopathy

**Mechanisms**

Syncope by whatever mechanism is caused by a lack of adequate cerebral blood flow with loss of consciousness and inability to remain upright.

Primary **cardiac causes** of syncope (Table 87.4) include arrhythmias such as long QT syndrome (LQTS), Wolff-Parkinson-White syndrome (particularly with atrial fibrillation), ventricular tachycardia (VT), and occasionally supraventricular tachycardia (see Chapter 462). VT may be associated with hypertrophic cardiomyopathy (HCM), arrhythmogenic cardiomyopathy, repaired congenital heart disease, or a genetic cause such as catecholaminergic polymorphous ventricular tachycardia (CPVT). Other arrhythmias that may lead to syncope are bradyarrhythmias such as sinus node dysfunction and high-grade second- or third-degree atrioventricular (AV) block. Patients with congenital complete AV block may present with syncope. Syncope may also be caused by cardiac obstructive lesions, such as critical aortic stenosis, or coronary artery anomalies, such as an aberrant left coronary artery arising from the right sinus of Valsalva. Patients with primary pulmonary hypertension or Eisenmenger syndrome may experience syncope. In all the obstructive forms of syncope, exercise increases the likelihood of an episode because the obstruction interferes with the ability of the heart to increased cardiac output in response to exercise.
Noncardiac causes of loss of consciousness include epilepsy, as well as basilar artery migraine, hysterical syncope, and pseudoseizures (see Table 87.1). Occasionally, patients with narcolepsy may present with syncope. Hypoglycemia and hyperventilation may also present as syncope.

**Evaluation**

The most important goal in the evaluation of the new patient with syncope is to diagnose life-threatening causes of syncope so that these causes can be managed. Many patients presenting with sudden cardiac arrest caused by conditions such as LQTS will have previously experienced an episode of syncope, so the presentation with syncope is an opportunity to prevent sudden death.

The most important tool in evaluation is a careful **history**. The characteristics of cardiac syncope differ significantly from the prodrome seen in neurocardiogenic syncope (Table 87.5). Several red flags can be identified that should lead the clinician to suspect that the mechanism is a life-threatening cardiac cause rather than simple fainting (Table 87.6). The occurrence during exercise suggests an arrhythmia or coronary obstruction. Injury because of an episode of syncope indicates sudden occurrence with a lack of adequate prodromal symptoms and suggests an arrhythmia. The occurrence of syncope while recumbent would be quite unusual in a patient with neurocardiogenic syncope and therefore suggests a cardiac or neurologic cause. Occasionally, a patient with syncope caused by a tachyarrhythmia will report the sensation of a racing heart before the event, but this is unusual.

### Table 87.6

**Red Flags in Evaluation of Patients With Syncope**

- Syncope with activity or exercise or supine
- Syncope not associated with prolonged standing
- Syncope precipitated by loud noise or extreme emotion
- Absence of presyncope or lightheadedness
- Family history of syncope, drowning, sudden death, familial ventricular arrhythmia syndromes,* cardiomypathy
- Syncope requiring CPR
- Injury with syncope
- Anemia
- Other cardiac symptoms
- Chest pain
- Dyspnea
- Palpitations
- History of cardiac surgery
- History of Kawasaki disease
- Implanted pacemaker
- Abnormal physical examination
  - Murmur
  - Gallop rhythm
  - Loud and single second heart sound
  - Systolic click

*cardiomyopathy
Increased apical impulse (tachycardia)  
Irregular rhythm  
Hypo- or hypertension  
Clubbing  
Cyanosis

* Long QT syndrome, Brugada syndrome, catecholamine polymorphic ventricular tachycardia, arrhythmogenic right ventricular dysplasia.

A careful family history is essential in evaluation of syncope. Specifically, if there are first-degree relatives with inherited syndromes, such as a LQTS or HCM, this should lead to more specific evaluation of the patient. Also, if relatives died suddenly at a young age without a clear and convincing cause, inherited cardiac arrhythmias or cardiomyopathies should also be suspected.

Patients with a history of heart disease, especially cardiac repair, may have causes that are specific to their repair. Sinus node dysfunction is common after the Senning or Mustard procedure for transposition of the great vessels. VT may be seen after repair of tetralogy of Fallot. A patient with a history of septal defect repair should be evaluated for the late occurrence of AV block, and patients with an implanted pacemaker should be evaluated for pacemaker lead failure.

The physical examination may also offer clues (Table 87.6). Patients with HCM may have a prominent cardiac impulse and/or an ejection murmur, as will patients with aortic stenosis. The patient with primary pulmonary hypertension will have a loud and single second heart sound and may also have an ejection click and the murmur of pulmonary insufficiency. Scars from prior cardiac surgery and pacemaker implantation would be evident.

All patients presenting with a first episode of syncope must have an electrocardiogram obtained, looking primarily for QT interval prolongation, preexcitation, ventricular hypertrophy, T-wave abnormalities, and conduction abnormalities. Other tests that may be needed depending on the results of the initial evaluation may include echocardiography, exercise testing, cardiac MRI, or 24 hr Holter monitoring. In patients for whom there is a strong suspicion of a paroxysmal arrhythmia, an implantable loop recorder may be the most effective means of diagnosis. Additional tests to look for anemia, hypoglycemia, drugs of abuse, and other etiologies noted in Table 87.1 will be determined by the history
and physical examination.

**Treatment**

Therapy for vasovagal syncope includes avoiding triggering events (if possible), fluid and salt supplementation, and if needed, midodrine (see Chapter 87.1, Table 87.7). Immediately after the event, the patient should remain supine until symptoms abate to avoid recurrence.

**Table 87.7**

First-Line Medications in Treatment of Postural Tachycardia Syndrome (POTS)

<table>
<thead>
<tr>
<th>DRUG</th>
<th>MECHANISM OF ACTION</th>
<th>SIDE EFFECTS</th>
<th>TREATMENT GUIDELINES</th>
</tr>
</thead>
</table>
| Fludrocortisone | Low dose: sensitizes α receptors  
Higher doses: mineralocorticoid effect | Peripheral edema, headache, irritability, hypokalemia, hypomagnesemia, acne | Monitor basic metabolic panel and magnesium.                                          |
| Midodrine       | α1-Agonist; produces vasoconstriction                                               | Scalp tingling, urinary retention, goose bumps, headache, supine hypertension | Monitor supine blood pressure 30-60 min after dose.                                  |
| Metoprolol      | β-Blocker                                                                            | Worsening of asthma, dizziness, fatigue                                        | Use with caution in asthma. If fatigue is severe, use at bedtime.                    |
| Propranolol     | Nonselective β-blocker                                                               | Bradycardia, gastrointestinal symptoms, lightheadedness, sleepiness, hypotension, syncope | Use with caution in diabetes and asthma.                                             |
| Pyridostigmine  | Peripheral acetylcholinesterase inhibitor that increases synaptic acetylcholine in autonomic ganglia and at peripheral muscarinic receptors | Symptoms of excessive cholinergic activity (diarrhea, urinary incontinence, salivation) | Very useful if patient has POTS and constipation. Use with caution in asthma. Contraindicated in urinary or bowel obstruction. |

Treatment for cardiac causes of syncope will be determined by the diagnosis. If a reentrant tachycardia (AVNRT, AVRT) is found, then a catheter ablation is
indicated. If bradycardia from AV block was the cause of the syncope, a pacemaker may be warranted. Patients with syncope from medically refractory malignant arrhythmias, as may be seen in HCM, LQTS, arrhythmogenic cardiomyopathy, or CPVT, require an implantable cardioverter-defibrillator. Patients with structural heart disease (valvular disease or coronary artery anomalies) should be referred for surgery.

87.1
Postural Tachycardia Syndrome

Gisela G. Chelimsky, Thomas C. Chelimsky

Keywords

orthostatic hypotension
POTS
reflex syncope

Several complex and interrelated mechanisms allow humans to stand despite the pull of gravity on the cerebral circulation. In the supine posture, most blood sits in the thoracic cavity, with 25–30% of total volume in the splanchnic vasculature. When an adult stands up, about 500 mL of blood shifts to the lower extremities and to the splanchnic vasculature. The decrease in hydrostatic pressure in the carotid sinuses produces vasoconstriction in the peripheral vessels mediated by sympathetic outflow, as well as in the splanchnic vasculature. This action is mediated by norepinephrine, adenosine triphosphate (ATP), and neuropeptide Y. The muscles in the legs and gluteal area work as a pump when the individual is upright and during exercise, to help return the blood to the heart.

Understanding postural tachycardia syndrome (POTS), or postural orthostatic tachycardia syndrome, requires an understanding of other orthostatic conditions.
Many adolescents have lightheadedness or tunnel vision in the first few seconds of assuming the upright posture. This phenomenon, termed initial orthostatic hypotension (IOH), can lead to syncope, but usually is very short, perhaps 30-60 sec, and occurs primarily with active standing, not passive upright tilt. Blood pressure (BP) may drop 30% of baseline at 10-20 sec of standing and may be associated with tachycardia. BP returns to baseline in 30-60 sec, whereas heart rate (HR) typically returns to a new, higher value above the baseline when supine. Because of its transient rapidity, IOH escapes detection with standard BP machines and requires beat-to-beat monitoring of BP and HR. The clinical diagnosis requires a careful history. The symptoms usually happen after prolonged recumbence and when the individual stands. The person complains of lightheadedness and “blackening out” or tunnel vision 5-10 sec after standing.

In contrast to IOH, orthostatic hypotension (OH) is defined as a sustained decrease in the systolic BP of >20 mm Hg or diastolic BP >10 mm Hg in the 1st 3 min of upright tilt. This 2nd type of orthostatic disorder rarely occurs in children. The patient frequently has no orthostatic symptoms while upright despite very low pressures (Fig. 87.1 ). This distinguishes OH from POTS, which requires symptoms while upright. A 3rd orthostatic disorder, reflex syncope (i.e., vasovagal or neurally mediated), is defined as relatively sudden change in autonomic nervous system activity that leads to a sudden decrease in BP, HR, and cerebral perfusion (Fig. 87.2 ).
FIG. 87.1  Example of orthostatic hypotension.
In children, POTS is defined as a syndrome characterized by HR increase of >40 beats/min during the 1st 10 min of upright tilt test without associated hypotension, (>30 beats/min if >19 yr old) while replicating orthostatic symptoms that occur when upright (Fig. 87.3 ). Improvement of symptoms in the supine position is expected. The diagnosis of POTS also requires daily orthostatic symptoms. In patients with POTS, the larger decline in cardiac stroke volume appears to be the primary trigger for the tachycardia, which may result from various pathophysiologic mechanisms, such as the following:
Neuropathic POTS, an autonomic neuropathy impairing sympathetic venoconstriction in the lower extremities or splanchnic circulation, decreasing stroke volume, and consequently resulting in a tachycardia.

Hypovolemic POTS, a common contributor, often related to decreased aldosterone with reduced renin activity, resulting in a tachycardia caused by decrease blood volume.

Hyperadrenergic POTS, with norepinephrine levels rising 3-4-fold in the standing position (norepinephrine normally doubles on standing), which
may occur in norepinephrine transporter deficiency or strong stimulation of central baroreflex responses

◆ *Autoimmune* POTS, typically assumed based on a postviral chronology, but seldom proven; such a form may or may not exist. The antiganglionic antibody is almost never elevated in these patients. Nonetheless, a group of patients report that intravenous immune globulin (IVIG) is helpful to them. Whether they benefit from the increase in intravascular volume or an actual immune effect is unknown.

Some patients have orthostatic symptoms while upright but do not meet criteria for syncope, OH, or POTS. This group has *orthostatic intolerance otherwise not specified* (OI-NOS).

**Clinical Presentation**

The symptoms that intrinsically relate to POTS are those that are replicated during upright tilt testing or standing. Many other symptoms also occur in patients with POTS, fitting the description of comorbid conditions, but not reproduced while upright. A patient may have nausea while upright associated with lightheadedness and has a diagnosis of POTS. Another patient may complain of nausea on awakening and have POTS, but has no nausea while upright. In the former patient the nausea is a symptom of POTS itself, whereas in the latter nausea is an associated condition. The symptoms that often directly relate to POTS include lightheadedness, orthostatic nausea, sometimes orthostatic headaches, fatigue, tunnel vision, and brain fog. About 20–30% of pediatric patients with POTS will also have syncope ([Fig. 87.4](#)). Other comorbid conditions frequently occur in these patients but are not caused by POTS (i.e., not an orthostatic phenomenon). These comorbidities include (1) sleep issues, usually delayed onset of sleep, frequent awakening, and not feeling refreshed in the morning; (2) aches in different parts of the body; (3) abdominal pain; (4) headaches and migraines; (5) nausea and vomiting; and (6) Raynaud
like symptoms and other, less frequent problems (e.g., urinary symptoms).

![Graph](image)

**FIG. 87.4** Example of postural tachycardia syndrome (POTS) followed by a neurally mediated syncope.

The association of upper gastrointestinal (GI) symptoms and POTS are well described. Nausea, early satiety, and bloating are described in association with POTS. Such GI symptoms relate mechanistically to POTS only when they occur in the upright position. Many patients with POTS have comorbid GI symptom that are not a consequence of the orthostatic challenge. Therefore, only the GI symptoms replicated during tilt testing will improve with treatment aimed at orthostasis. Patients with POTS have changes in the electrical activity of the stomach while upright, which may explain the upright GI symptoms; they usually do not have delayed gastric emptying. The emptying is either normal or accelerated, implying that the cause of nausea is not gastroparesis.

Patients with hypermobility Ehlers-Danlos syndrome (h-EDS) may have POTS. Typically, such individuals have more migraine and syncope. Joint hypermobility itself in **adults** is associated with more autonomic complaints such as syncope, presyncope, palpitations, chest discomfort, fatigue, and heat
intolerance. Those with hypermobility have more frequent positive tilt tests than healthy controls. Interestingly, in children, joint hypermobility does not influence the number of comorbidities or autonomic disorders. Similarly, those with pediatric chronic overlapping pain conditions with or without POTS have the same comorbidities, suggesting that neither POTS nor hypermobility are drivers of the comorbidities or the chronic overlapping pain condition, but rather another associated disorder (Chapter 147).

**Diagnosis**

*Orthostatic intolerance* is clinically diagnosed by detailed history attending specifically to symptoms as they relate to body position. Dizziness that begins in the supine position cannot be a manifestation of orthostatic intolerance. Furthermore, those symptoms that do develop while upright should improve or resolve when supine. Importantly, the history should include a detailed description of current physical exercise habits, with frequency, type, and endurance. One should also assess sleep, diet (mainly evaluating intake of salt), fluid intake, and other comorbidities. The physical examination is also important and should include a cardiac and neurologic evaluation with supine and standing BP and HR. Examination of the extremities may provide information about venous pooling, such as mild edema or reddish purple discoloration when sitting or standing. Cold, clammy hands can signify excess sympathetic activity.

To diagnose POTS the patient needs to undergo a **head-up tilt test for at least 10 min**. It is important to have the patient supine for at least 20 min before the tilt test. POTS can also be assessed by a standing test, measuring BP and HR at 1, 3, 5, and 10 min standing, but to have a reliable test similar to the tilt test, the patient needs to be supine for 1 hr before standing. The HR increase with active standing is typically less than with tilt, because the lower-extremity muscle pump is less active in tilt. The diagnosis of POTS requires replication of the day-to-day symptoms while upright, not just the increased HR while upright. A small but significant proportion of healthy teenagers in school will have an increased HR that may be diagnosed as POTS but will not have associated symptoms.

Other tests may include electrocardiogram, echocardiogram, and Holter monitor when there is concern of a primary cardiac cause of tachycardia, or if there is a need to determine if symptoms correlate with tachycardia (see Chapter 87). Supine and standing plasma catecholamines help confirm the diagnosis of POTS, as one expects to see either the normal doubling of norepinephrine levels
from supine to standing, or a tripling with hyperadrenergic POTS. Beyond tilt table testing, autonomic testing will also include cardiac response to deep breathing (checking cardiac parasympathetic function), Valsalva maneuver (checking cardiac sympathetic and parasympathetic functions and vasomotor sympathetic function), and quantitative axon reflex sudomotor test (to assess for an autonomic neuropathy and vasomotor sympathetic dysfunction).

Additional studies depend on the clinical symptoms and include morning cortisol (to rule out Addison disease) and hypo- or hyperthyroid studies if the patient has unusually severe fatigue or is not responsive to usual treatment. Serum tryptase and urine methylhistamine are tested if mast cell activation disorder is suspected, based on a history of flushing during the spells. If an autoimmune cause for the POTS is a concern, antibodies such as voltage-gated potassium channel and acetylcholine receptor antibodies could be checked, but this etiology for POTS is being questioned. Patients rarely (<5 in 1000) benefit from IVIG; if this mechanism is really causing POTS, such patients will experience peak benefit at about 10 days after the infusion, rather than immediately, which may simply reflect increasing intravascular volume. If the patient has hypertension, plasma and urine metanephrines should be measured to test for a pheochromocytoma. In addition, if symptoms are associated with perimenstrual timing, an assessment of sex hormone axis is helpful, with occult polycystic ovarian syndrome or low testosterone levels sometimes present.

Management

The core of POTS management is nonpharmacologic. Medications will be of little benefit without these measures being undertaken first. The best measure for treating POTS is a regular aerobic exercise program. Given the combination of orthostatic symptoms and severe deconditioning found in most patients, the exercise program must be introduced in a slow, progressive manner. Patients with POTS typically have moderate to severe exercise intolerance, and compared with sedentary healthy controls, have decreased peak oxygen uptake. After 3 mo of exercise, POTS patients have an increase in cardiac mass and size, blood volume, and peak oxygen uptake, as reflected in a better exercise performance. The tachycardia in POTS is caused by a decrease in stroke volume and not an intrinsic circulatory problem. An exercise program should start with water exercises combined with recumbent aerobic activities (recumbent bike or rowing machine). Slowly increase the exercise time to 45 min at least 5 times
per week. When tolerance increases, patients can advance to more upright aerobic activities. These aerobic activities need to be combined with light core- and limb-strengthening exercises.

Exercise usually cannot be performed without simultaneous expansion of the intravascular volume. To this end, encourage teenagers to drink >80 oz of fluids daily and to add 2 g of salt to usual diet in both the morning and the early afternoon. **Salt supplementation** increases plasma and blood volume, improves orthostatic tolerance, and decreases baroreflex sensitivity. Salt also reduces nitric oxide production, resulting in less vasodilation. Trial and error of different salt formulation can help to identify the best method for each individual patient. Salt tablets are simple and inexpensive but may make some people nauseous. An alternative is simply to obtain empty capsules on the internet and fill them with table salt. A “0” size capsule contains about 400 mg of salt.

The content of sodium in the body determines the extracellular fluid volume that in turn dictates orthostatic tolerance. Patients with POTS who have lower urinary sodium excretion have more symptoms than those with higher urinary sodium (> 123 mmol/24 hr), and they often respond less well to salt supplementation. Those with severe orthostatic symptoms either in the morning or before sports should drink 16 oz of plain water, which is known to increase sympathetic response mainly in individuals with baroreflex dysregulation. The effect starts soon after drinking the water and lasts for about 1 hr. Compression garments may also be useful. These can be thigh or waist high; the waist-high compression garments may not be tolerated.

**Medications** can be added when the nonpharmacologic interventions are not insufficient (). Different centers use different strategies, and there is no single correct evidence-based approach. Table 87.3 addresses first-line medications that primary care physicians could use; only the most common side effects are included.

**Bibliography**

Shock is an acute process characterized by the body's inability to deliver adequate oxygen to meet the metabolic demands of vital organs and tissues. Insufficient oxygen at the tissue level is unable to support normal aerobic cellular metabolism, resulting in a shift to less efficient anaerobic metabolism. As shock progresses, increases in tissue oxygen extraction are unable to compensate for this deficiency in oxygen delivery, leading to progressive clinical deterioration and lactic acidosis. If inadequate tissue perfusion persists, adverse vascular, inflammatory, metabolic, cellular, endocrine, and systemic responses worsen physiologic instability.

Compensation for inadequate oxygen delivery involves a complex set of responses that attempt to preserve oxygenation of the vital organs (i.e., brain, heart, kidneys, liver) at the expense of other organs (i.e., skin, gastrointestinal tract, muscles). Of importance, the brain is especially sensitive to periods of poor oxygen supply given its lack of capacity for anaerobic metabolism. Initially, shock is often well compensated, but it may rapidly progress to an uncompensated state requiring more aggressive therapies to achieve clinical recovery. The combination of a continued presence of an inciting trigger and the body's exaggerated and potentially harmful neurohumoral, inflammatory, and cellular responses lead to the progression of shock. Irrespective of the underlying cause of shock, the specific pattern of response, pathophysiology, clinical manifestations, and treatment may vary significantly depending on the specific etiology (which may be unknown), the clinical circumstances, and an individual patient's biologic response to the shock state. Untreated shock causes irreversible tissue and organ injury (i.e., irreversible shock) and, ultimately, death.
Epidemiology

Shock occurs in approximately 2% of all hospitalized infants, children, and adults in developed countries, and the mortality rate varies substantially depending on the etiology and clinical circumstances. Of patients who do not survive, most do not die in the acute hypotensive phase of shock, but rather as a result of associated complications and multiple-organ dysfunction syndrome (MODS). MODS is defined as any alteration of organ function that requires medical support for maintenance, and the presence of MODS in patients with shock substantially increases the probability of death. In pediatrics, educational efforts and the utilization of standardized management guidelines that emphasize early recognition and intervention along with the rapid transfer of critically ill patients to a pediatric intensive care unit (PICU) have led to decreases in the mortality rate for shock (Figs. 88.1 and 88.2).
FIG. 88.1  American College of Critical Care Medicine algorithm for time-sensitive, goal-directed stepwise management of hemodynamic support in newborns. Proceed to next step if shock persists. (1) First-hour goals—restore and maintain heart rate thresholds, capillary refill ≤ 2 sec, and normal blood pressure in the 1st hr. (2) Subsequent ICU goals—restore normal perfusion pressure (mean arterial pressure – central venous pressure), preductal and postductal oxygen saturation difference < 5%, and either ScvO₂ > 70% (*except congenital heart patients with mixing lesions), superior vena cava flow > 40 mL/kg/min, or cardiac index > 3.3 L/min/m² in NICU. (From Davis AL, Carcillo JA, Aneja RK, et al: American College of Critical Care Medicine clinical practice parameters for hemodynamic support of pediatric and neonatal septic shock, Crit Care Med 45:1061–1093, 2017, Fig 4.)
**Types of Shock**

Shock classification systems generally define 5 major types of shock:

1. **Hypovolemic Shock**
   - Typically due to blood loss or fluid depletion.
   - Characterized by decreased cardiac output and systemic perfusion.

2. **Cardiogenic Shock**
   - Caused by cardiac dysfunction or failure.
   - May result from myocardial infarction,心肌梗死, or severe valvular disease.

3. **Septic Shock**
   - Associated with severe infection and inflammation.
   - Leads to systemic hyperperfusion and organ dysfunction.

4. **Hypotensive Shock**
   - Refers to a condition where the arterial blood pressure is lower than normal.
   - May be due to various causes including sepsis, anaphylaxis, and trauma.

5. **Neurogenic Shock**
   - Occurs with central nervous system dysfunction.
   - Can be seen in conditions such as spinal cord injury or shock caused by neurologic events.

These types of shock are further classified based on their specific causes and clinical manifestations. Each type requires specific diagnostic and therapeutic approaches to manage effectively.
hypovolemic, cardiogenic, distributive, obstructive, and septic (Table 88.1).

**Hypovolemic shock**, the most common cause of shock in children worldwide, is most frequently caused by diarrhea, vomiting, or hemorrhage. **Cardiogenic shock** is seen in patients with congenital heart disease (before or after surgery, including heart transplantation) or those with congenital or acquired cardiomyopathies, including acute myocarditis. **Obstructive shock** stems from any lesion that creates a mechanical barrier that impedes adequate cardiac output, which includes pericardial tamponade, tension pneumothorax, pulmonary embolism, and ductus-dependent congenital heart lesions. **Distributive shock** is caused by inadequate vasomotor tone, which leads to capillary leak and maldistribution of fluid into the interstitium. **Septic shock** is often discussed synonymously with distributive shock, but the septic process usually involves a more complex interaction of distributive, hypovolemic, and cardiogenic shock.

**Table 88.1**
Types of Shock

**Pathophysiology**
An initial insult triggers shock, leading to inadequate oxygen delivery to organs and tissues. Compensatory mechanisms attempt to maintain blood pressure (BP) by increasing cardiac output and systemic vascular resistance (SVR). The body also attempts to optimize oxygen delivery to the tissues by increasing oxygen extraction and redistributing blood flow to the brain, heart, and kidneys at the expense of the skin and gastrointestinal (GI) tract. These responses lead to an initial state of **compensated shock** in which BP is maintained. If treatment is not initiated or is inadequate during this period, **decompensated shock** develops, with hypotension and tissue damage that may lead to **multisystem organ dysfunction** and, ultimately, death (Tables 88.2 and 88.3).

In the early phases of shock, multiple compensatory physiologic mechanisms act to maintain BP and preserve tissue perfusion and oxygen delivery. Cardiovascular effects include increases in heart rate (HR), stroke volume, and vascular smooth muscle tone, which are regulated through sympathetic nervous system activation and neurohormonal responses. Respiratory compensation involves greater carbon dioxide (CO₂) elimination in response to the metabolic acidosis and increased CO₂ production from poor tissue perfusion. Renal excretion of hydrogen ions (H⁺) and retention of bicarbonate (HCO₃⁻) also increase in an effort to maintain normal body pH (see Chapter 68.7).

Maintenance of intravascular volume is facilitated via sodium regulation through the renin-angiotensin-aldosterone and atrial natriuretic factor axes, cortisol and catecholamine synthesis and release, and antidiuretic hormone secretion. Despite these compensatory mechanisms, the underlying shock and host response lead to vascular endothelial cell injury and significant leakage of intravascular fluids into the interstitial extracellular space.

Another important aspect of the initial pathophysiology of shock is the impact
on cardiac output. All forms of shock affect cardiac output through several mechanisms, with changes in HR, preload, afterload, and myocardial contractility occurring separately or in combination (Table 88.4). **Hypovolemic shock** is characterized primarily by fluid loss and decreased preload. Tachycardia and an increase in SVR are the initial compensatory responses to maintain cardiac output and systemic BP. Without adequate volume replacement, hypotension develops, followed by tissue ischemia and further clinical deterioration. When there is preexisting low plasma oncotic pressure (caused by nephrotic syndrome, malnutrition, hepatic dysfunction, acute severe burns, etc.), even further volume loss and exacerbation of shock may result from endothelial breakdown and worsening capillary leak.

**Table 88.4**

**Pathophysiology ofShock**

**Extracorporeal Fluid Loss**

Hypovolemic shock may be a result of direct blood loss through hemorrhage or abnormal loss of body fluids (diarrhea, vomiting, burns, diabetes mellitus or insipidus, nephrosis).

**Lowering Plasma Oncotic Forces**

Hypovolemic shock may also result from hypoproteinemia (liver injury, or as a progressive complication of increased capillary permeability).

**Abnormal Vasodilation**

Distributive shock (neurogenic, anaphylaxis, or septic shock) occurs when there is loss of vascular tone—venous, arterial, or both (sympathetic blockade, local substances affecting permeability, acidosis, drug effects, spinal cord transection).

**Increased Vascular Permeability**

Sepsis may change the capillary permeability in the absence of any change in capillary hydrostatic pressure (endotoxins from sepsis, excess
Cardiac Dysfunction

Peripheral hypoperfusion may result from any condition that affects the heart's ability to pump blood efficiently (ischemia, acidosis, drugs, constrictive pericarditis, pancreatitis, sepsis).

In contrast, the underlying pathophysiologic mechanism leading to 
**distributive shock** is a state of abnormal vasodilation and decreased SVR. Sepsis, hypoxia, poisoning, anaphylaxis, spinal cord injury, or mitochondrial dysfunction can cause **vasodilatory shock** (Fig. 88.3). The lowering of SVR is accompanied initially by a maldistribution of blood flow away from vital organs and a compensatory increase in cardiac output. This process leads to significant decreases in both preload and afterload. Therapies for distributive shock must address both these problems simultaneously.

![Mechanisms of vasodilatory shock](From Landry DW, Oliver JA: histamine release in anaphylaxis).
Cardiogenic shock may be seen in patients with myocarditis, cardiomyopathy, arrhythmias and congenital heart disease (generally following cardiac surgery) (see Chapter 461). In these patients, myocardial contractility is affected, leading to systolic and/or diastolic dysfunction. The later phases of all forms of shock frequently have a negative impact on the myocardium, leading to development of a cardiogenic component to the initial shock state.

Septic shock is generally a unique combination of distributive, hypovolemic, and cardiogenic shock. Hypovolemia from intravascular fluid losses occurs through capillary leak. Cardiogenic shock results from the myocardial-depressant effects of sepsis, and distributive shock is the result of decreased SVR. The degree to which a patient exhibits each of these responses varies, but there are frequently alterations in preload, afterload, and myocardial contractility.

In septic shock, it is important to distinguish between the inciting infection and the host inflammatory response. Normally, host immunity prevents the development of sepsis through activation of the reticular endothelial system along with the cellular and humoral immune systems. This host immune response produces an inflammatory cascade of toxic mediators, including hormones, cytokines, and enzymes. If this inflammatory cascade is uncontrolled, derangement of the microcirculatory system leads to subsequent organ and cellular dysfunction.

The systemic inflammatory response syndrome (SIRS) is an inflammatory cascade that is initiated by the host response to an infectious or noninfectious trigger (Table 88.5). This inflammatory cascade is triggered when the host defense system does not adequately recognize and/or eliminate the triggering event. The inflammatory cascade initiated by shock can lead to hypovolemia, cardiac and vascular failure, acute respiratory distress syndrome (ARDS), insulin resistance, decreased cytochrome P450 activity (decreased steroid synthesis), coagulopathy, and unresolved or secondary infection. Tumor necrosis factor (TNF) and other inflammatory mediators increase vascular permeability, causing diffuse capillary leak, decreased vascular tone, and an imbalance between perfusion and metabolic demands of the tissues. TNF and interleukin (IL)-1 stimulate the release of proinflammatory and antiinflammatory mediators, causing fever and vasodilation. Proinflammatory mediators include IL-6, IL-12, interferon-γ, and macrophage migration inhibitory factor; antiinflammatory
cytokines include IL-10, transforming growth factor-β, and IL-4. Arachidonic acid metabolites lead to the development of fever, tachypnea, ventilation-perfusion abnormalities, and lactic acidosis. Nitric oxide (NO), released from the endothelium or inflammatory cells, is a major contributor to hypotension. Myocardial depression is caused directly by myocardial-depressant factors, TNF, and some interleukins and is further depressed by depleted catecholamines, increased β-endorphin, and production of myocardial NO.

Macrophage activation syndrome
Idiopathic systemic capillary leak (Clarkson) syndrome

The inflammatory cascade is initiated by toxins or superantigens through macrophage binding or lymphocyte activation (Fig. 88.4). The vascular endothelium is both a target of tissue injury and a source of mediators that may cause further injury. Biochemical responses include the production of arachidonic acid metabolites, release of myocardial-depressant factors and endogenous opiates, activation of the complement system, and production and release of other mediators, which may be proinflammatory or antiinflammatory. The balance among these mediator groups for an individual patient contributes to the progression (and resolution) of disease and affects the prognosis.
FIG. 88.4 Hypothetical pathophysiology of the septic process.
Clinical Manifestations

Table 88.1 shows a classification system for shock. Categorization is important, but there may be significant overlap among these groups, especially in septic shock. The clinical presentation of shock depends in part on the underlying etiology, but if unrecognized and untreated, all forms of shock follow a common and untoward progression of clinical signs and pathophysiologic changes that may ultimately lead to irreversible organ injury and death.

Shock may initially manifest as only tachycardia, with or without tachypnea. Progression leads to decreased urine output, poor peripheral perfusion, respiratory distress or failure, alteration of mental status, and low BP (see Table 88.3). A significant misconception is that shock occurs only with low BP; hypotension is often a late finding and is not a criterion for the diagnosis of shock because of a complex set of compensatory mechanisms that attempt to preserve BP and peripheral perfusion. Hypotension reflects an advanced state of decompensated shock and is associated with increased morbidity and mortality.

Hypovolemic shock often manifests initially as orthostatic hypotension and is associated with dry mucous membranes, dry axillae, poor skin turgor, and decreased urine output. Depending on the degree of dehydration, the patient with hypovolemic shock may present with either normal or slightly cool distal extremities, and pulses may be normal, decreased, or absent depending on disease severity. The presenting signs of cardiogenic shock are tachypnea, cool extremities, delayed capillary filling time, poor peripheral and/or central pulses, declining mental status, and decreased urine output caused by the combination of decreased cardiac output and compensatory peripheral vasoconstriction (see Chapter 469.1). Obstructive shock often also manifests as inadequate cardiac output because of a physical restriction of forward blood flow, and the acute presentation may quickly progress to cardiac arrest. Distributive shock manifests initially as peripheral vasodilation and increased but inadequate cardiac output.

Regardless of etiology, uncompensated shock, with hypotension, high SVR, decreased cardiac output, respiratory failure, obtundation, and oliguria, occurs late in the progression of disease. Table 88.6 lists the hemodynamic findings in various shock states. Additional clinical findings in shock include cutaneous lesions such as petechiae, diffuse erythema, ecchymoses, ecchyma gangrenosum, and peripheral gangrene. Jaundice can be present either as a sign of infection or as a result of MODS.

* Systolic or diastolic dysfunction.
† Wedge pressure, central venous pressure, and pulmonary artery diastolic pressures are equal.
‡ Wide pulse pressure.

Sepsis is defined as SIRS resulting from a suspected or proven infectious etiology. The clinical spectrum of sepsis begins when a systemic (e.g., bacteremia, rickettsial disease, fungemia, viremia) or localized (e.g., meningitis, pneumonia, pyelonephritis, peritonitis, necrotizing fasciitis) infection progresses from sepsis to severe sepsis (i.e., presence of sepsis combined with organ dysfunction). Further clinical deterioration leads to septic shock (severe sepsis plus the persistence of hypoperfusion or hypotension despite adequate fluid resuscitation or a requirement for vasoactive agents), MODS, and possibly death (Table 88.7). This is a complex spectrum of clinical problems that is a leading cause of mortality in children worldwide. Mortality can be mitigated and outcomes improved with early recognition and treatment.

Table 88.7
International Consensus Definitions for Pediatric Sepsis

Infection

Suspected or proven infection or a clinical syndrome associated with high probability of infection.
Systemic Inflammatory Response Syndrome (SIRS)

Two of 4 criteria, 1 of which must be abnormal temperature or abnormal leukocyte count:
1. Core temperature >38.5°C (101.3°F) or <36°C (96.8°F) (rectal, bladder, oral, or central catheter)
2. Tachycardia:
   Mean heart rate >2 SD above normal for age in absence of external stimuli, chronic drugs or painful stimuli
   or
   Unexplained persistent elevation over 0.5-4 hr
   or
   In children <1 yr old, persistent bradycardia over 0.5 hr (mean heart rate <10th percentile for age in absence of vagal stimuli, β-blocker drugs, or congenital heart disease)
3. Respiratory rate >2 SD above normal for age or acute need for mechanical ventilation not related to neuromuscular disease or general anesthesia
4. Leukocyte count elevated or depressed for age (not secondary to chemotherapy) or >10% immature neutrophils

Sepsis

SIRS plus a suspected or proven infection

Severe Sepsis

Sepsis plus 1 of the following:
1. Cardiovascular organ dysfunction, defined as:
   Despite >40 mL/kg of isotonic intravenous fluid in 1 hr:
   • Hypotension <5th percentile for age or systolic blood pressure <2 SD below normal for age
   or
   • Need for vasoactive drug to maintain blood pressure
   or
   Two of the following:
   • Unexplained metabolic acidosis: base deficit >5 mEq/L
Increased arterial lactate: >2 times upper limit of normal
- Oliguria: urine output <0.5 mL/kg/hr
- Prolonged capillary refill: >5 sec
- Core-to-peripheral temperature gap: >3°C (5.4°F)

2. Acute respiratory distress syndrome (ARDS), as defined by the presence of a \( \text{Pao}_2 / \text{Fio}_2 \) ratio \( \leq 300 \text{ mm Hg} \), bilateral infiltrates on chest radiograph, and no evidence of left-sided heart failure.

or

Sepsis plus \( \geq 2 \) organ dysfunctions (respiratory, renal, neurologic, hematologic, or hepatic).

**Septic Shock**

Sepsis plus cardiovascular organ dysfunction as defined above.

**Multiple-Organ Dysfunction Syndrome (MODS)**

Presence of altered organ function such that homeostasis cannot be maintained without medical intervention.

\( \text{Fio}_2 \), Fraction of inspired oxygen; \( \text{Pao}_2 \), partial pressure of arterial oxygen; SD, standard deviations.

Although septic shock is primarily distributive in nature, multiple other elements of pathophysiology are represented in this disease process. The initial signs and symptoms of sepsis include alterations in temperature regulation (hyperthermia or hypothermia), tachycardia, and tachypnea. In the early stages (hyperdynamic phase, low SVR, or warm shock), cardiac output increases to maintain adequate oxygen delivery and meet the greater metabolic demands of the organs and tissues. As septic shock progresses, cardiac output falls in response to the effects of numerous inflammatory mediators, leading to a compensatory elevation in SVR and the development of cold shock.

**Diagnosis**
Shock is a clinical diagnosis based on a thorough history and physical examination (see Tables 88.2 and 88.3). Septic shock has a specific consensus conference definition (see Table 88.7). In cases of suspected septic shock, an infectious etiology should be sought through culture of clinically appropriate specimens and prompt initiation of empirical antimicrobial therapy based on patient age, underlying disease, and geographic location, recognizing that time is necessary for incubation of cultures, and results often are not positive. Additional evidence for identifying an infectious etiology as the cause of SIRS includes physical examination findings, imaging, presence of white blood cells in normally sterile body fluids, and suggestive rashes such as petechiae and purpura. Affected children should be admitted to a PICU or other highly monitored environment as indicated by clinical status and the resources of the medical facility. These patients necessitate continuous monitoring, with a combination of noninvasive (e.g., pulse oximetry, capnography, near-infrared spectroscopy) and invasive (e.g., central venous pressure, arterial BP) techniques as clinically indicated.

**Laboratory Findings**

Laboratory findings often include evidence of hematologic abnormalities and electrolyte disturbances. Hematologic abnormalities may include thrombocytopenia, prolonged prothrombin and partial thromboplastin times, reduced serum fibrinogen level, elevation of fibrin split products, and anemia. Elevated neutrophil counts and increased immature forms (i.e., bands, myelocytes, promyelocytes), vacuolation of neutrophils, toxic granulations, and Döhle bodies can be seen with infection. Neutropenia or leukopenia may be an ominous sign of overwhelming sepsis.

Glucose dysregulation, a common stress response, may manifest as hyperglycemia or hypoglycemia. Other electrolyte abnormalities are hypocalcemia, hypoalbuminemia, and metabolic acidosis. Renal and/or hepatic function may also be abnormal. Patients with ARDS or pneumonia have impairment of oxygenation (decreased partial pressure of arterial oxygen [PaO₂]) as well as of ventilation (increased arterial partial pressure of carbon dioxide [Paco₂]) in the later stages of lung injury (see Chapter 89).

The hallmark of *uncompensated* shock is an imbalance between oxygen delivery (Do₂) and oxygen consumption (Vo₂). Oxygen delivery normally
exceeds oxygen consumption by threefold. The oxygen extraction ratio is approximately 25%, thus producing a normal mixed venous oxygen saturation (Svo\textsubscript{2}) of approximately 75%. A falling Svo\textsubscript{2} value, as measured by cooximetry, reflects an increasing oxygen extraction ratio and documents a decrease in oxygen delivery relative to consumption. This increase in oxygen extraction by the end organs is an attempt to maintain adequate oxygen delivery at the cellular level. This state is manifested clinically by increased lactic acid production (e.g., high anion gap, metabolic acidosis) caused by anaerobic metabolism and a compensatory increase in tissue oxygen extraction. The gold standard measurement of Svo\textsubscript{2} is from a pulmonary arterial catheter, but measurements from this location are often not clinically feasible. Sites such as the right ventricle, right atrium, superior vena cava (SvCO\textsubscript{2}), or inferior vena cava can be as surrogate measures of mixed venous blood to follow the adequacy of oxygen delivery and effectiveness of therapeutic interventions. *Elevated blood lactate levels reflect poor tissue oxygen delivery noted in all forms of shock.*

**Treatment**

**Initial Management**

Early recognition and prompt intervention are extremely important in the management of all forms of shock (Tables 88.8 to 88.12; see Figs. 88.1 and 88.2). *The vital sign targets and dose recommendations in Tables 88.9 to 88.12 should be adjusted to pediatric-size patients.* Baseline mortality is much lower in pediatric shock than in adult shock, and further improvements in mortality are associated with early interventions (see Fig. 81.1). The initial assessment and treatment of the pediatric shock patient should include stabilization of airway, breathing, and circulation as established by the American Heart Association's pediatric advanced life support and neonatal advanced life support guidelines (see Chapter 81). Depending on the severity of shock, further airway intervention, including intubation and mechanical ventilation, may be necessary to lessen the work of breathing and decrease the body's overall metabolic demands.

---

### Table 88.9

**Recommendations for Shock: Initial Resuscitation and Infection Issues—Adults**

**Initial Resuscitation**
1. Protocolized, quantitative resuscitation of patients with sepsis-induced tissue hypoperfusion (defined as hypotension persisting after initial fluid challenge or blood lactate concentration ≥4 mmol/L). Goals during the 1st 6 hr of resuscitation:
   a. Central venous pressure 8-12 mm Hg
   b. Mean arterial pressure (MAP) ≥65 mm Hg
   c. Urine output ≥0.5 mL kg\(^{-1}\) hr
   d. Central venous (superior vena cava) or mixed venous oxygen saturation: 70% or 65%, respectively
2. In patients with elevated lactate levels, targeting resuscitation to normalize lactate as rapidly as possible.

**Screening for Sepsis and Performance Improvement**

1. Routine screening of potentially infected seriously ill patients for severe sepsis to allow earlier implementation of therapy.
2. Hospital-based performance improvement efforts in severe sepsis.

**Diagnosis**

1. Cultures as clinically appropriate before antimicrobial therapy if no significant delay (>45 min) in the start of antimicrobial(s). At least 2 sets of blood cultures (both aerobic and anaerobic bottles) should be obtained before antimicrobial therapy with at least 1 drawn percutaneously and 1 drawn through each vascular access device, unless the device was recently (<48 hr) inserted.
2. Use of the 1,3 β-D-glucan assay, mannan and antimannan antibody assays, if available, and invasive candidiasis is in differential diagnosis of cause of infection.
3. Imaging studies performed promptly to confirm a potential source of infection.

**Antimicrobial Therapy**

1. Administration of effective intravenous antimicrobials within the 1st hr of
recognition of septic shock and severe sepsis without septic shock as the goal of therapy.

2a. Initial empirical antiinfective therapy of 1 or more drugs that have activity against all likely pathogens (bacterial and/or fungal or viral) and that penetrate in adequate concentrations into tissues presumed to be the source of sepsis.

2b. Antimicrobial regimen should be reassessed daily for potential deescalation.

3. Use of low procalcitonin levels or similar biomarkers to assist the clinician in the discontinuation of empirical antibiotics in patients who initially appeared septic, but have no subsequent evidence of infection.

4a. Combination empirical therapy for neutropenic patients with severe sepsis and for patients with difficult-to-treat, multidrug-resistant bacterial pathogens such as *Acinetobacter* and *Pseudomonas* spp.

   For patients with severe infections associated with respiratory failure and septic shock, combination therapy with an extended-spectrum β-lactam and either an aminoglycoside or a fluoroquinolone is for *Pseudomonas aeruginosa* bacteremia. A combination of β-lactam and macrolide for patients with septic shock from bacteremic *Streptococcus pneumoniae* infections.

4b. Empirical combination therapy should not be administered for more than 3-5 days. Deescalation to the most appropriate single therapy should be performed as soon as the susceptibility profile is known.

5. Duration of therapy typically 7-10 days; longer courses may be appropriate in patients who have a slow clinical response, undrainable foci of infection, bacteremia with *Staphylococcus aureus*, some fungal and viral infections, or immunodeficiencies (e.g., neutropenia).

6. Antiviral therapy initiated as early as possible in patients with severe sepsis or septic shock of viral origin.

7. Antimicrobial agents should *not* be used in patients with severe inflammatory states determined to be of noninfectious cause.

**Source Control**

1. A specific anatomic diagnosis of infection requiring consideration for
emergent source control should be sought and diagnosed or excluded as rapidly as possible, and intervention undertaken for source control within the 1st 12 hr after the diagnosis is made, if feasible.

2. When infected peripancreatic necrosis is identified as a potential source of infection, definitive intervention is best delayed until adequate demarcation of viable and nonviable tissues has occurred.

3. When source control in a severely septic patient is required, the effective intervention associated with the least physiologic insult should be used (e.g., percutaneous rather than surgical drainage of an abscess).

4. If intravascular access devices are a possible source of severe sepsis or septic shock, these should be removed promptly after other vascular access has been established.

**Infection Prevention**

1a. Selective oral decontamination and selective digestive decontamination should be introduced and investigated as a method to reduce the incidence of ventilator-associated pneumonia; this infection control measure can then be instituted in healthcare settings and regions where this methodology is found to be effective.

1b. Oral chlorhexidine gluconate be used as a form of oropharyngeal decontamination to reduce the risk of ventilator-associated pneumonia in ICU patients with severe sepsis.

**Table 88.10**

**Surviving Sepsis Campaign: Care Bundles**

> To be completed within 3 hr:
> 1. Measure lactate level.
> 2. Obtain blood cultures before administration of antibiotics.
> 3. Administer broad-spectrum antibiotics.
> 4. Administer 30 mL/kg crystalloid for hypotension or lactate ≥4 mmol/L.
To completed within 6 hr:
5. Apply vasopressors (for hypotension that does not respond to initial fluid resuscitation) to maintain a mean arterial pressure (MAP) ≥65 mm Hg.
6. In the event of persistent arterial hypotension despite volume resuscitation (septic shock) or initial lactate ≥4 mmol/L (36 mg/dL):
   - Measure central venous pressure (CVP).*
   - Measure central venous oxygen saturation (ScvO₂).*
7. Remeasure lactate if initial lactate was elevated.*

* Targets for quantitative resuscitation included in the guidelines are CVP of ≥8 mm Hg, ScvO₂ of ≥70%, and normalization of lactate.

Table 88.11
Recommendations for Shock: Hemodynamic Support and Adjunctive Therapy—Adults

Fluid Therapy of Severe Sepsis

1. Crystalloids as the initial fluid of choice in the resuscitation of severe sepsis and septic shock.
2. Against the use of hydroxyethyl starches for fluid resuscitation of severe sepsis and septic shock.
3. Albumin in the fluid resuscitation of severe sepsis and septic shock when patients require substantial amounts of crystalloids.
4. Initial fluid challenge in patients with sepsis-induced tissue hypoperfusion with suspicion of hypovolemia, to achieve a minimum of 30 mL/kg of crystalloids (a portion of this may be albumin equivalent). More rapid administration and greater amounts of fluid may be needed in some patients.
5. Fluid challenge technique be applied in which fluid administration is continued as long as there is hemodynamic improvement either based on
dynamic (e.g., change in pulse pressure, stroke volume variation) or static (e.g., arterial pressure, heart rate) variables.

**Vasopressors**

1. Vasopressor therapy initially to target a mean arterial pressure (MAP) of 65 mm Hg.
2. Norepinephrine as the first-choice vasopressor.
3. Epinephrine (added to and potentially substituted for norepinephrine) when an additional agent is needed to maintain adequate blood pressure.
4. Vasopressin 0.03 units/min can be added to norepinephrine (NE) with intent of either raising MAP or decreasing NE dosage.
5. Low-dose vasopressin is not recommended as the single initial vasopressor for treatment of sepsis-induced hypotension, and vasopressin doses >0.03-0.04 units/min should be reserved for salvage therapy (failure to achieve adequate MAP with other vasopressor agents).
6. Dopamine as an alternative vasopressor agent to NE only in highly selected patients (e.g., with low risk of tachyarrhythmias and absolute or relative bradycardia).
7. Phenylephrine is not recommended in the treatment of septic shock except in circumstances where (a) NE is associated with serious arrhythmias, (b) cardiac output is known to be high and blood pressure persistently low, or (c) as salvage therapy when combined inotrope/vasopressor drugs and low-dose vasopressin have failed to achieve MAP target.
8. Low-dose dopamine should not be used for renal protection.
9. All patients requiring vasopressors have an arterial catheter placed as soon as practical if resources are available.

**Inotropic Therapy**

1. A trial of dobutamine infusion up to 20 µg/kg/min be administered or added to vasopressor (if in use) in the presence of (a) myocardial dysfunction as suggested by elevated cardiac filling pressures and low cardiac output, or (b) ongoing signs of hypoperfusion, despite achieving adequate intravascular volume and adequate MAP.
2. Not using a strategy to increase cardiac index to predetermined
Corticosteroids

1. Not using intravenous hydrocortisone to treat adult septic shock patients, if adequate fluid resuscitation and vasopressor therapy are able to restore hemodynamic stability (see goals for Initial Resuscitation). In the event this is not achievable, we suggest IV hydrocortisone alone at a dose of 200 mg/day.
2. Not using the ACTH stimulation test to identify adults with septic shock who should receive hydrocortisone.
3. In treated patients, hydrocortisone tapered when vasopressors are no longer required.
4. Corticosteroids should not be administered for the treatment of sepsis in the absence of shock.
5. When hydrocortisone is given, use continuous flow.

Table 88.12

Recommendations for Shock: Special Considerations in Pediatric Patients

Initial Resuscitation

1. For respiratory distress and hypoxemia, start with face mask oxygen or, if needed and available, high-flow nasal cannula oxygen or nasopharyngeal CPAP (NP CPAP). For improved circulation, peripheral intravenous access or intraosseous access can be used for fluid resuscitation and inotrope infusion when a central line is not available. If mechanical ventilation is required, cardiovascular instability during intubation is less likely after appropriate cardiovascular resuscitation.
2. Initial therapeutic end-points of resuscitation of septic shock: capillary refill of ≤2 sec, normal blood pressure for age, normal pulses with no
The differential between peripheral and central pulses, warm extremities, urine output >1 mL kg$^{-1}$ hr$^{-1}$, and normal mental status. Scvo$_2$ saturation ≥70% and cardiac index between 3.3 and 6.0 L/min/m$^2$ should be targeted thereafter.

4. Evaluate for and reverse pneumothorax, pericardial tamponade, or endocrine emergencies in patients with refractory shock.

**Antibiotics and Source Control**

1. Empirical antibiotics should be administered within 1 hr of the identification of severe sepsis. Blood cultures should be obtained before administering antibiotics when possible, but this should not delay administration of antibiotics. The empirical drug choice should be changed as epidemic and endemic ecologies dictate (e.g., H1N1, methicillin-resistant *Staphylococcus aureus* [MRSA], chloroquine-resistant malaria, penicillin-resistant pneumococci, recent ICU stay, neutropenia).

2. Clindamycin and antitoxin therapies for toxic shock syndromes with refractory hypotension.
3. Early and aggressive source control.
4. *Clostridium difficile* colitis should be treated with enteral antibiotics if tolerated. Oral vancomycin is preferred for severe disease.

**Fluid Resuscitation**

1. In the industrialized world with access to inotropes and mechanical ventilation, initial resuscitation of hypovolemic shock begins with infusion of isotonic crystalloids or albumin with boluses of up to 20 mL/kg crystalloids (or albumin equivalent) over 5-10 min, titrated to reversing hypotension, increasing urine output, and attaining normal capillary refill, peripheral pulses, and level of consciousness without inducing hepatomegaly or rales. If hepatomegaly or rales present, inotropic support should be implemented, not fluid resuscitation. In
nonhypotensive children with severe hemolytic anemia (severe malaria or sickle cell crises), blood transfusion is considered superior to crystalloid or albumin bolus.

**Inotropes, Vasopressors, and Vasodilators**

1. Begin peripheral inotropic support until central venous access can be attained in children who are not responsive to fluid resuscitation.
2. Patients with low cardiac output and elevated systemic vascular resistance states with normal blood pressure should be given vasodilator therapies in addition to inotropes.

**Extracorporeal Membrane Oxygenation**

1. Consider ECMO for refractory pediatric septic shock and respiratory failure.

**Corticosteroids**

1. Timely hydrocortisone therapy in children with fluid-refractory, catecholamine-resistant shock and suspected or proven absolute (classic) adrenal insufficiency.

**Protein C and Activated Protein Concentrate**

No recommendations (no longer available).

**Blood Products and Plasma Therapies**

1. Similar hemoglobin targets in children as in adults. During resuscitation of low superior vena cava oxygen saturation shock (<70%), hemoglobin levels of 10 g/dL are targeted. After stabilization and recovery from shock and hypoxemia, a lower target (>7.0 g/dL) can be considered reasonable.
2. Similar platelet transfusion targets in children as in adults.
3. Use plasma therapies in children to correct sepsis-induced thrombotic purpura disorders, including progressive disseminated intravascular coagulation, secondary thrombotic microangiopathy, and thrombotic thrombocytopenic purpura.

Mechanical Ventilation

1. Lung-protective strategies during mechanical ventilation.

Sedation, Analgesia, and Drug Toxicities

1. We recommend use of sedation with a sedation goal in critically ill, mechanically ventilated patients with sepsis.
2. Monitor drug toxicity lab results because drug metabolism is reduced during severe sepsis, putting children at greater risk of adverse drug-related events.

Glycemic Control

1. Control hyperglycemia using a similar target as in adults (≤180 mg/dL). Glucose infusion should accompany insulin therapy in newborns and children because some hyperglycemic children make no insulin whereas others are insulin resistant.

Diuretics and Renal Replacement Therapy

1. Use diuretics to reverse fluid overload when shock has resolved, and if unsuccessful, use continuous venovenous hemofiltration (CVVH) or intermittent dialysis to prevent >10% total body weight fluid overload.

Deep Vein Thrombosis (DVT) Prophylaxis

No recommendation on the use of DVT prophylaxis in prepubertal children with severe sepsis.
**Stress Ulcer (SU) Prophylaxis**

No recommendation on the use of SU prophylaxis in prepubertal children with severe sepsis.

**Nutrition**

1. Enteral nutrition given to children who can be fed enterally, and parenteral feeding in those who cannot (grade 2C).

CPAP, Continuous positive airway pressure.

Given the predominance of sepsis and hypovolemia as the most common causes of shock in the pediatric population, most therapeutic regimens are based on guidelines established in these settings. Immediately following establishment of intravenous (IV) or intraosseous (IO) access, aggressive, early goal-directed therapy should be initiated unless there are significant concerns for cardiogenic shock as an underlying pathophysiology. Rapid IV administration of 20 mL/kg isotonic fluid should be initiated to reverse the shock state. This bolus should be repeated quickly up to 60-80 mL/kg; it is not unusual for severely affected patients to require this volume within the 1st 3 hr of treatment.

Rapid fluid resuscitation totaling 60-80 mL/kg or more is associated with improved survival without an increased incidence of pulmonary edema. Fluid resuscitation in increments of 20 mL/kg should be titrated to normalize HR (according to age-based HRs), urine output (to 1 mL/kg/hr), capillary refill time (to <2 sec), and mental status. If shock remains refractory following 60-80 mL/kg of volume resuscitation, vasopressor therapy (e.g., norepinephrine, epinephrine) should be instituted while additional fluids are administered. Pediatric guidelines for septic shock unresponsive to fluid resuscitation suggest epinephrine (Fig. 88.2) or dopamine (Fig. 88.1), whereas adult guidelines recommend norepinephrine.

Fluid resuscitation may sometimes require as much as 200 mL/kg or greater. It
must be stressed that hypotension is often a late and ominous finding, and BP normalization alone is not a reliable end-point for assessing the effectiveness of resuscitation. Although the type of fluid (crystalloid vs colloid) is an area of ongoing debate, fluid resuscitation (usually crystalloid) in the 1st hr is unquestionably essential to survival in septic shock, regardless of the fluid type administered.

**Additional Early Considerations**

In *septic shock* specifically, early (*within 1 hr*) administration of broad-spectrum antimicrobial agents is associated with a reduction in mortality. The choice of antimicrobial agents depends on the predisposing risk factors and the clinical situation. Bacterial resistance patterns in the community and/or hospital should be considered in the selection of optimal antimicrobial therapy. Neonates should be treated with ampicillin plus cefepime and/or gentamicin. Acyclovir should be added if herpes simplex virus is suspected clinically. In infants and children, community-acquired infections with *Neisseria meningitidis* can initially be treated empirically with a third-generation cephalosporin (e.g., ceftriaxone, cefepime), as can *Haemophilus influenzae* infections. The prevalence of resistant *Streptococcus pneumoniae* requires the addition of vancomycin. Suspicion of community- or hospital-acquired, methicillin-resistant *Staphylococcus aureus* (MRSA) infection warrants coverage with vancomycin, depending on local resistance patterns. If an intraabdominal process is suspected, anaerobic coverage should be included with an agent such as metronidazole, clindamycin, or piperacillin-tazobactam.

Nosocomial sepsis should generally be treated with at least a third- or fourth-generation cephalosporin or a penicillin with an extended gram-negative spectrum (e.g., piperacillin-tazobactam). An aminoglycoside should be added as the clinical situation warrants. Vancomycin should be added to the regimen if the patient has an indwelling medical device (see Chapter 206), if gram-positive cocci are isolated from the blood, if MRSA infection is suspected, or as empirical coverage for *S. pneumoniae* in a patient with meningitis. Empirical coverage for fungal infections should be considered for selected immunocompromised patients (see Chapter 205). It should be noted that these are broad, generalized recommendations that must be tailored to the individual clinical scenario and to the local resistance patterns of the community and hospital.
**Distributive shock** that is not secondary to sepsis is caused by a primary abnormality in vascular tone. Cardiac output in affected patients is usually maintained and may initially be supranormal. These patients may benefit temporally from volume resuscitation, but the early initiation of a vasoconstrictive agent to increase SVR is an important element of clinical care. Patients with spinal cord injury and spinal shock may benefit from either phenylephrine or vasopressin to increase SVR; epinephrine is the treatment of choice for patients with anaphylaxis (Table 88.13). Epinephrine has peripheral $\alpha$-adrenergic as well as inotropic effects that may improve the myocardial depression seen with anaphylaxis and its associated inflammatory response (see Chapter 174).

Patients with **cardiogenic shock** have poor cardiac output secondary to systolic and/or diastolic myocardial depression, often with a compensatory elevation in SVR. These patients may show poor response to fluid resuscitation and may decompensate quickly when fluids are administered. Smaller boluses of fluid (5-10 mL/kg) should be given in cardiogenic shock to replace deficits and maintain preload. In any patient with shock whose clinical status deteriorates with fluid resuscitation, a cardiogenic etiology should be considered, and further administration of IV fluids should be provided judiciously. Early initiation of myocardial support with epinephrine or dopamine to improve cardiac output is important in this context, and early consideration should be given to
administration of an inodilator, such as milrinone.

Despite adequate cardiac output with the support of inotropic agents, a high SVR with poor peripheral perfusion and acidosis may persist in cardiogenic shock. Therefore, if not already started, milrinone therapy may improve systolic function and decrease SVR without causing a significant increase in HR. Furthermore, this agent has the added benefit of enhancing diastolic relaxation. Dobutamine or other vasodilating agents, such as nitroprusside, may also be considered in this setting (Table 88.14). Titration of these agents should target clinical end-points, including increased urine output, improved peripheral perfusion, resolution of acidosis, and normalization of mental status. Even though they may be beneficial in other forms of shock, agents that improve BP by increasing SVR, such as norepinephrine and vasopressin, should generally be avoided in patients with cardiogenic shock. These agents may cause further decompensation and potentially precipitate cardiac arrest as a result of the increased afterload and additional work imposed on the myocardium. The combination of inotropic and vasoactive agents must be tailored to the pathophysiology of the individual patient with close and frequent reassessment of the patient's cardiovascular status.

For patients with obstructive shock, fluid resuscitation may be briefly temporizing in maintaining cardiac output, but the primary insult must be
immediately addressed. Examples of lifesaving therapeutic interventions for such patients are pericardiocentesis for pericardial effusion, pleurocentesis or chest tube placement for pneumothorax, thrombectomy/thrombolysis for pulmonary embolism, and the initiation of a prostaglandin infusion for ductus-dependent cardiac lesions. There is often a last-drop phenomenon associated with some obstructive lesions, in that small additional amounts of intravascular volume depletion may lead to a rapid deterioration, including cardiac arrest, if the obstructive lesion is not corrected.

Regardless of the etiology of shock, metabolic status should be meticulously maintained (see Table 88.8). Electrolyte levels should be monitored closely and corrected as needed. Hypoglycemia is common and should be promptly treated. Neonates and infants in particular may have profound glucose dysregulation in association with shock. Glucose levels should be checked routinely and treated appropriately, especially early in the course of illness. Hypocalcemia, which may contribute to myocardial dysfunction, should be treated with a goal of normalizing the ionized calcium concentration. There is no evidence that supranormal calcium levels benefit the myocardium, and hypercalcemia may be associated with increased myocardial toxicity.

Adrenal function is another important consideration in shock, and hydrocortisone replacement may be beneficial. Up to 50% of critically ill patients may have absolute or relative adrenal insufficiency. Patients at risk for adrenal insufficiency include those with congenital adrenal hypoplasia, abnormalities of the hypothalamic-pituitary axis, and recent therapy with corticosteroids (including those with asthma, rheumatic diseases, malignancies, and inflammatory bowel disease). These patients are at high risk for adrenal dysfunction and should receive stress doses of hydrocortisone. Corticosteroids may also be considered in patients with shock that is unresponsive to fluid resuscitation and catecholamines. Although a subset of pediatric septic shock patients may benefit from treatment with hydrocortisone, currently available pediatric data do not demonstrate an overall survival benefit in patients with shock treated with hydrocortisone. Determination of baseline cortisol levels before corticosteroid administration may be beneficial in guiding therapy, although this approach remains controversial.

Considerations for Continued Therapy

After the 1st hr of therapy and attempts at early reversal of shock, focus on goal-
directed end-points should continue in an intensive care setting (see Figs. 88.1 and 88.2 and Table 88.8 ). Clinical end-points serve as global markers for organ perfusion and oxygenation. Laboratory parameters such as Svo₂ (or ScvO₂), serum lactate concentration, cardiac index, and hemoglobin serve as adjunctive measures of tissue oxygen delivery. Hemoglobin should be generally maintained at 10 g/dL, Svo₂ (or ScvO₂) >70%, and cardiac index at 3.3-6.0 L/min/m² to optimize oxygen delivery in the acute phase of shock. It is important to note that cardiac index is rarely monitored in the clinical setting because of the limited use of pulmonary artery catheters and lack of accurate noninvasive cardiac output monitors for infants and children. Blood lactate levels and calculation of base deficit from arterial blood gas values are very useful markers for the adequacy of oxygen delivery. These traditional markers are indicators of global oxygen utilization and delivery. There is increasing use of measures of local tissue oxygenation, including near-infrared spectroscopy of the cerebrum, flank, or abdomen.

Respiratory support should be used as clinically appropriate. When shock leads to ARDS requiring mechanical ventilation, lung-protective strategies to keep plateau pressure <30 cm H₂ O and maintain tidal volume at 6 mL/kg have been shown to improve mortality in adult patients (see Chapter 89). These data are extrapolated to pediatric patients because of the lack of definitive pediatric studies in this area. Additionally, after the initial shock state has been reversed, data demonstrate that judicious fluid administration, renal replacement therapy, and fluid removal may also be useful in children with anuria or oliguria and fluid overload (see Chapter 550). Other interventions include correction of coagulopathy with fresh-frozen plasma or cryoprecipitate and platelet transfusions as necessary, especially in the presence of active bleeding.

If shock remains refractory despite maximal therapeutic interventions, mechanical support with extracorporeal membrane oxygenation (ECMO) or a ventricular assist device (VAD) may be indicated. ECMO may be lifesaving in cases of refractory shock regardless of underlying etiology. Similarly, a VAD may be indicated for refractory cardiogenic shock in the setting of cardiomyopathy or recent cardiac surgery. Systemic anticoagulation, which is required while patients are receiving mechanical support, may be difficult, given the significant coagulopathy often encountered in refractory shock, especially when the underlying etiology is sepsis. Mechanical support in refractory shock poses substantial risks but can improve survival in specific populations of
Prognosis

In septic shock, mortality rates are as low as 3% in previously healthy children and 6–9% in children with chronic illness (compared with 25–30% in adults). With early recognition and therapy, the mortality rate for pediatric shock continues to improve, but shock and MODS remain one of the leading causes of death in infants and children. The risk of death involves a complex interaction of factors, including the underlying etiology, presence of chronic illness, host immune response, and timing of recognition and therapy.

Larsen GY, Mecham N, Grenberg R. An emergency department

2018;378(9):797–808.
The term respiratory distress is used to indicate signs and symptoms of abnormal respiratory pattern. A child with nasal flaring, tachypnea, chest wall retractions, stridor, grunting, dyspnea, and wheezing has respiratory distress. Taken together, the magnitude of these findings is used to judge clinical severity. Nasal flaring is nonspecific, but the other signs are useful in localizing the site of pathology (see Chapter 400). Respiratory failure is defined as inability of the lungs to provide sufficient oxygen (hypoxic respiratory failure) or remove carbon dioxide (ventilator failure) to meet metabolic demands. Therefore, whereas respiratory distress is determined by a clinical impression, the diagnosis of respiratory failure is indicated by inadequacy of oxygenation or of ventilation, or both. Respiratory distress can occur in patients without respiratory disease, and respiratory failure can occur in patients without respiratory distress.

**Respiratory Distress**

A careful physical examination must be performed when managing a child in respiratory distress. Nasal flaring, although nonspecific, is an extremely important sign of distress in infants. It may indicate discomfort, pain, fatigue, or breathing difficulty. The state of responsiveness is another crucial sign. Lethargy, disinterest in surroundings, and poor cry are suggestive of exhaustion, hypercarbia, and impending respiratory failure. Abnormalities of the rate and depth of breathing can occur with both pulmonary and nonpulmonary causes of respiratory distress. In diseases of decreased lung compliance, such as pneumonia and pulmonary edema, breathing is characteristically rapid and shallow (decreased tidal volume). In obstructive airway diseases, such as asthma and laryngotracheitis, breathing is deep with increased tidal volume, but less
rapid. Rapid and deep breathing without other respiratory signs should alert the physician to possible nonpulmonary or nonthoracic causes of respiratory distress, such as response to metabolic acidosis (e.g., diabetic ketoacidosis, renal tubular acidosis) or stimulation of the respiratory center (e.g., encephalitis, ingestion of central nervous system stimulants). Chest wall, suprasternal, and subcostal relocations are manifestations of increased inspiratory effort, weak chest wall, or both. Inspiratory stridor indicates airway obstruction above the thoracic inlet, whereas expiratory wheezing results from airway obstruction below the thoracic inlet. Grunting is most commonly heard in diseases with decreased functional residual capacity (e.g., pneumonia, pulmonary edema) and peripheral airway obstruction (e.g., bronchiolitis).

**Respiratory Disease Manifesting as Respiratory Distress**

Clinical examination is important in localizing the site of pathology (see Chapter 400). Extrathoracic airway obstruction occurs anywhere above the thoracic inlet. Inspiratory stridor, suprasternal, chest wall, and subcostal relocations; and prolongation of inspiration are hallmarks of extrathoracic airway obstruction. By comparison, features of intrathoracic airway obstruction are prolongation of expiration and expiratory wheezing. Typical manifestations of alveolar interstitial pathology are rapid, shallow respirations, chest wall relocations, and grunting. The site of pathology can be localized and the differential diagnosis established on the basis of the clinical signs and symptoms (Tables 89.1 and 89.2).

# Respiratory Distress Without Respiratory Disease

Although respiratory distress most frequently results from diseases of lungs, airways, and chest wall, pathology in other organ systems can manifest as respiratory distress and lead to misdiagnosis and inappropriate management (Table 89.3). Respiratory distress resulting from heart failure or diabetic ketoacidosis may be misdiagnosed as asthma and improperly treated with...
albuterol, resulting in worsened hemodynamic state or ketoacidosis. Careful history and physical examination provide essential clues in avoiding misdiagnosis.

**Cardiovascular Disease Manifesting as Respiratory Distress**

A child with cardiovascular pathology may present with respiratory distress caused by either *decreased lung compliance* or *cardiogenic shock* (Table 89.4). Diseases that result in increased pulmonary arterial blood flow (e.g., left-to-right shunts) or increased pulmonary venous pressure (e.g., left ventricular dysfunction from hypertension or myocarditis, obstructed total anomalous pulmonary venous return) cause an increase in pulmonary capillary pressure and transudation of fluid into the pulmonary interstitium and alveoli. The increased pulmonary blood and water content lead to decreased lung compliance and result in rapid shallow breathing.

### Table 89.4

**Cardiovascular Pathology Manifesting as**
Respiratory Distress

I. Decreased lung compliance
   A. Left-to-right shunts
      1. Ventricular septal defect, atrial septal defect, patent ductus arteriosus, atrioventricular canal, truncus arteriosus
      2. Cerebral or hepatic arteriovenous fistula
   B. Ventricular failure
      1. Left heart obstructive lesions
         a. Aortic stenosis
         b. Coarctation of the aorta
         c. Mitral stenosis
         d. Interrupted aortic arch
         e. Hypoplastic left heart syndrome
      2. Myocardial infarction
         a. Anomalous left coronary artery arising from the pulmonary artery
      3. Hypertension
         a. Acute glomerulonephritis
      4. Inflammatory/infectious
         a. Myocarditis
         b. Pericardial effusion
      5. Idiopathic
         a. Dilated cardiomyopathy
         b. Hypertrophic obstructive cardiomyopathy
   C. Pulmonary venous obstruction
      1. Total anomalous pulmonary venous return with obstruction
      2. Cor triatriatum

II. Shock resulting in metabolic acidosis
   A. Left heart obstructive lesions
   B. Acute ventricular failure
      1. Myocarditis, myocardial infarction

It is important to recognize that interstitial lung edema cannot only manifest as
alveolar fluid, but as small airway obstruction as well. **Wheezing** as a sign of congestive cardiac disease is common in infants and young children and should be recognized. Patients with cardiac lesions, resulting in low cardiac output, often present in shock. For example, obstructive lesions of left side of the heart and acquired or congenital cardiomyopathy result in decreased perfusion and metabolic acidosis, as well as respiratory distress because of chemoreceptor and baroreceptor stimulation. The likelihood of a particular cardiovascular illness manifesting as respiratory distress depends on age at presentation (Table 89.5).

### Neurologic Disease Manifesting as Respiratory Distress

Central nervous system (CNS) dysfunction can lead to alterations in respiratory patterns and manifest as respiratory distress. Increased intracranial pressure (ICP) may manifest as respiratory distress. Early rise in intracranial pressure (ICP) results in stimulation of respiratory centers, leading to increases in the rate (**tachypnea**) and depth (**hyperpnea**) of respiration. The resultant decrease in arterial blood partial pressure of carbon dioxide (**Paco\(_2\)**) and elevation of cerebrospinal fluid (CSF) pH lead to cerebral vasoconstriction and amelioration of intracranial hypertension. Stereotypical respiratory patterns are associated with dysfunction at multiple levels of the brain. Cerebral hemisphere and midbrain lesions result in hyperpnea as well as tachypnea. In such situations, arterial blood gas (ABG) measurements typically show respiratory alkalosis.
without hypoxemia. Pathology affecting the pons and medulla manifests as irregular breathing patterns such as **apneustic breathing** (prolonged inspiration with brief expiratory periods), **Cheyne-Stokes breathing** (alternate periods of rapid and slow breathing), and irregular, ineffective breathing or apnea (**Table 89.6**). Along with respiratory changes, other manifestations of CNS dysfunction and increased ICP may be present, such as focal neurologic signs, pupillary changes, hypertension, and bradycardia (see Chapter 85). Occasionally, severe CNS dysfunction can result in **neurogenic pulmonary edema** and respiratory distress, which may follow excessive sympathetic discharge resulting in increased pulmonary venous hydrostatic pressure as well as increased pulmonary capillary permeability. **Central neurogenic hyperventilation** is characteristically observed in CNS involvement by illnesses such as urea cycle defects and encephalitis. **Bradycardia** and **apnea** may be caused by CNS-depressant medications, poisoning, prolonged hypoxia, trauma, or infection (see **Table 89.2**).

**Toxic Metabolic States Manifesting as Respiratory Distress**
Direct stimulation of respiratory centers resulting in respiratory alkalosis is encountered in intoxication involving agents such as salicylates and theophylline. Similarly, intoxication with general CNS stimulants, such as cocaine and amphetamines, may result in increased respiration. Presence of endogenous and exogenous toxins, such as organic acidemias, ingestion of methanol and ethylene glycol, and late stages of salicylism, cause metabolic acidosis and compensatory hyperventilation, which can manifest as respiratory distress. ABG measurements show decreased pH and compensatory hypocarbia with normal oxygenation. Metabolic disorders causing hyperammonemia, on the other hand, cause respiratory alkalosis (decreased PaCO$_2$ with increased pH) because ammonia stimulates the respiratory centers. Carbon monoxide and cyanide poisoning or methemoglobinemia may produce respiratory distress.

Other Nonpulmonary Entities Manifesting as Respiratory Distress

Sepsis and septic shock may cause an acute respiratory distress syndrome (ARDS) with hypovolemic stimulation of baroreceptors, cytokine stimulation of respiratory centers, and lactic acidosis. Other indirect causes of lung injury include systemic inflammatory conditions, trauma, transfusion-related acute lung injury, and pancreatitis. Similarly, renal disease may manifest as respiratory distress by causing metabolic acidosis (e.g., renal tubular acidosis or renal failure) or hypertensive left ventricular failure and fluid overload.

Respiratory Failure

Respiratory failure occurs when oxygenation and ventilation are insufficient to meet the metabolic demands of the body. Respiratory failure may result from an abnormality in (1) lung and airways, (2) chest wall and muscles of breathing, or (3) central and peripheral chemoreceptors. Clinical manifestations depend largely on the site of pathology. Although respiratory failure is traditionally defined as respiratory dysfunction resulting in arterial partial pressure of oxygen (Pao$_2$) <60 mm Hg when breathing room air and PaCO$_2$ >50 mm Hg resulting in acidosis, the patient's general state, respiratory effort, and potential for impending exhaustion are more important indicators than ABG values.

The Berlin definition of ARDS was once used to describe pediatric patients with ARDS, even though the pathophysiology is different between children and
adults. The current pediatric definition differs in chest imaging findings, definition of oxygenation, consideration of both noninvasive and invasive mechanical ventilation, and consideration of special populations (Table 89.7 and Fig. 89.1).

b If altitude is $>1,000 \text{ m}$, the correction factor should be calculated as follows: $\text{PaO}_2 / \text{FiO}_2 \times \text{Barometric pressure}/760$.
c This may be delivered noninvasively in the mild acute respiratory distress syndrome group.
d Use $\text{PAO}_2$ -based metric when available. If $\text{PaO}_2$ not available, wean $\text{FiO}_2$ to maintain $\text{SpO}_2 < 97\%$ to calculate OSI or SF ratio.
e For nonintubated patients treated with supplemental oxygen or nasal modes of noninvasive ventilation, refer to reference below for “At Risk Criteria.”
ARDS severity groups stratified by OI or OSI should not be applied to children with chronic lung disease who normally receive invasive mechanical ventilation or children with cyanotic heart disease.

In addition to the above, the Pediatric Acute Lung Injury Consensus Conference Group added definitions for special populations, including cyanotic heart disease, chronic lung disease, and left ventricular function.

CPAP, Continuous positive airway pressure; FIO₂, fraction of inspired oxygen; PaO₂, partial pressure of arterial oxygen; PEEP, positive end-expiratory pressure. OI, oxygenation index; OSI, oxygen saturation index.

Adapted from Pediatric Acute Lung Injury Consensus Conference Group, Pediatric Acute Respiratory Distress Syndrome: Consensus recommendations from the Pediatric Acute Lung Injury Consensus Conference, Pediatr Crit Care Med 16;428–439, 2015.

Pathophysiology

Respiratory failure can be classified into hypoxic respiratory failure (failure of oxygenation) and hypercarbic respiratory failure (failure of ventilation). Systemic venous (pulmonary arterial) blood is arterialized after equilibration with alveolar gas in the pulmonary capillaries and is carried back to the heart by pulmonary veins. The ABG is influenced by the composition of inspired gas, effectiveness of alveolar ventilation, pulmonary capillary perfusion, and diffusion capacity of the alveolar capillary membrane. Abnormality in any of these steps can result in respiratory failure. Hypoxic respiratory failure results from intrapulmonary shunting and venous admixture or insufficient diffusion of oxygen from alveoli into pulmonary capillaries. This physiology can be caused by small airways obstruction, increased barriers to diffusion (e.g., interstitial
edema, fibrosis), and conditions in which alveoli are collapsed or filled with fluid (e.g., ARDS, pneumonia, atelectasis, pulmonary edema). In most cases, hypoxic respiratory failure is associated with decreased functional residual capacity and can be managed by lung volume recruitment with positive pressure ventilation. Hypercarbic respiratory failure is caused by decreased minute ventilation (i.e., tidal volume multiplied by respiratory rate). This physiology can result from centrally mediated disorders of respiratory drive, increased dead space ventilation, or obstructive airways disease. Hypoxic and hypercarbic respiratory failure may coexist as a combined failure of oxygenation and ventilation.

**Ventilation-Perfusion Mismatch**

For exchange of O₂ and CO₂ to occur, alveolar gas must be exposed to blood in pulmonary capillaries. Both ventilation and perfusion are lower in nondependent areas of the lung and higher in dependent areas. The difference in perfusion (Q) is greater than the difference in ventilation (V). Perfusion in excess of ventilation results in incomplete arterialization of systemic venous (pulmonary arterial) blood and is referred to as **venous admixture**. Perfusion of unventilated areas is referred to as **intrapulmonary shunting** of systemic venous blood to systemic arterial circulation. Conversely, ventilation that is in excess of perfusion is wasted; that is, it does not contribute to gas exchange and is referred to as **dead space ventilation**. Dead space ventilation results in return of greater amounts of atmospheric gas (which has not participated in gas exchange and has negligible CO₂) back to the atmosphere during exhalation. The respiratory dead space is divided into the anatomic dead space and the alveolar dead space. The **anatomic dead space** includes the conducting airways from the nasopharynx to the terminal bronchioles, ends at the alveoli, and has no contact with the pulmonary capillary bed. The **alveolar dead space** refers to areas of the lung where alveoli are ventilated but not perfused. Under normal conditions, this physiology usually occurs in West zone I, where alveolar pressure is greater than pulmonary capillary pressure. Under clinical conditions, this physiology may result from dynamic hyperinflation, high levels of positive end-expiratory pressure (PEEP), or large tidal volume in ventilated patients. Additionally, decreased pulmonary artery perfusion from pulmonary embolism or decreased cardiac output and hypovolemia can result in alveolar dead space. The end result is a decrease in mixed expired CO₂ (P_{ECO₂}) and an increase in the P_{ACO₂} – P_{ECO₂} gradient. Deₐ
space as a fraction of tidal volume \((V_d/V_t)\) is calculated as:

\[
(PaCO_2 - PEO_2) + PaCO_2
\]

Normal \(V_d/V_t\) is approximately 0.33. Venous admixture and intrapulmonary shunting predominantly affect oxygenation, resulting in an alveolar oxygen (\(PaO_2\)) to \(PaO_2\) (A-ao \(O_2\)) gradient without elevation in \(PaCO_2\). This physiology is caused by greater ventilation of perfused areas, which is sufficient to normalize \(PaCO_2\) but not \(PaO_2\) because of their respective dissociation curves. The relative straight-line relationship of the hemoglobin-CO2 dissociation allows for averaging of capillary \(Pco_2\) (\(Pcco_2\)) from hyperventilated and hypoventilated areas. Because the association between oxygen tension and hemoglobin saturation plateaus with increasing \(PaO_2\), the decreased hemoglobin-O2 saturation in poorly ventilated areas cannot be compensated for by well-ventilated areas where hemoglobin-O2 saturation has already reached near-maximum. This physiology results in decreased arterial oxyhemoglobin saturation (\(Sao_2\)) and \(PaO_2\). Elevation of \(PaCO_2\) in such situations is indicative of coincident alveolar hypoventilation. Examples of diseases leading to venous admixture include asthma and aspiration pneumonia, and those of intrapulmonary shunt include lobar pneumonia and ARDS.

**Diffusion**

Even if ventilation and perfusion are matched, gas exchange requires diffusion across the interstitial space between alveoli and pulmonary capillaries. Under normal conditions, there is sufficient time for the pulmonary capillary blood to equilibrate with alveolar gas across the interstitial space. When the interstitial space is filled with inflammatory cells or fluid, diffusion is impaired. Because the diffusion capacity of CO2 is 20 times greater than that of O2, diffusion defects manifest as hypoxemia rather than hypercarbia. Even with the administration of 100% oxygen, \(PaO_2\) increases to approximately 660 mm Hg from 100 mm Hg at sea level, and the concentration gradient for diffusion of O2 is increased by only 6.6 times. Therefore, with diffusion defects, lethal hypoxemia will set in before clinically significant CO2 retention results. In fact,
in such situations, $\text{Paco}_2$ is often decreased because of the hyperventilation that accompanies hypoxemia. Presence of hypercarbia in diseases that impair diffusion is indicative of alveolar hypoventilation from coexisting airway obstruction, exhaustion, or CNS depression. Examples of disease that impair diffusion are interstitial pneumonia, ARDS, scleroderma, and pulmonary lymphangiectasia.

**Monitoring a Child in Respiratory Distress and Respiratory Failure**

**Clinical Examination**

It cannot be overemphasized that clinical observation is the most important component of monitoring. The presence and magnitude of abnormal clinical findings, their progression with time, and their temporal relation to therapeutic interventions serve as guides to diagnosis and management (see Chapter 400). As much as possible, the child with respiratory distress or failure should be observed in the position of greatest comfort and in the least threatening environment.

**Pulse oximetry** is the most commonly used technique to monitor oxygenation. Noninvasive and safe, it is the standard of care in bedside monitoring of children during transport, procedural sedation, surgery, and critical illness. It indirectly measures arterial hemoglobin-O$_2$ saturation by differentiating oxyhemoglobin from deoxygenated hemoglobin using their respective light absorption at wavelengths of 660 nm (red) and 940 nm (infrared). A pulsatile circulation is required to enable detection of oxygenated blood entering the capillary bed. Percentage of arterial oxyhemoglobin is reported as $\text{SaO}_2$; however, the correct description is *oxyhemoglobin saturation as measured by pulse oximetry* ($\text{SpO}_2$). Such precision is needed because $\text{SpO}_2$ may not always reflect $\text{SaO}_2$. It is important to be familiar with the hemoglobin-O$_2$ dissociation curve (see Chapter 400) to estimate $\text{Pao}_2$ at a given oxyhemoglobin saturation. Because of the shape of the hemoglobin-O$_2$ dissociation curve, changes in $\text{Pao}_2$ above 70 mm Hg are not readily identified by pulse oximetry. Also, at the same $\text{Pao}_2$, there may be significant change in $\text{SpO}_2$ at a different blood pH value. In most situations, $\text{SpO}_2 > 95\%$ is a
reasonable goal, especially in emergency care. In some adult studies of ARDS, the recommended saturation is 94–96% to avoid oxygen toxicity. There are exceptions, such as in patients with single-ventricle cardiac lesions, in whom the pulmonary and systemic circulations are receiving blood flow from the same ventricle (e.g., after Norwood procedure for hypoplastic left heart syndrome), or with large left-to-right shunts (e.g., ventricular septal defect, patent ductus arteriosus). In these types of pathophysiologic situations, a lower Spo₂ is desired to avoid excessive blood flow to the lungs and pulmonary edema from the pulmonary vasodilatory effects of oxygen, in the patient with a single ventricle, diverting blood flow away from the systemic circulation. Because most commercially available pulse oximeters recognize all types of hemoglobin as either oxyhemoglobin or deoxygenated hemoglobin, they provide inaccurate information in the presence of carboxyhemoglobin and methemoglobin. In carbon monoxide poisoning, carboxyhemoglobin absorbs light in the same (red) wavelength as oxyhemoglobin, leading to overestimation of oxygen saturation. Methemoglobin absorbs light in both the oxygenated and deoxygenated wavelengths, which can cause either an overestimation or underestimation of oxygen saturation. Data suggest that increasing methemoglobin concentrations tend to drive Spo₂ toward 85%, no matter the actual percent of oxyhemoglobin. At lower methemoglobin levels, the pulse oximetry reading is falsely low, whereas high levels lead to a falsely high pulse oximetry reading. Newer pulse oximeters may have the ability to distinguish dyshemoglobinemias and to prevent false readings, but these are not currently in widespread use. It should be recognized that dangerous levels of hypercarbia may exist in patients with ventilatory failure, who have satisfactory Spo₂ if they are receiving supplemental oxygen. Pulse oximetry should not be the only monitoring method in patients with primary ventilatory failure, such as neuromuscular weakness and CNS depression. It is also unreliable in patients with poor perfusion and poor pulsatile flow to the extremities. Despite these limitations, pulse oximetry is a noninvasive, easily applicable, and effective means of evaluating the percentage of oxyhemoglobin in most patients.

**Volumetric capnography** (end-tidal CO₂ [PetCO₂] measurement) is helpful in non-invasively determining the effectiveness of ventilation and pulmonary circulation. The PetCO₂ can be used to determine the alveolar dead space fraction and is calculated as follows: \([(Paco₂ - PetCO₂) / Paco₂]\). Changes in the alveola dead space fraction usually correlate well with changes in the gradient of Paco₂
and PetCO₂ (Paco₂ – PetCO₂). Thus a change in Paco₂ – PetCO₂ can be used as an index of changes in alveolar dead space. In healthy children the gradient is smaller than in adults and is usually <3 mm Hg. Diseases resulting in increased alveolar dead space (e.g., dynamic hyperinflation) or decreased pulmonary blood flow (e.g., pulmonary embolism, low cardiac output) lead to decreases in PetCO₂ and an increase in Paco₂ – PetCO₂. PetCO₂ alone may overestimate adequacy of ventilation.

**Blood Gas Abnormalities**

Arterial blood gas analysis offers valuable assistance in diagnosis, monitoring, and management of a child in respiratory distress and failure. Because of technical difficulties in obtaining an arterial sample in children, a capillary blood gas (CBG) sample is most often obtained in emergency situations. A properly arterialized CBG sample obtained by warming the digit and obtaining free-flowing blood is acceptable. The blood sample needs to be processed without delay. CBG provides a good estimate of Paco₂ and arterial pH, but less so for Pao₂. In patients who mainly require monitoring of ventilation (especially those whose oxygenation is being monitored with pulse oximetry) a venous blood gas sample provides reliable estimate of arterial pH and Paco₂ values, provided tissue perfusion is reasonably adequate. Venous Pco₂ (Pvco₂) is approximately 6 mm Hg higher and pH approximately 0.03 lower than the arterial values. Pvo₂ has a poor correlation with Pao₂. Mixed venous O₂ saturation obtained from a central venous catheter in the right atrium is an excellent marker of the balance between oxygen delivery and oxygen consumption. In patients with a constant arterial O₂ content and O₂ consumption, mixed venous O₂ saturation offers valuable information about cardiac output.

Blood gas analysis is important not only for determining the adequacy of oxygenation and ventilation but also for determining site of respiratory pathology and planning treatment (see Chapter 400). Briefly, in the presence of pure alveolar hypoventilation (e.g., airway obstruction above carina, decreased CO₂ responsiveness, neuromuscular weakness), the blood gas will show respiratory acidosis with an elevated Paco₂ but a relative sparing of oxygenation. V/Q mismatch (peripheral airway obstruction, bronchopneumonia) will be reflected in increasing hypoxemia and variable levels of Paco₂ (low, normal,
high) depending on severity of disease. Intrapulmonary right-to-left shunting and diffusion defects (alveolar-interstitial diseases such as pulmonary edema, ARDS) will be associated with a large A-aO\textsubscript{2} gradient and hypoxemia with relative sparing of CO\textsubscript{2} elimination, unless there is coincident fatigue or CNS depression.

**Acid-Base Abnormalities**

It is crucial to analyze the magnitude and appropriateness of changes in pH, Paco\textsubscript{2}, and bicarbonate concentration ([HCO\textsubscript{3} ]) because they provide useful clues to the underlying pathophysiology and presence of more than 1 disorder. To do so, it is useful to assume baseline values of pH 7.40, Paco\textsubscript{2} 40 mm Hg, and [HCO\textsubscript{3} ] 24 mEq/L. Newborns have lower renal threshold for bicarbonate and therefore have slightly different baseline values of pH 7.38, Paco\textsubscript{2} 35 mm Hg, and [HCO\textsubscript{3} ] 20 mEq/L.

**Metabolic Acidosis With Respiratory Compensation**

Patients with metabolic acidosis have decreased pH resulting from decreased serum [HCO\textsubscript{3} ]. Chemoreceptor stimulation results in hyperventilation and respiratory compensation that may clinically manifest as respiratory distress. Normal compensation does not completely correct the pH but rather minimizes a change in pH that would otherwise occur without compensation. The adequacy of respiratory compensation is judged by the extent of the decline in Paco\textsubscript{2} in response to the decline in [HCO\textsubscript{3} ] or pH. A normal compensation for metabolic acidosis results in a fall in Paco\textsubscript{2} by 1.2 mm Hg for every 1 mEq/L fall in [HCO\textsubscript{2} ]. The most commonly used method to analyze the adequacy of respiratory compensation is Winter's formula:

\[
\text{PaCO}_2 = ([\text{HCO}_3^-] \times 1.5) + 8 \pm 2
\]

A quick method is to look at the last 2 digits of pH (provided it is not <7.10), which should be within 2 mm Hg of Paco\textsubscript{2}. For example, pH 7.27, Paco\textsubscript{2} 26 mm Hg, and [HCO\textsubscript{3} ] 12 mEq/L represents metabolic acidosis with a normal
respiratory compensation response. On the other hand, pH 7.15, Paco₂ 30 mm Hg, and [HCO₃⁻] 10 mEq/L constitutes metabolic acidosis with inadequate respiratory compensation. The reasons for inadequate compensation include decreased CO₂ responsiveness (e.g., narcotic poisoning, cerebral edema), abnormalities of lungs and airways, or neuromuscular weakness. A decrease in Paco₂ that is greater than what could be expected as a normal compensatory response to metabolic acidosis is indicative of a mixed disorder. A pH 7.20, Paco₂ 15 mm Hg, and [HCO₃⁻] 7.5 mEq/L represents metabolic acidosis with a concomitant respiratory alkalosis because the decline in Paco₂ is greater than what can be expected as normal compensation. Combination of metabolic acidosis and respiratory alkalosis is often encountered in serious conditions such as cardiogenic shock (e.g., anxiety, stimulation of baroreceptors), sepsis, or toxic-metabolic states (e.g., salicylates, organic acidemia).

**Respiratory Acidosis With Metabolic Compensation**

Patients with respiratory acidosis have decreased pH as a result of elevated Paco₂. An acute increase in Paco₂ of 10 mm Hg results in a decrease in pH by 0.08. Thus a child with severe status asthmaticus and a Paco₂ of 60 mm Hg will have blood pH of approximately 7.24. Chronically elevated (>3-5 days) Paco₂ is accompanied by renal compensation and increase in serum [HCO₃⁻], limiting the fall in pH to 0.03 for every 10 mm Hg rise in Paco₂. Thus an infant with bronchopulmonary dysplasia who has a basal Paco₂ of 60 mm Hg will have blood pH of approximately 7.34. These findings are helpful in distinguishing acute from chronic changes in Paco₂. Also, for a given level of CO₂ accumulation, a decrease in pH that is greater than expected is indicative of concomitant metabolic acidosis, and a decline in pH that is less than expected is caused by accompanying metabolic alkalosis.

**Assessment of Oxygenation and Ventilation Deficits**

For standardizing management, following clinical progress, and determining prognosis for patients with defects in oxygenation or ventilation, the following indicators have been proposed, each with its strengths and limitations:
A-ao \textsubscript{2} gradient is calculated by the subtraction, P\textsubscript{AO\textsubscript{2}} − P\textsubscript{ao\textsubscript{2}}. For the comparison to be valid, both values must be taken at the same time and with the same fraction of oxygen in the inspired gas (F\textsubscript{IO\textsubscript{2}}).

P\textsubscript{ao\textsubscript{2}}/F\textsubscript{IO\textsubscript{2}} ratio (P/F) is calculated by dividing P\textsubscript{ao\textsubscript{2}} by F\textsubscript{IO\textsubscript{2}}. In hypoxic respiratory failure, a P\textsubscript{ao\textsubscript{2}}/F\textsubscript{IO\textsubscript{2}} value <300 mm Hg is consistent with acute lung injury, and a value <200 mm Hg is consistent with ARDS. Although the intent is to measure V/Q mismatch, intrapulmonary shunt, and diffusion defect, the status of alveolar hypoventilation could have a significant impact on P\textsubscript{ao\textsubscript{2}}/F\textsubscript{IO\textsubscript{2}}.

Spo\textsubscript{2}/F\textsubscript{IO\textsubscript{2}} ratio is a surrogate measure of oxygenation when P\textsubscript{ao\textsubscript{2}} is not available. It is calculated by dividing the pulse oximeter saturation by the F\textsubscript{IO\textsubscript{2}}. P/F ratios of 200 mm Hg and 300 mm Hg correlate approximately with S/F ratios of 235 and 315 respectively. This relationship is most valid for Spo\textsubscript{2} values between 80% and 97%.

P\textsubscript{ao\textsubscript{2}}/P\textsubscript{AO\textsubscript{2}} ratio is determined by dividing P\textsubscript{ao\textsubscript{2}} by P\textsubscript{AO\textsubscript{2}}. The level of alveolar ventilation is accounted for in the calculation of P\textsubscript{ao\textsubscript{2}}. Therefore, P\textsubscript{ao\textsubscript{2}}/P\textsubscript{AO\textsubscript{2}} is more indicative of V/Q mismatch and alveolar capillary integrity.

Oxygenation index (OI) is aimed at standardizing oxygenation to the level of therapeutic interventions, such as mean airway pressure (MAP) and F\textsubscript{IO\textsubscript{2}} used during mechanical ventilation, which are directed toward improving oxygenation. None of the indicators of oxygenation mentioned above takes into account the degree of positive pressure respiratory support.

\[
\text{OI} = (\text{MAP} \times \text{FIO}_{2} \times 100) / P\text{ao}_{2}
\]

The limitation of OI is that level of ventilation is not accounted for in the assessment.

Ventilation index (VI) is aimed at standardizing alveolar ventilation to the level of therapeutic interventions, such as peak inspiratory pressure (PIP), positive end-expiratory pressure (PEEP), and ventilator rate ([R]) directed toward lowering P\textsubscript{aco\textsubscript{2}}.
Management

The goal of management for respiratory distress and respiratory failure is to ensure a patent airway and provide necessary support for adequate oxygenation of the blood and removal of $CO_2$. Compared with hypercapnia, hypoxemia is a life-threatening condition; therefore initial therapy for respiratory failure should be aimed at ensuring adequate oxygenation.

Oxygen Administration

Supplemental oxygen administration is the least invasive and most easily tolerated therapy for hypoxemic respiratory failure. Nasal cannula oxygen provides low levels of oxygen supplementation and is easy to administer. Oxygen is humidified in a bubble humidifier and delivered via nasal prongs inserted in to the nares. In children, a flow rate $<$5 L/min is most often used because of increasing nasal irritation with higher flow rates. A common formula for an estimation of the $F_{IO_2}$ during use of a nasal cannula in older children and adults follows:

$$F_{IO_2} \text{(as percentage)} = 21\% + [(\text{Nasal cannula flow (L/min)} \times 3)]$$

The typical $F_{IO_2}$ value (expressed as percentage rather than fraction of 1) using this method is between 23% and 40%, although the $F_{IO_2}$ varies according to the size of the child, the respiratory rate, and the volume of air moved with each breath. In a young child, because typical nasal cannula flow rates are a greater percentage of total minute ventilation, significantly higher $F_{IO_2}$ may be provided. Alternately, a simple mask may be used, which consists of a mask with open side ports and a valveless oxygen source. Variable amounts of room air are entrained through the ports and around the side of the mask, depending on the fit, size, and minute volume of the child. Oxygen flow rates vary from 5-10 L/min, yielding typical $F_{IO_2}$ values (expressed as percentage rather than fraction}
of 1) between 30% and 65%. If more precise delivery of oxygen is desired, other mask devices should be used.

A **Venturi mask** provides preset $F_{IO_2}$ through a mask and reservoir system by entraining precise flow rates of room air into the reservoir along with high-flow oxygen. The adapter at the end of each mask reservoir determines the flow rate of entrained room air and the subsequent $F_{IO_2}$. (Adapters provide $F_{IO_2}$ of 0.30-0.50.) Oxygen flow rates of 5-10 L/min are recommended to achieve the desired $F_{IO_2}$ and to prevent rebreathing. Partial rebreather and non-rebreather masks use a reservoir bag attached to a mask to provide higher $F_{IO_2}$. **Partial rebreather masks** have 2 open exhalation ports and contain a valveless oxygen reservoir bag. Some exhaled gas can mix with reservoir gas, although most exhaled gas exits the mask via the exhalation ports. Through these same ports, room air is entrained, and the partial rebreather mask can provide $F_{IO_2}$ up to 0.60, for as long as oxygen flow is adequate to keep the bag from collapsing (typically 10-15 L/min). As with nasal cannulas, smaller children with smaller tidal volumes entrain less room air, and their $F_{IO_2}$ values will be higher. **Non-rebreather masks** include 2 one-way valves, 1 between the oxygen reservoir bag and the mask and the other on 1 of the 2 exhalation ports. This arrangement minimizes mixing of exhaled and fresh gas and entrainment of room air during inspiration. The 2nd exhalation port has no valve, a safeguard to allow some room air to enter the mask in the event of disconnection from the oxygen source. A non-rebreather mask can provide $F_{IO_2}$ up to 0.95. The use of a non-rebreather mask in conjunction with an oxygen blender allows delivery of $F_{IO_2}$ between 0.50 and 0.95 (**Table 89.8**). When supplemental oxygen alone is inadequate to improve oxygenation, or when ventilation problems coexist, additional therapies may be necessary.

* Individual delivery varies and depends on the patient's size, respiratory rate, and volume moved with every breath.

**Airway Adjuncts**

Maintenance of a patent airway is a critical step in maintaining adequate oxygenation and ventilation. Artificial pharyngeal airways may be useful in patients with oropharyngeal or nasopharyngeal airway obstruction and in those with neuromuscular weakness in whom inherent extrathoracic airway resistance contributes to respiratory compromise. An oropharyngeal airway is a stiff plastic spacer with grooves along each side that can be placed in the mouth to run from the teeth along the tongue to its base just above the vallecula. The spacer prevents the tongue from opposing the posterior pharynx and occluding the airway. Because the tip sits at the base of the tongue, it is usually not tolerated by patients who are awake or whose gag reflex is strong. The nasopharyngeal airway, or nasal trumpet, is a flexible tube that can be inserted into the nose to run from the nasal opening along the top of the hard and soft palate with the tip ending in the hypopharynx. It is useful in bypassing obstruction from enlarged adenoids or from contact of the soft palate with the posterior nasopharynx. Because it is inserted past the adenoids, a nasopharyngeal airway should be used with caution in patients with bleeding tendencies.

**Inhaled Gases**

**Helium-oxygen mixture** (heliox) is useful in overcoming airway obstruction and improving ventilation. Helium is much less dense and slightly more viscous than nitrogen. When substituted for nitrogen, helium helps maintain laminar flow across an obstructed airway, decreases airway resistance, and improves ventilation. It is especially helpful in diseases of large airways obstruction in which turbulent airflow is more common, such as acute laryngotraacheobronchitis, subglottic stenosis, and vascular ring. It is also used in patients with severe status asthmaticus. To be effective, helium should be administered in concentrations of at least 60%, so associated hypoxemia may limit its use in patients requiring >40% oxygen.

**Inhaled nitric oxide** (iNO) is a powerful inhaled pulmonary vasodilator. Its use may improve pulmonary blood flow and V/Q mismatch in patients with
diseases that elevate pulmonary vascular resistance, such as occurs in persistent pulmonary hypertension of the newborn, primary pulmonary hypertension, and secondary pulmonary hypertension as a result of chronic excess pulmonary blood flow (e.g., ventriculoseptal defect) or collagen vascular diseases. iNO is administered in doses ranging from 5 to 20 parts per million of inspired gas. Although administration of iNO to unintubated patients is possible, it is usually administered to patients undergoing mechanical ventilation via an endotracheal tube, because of the need for precision in iNO dosing.

Positive Pressure Respiratory Support

Noninvasive positive pressure respiratory support is useful in treating both hypoxemic and hypoventilatory respiratory failure. Positive airway pressure helps with aeration of partially atelectatic or filled alveoli, prevention of alveolar collapse at end-exhalation, and increase in functional residual capacity (FRC). These actions improve pulmonary compliance and hypoxemia, as well as decrease intrapulmonary shunt. In addition, positive pressure ventilation is useful in preventing collapse of extrathoracic airways by maintaining positive airway pressure during inspiration. Improving compliance and overcoming airway resistance also improves tidal volume and therefore ventilation. A high-flow nasal cannula delivers gas flow at 4-16 L/min and up to 60 L/min, with newer systems for older children and adolescents, capable of providing significant continuous positive airway pressure (CPAP). In this setting, the amount of CPAP provided is not quantifiable and varies with each patient, depending on the percentage of total inspiratory flow that is delivered from the cannula, airway anatomy, and degree of mouth breathing. In small children the relative amount of CPAP for a given flow is usually greater than in older children and may provide significant positive pressure. The F\textsubscript{IO}\textsubscript{2} can be adjusted by provision of gas flow through an oxygen blender. Another benefit of a high-flow nasal cannula system is the washout of CO\textsubscript{2} from the nasopharynx, which decreases rebreathing of CO\textsubscript{2} and dead space ventilation. When delivering high-flow air or oxygen, adequate humidification is essential, by using a separate heated humidification chamber. CPAP can also be provided through snugly fitting nasal prongs or a tight-fitting face mask attached to a mechanical ventilator or other positive pressure device. Noninvasive CPAP is most useful in diseases of mildly decreased lung compliance and low FRC, such as atelectasis and pneumonia. Patients with diseases of extrathoracic airway obstruction, in
which extrathoracic negative airway pressures during inspiration lead to airway narrowing (e.g., laryngotracheitis, obstructive sleep apnea, postextubation airway edema), may also benefit from CPAP. Potential risks include nasal irritation, hyperinflation from excessive CPAP in smaller patients, and abdominal distention from swallowed air.

**Noninvasive positive airway pressure ventilation (NIPPV)** provides positive airway pressure during exhalation, and bilevel modes can apply additional positive pressure during inspiration (see Chapter 89.1).

### Endotracheal Intubation and Mechanical Ventilation

When hypoxemia or significant hypoventilation persists despite the interventions already described, endotracheal intubation and mechanical ventilation are indicated. Additional indications for intubation include maintaining airway patency in patients who have the potential for airway compromise, such as those with actual or potential neurologic deterioration, and in patients with hemodynamic instability.

Proper monitoring is essential to ensuring a safe and successful endotracheal intubation. Pulse oximetry, heart rate, and blood pressure monitoring are mandatory and should be forgone only in situations calling for emergency intubation. All necessary equipment, including bag-mask ventilation device, laryngoscope, endotracheal tube (ETT) with stylet, and suction equipment, must be available and working properly before the procedure of intubation. The proper internal diameter (ID) for the ETT can be estimated using the following formula:

\[ \text{ID} = \left( \frac{\text{Age [yr]}}{4} \right) + 4 \]

*Table 89.9* provides average values for age, size, and depth of insertion for tracheal tubes. Preoxygenation of the patient with high $\text{FiO}_2$ is essential and will allow maximum procedure time before the onset of hypoxemia. Although intubation can be accomplished without sedation and pharmacologic paralysis in selected patients, the physiologic benefits of these measures to the patient as well as to the facilitation of the intubation usually far outweigh the risks. Administration of a sedative and analgesic followed by a paralytic agent is a
common pharmacologic regimen for facilitating intubation. In fact, sedation and paralysis with neuromuscular blocking agents should be considered standard unless contraindicated. The particular type and dose of each agent often depends on the underlying disease and clinician preference. Table 89.10 lists commonly used agents. *Dexmedetomidine* has been a standard sedating agent for maintenance during mechanical ventilation. An alternative to this pharmacologic approach is rapid sequence intubation, used when endotracheal intubation is urgent, or the patient is suspected of having a full stomach and at increased risk of aspiration (see Chapter 81).

BP, Blood pressure; HR, heart rate; ICP, intracranial pressure; IM, intramuscularly; IV, intravenously.

Once adequate sedation and/or paralysis have been achieved, ventilation should be assisted with a **bag-mask device**. After optimal preoxygenation, intubation can be performed. The clinician uses the dominant hand to open the patient's mouth and insert the laryngoscope blade gently along the tongue to its base. The airway opening can be visualized by applying lift up-and-away from the clinician, along the axis of the laryngoscope handle. When a *straight* (Miller) laryngoscope blade is used to visualize the glottis, the tip of the blade lifts the epiglottis anteriorly. When a *curved* (Macintosh) blade is used to visualize the glottis, the tip of the blade should be advanced into the vallecula and then lifted. Secretions often obscure visualizations at this step and should be suctioned clear. Once clear visualization of the vocal cords is accomplished, the ETT can be placed through the vocal cords. Rapid confirmation of ETT placement is essential and should be assessed by as many of the following steps as possible: presence of PetCO₂ determined by a monitor attached in-line with ETT; auscultation of both lung fields as well as the epigastrium for equal breath sounds; and, good air movement and evaluation of the abdomen for increasing distention. Adequate, bilateral chest expansion and misting inside the ETT with each breath confirm proper tube placement. An increasing heart rate, if heart rate has decreased during the attempt, and a rising or normal SpO₂ reading are suggestive of successful tube placement. Preoxygenation may significantly delay any drop in SpO₂ with improper tube placement, leading to a significant delay in its recognition. Confirmation of exhaled PetCO₂ is mandatory, using a disposable colorimetric CO₂ detector or with capnography. In situations of very low pulmonary perfusion, such as cardiac arrest, PetCO₂ may not be detected. A chest radiograph should also be obtained to confirm proper placement of the ETT,
which should lie with the tip about halfway between the glottis and the carina (see Chapter 81).

**Transient Manual Ventilation in Immediate Preintubation and Postintubation Periods**

Establishment of supportive ventilation via bag-mask or bag-ETT is required before transport of the patient to a setting of continued critical care. The technique of manual ventilation should take into account the underlying pathology. Mechanical ventilation of patients with diseases characterized by low FRC (e.g., pneumonia, pulmonary edema, ARDS) should include the application of PEEP to prevent alveolar derecruitment. Lung volume recruitment can be accomplished with a PEEP valve on a self-inflating ventilation bag or by careful manipulation of exhaust gas using an anesthesia bag. Such diseases are also characterized by a short time constant for lung deflation and therefore are best managed with relatively small tidal volumes and high ventilation rates.

In contrast, diseases characterized by airway obstruction have prolonged deflation time constants and are therefore best managed with relatively slow rates and high tidal volumes.

barotrauma  
biotrauma
The decision to institute support with mechanical ventilation is based mainly on the need to assist lung function; supporting left ventricular (LV) performance and treating intracranial hypertension are additional indications. Although there are no absolute criteria for derangement of gas exchange, \( P_{aO_2} < 60 \text{ mm Hg} \) while breathing >60% oxygen, \( P_{aco_2} > 60 \text{ mm Hg} \), and pH <7.25 are often reasons to initiate mechanical ventilation. Clinical impressions of fatigue and impending exhaustion are also indications for ventilatory support, even in the presence of adequate gas exchange. Positive pressure ventilation is a powerful means of decreasing LV afterload, and it is used for this purpose in patients with cardiogenic shock resulting from LV dysfunction. Mechanical ventilation is also used in patients whose breathing is unreliable (e.g., unconscious patients, those with neuromuscular dysfunction) and when deliberate hyperventilation is desired, such as in patients with intracranial hypertension.

Mechanical ventilation is not intended to normalize gas exchange, nor is it a cure. The goals are to maintain sufficient oxygenation and ventilation to ensure tissue viability until the disease process that has compromised the patient's lung function has resolved, while minimizing any complications. Thus, \( P_{aO_2} \), \( P_{aco_2} \) and pH levels are maintained in ranges that provide a safe environment for the patient, while protecting the lungs from damage caused by oxygen toxicity, pressure (barotrauma), tidal volume overdistention (volutrauma), atelectrauma, and cytokine release (biotrauma) (Figs. 89.2 and 89.3).
Atelectrauma. The interface between collapsed and consolidated lung (A) and overdistended lung units (B) is heterogeneous and unstable. Depending on ambient conditions, this region is prone to cyclic recruitment and derecruitment and localized asymmetric stretch of lung units (C) immediately apposed to regions of collapsed lung.

FIG. 89.3  Pulmonary pressure-volume relation in a patient with acute lung injury. Top, The lower inflection point is typically 12-18 cm H₂ O, and the upper inflection point 26-32 cm H₂ O. Bottom, Specific protective ventilation strategies require that positive end-expiratory pressure (PEEP) is set just above the lower inflection point and the pressure limit (Pmax) just below the upper inflection point. Thus the lung is ventilated in the safe zone between the zone of recruitment and derecruitment and the zone of overdistention, and both high-volume and low-volume injuries are avoided. (From Pinhu L, Whitehead T, Evans T, et al: Ventilator-associated lung injury, Lancet 361:332–340, 2003.)

Basic Concepts of Ventilator Management
Equation of Motion

A pressure gradient is required for air to move from one place to another. During natural spontaneous ventilation, inspiration results from generation of negative intrapleural pressure from contraction of the diaphragm and intercostal muscles, drawing air from the atmosphere across the airways into the alveoli. During mechanical ventilation, inspiration results from positive pressure created by compressed gases through the ventilator, which pushes air across the airways into alveoli. In both spontaneous and mechanical ventilation, exhalation results from alveolar pressure generated by the elastic recoil of the lung and the chest wall. Pressure necessary to move a given amount of air into the lung is determined by 2 factors: lung and chest wall elastance and airway resistance. Fig. 89.4 describes the relationship in pressure gradient, compliance, and resistance. Elastance —defined as the change in pressure (ΔP) divided by the change in volume (ΔV)—refers to the property of a substance to oppose deformation. It is opposite of compliance (ΔV ÷ ΔP), the property of a substance to allow distention or lengthening when subjected to pressure. Compliance (C) is therefore expressed as 1/elastance.
place to another. In the lungs, the required pressure gradient must overcome the lung and chest wall elastance (static component) and the flow-resistive properties (dynamic component). The static component is increased in alveolar interstitial diseases and stiff chest wall, whereas the dynamic component is increased with airway obstruction.

The pressure needed to overcome tissue elastance is measured in conditions in which there is no flow (at end-inspiration and end-expiration) and is therefore a reflection of static conditions in the lung. It is influenced by tidal volume ($V_T$) and compliance ($P = \Delta V \div C$). It is increased with high $V_T$ and low compliance. This pressure gradient is used to calculate the static compliance of the respiratory system ($C_{STAT}$).

*Resistance* ($R$) refers to the opposition to generation of flow. It is measured as the amount of pressure needed to generate a unit of flow ($\Delta P \div \Delta Flow$). Pressure needed to overcome airway resistance is calculated as flow multiplied by resistance. Because this pressure is needed only when the flow is occurring through the airways, it is referred to as the *dynamic component*. Pressure to overcome flow-resistive properties is measured when there is maximum flow and is therefore under dynamic conditions. It is increased in conditions with greater airway resistance and flow rate. Flow rate depends on the time allowed for inspiration and expiration. At higher respiratory rates, there is less time available for each inspiration and expiration, necessitating higher flows; therefore higher pressure is required to overcome flow-resistive properties. The pressure gradient necessary to move air from one place to another is the sum of pressure needed to overcome the elastic and flow-resistive properties of the lung. This pressure gradient is taken into account to calculate the dynamic compliance of the respiratory system ($C_{DYN}$). The difference in change in pressure between static conditions and dynamic conditions is attributable to airway resistance.

**Functional Residual Capacity**

During inspiration, oxygen-enriched gas enters alveoli. During exhalation, oxygen continues to be removed by the pulmonary capillary circulation. FRC is the volume of gas left in the alveoli at end-expiration. It is the only source of gas available for gas exchange during exhalation. In diseases with decreased FRC (e.g., ARDS, pulmonary edema), $P_{A0_2}$ declines sharply throughout expiration, resulting in hypoxemia. Two ventilator strategies used to improve oxygenation in such situations are the application of PEEP and increasing the *inspiratory time* ($T_i$) ([Fig. 89.5](#)). PEEP increases FRC, whereas a longer $T_i$ allows longer
exposure of pulmonary capillary blood to a higher concentration of O₂ during inspiration. (See also Chapter 400.)

**FIG. 89.5** Five different ways to increase mean airway pressure. (1) Increase the respiratory flow rate, producing a square wave inspiratory pattern; (2) increase the peak inspiratory pressure; (3) reverse the inspiratory-expiratory ratio or prolong the inspiratory time without changing the rate; (4) increase positive end-expiratory pressure; and (5) increase the ventilatory rate by reducing the expiratory time without changing the inspiratory time. (From Harris TR, Wood BR: Physiologic principles. In Goldsmith JP, Karotkin EH, editors: Assisted ventilation of the neonate, ed 3, Philadelphia, 1996, Saunders.)

**Time Constant**

At the beginning of inspiration, the atmospheric pressure is higher than the pressure in the alveoli, resulting in movement of air into the alveoli. During mechanical ventilation, the ventilator circuit serves as the patient's atmosphere. As alveoli expand with air, the alveolar pressure rises throughout inspiration until it equilibrates with the ventilator pressure, at which time airflow ceases. Expiration starts when the ventilator pressure falls below the alveolar pressure. Alveolar pressure decreases throughout expiration until it reaches the ventilator pressure, at which time no further egress of air from the alveoli occurs. If inspiration or expiration is terminated before pressure equilibration between alveoli and the ventilator is allowed to occur, alveolar expansion during inspiration or alveolar emptying during expiration is incomplete. Incomplete inspiration results in delivery of decreased Vₚ, whereas incomplete expiration is associated with air trapping and the presence of residual PEEP in the alveoli that
is greater than the ventilator pressure, referred to as **auto-PEEP**. Some time is required for pressure equilibration to occur between alveoli and the atmosphere, which is reflected in the *time constant* (TC). It takes 3 TCs for 95% (and 5 TCs for 99%) of pressure equilibration to occur. The TC depends on compliance (C) and resistance (R), and their relationship is depicted in Fig. 89.6. TC is calculated as compliance multiplied by resistance (C × R) and is measured in seconds.

![Fig. 89.6](image.png)

**Fig. 89.6** Time constant (TC). A certain amount of time is necessary for pressure equilibration (and therefore completion of delivery of gas) to occur between proximal airway and alveoli. TC, a reflection of time required for pressure equilibration, is a product of compliance and resistance. In diseases of decreased lung compliance, less time is needed for pressure equilibration to occur, whereas in diseases of increased airway resistance, more time is required. Expiratory TC is increased much more than inspiratory TC in obstructive airway diseases, because airway narrowing is exaggerated during expiration.

Diseases with decreased compliance (increased elastance) are characterized by high elastic recoil pressure, which results in more rapid equilibration of alveolar and ventilator pressures, thereby decreasing TC. Diseases with increased airway resistance are associated with slower flow rates, require longer time for movement of air from one place to another, and therefore have increased TC. Airways expand during inspiration and narrow during expiration. Therefore, expiratory time constant (TCₑ) is longer than inspiratory time constant (TCᵢ). In intrathoracic airway obstruction (e.g., asthma, bronchiolitis, aspiration syndromes), airway narrowing is much more pronounced during expiration.
Therefore, although both $T_{CE}$ and $T_{CI}$ are prolonged in such diseases, $T_{CE}$ is much more prolonged than $T_{CI}$. Patients with such diseases therefore are best ventilated with slower rates, higher $V_T$, and longer expiratory time than inspiratory time. In diseases characterized by decreased compliance, both $T_{CE}$ and $T_{CI}$ are short; however, the $T_{CE}$ is closer to $T_{CI}$ than in normal lungs because of the stiffer alveoli recoil with greater force. Patients with these diseases are best ventilated with small $V_T$ to prevent ventilator-induced lung injury and with a relatively longer inspiratory time in each breath to improve oxygenation.

**Critical Opening Pressure**

Collapsed or atelectatic alveoli require a considerable amount of pressure to open. Once open, the alveoli require relatively less pressure for continued expansion. The process of opening atelectatic alveoli is called recruitment. In a normal lung, alveoli remain open at end-expiration, and therefore the lung requires relatively less pressure to receive its $V_T$. In a disease process in which the alveoli collapse at end-expiration (e.g., ARDS), a substantial amount of pressure is required to open the alveoli during inspiration. This pressure causes ventilator-induced lung injury by 2 mechanisms: barotrauma at the terminal airway–alveolar junction and volutrauma as a result of overdistention of alveoli that are already open (see Figs. 89.2 and 89.3). Although a pulmonary parenchymal disease process is rarely uniform, and each of the millions of alveoli may have its own mechanical characteristics, a composite volume-pressure relationship could be conceptualized for the whole lung (Fig. 89.7).
In these situations, the lower and upper portions of the curve are relatively horizontal, and the middle portion is more vertical. At the beginning of inspiration, atelectatic alveoli are being recruited, requiring high pressure for a relatively small increase in volume. Once they are recruited, further increase in volume requires relatively less pressure. The pressure at which most alveoli are open is called critical opening pressure; this point is also referred to as the lower inflection point (lower $P_{FLEX}$). After the lower $P_{FLEX}$, greater volume can be delivered for relatively less pressure until the upper $P_{FLEX}$ is reached, at which the volume-pressure curve again becomes relatively horizontal. The goal of mechanical ventilation in alveolar interstitial pathology is to deliver a $V_T$ between the lower and upper inflection points, the so-called safe zone of ventilation. If $V_T$ is delivered with a change in inflation pressure that includes the lower $P_{FLEX}$, alveoli are likely to open and close during every breath, a process termed tidal recruitment that is injurious to the lung, especially at the terminal airway–alveolar junction. If $V_T$ is delivered with a change of pressure that includes the upper $P_{FLEX}$, overdistention of alveoli is likely to occur, resulting in volutrauma and barotrauma. Keeping tidal ventilation between the
upper and lower $P_{FLEX}$ values is accomplished by maintaining a level of PEEP to produce baseline alveolar recruitment and delivering a relatively small (6 mL/kg) $V_T$. Called “open lung” strategy, this approach has proved to be beneficial in alveolar interstitial diseases such as ARDS.

Mechanical ventilation may be delivered either noninvasively with a patient-machine interface other than an ETT or invasively after endotracheal intubation.

**Noninvasive Mechanical Ventilation**

Delivering positive pressure mechanical respiratory support without the use of endotracheal intubation is called noninvasive positive pressure ventilation (NIPPV). This type of respiratory support has been increasingly used in the pediatric intensive care setting.

The most common techniques applied are continuous positive airway pressure (CPAP) or biphasic (inspiratory and expiratory) positive airway pressure (BiPAP). A variety of devices with increasing sophistication has been developed in recent years, and different interfaces are available, such as nasal prongs, nasal and full-face masks, as well as helmets. Especially in the pediatric population a comfortable interface is critical for the successful application of NIPPV. NIPPV has been successfully used in acute and chronic hypoxic and/or hypercarbic respiratory failure. Indications range from acute lower airway obstruction such as asthma or acute upper airway obstruction including postextubation airway swelling, to parenchymal lung diseases such as pneumonia and ARDS. Acute and chronic respiratory failure, from neuromuscular weakness and chest wall deformities, has been the classic indication for its use. NIPPV can also be used to help prevent reintubation after prolonged mechanical ventilation.

BiPAP provides positive airway pressure during exhalation and additional positive pressure during inspiration. These pressures can be adjusted independently to suit individual needs and comfort, and a respiratory rate can be delivered. The additional positive pressure during inspiration helps improve alveolar ventilation in low compliance and obstructive lung disease. During exhalation, expiratory positive airway pressure can decrease the effects of airway closure by raising intraluminal pressure and ameliorating intrathoracic airway collapse. During inspiration, inspiratory positive airway pressure can unload inspiratory muscle work.
These mechanics may explain many of the physiological benefits of NIPPV including an increase in lung compliance and FRC, a decrease of dynamic airway narrowing (“stenting” of the airway), augmentation of VT and alveolar ventilation, and decreased work of breathing. Physiologic benefits of NIPPV in obstructive (e.g., asthma) and restrictive (e.g., ARDS) lung disease are schematically presented in Figs. 89.8 and 89.9. Additional benefits result from improving cardiopulmonary interactions, especially LV afterload reduction, thereby improving cardiac output in patients with acute or chronic LV dysfunction.

**FIG. 89.8** Work of breathing (WOB) in status asthmaticus with and without noninvasive positive pressure ventilation. In the expiratory limb of the respiratory cycle, the equal pressure point is displaced distally, causing airways to begin to close at a higher lung volume (increased closing capacity), leading to dynamic hyperinflation, and auto-positive end-expiratory pressure (auto-PEEP) (A). Application of expiratory positive airway pressure (EPAP) stents the airways, reducing intrathoracic airway collapse, dynamic hyperinflation, auto-PEEP (B), and WOB. In the inspiratory limb, the patient needs to generate less negative pressure to initiate inspiration because of lower auto-PEEP. Inspiratory muscles are further unloaded by inspiratory positive airway pressure (IPAP) throughout inspiration for the given tidal volume. Both expiratory and inspiratory WOB are thus reduced by application of noninvasive positive pressure ventilation. P-V, Pressure-volume. (From Sarnaik AA, Sarnaik AP: Noninvasive ventilation in pediatric status asthmaticus: sound physiologic rationale but is it really safe, effective, and cost-efficient? *Pediatr Crit Care Med* 13:484–485, 2012.)
NIPPV is usually well tolerated and safer than invasive mechanical ventilation. Airway trauma from endotracheal intubation can be avoided, and less sedation is required. Breaks can be given for the application of oral medications and clearance of respiratory secretions, and selected stable patients can be fed by mouth. The number of nosocomial infections, ventilator-associated pneumonia, and ventilator-induced lung injury is expected to decrease as well. In addition, aerosol therapy driven by NIPPV, appears to be more effective.

Complications of NIPPV may include upper airway mucosal irritation, pulmonary hyperinflation with resulting interstitial emphysema and pneumothorax, abdominal distention, aspiration, and feeding intolerance. Patients initiated on NIPPV need close cardiorespiratory monitoring because the respiratory failure may progress, leading to the need for endotracheal intubation.

Some authorities have suggested independent predictors of NIPPV failure. Patients with more severe respiratory distress and those who do not show improvement of respiratory indices (i.e., respiratory rate, reduction in FIO₂) within 2 hr of initiation are more likely to fail. Underlying severe systemic diseases such as sepsis, multiorgan dysfunction, and malignancies are less likely to respond favorably to NIPPV. Absolute contraindications include loss of airway reflexes, acute severe neurologic insults, cardiorespiratory arrest, and severe hemodynamic instability. Patients with mid-face abnormalities or facial
trauma and burns should not be considered as candidates for NIPPV. Other contraindications include the immediate postoperative period after facial and upper airway surgery, recent gastrointestinal surgery, or patients with bowel obstruction and vomiting. Patients who are severely agitated and confused should not be initiated on NIPPV. NIPPV has been shown to decrease intubation rates, as well as reintubation rates, and is increasingly used to treat acute or chronic respiratory failure in pediatric patients.

**Invasive Mechanical Ventilation**

Mechanical ventilation involves considering the four phases of the respiratory cycle: (1) initiation of respiration and a variable that is controlled, often referred to as *mode*; (2) inspiratory phase characteristics, which determine the duration of inspiration and how the pressure or volume is delivered; (3) termination of inspiration, often referred to as *cycle*; and (4) expiratory phase characteristics. Ideally, mechanical ventilation should not completely take over the work of breathing, but rather should assist the patient's own respiratory effort. In the absence of any patient effort, respiratory muscle deconditioning may occur, making weaning from mechanical ventilation more difficult.

**Initiation of Inspiration and the Control Variable (Mode)**

The initiation of inspiration may be set to occur at a predetermined rate and interval regardless of patient effort, or it could be timed in response to patient effort. Once inspiration is initiated, the ventilator breath either is controlled entirely by the ventilator (*control mode*) or supports the patient's inspiratory effort to a predetermined inspiratory volume or pressure target (*support mode*). Advances in technology allow for greater patient-ventilator synchrony to occur. The ventilator may be set to be *triggered* by the signal it receives as a result of patient effort. This feature may be in the form of lowering of either pressure (*pressure trigger*) or airflow (*flow trigger*) in the ventilator circuit generated by the patient's inspiratory effort. If no such signal is received because of lack of patient effort, the ventilator delivers a breath at an interval selected by the operator.
Control Modes

Intermittent Mandatory Ventilation Mode.

In intermittent mandatory ventilation (IMV), the inspiration is initiated at a set frequency with a timing mechanism independent of patient effort. In between machine-delivered breaths, the patient can breathe spontaneously from a fresh source of gas. IMV allows for adjustment of ventilator support according to the patient's needs, making it useful in the weaning process. Lack of synchrony between machine-delivered breaths and patient efforts may result in ineffective ventilation and patient discomfort, especially when IMV is delivered at a high rate. In such cases the patient may require sedation and pharmacologic neuromuscular blockade for efficient delivery of $V_T$. To obviate this problem, synchronized IMV (SIMV) is used, whereby the machine-delivered breaths are triggered by the patient's inspiratory efforts (Fig. 89.10). In between the machine-delivered breaths, a fresh source of gas is available for spontaneous patient breaths. In the absence of patient effort, the patient receives a backup rate, as in IMV mode. Even with SIMV, ventilator-patient asynchrony can occur, because $V_T$, inflation pressure, and inspiratory time are determined by the ventilator alone.

![Synchronized intermittent mandatory ventilation](image)

**FIG. 89.10** Synchronized intermittent mandatory ventilation. At set intervals, the ventilator’s timing circuit becomes activated and a timing “window” appears (dotted line area). If the patient initiates a breath in the timing window, the ventilator delivers a mandatory breath (A). If no spontaneous effort occurs, the ventilator delivers a mandatory breath at a fixed time after the timing window (B). (From Banner MJ, ...
Assist-Control Mode.

In assist-control (AC) mode, every patient breath is triggered by pressure or flow generated by patient inspiratory effort and “assisted” with either preselected inspiratory pressure or volume. The rate of respirations is therefore determined by the patient's inherent rate. A backup total (patient and ventilator) obligatory rate is set to deliver a minimum number of breaths. On AC mode, with a backup rate of 20 breaths/min and a patient's inherent rate of 15 breaths/min; the ventilator will assist all the patient's breaths, and the patient will receive 5 additional breaths/min. On the other hand, a patient with an inherent rate of 25 breaths/min will receive all 25 breaths assisted. Although useful in some patients, the AC mode cannot be used in the weaning process, which involves gradual decrease in ventilator support.

Control Variable

Once initiated, either the VT or the pressure delivered by the machine can be controlled. The machine-delivered breath is thus referred to as either volume controlled or pressure controlled (Table 89.11). With volume-controlled ventilation (VCV), machine-delivered volume is the primary control, and the inflation pressure generated depends on the respiratory system's compliance and resistance. Changes in respiratory system compliance and resistance are therefore easily detected from changes observed in inflation pressure. In pressure-controlled ventilation (PCV) the pressure change above the baseline is the primary control, and the Vt delivered to the lungs depends on the respiratory system's C and R. Changes in respiratory system C and R do not affect inflation pressure and may therefore go undetected unless the exhaled Vt is monitored.

VCV and PCV have their own advantages and disadvantages (Table 89.11). Generally speaking, PCV is more efficient than VCV in terms of amount of VT delivered for a given inflation pressure during ventilation of a lung that has nonuniform TC, as in asthma. In VCV, relatively less-obstructed airways are likely to receive more of the machine-delivered volume throughout inspiration than relatively more-obstructed airways with longer TC (Fig. 89.11 A). This situation would result in uneven ventilation, higher peak inspiratory pressure (PIP), and a decrease in $C_{DYN}$. In PCV, because of a constant inflation pressure that is held throughout inspiration, relatively less-obstructed lung units with shorter TC would achieve pressure equilibration earlier during inspiration than the relatively more-obstructed areas. Thus, units with shorter TCs would attain their final volume earlier in inspiration, and those with longer TCs would continue to receive additional volume later in inspiration (Fig. 89.11 B). This situation would result in more even distribution of inspired gas, delivery of more VT for the same inflation pressure, and improved $C_{DYN}$ compared with VCV.
Pressure-regulated volume control (PRVC) combines the advantages of VCV and PCV. In this mode, the VT and TI are controlled as primary variables, but the ventilator determines the amount of pressure needed to deliver the desired VT. Inflation pressure is thus adjusted to deliver the prescribed VT over the TI, depending on the patient's respiratory C and R.

**Support Modes**

Pressure-support ventilation (PSV) and volume-support ventilation (VSV) are designed to support the patient's spontaneous respirations. With PSV, initiation of inspiration is triggered by the patient's spontaneous breath, which is then “supported” by a rapid rise in ventilator pressure to a preselected level. The inspiration is continued until the inspiratory flow rate falls to a set level (generally 25% of peak flow rate) as the patient's lungs fill up. Thus, TI is controlled by the patient's own efforts. PSV can be combined with SIMV so that any breath above the SIMV rate is supported by PSV. Allowing the patient to control as much of the rate, VT, and inspiratory time as possible is considered a gentler form of mechanical ventilation than SIMV, in which the VT (or inflation...
pressure) and T1 are preset. PSV as the sole source of mechanical ventilator support is often not adequate for patients with severe lung disease. However, PSV is especially useful in patients being weaned and in those who require mechanical ventilation for relatively minor lung disease or for neuromuscular weakness.

VSV is similar to PSV, in that all the spontaneous breaths are supported. In VSV, inspiratory pressure to support spontaneous breaths is adjusted to guarantee a preset VT. If there is a change in respiratory mechanics or patient effort, the inspiratory pressure to support the breath initiated by patient effort is automatically adjusted to deliver the set VT.

**Inspiratory Phase Characteristics**

T1, inspiratory flow waveform, and pressure rise time can be adjusted in the inspiratory phase to suit the patient's respiratory mechanics.

In PCV the duration of T1 is directly set in seconds. In VCV the T1 can be adjusted by adjusting the inspiratory flow (volume/time). The choice of T1 value depends on the respiratory rate, which determines the total duration of each breath, and on the estimation of inspiratory and expiratory TCs. Decreasing the flow rate delivery increases T1, and vice versa. With an increase in T1, the pulmonary capillary blood is exposed to a higher level of PAO₂ for a longer time. This feature is beneficial in diseases with decreased FRC, such as ARDS and pulmonary edema. An increase in T1 also increases VT without increasing inflation pressure in PCV if inspiratory flow is still occurring at end-expiration. It must be recognized that at a given ventilator rate, an increase in T1 decreases expiratory time (TE). Therefore, any strategy that employs an increase in the inspiratory component of the respiratory cycle should ensure that the decreased TE is still sufficient for complete exhalation.

*Inspiratory flow waveform* can be adjusted in VCV mode as either a constant flow (square waveform) or a decelerating flow (descending ramp waveform). With a square waveform, flow is held constant throughout inspiration. In a descending ramp waveform, flow is maximal at the start of inspiration and declines throughout its duration. It is debatable which flow pattern is better for a given disease.

In PCV and PSV, the prescribed PIP is reached through delivery of airflow. *Pressure rise time* reflects the time required for the ventilator to reach PIP and can be adjusted by control of flow at the beginning of the inspiratory phase. The
inspiratory flow rise time is adjusted to provide comfort for a patient who is awake and also to prevent an extremely rapid rise in inspiratory pressure, which might result in barotrauma.

**Termination of Inspiration (Cycle)**

The 2 most commonly used inspiratory terminating mechanisms in control modes are time-cycled and volume-cycled. With a *time-cycled* mechanical breath, inspiration is terminated after a preselected Tı has elapsed, whereas with *volume-cycled* breath the inspiration ends after a preselected volume has been delivered by the machine into the ventilator circuit. A time-cycled breath is almost always pressure-limited, with the PIP held constant for the duration of inspiration. A volume-cycled breath can be pressure-limited as a safety mechanism to avoid barotrauma. The inspiration-terminating mechanism is set somewhat differently in support modes. In PSV the inspiration is set to end after the inspiratory flow decreases below a certain percentage (usually 25%) of peak inspiratory flow. This happens when the patient no longer desires to receive additional V̇. Such a breath can be termed *flow-cycled*. In VSV the inspiration is terminated when the patient has received the desired VT.

**Expiratory Phase Maneuvers**

The most useful expiratory phase maneuver is the application of PEEP, which is applied to both the control breath and the assisted breath. The most important clinical benefits of PEEP are to recruit atelectatic alveoli and to increase FRC in patients with alveolar-interstitial diseases and thereby improve oxygenation. There is growing recognition that even a brief disconnection from a ventilator, and therefore having zero end-expiratory pressure (ZEEP), can result in significant alveolar derecruitment and decline in oxygenation. In patients with obstructive lesions in which insufficient exhalation results in air trapping and auto-PEEP, extrinsic PEEP (that applied through a mechanical device) can prevent airway closure during expiration and improve ventilation. Other salutary effects of PEEP include redistribution of extravascular lung water away from gas-exchanging areas, improved V/Q relationship, and stabilization of the chest wall. The effect of PEEP on lung C is variable, depending on the level of PEEP provided and the patient's pulmonary mechanics. By shifting the V̇ ventilation to a more favorable part of the pressure-volume curve, PEEP may recruit more
alveoli, delay airway closure, and improve lung C. Excessive PEEP, on the other hand, may lead to overdistention of alveoli and reduced C. The effect of PEEP in individual patients can be ascertained by measuring exhaled $V_t$ and calculating $C_{\text{DYN}}$. Other deleterious effects of PEEP include decreased venous return, increased pulmonary vascular resistance, and decreased cardiac output.

**Additional Ventilatory Modalities**

**Airway Pressure Release Ventilation**

Airway pressure release ventilation (APRV) improves oxygenation in patients with severe hypoxemic respiratory failure resulting from alveolar-interstitial disease. This modality applies a CPAP, designated CPAP$_{\text{HIGH}}$, to recruit and maintain FRC with brief intermittent release phases of CPAP$_{\text{LOW}}$ to allow alveolar gas to escape. CPAP$_{\text{HIGH}}$ is analogous to PIP, and CPAP$_{\text{LOW}}$ is similar to setting PEEP. In contrast to the patient receiving conventional mechanical ventilation, a patient receiving APRV spends the majority of time in the CPAP$_{\text{HIGH}}$ phase, which may last as long as 3-5 sec with a brief (0.3-0.5 sec) time in the CPAP$_{\text{LOW}}$ phase. These atypically long $T_i$'s are tolerated because of a floating expiratory valve in the ventilator circuit that permits spontaneous breathing during CPAP$_{\text{HIGH}}$ phase. Therefore, even if the CPAP$_{\text{HIGH}}$ phase can be considered “inspiratory” and the CPAP$_{\text{LOW}}$ phase “expiratory” in regard to the ventilator, the patient is able to breathe spontaneously during both these phases. The longer ventilator $T_i$ recruits lung units, and the ability to breathe spontaneously during this phase allows distribution of gas flow to atelectatic lung regions. The outcome benefit of APRV in pediatric hypoxemic respiratory failure has not been proved.

**High-Frequency Ventilation**

Mechanical ventilation at supraphysiologic rates and low $V_t$, known as high-frequency ventilation (HFV), improves gas exchange in a select group of patients who show no response to traditional ventilatory modalities. The mechanism of alveolar ventilation in HFV is very different from that in conventional ventilation, in that HFV is less dependent on $V_t$ and more dependent on asymmetric velocities and convective dispersion of inspired gas.
Patients with severe persistent hypoxic failure are most likely to benefit from HFV. HFV is also helpful in patients with bronchopleural fistula and persistent air leaks. The main tenet of HFV is to recruit lung volume with a high MAP and produce smaller fluctuations in alveolar pressure during inspiration and expiration, thus maintaining a satisfactory FRC and reducing alveolar stretch. The 2 most investigated techniques of HFV are HFO and HFJV.

The most commonly used HFV modality is high-frequency oscillation (HFO), which employs a mechanism to generate to-and-fro air movement. Additional air is drawn in (entrained) through a parallel circuit via a Venturi effect. Air is pushed in during inspiration and actively sucked out during expiration. The main determinants of oxygenation are F\textsubscript{IO\textsubscript{2}} and MAP, whereas ventilation is determined by changes in pressure (amplitude) from the MAP. Commonly used respiratory frequency varies from 5 Hz (300 breaths/min) in adults and older children, to 6-8 Hz (360-480 breaths/min) in young children, 8-10 Hz (480-600 breaths/min) in infants, and 10-12 Hz (600-720 breaths/min) in newborn and premature infants.

In high-frequency jet ventilation (HFJV), a high-frequency interrupter is interposed between a high-pressure gas source and a small cannula that is incorporated in the ETT. The cannula propels tiny amounts of gas (jets) at high velocity and high frequency through the ETT. An additional amount of gas is entrained from a parallel circuit. Unlike in HFO, expiration occurs passively in HFJV as a result of elastic recoil of the lung and the chest wall. PEEP is set through the parallel circuit by a conventional ventilator in line. Respiratory rate is generally set at 420 breaths/min. Major determinants of oxygenation are F\textsubscript{Io\textsubscript{2}} and PEEP, and the major determinant of ventilation is PIP.

**Conventional Ventilator Settings**

**Fraction of Inspired Oxygen**

The shape of the hemoglobin-O\textsubscript{2} dissociation curve dictates that oxygen content in the blood is not linearly related to P\textsubscript{ao\textsubscript{2}}. A P\textsubscript{ao\textsubscript{2}} value that results in an oxyhemoglobin saturation of 94% is reasonable in most situations, because a higher P\textsubscript{ao\textsubscript{2}} would cause minimal increase in arterial oxygen content, and a modest (10 mm Hg) drop in P\textsubscript{ao\textsubscript{2}} would result in minimal decrease in oxyhemoglobin saturation. In most cases, a P\textsubscript{ao\textsubscript{2}} value of 70-75 mm Hg is a
reasonable goal. $F_{\text{IO}_2}$ values that are higher than those necessary to attain oxyhemoglobin saturations of approximately 95% expose the patient to unnecessary oxygen toxicity. Whenever possible, $F_{\text{IO}_2}$ values should be decreased to a level $\leq 0.40$ as long as oxyhemoglobin saturation remains $\geq 95%$.

**Mode**

The choice of mode of ventilation depends on how much ventilator-patient interaction is desired and the disease entity that is being treated. SIMV or AC is chosen as the control mode; PCV, VCV, or PRVC as the variable that is to be controlled; and pressure support and volume support are the choices for support modes.

**Tidal Volume and Rate**

As previously discussed, alveolar ventilation, the chief determinant of $P_{\text{aco}_2}$, is calculated using $V_T$, respiratory rate, and $V_D$. A change in $V_T$ results in a corresponding change in alveolar ventilation without affecting $V_D$-ventilation. A change in respiratory rate will affect alveolar ventilation as well as the $V_D$-ventilation. Choice of $V_T$ and rate depends on the TC. In a patient with relatively normal lungs, an age-appropriate ventilator rate and a $V_T$ of 7-10 mL/kg would be appropriate initial settings. Diseases associated with decreased TC (decreased static compliance; e.g., ARDS, pneumonia, pulmonary edema) are best treated with small (6 mL/kg) $V_T$ and relatively rapid rates (e.g., 25-40 breaths/min). Diseases associated with prolonged TCs (increased airway resistance; e.g., asthma, bronchiolitis) are best treated with relatively slow rates and higher (10-12 mL/kg) $V_T$. In PCV the delivered $V_T$ depends on the $C$ and $R$ of the patient's respiratory system and needs to be monitored to ensure the appropriate amount for a given situation. An inflation pressure of 15-35 cm H$_2$O is sufficient for most patients, but it may need adjustment, depending on the volume of exhaled $V_T$. It should be emphasized that achieving a *normal* $P_{\text{aco}_2}$ value is not a goal of mechanical ventilation. Mild hypercapnia (permissive hypercapnia) should be acceptable, especially when one is attempting to limit injurious inflation pressures or $V_T$s.

**Inspiratory Time and Expiratory Time**
T₁ and Tₑ are adjusted by setting inspiratory flow rate in VCV and by setting the precise T₁ in PCV. Increasing the T₁ results in increased MAP, improved oxygenation in diseases with decreased FRC, and better distribution of VT in obstructive lung disease. Sufficient expiratory time must be provided to ensure adequate emptying of the alveoli.

**Positive End-Expiratory Pressure**

The best level of PEEP depends on the disease entity that is being treated, and it may change in the same patient from time to time. Decisions are often based on the PaO₂/FIO₂ ratio and the measurement of C_DYN.

**Patient-Ventilator Asynchrony**

Patient-ventilator asynchrony occurs when the patient's respiratory pattern does not match that of the ventilator. This can occur during all phases of respiration. Adverse effects of patient-ventilator asynchrony include wasted effort, ineffective delivery of desired VT, excessive generation of intrathoracic pressure resulting in barotrauma and adverse effects on cardiac output, increased work of breathing, and patient discomfort. Although several mechanisms exist to facilitate patient-ventilator asynchrony, a certain amount of asynchrony is inevitable unless the patient is pharmacologically sedated and paralyzed.

**Triggering the Ventilator**

The patient must be able to trigger the ventilator without excessive effort. Ventilators can be pressure-triggered or flow-triggered. With pressure triggering, the inspiratory valve opens and flow is delivered when a set negative pressure is generated within the patient-ventilator circuit during inspiration. The amount of pressure required to trigger an inspiration depends on the pressure trigger sensitivity. In flow triggering the ventilator provides a base flow of gas through the ventilator-patient circuit. When a flow sensor on the expiratory limb of the patient-ventilator circuit detects a decrease in flow as a result of the patient's inspiratory effort, the inspiratory valve opens and a ventilator breath is delivered. The degree of change in flow required to trigger an inspiration depends on the flow trigger sensitivity. Flow triggering is considered to be more comfortable, primarily because the patient receives some flow before...
triggering the ventilator, in contrast to pressure triggering, in which no flow is
provided until the ventilator breath is triggered. Increasing the trigger sensitivity
by decreasing the change in either pressure or flow needed to trigger an
inspiration decreases the work of breathing. However, reducing the required
pressure or flow excessively could result in accidental triggering and unwanted
breaths by turbulence, caused by condensation in the ventilator circuit, ETT air
leaks, or cardiac oscillations.

**Selection of Appropriate Inspiratory Time**

The duration of \( T_I \) should match the patient's own inspiratory phase. If \( T_I \) is too
long, the patient's drive to exhale may begin before the ventilator breath has
cycled off. When this occurs, exhalation occurs against inspiratory flow and a
closed exhalation valve, resulting in increased work of breathing, excessive rise
in intrathoracic pressure, and discomfort. If \( T_I \) is too short, the patient may be
still inhaling without respirator support. In general terms, \( T_I \) is usually initiated
at 0.5-0.7 sec for neonates, 0.8-1 sec in older children, and 1-1.2 sec for
adolescents and adults. Adjustments need to be made through individual patient
observations and according to the type of lung disease present. In patients with
severe lung disease (both obstructive and restrictive), unnatural \( T_I \) and \( T_E \) values
may have to be selected, as discussed earlier. In such situations, adequate
analgesia, sedation, and in extreme cases neuromuscular blockade may be
needed.

**Selection of Inspiratory Flow Pattern**

In VCV, inappropriate flow may be another source of patient-ventilator
dyssynchrony. After initiation of inspiration, if the set amount of flow is
inadequate to meet patient demand, a state of **flow starvation** occurs, resulting
in excessive work of breathing and discomfort. Such patients may require a
decelerating inspiratory flow pattern, in which a higher flow is provided in the
beginning of inspiration and less toward the end as the lungs fill up. On the other
hand, such a pattern may be uncomfortable for a patient who desires more
gradual alveolar filling. The selection of inspiratory flow pattern should be based
on the individual patient's respiratory mechanics. In PCV and PSV, the
inspiratory rise time determines the manner in which the airway pressure is
raised and \( V_T \) delivered. Considerations for choosing the appropriate rise time in
PCV and PSV are similar to those for choosing the inspiratory flow pattern in VCV.

**Use of Support Modes**

A conscious patient should be allowed to have spontaneous breaths that are supported by either PSV or VSV. This approach minimizes the mandatory breaths generated by the ventilator that are beyond the patient's control to modulate. Therefore, continued assessments should be made to determine whether the patient is able to maintain ventilatory requirements more in support modes and less in control modes.

**Use of Sedation and Pharmacologic Neuromuscular Blockade**

Having a conscious but comfortable patient is a desirable goal during mechanical ventilation. Spontaneous breaths with good muscle tone and presence of cough are important for adequate clearance of tracheobronchial secretions. The patient's ability to indicate distress is also important in identifying and preventing potential injurious factors. In certain situations, management of patient-ventilator asynchrony assumes much greater importance when the asynchrony is causing unacceptable derangement of gas exchange and ventilator-induced lung injury. Both alveolar interstitial lung pathology and obstructive airway diseases may necessitate unnatural and uncomfortable settings for respiratory rate, $T_1$, and inflation pressures. In such patients, deep sedation is often necessary; dexmedetomidine, benzodiazepines, and opiates are the agents most commonly used for this purpose. In extreme situations, pharmacologic neuromuscular blockade with a nondepolarizing agent, such as vecuronium, is required to abolish any patient effort and respiratory muscle tone. When such pharmacologic paralysis is used, deep sedation must be ensured so that the patient does not sense pain and discomfort. Pharmacologic sedation and paralysis can ensure total control of the patient's ventilation by mechanical means and may result in lifesaving improvement in gas exchange with reduction in inflation pressures. However, long-term use of such agents may be associated with undesirable consequences and higher morbidity. The risk of inadequate tracheobronchial secretions and atelectasis is potentially greater. Long-term use of pharmacologic sedation may be associated with chemical dependency and
withdrawal manifestations, and prolonged neuromuscular blockade is associated with neuromyopathy in critically ill patients. The benefits of sedation and pharmacologic paralysis therefore should be carefully balanced with the risks, and periodic assessments should be made to determine the need for their continuation.

**Cardiopulmonary Interactions**

Mechanical ventilation can have salutary as well as adverse effects on cardiac performance. By decreasing oxygen consumption necessary for work of breathing, oxygen supply to vital organs is improved. Positive pressure breathing decreases LV afterload, thus enhancing stroke volume and cardiac output in patients with failing myocardium (e.g., myocarditis). On the other hand, the decreased systemic venous return may further compromise stroke volume in hypovolemic patients. Such patients will require intravascular fluid loading. Also, an increase in pulmonary vascular resistance (PVR) caused by positive intrathoracic pressure may result in further decompensation of a poorly performing right ventricle. PVR is at its lowest value at an optimum FRC. When FRC is too low or too high, PVR (and therefore the right ventricular afterload) is increased. Both desirable and undesirable effects of cardiopulmonary interactions may coexist and require ongoing assessment and necessary interventions (Table 89.12).

**Monitoring Respiratory Mechanics**
Exhaled Tidal Volume

Exhaled tidal volume ($V_{TE}$) is measured by a pneumotachometer in the ventilator circuit during exhalation. In VCV, part of the machine-delivered volume may leak out during inspiration and therefore never reach the patient. Measurement of $V_{TE}$ more accurately describes the $V_t$ that is contributing to the patient's alveolar ventilation. In PCV the $V_{TE}$ depends on the patient's respiratory system compliance and resistance and therefore offers valuable diagnostic clues. A decrease in $V_{TE}$ during PCV is indicative of either decrease in compliance or increase in resistance and is helpful in directing the clinician to appropriate investigation and management. An increase in $V_{TE}$ is indicative of improvement and may require weaning of inflation pressures to adjust the $V_{TE}$.

Peak Inspiratory Pressure

In VCV and PRVC, the PIP is the secondary variable determined by the patient's respiratory system compliance and resistance. An increase in PIP in these modes is indicative of decreased C (e.g., atelectasis, pulmonary edema, pneumothorax) or increased R (e.g., bronchospasm, obstructed ET). During VCV and PRVC, decreasing the respiratory rate or prolonging the TI will result in a lower PIP in patients with prolonged TCs because more time will be available for alveoli to fill. In such patients, a decrease in PIP suggests increased C or decreased R of the respiratory system.

Respiratory System Dynamic Compliance and Static Compliance

The changes in PIP during VCV and PRVC, and in $V_{TE}$ during PCV, are determined by $C_{DYN}$ of the respiratory system (lung and chest wall). $C_{DYN}$ is calculated as follows:

$$C_{DYN} = \frac{V_{TE}}{\nu} \div (\text{PIP} - \text{PEEP})$$

$C_{DYN}$ takes into account both the flow-resistive and the elastic properties of the respiratory system. Changes in $C_{DYN}$ can be used to assess effects of
different levels of PEEP as tidal ventilation is shifted along the slope of the volume-pressure curve (see Fig. 89.7). An increase in PEEP in alveolar-interstitial diseases (increased elastance), resulting in an increase in $C_{\text{DYN}}$ suggests alveolar recruitment, whereas a decrease in $C_{\text{DYN}}$ may indicate overdistention. Similarly, in obstructive diseases (increased R), adjustment in PEEP levels to ameliorate airway collapse during exhalation can be guided by monitoring $C_{\text{DYN}}$. To assess only the elastic recoil of the lung, measurement of $C_{\text{STAT}}$ when there is no airflow is required. This measurement is performed by using an inspiratory hold maneuver with the patient under neuromuscular blockade and observing pressure-time and flow-time waveforms (Fig. 89.12). During this maneuver, inspiratory flow ceases while the expiratory valve continues to remain closed, thus allowing pressure to equilibrate throughout the ventilator circuit and the patient's lungs. This pressure, referred to as the plateau pressure ($P_{\text{plat}}$), reflects alveolar pressure. $C_{\text{STAT}}$ is calculated as follows:

$$C_{\text{STAT}} = V_{\text{TE}} \cdot (P_{\text{plat}} - \text{PEEP})$$
The difference between $C_{DYN}$ and $C_{STAT}$ is attributable to airway resistance. This difference is minimal in alveolar-interstitial diseases but substantial in airway obstruction.

**Assessment of Auto-PEEP**

Auto-PEEP is assessed with the use of an expiratory pause maneuver in which inspiration is delayed and alveolar pressure is allowed to equilibrate with the airway. In diseases with airway obstruction, insufficient alveolar emptying may occur if exhalation time is not adequate. The alveolar pressure in excess of the set PEEP at the completion of the expiratory pause is measured as auto-PEEP or intrinsic PEEP. Auto-PEEP can have adverse effects on ventilation and hemodynamic status. It can be managed by decreasing the respiratory rate or $T_i$ and thus allowing longer time for exhalation. Auto-PEEP may also be managed by increasing the set PEEP (extrinsic PEEP), thereby delaying airway closure during exhalation and improving alveolar emptying.

**Assessment of Dead Space Ventilation**

Positive pressure ventilation and application of PEEP may result in a decrease in venous return, cardiac output, and therefore pulmonary perfusion as well. Ventilation of poorly perfused alveoli results in dead space ventilation, which does not contribute to gas exchange. The $V_D / V_T$ fraction can be calculated (see Chapter 89). Normal $V_D / V_T$ is 0.33. Increased $V_D / V_T$ is indicative of poorly perfused alveoli. Patients with increased $V_D / V_T$ may require intravascular volume infusion or other means of augmenting the cardiac output to improve pulmonary perfusion. The $V_D / V_T$ fraction is calculated and displayed by commercially available capnographs, which measure endotracheal $PetCO_2$ continuously.

**Ventilator-Induced Lung Injury**

As with most medical therapies, mechanical ventilation can be harmful. Pathophysiology of ventilator-induced lung injury can be multifactorial. Large lung volumes and high pressures delivered with increased frequency cause cyclic strain, which may lead to disruption of the tight junctions between the alveolar epithelial and capillary endothelial cells, with intracapillary blebs resulting in
alveolar and interstitial edema. This biotrauma may cause the release of proinflammatory cytokines that further injure the lung and travel in the blood outside the lung, leading to multiorgan failure. Evidence shows that in patients with ARDS, avoidance of $V_T \geq 10 \text{ mL/kg}$ and $P_{\text{plat}} \geq 30 \text{ cm H}_2\text{O}$ limits diffuse alveolar damage.

Atelectrauma is shear stress on the alveolar walls caused by cyclic opening and closing of the alveoli. PEEP can be used to prevent collapse and keep alveoli open. It is important that alveolar units are neither overdistended nor collapsed. Careful adjustments of PEEP may also permit the clinician to wean a patient from a high $F_{\text{io}}\_2$, another potential source of lung injury (oxytrauma). Although most patients receive an $F_{\text{io}}\_2$ of 1.00 during endotracheal intubation and at the beginning of mechanical ventilation, increasing PEEP to recruit alveoli without overdistention should be quickly instituted to improve oxygenation and permit weaning of the $F_{\text{io}}\_2$. Although the $F_{\text{io}}\_2$ value below which there is no risk of oxygen toxicity is unknown, most clinicians aim for a value $<0.6$. Regional mechanics may play a role in lung injury.

**Ventilator-Associated Pneumonia**

The pathophysiology of ventilator-associated pneumonia (VAP) is multifactorial. Aspiration of oral and/or gastric secretions, colonization of ETTs, and suppression of cough reflexes with sedation all play a role. New-onset fever and leukocytosis accompanied by demonstration of an infiltrative process on chest radiography are consistent with a diagnosis of VAP. This complication can lead to worsened gas exchange, increased duration of ventilation, and even death. Elevation of the head of the bed to 30 degrees after initiation of mechanical ventilation and use of a protocol for oral decontamination during mechanical ventilation are 2 means of reducing the risk for VAP. The most effective strategy to minimize any of the aforementioned complications is regular assessment of extubation readiness and liberation from mechanical ventilation as soon as clinically possible.

**Weaning**

Weaning from mechanical ventilation should be considered as a patient's respiratory insufficiency begins to improve. Most pediatricians favor gradual weaning from ventilator support. With SIMV, the ventilator rate is slowly
reduced, allowing the patient's spontaneous breaths (typically assisted with pressure or volume support) to assume a larger proportion of the minute ventilation. When the ventilator rate is low (<5 breaths/min) such that its contribution to minute ventilation is minimal, assessment of extubation readiness is performed. An alternative method of gradual weaning is transition to PSV. In this mode, no ventilator rate is set, allowing all triggered breaths to be assisted with pressure support. The clinician reduces the pressure support slowly to a low value (<5-10 cm H$_2$O), at which point assessment of extubation readiness is performed. During either technique, weaning should be halted if tachypnea, increased work of breathing, hypoxemia, hypercapnia, acidosis, diaphoresis, tachycardia, or hypotension occurs.

The most objective means of assessing extubation readiness is a **spontaneous breathing trial (SBT)**. Before performance of an SBT, a patient should be awake with intact airway reflexes, capable of handling oropharyngeal secretions, and with stable hemodynamic status. In addition, gas exchange should be adequate, defined as Pao$_2$ >60 mm Hg while receiving Fio$_2$ <0.4 and PEEP ≤5 cm H$_2$O. If these criteria are present, a patient should be started on CPAP with minimal or no pressure support (≤5 cm H$_2$O). If this SBT is tolerated with no episodes of respiratory or cardiovascular decompensation, successful extubation is likely.

Some neonates and small children cannot be calmed or consoled long enough to complete the SBT. In this situation, extubation readiness must be assessed on a low level of ventilator support. Data suggest a low risk of extubation failure if the patient is comfortable and has stable hemodynamic status, with adequate gas exchange and spontaneous V$_T$ >6.5 mL/kg, while receiving <20% of total minute ventilation from the ventilator. Certain patient populations are at increased risk for extubation failure, such as young infants, children mechanically ventilated for >7 days, and patients with chronic respiratory or neurologic conditions. These children often benefit from transition to a noninvasive form of positive pressure ventilation (e.g., high-flow nasal cannula, CPAP, or BiPAP) delivered via nasal prongs or face mask to increase the odds of successful extubation.

The likelihood of **postextubation upper airway obstruction**, the most common cause of extubation failure in children, cannot be predicted on the basis of an SBT result or bedside measurements of physiologic variables. Traumatic endotracheal intubation and subglottic swelling from ETT irritation, especially in
patients who exhibit agitation while receiving mechanical ventilation, are common causes of airway narrowing after extubation. Administration of intravenous corticosteroids (dexamethasone, 0.5 mg/kg every 6 hr for 4 doses before extubation) has been shown to minimize the incidence of postextubation airway obstruction. In patients in whom postextubation airway obstruction develops, the need for reintubation may be obviated by administration of nebulized racemic epinephrine and heliox.

Bibliography

High-altitude illness represents a spectrum of clinical entities with neurologic and pulmonary manifestations that overlap in their presentations and share common elements of pathophysiology. **Acute mountain sickness (AMS)** is the relatively benign and self-limited presentation, whereas **high-altitude pulmonary edema (HAPE)** and **high-altitude cerebral edema (HACE)** have potentially life-threatening manifestations.

Often overlooked by travelers as high-altitude destinations are cities such as La Paz, Bolivia (3,700 meters, approximately 12,100 feet), Lhasa, Tibet (3,600 m, ~11,800 ft), Cusco, Peru (3,400 m, ~11,200 ft), and Quito, Ecuador (2,850 m, ~9,350 ft), which reside at an elevation where altitude illness is likely to develop. In 2014, >15 million people visited Lhasa, a 6-fold increase over 8 yr since the opening of the Qinghai-Tibet Railway. In the western United States, 35 million people visit alpine resorts each year. Over 40% of those who stay above 3,300 m (~11,000 ft) have been found to suffer from AMS. In Colorado alone, approximately 150,000 children <12 yr old visit the mountains annually on ski holidays with their families. In 2014, AMS symptoms were severe enough to result in 1,350 visits to emergency departments (EDs) throughout Colorado. Because of the increasing family travel to high altitude, thousands of children are likely to develop AMS symptoms.

**Etiology**

The altitude threshold where clinical illness may begin to occur is 1,500 m (~4,900 ft). At this altitude a mild impairment in oxygen transport begins,
although altitude illness is relatively rare until higher elevations are reached. Children with underlying medical problems that impair oxygen transport may be predisposed to developing altitude illness at these lower levels. At moderate high altitude, 2,500-3,500 m (~8,000-11,500 ft), arterial oxygen saturation (SaO₂) is generally well maintained; however, mild tissue hypoxia may occur as a result of low arterial oxygen partial pressure (PaO₂), and altitude illness becomes common after rapid ascent above 2,500 m (~8,200 ft). This is the altitude range that most people visit and the elevation of many popular U.S. ski resorts and thus the most common range to find the greatest number of altitude illness cases. Very high altitude, 3,500-5,500 m (~11,500-18,000 ft), is associated with the most serious altitude illness; SaO₂ falls below 90%, on the steep portion of the oxyhemoglobin dissociation curve, and marked desaturation may occur with relatively small increases in altitude. At these heights, severe hypoxemia is seen with sleep, exercise, and illness. HAPE and HACE are most common in this environment. Extreme high altitude, above 5,500 m (~18,000 ft), generally results in severe altitude illness during acute ascent without supplemental oxygen. Acclimatization at intermediate altitudes is required to reach extreme altitudes. Complete acclimatization is not possible, and long visits result in progressive deterioration.

**General Effects of Hypobaric Hypoxia**

The partial pressure of oxygen (Po₂) in the atmosphere decreases logarithmically as geographic altitude rises, but oxygen remains a constant 20.93% of the barometric pressure. SaO₂ falls with increasing altitude, eventually triggering central chemoreceptor responses to produce hyperventilation in an attempt to normalize SaO₂; relative hypoventilation exacerbates the hypoxemia of high-altitude exposure. During sleep, periodic breathing associated with high-altitude exposure may result in periods of apnea, causing further arterial oxygen desaturation. Fluid homeostasis often shifts at altitude, resulting in a generalized fluid retention and redistribution into intracellular and interstitial spaces, manifested by peripheral edema, decreased urine output, and impaired gas exchange.

**Acclimatization**
Gradual ascents allowing for acclimatization over several weeks have allowed successful summiting of many of the world's highest peaks without supplemental oxygen. Without this gradual approach, rapid exposure to extreme altitude results in loss of consciousness and asphyxia in minutes. Children acclimatize as well as, if not better than, adults when comparing heart rate and \( \text{Sao}_2 \) of 7-9 yr olds to their parents during a slow ascent.

Some of the responses to hypoxia are mediated at the molecular level by hypoxia-inducible factor (HIF). This transcriptional activator orchestrates the expression of hundreds of genes in response to both acute and chronic hypoxic conditions. Acclimatization begins at the altitude that causes \( \text{Sao}_2 \) to fall below sea-level values. Most healthy, unacclimatized visitors to high altitude will not experience a significant drop in \( \text{Sao}_2 \) (<90%) until they reach elevations above 2,500 m (~8,200 ft). Children with preexisting conditions that reduce oxygen transport may have altitude intolerance and hypoxic stress at lower levels. Of particular importance are both acute and chronic cardiac and respiratory illnesses. An individual's inherent ability to acclimatize is also important. Previous successful acclimatization may be predictive of future responses for adults in similar conditions but may not be the case for children. Some acclimatize easily without developing clinical symptoms; others may transiently develop AMS during acclimatization; and a few have marked reactions to altitude exposure, fail to acclimatize, and develop severe altitude illness.

The most important response to acute hypoxia is an increase in minute ventilation. Peripheral chemoreceptors in the carotid bodies respond to hypoxia by signaling the respiratory control center in the medulla to increase ventilation. This decreases alveolar carbon dioxide partial pressure (\( \text{Paco}_2 \)), resulting in a corresponding increase of \( \text{Pao}_2 \) and arterial oxygenation. This increased ventilation, known as the hypoxic ventilatory response (HVR), varies in magnitude among individuals, may be genetically predetermined, and is related to the ability to acclimatize. Changes in the HVR and the onset of AMS with ascent to high altitude have been found to be remarkably similar between children and their fathers. Additional research has demonstrated that familial clustering of AMS accounts for up to 50% of the variability of AMS onset among children. A low HVR and relative hypoventilation are implicated in the pathogenesis of both AMS and HAPE, whereas a strong HVR enhances acclimatization. As ventilation increases, a respiratory alkalosis occurs, exerting negative feedback on central respiratory control and limiting further ventilation.
increase. The kidneys excrete bicarbonate in an effort to compensate for the alkalosis. As the pH normalizes, ventilation rises slowly, reaching a maximum after 4-7 days. *This process is enhanced by acetazolamide, which induces a bicarbonate diuresis.*

Increased sympathetic activity and catecholamine release on ascent result in elevation of heart rate, blood pressure, cardiac output, and venous tone. Except at extreme altitudes, acclimatization results in the resting heart rate gradually returning to near sea-level values. *Resting relative tachycardia is evidence of poor acclimatization.*

Hematopoietic acclimatization consists of an increase in hemoglobin (Hb) and red blood cells (RBCs) and in 2,3-diphosphoglycerate (DPG). After acute ascent, an early increase of up to 15% occurs in Hb concentration primarily from fluid shifting into the extravascular space. Acclimatization leads to an increase in plasma volume and total blood volume. Erythropoietin is secreted in a HIF-mediated response to hypoxemia within hours of ascent, stimulating the production of new RBCs, which begin to appear in the circulation in 4 or 5 days. Hypoxemia also increases 2,3-DPG, resulting in a rightward shift of the oxyhemoglobin dissociation curve, favoring release of oxygen from the blood to the tissues. This is counteracted by the leftward shift of the curve caused by the respiratory alkalosis from hyperventilation. The result is a net null change in the oxyhemoglobin dissociation curve and an increase in O$_2$-Hb binding in the lung, raising SaO$_2$. Climbers at extreme altitude respond with marked hyperventilation, alkalosis, and a leftward shift that favors oxygen loading in a hypoxic environment and increases SaO$_2$.

**Acute Mountain Sickness**

**Epidemiology and Risk Factors**

The incidence of high-altitude illness depends on several variables, including the rate of ascent, previous altitude exposure, and individual genetic susceptibility. Sleeping altitude, final altitude reached, and duration of stay at altitude are also clear risk factors for AMS development. AMS is very common with rapid ascent. Climbers around the world who ascend quickly (1 or 2 days) from sea level to altitudes of about 4,300-6,100 m (14,000-20,000 ft) have a very high incidence of AMS (27–83%). The rapid ascent profile associated with air travel
to high-altitude locations also results in high AMS attack rates. Trekkers who fly into the Khumbu region to explore the Mt. Everest area have a higher incidence of AMS (47%) compared with those who walk (23%). Skiers who visit resorts in the western United States from sea level generally fly or drive to the region but sleep at relatively moderate altitudes (2,000-3,000 m, 6,300-9,700 ft). Among this population, AMS occurs in approximately 25%.

Children have the same incidence of AMS as adults. Individual (genetic) susceptibility for the development of AMS plays a significant role in risk assessment. Most individuals with a previous history of AMS after acute ascent are likely to experience similar symptoms with repeated visits to altitude. Gender does not affect the incidence of AMS.

Pathophysiology

The symptoms of AMS develop several hours after arrival at high altitude, whereas the development of HAPE and HACE generally requires several days of altitude exposure. Because hypoxemia occurs within minutes of arrival, it cannot be the direct cause of high-altitude illness, but rather the initiating factor.

The clinical manifestations of AMS/HACE are primarily the result of central nervous system (CNS) dysfunction caused by hemodynamic mechanical factors and biochemical mediators of permeability. The CNS vasodilatory response to hypoxemia causes an increase in cerebral blood flow and volume. Significant elevation of brain volume is observed in moderate to severe AMS and HACE but has not been demonstrated in mild AMS. Hypoxic alteration of CNS vascular autoregulation and hypertension from exercise may increase pressure transmission to the brain's capillary beds, resulting in transcapillary leakage and vasogenic edema. HIF-mediated vascular endothelial growth factor, the inducible form of nitric oxide synthase, reactive cytokines, and free radical formation may increase permeability. Both mechanical and biochemical activation of the trigeminovascular system have been proposed as the cause of high-altitude headache, the primary symptom of AMS. Vasogenic edema has been implicated in severe AMS and HACE, but MRI reveals signal changes in persons with and without clinical AMS. It has been well established that adults can have changes in cognitive function with acute exposure to high altitude. Investigation of cognitive dysfunction in healthy, lowlander European children found significant impairment in verbal short-term memory, episodic memory, and executive functions 24 hr after arrival at 3,450 m (11,400 ft). These
impairments were attributed to hypoxia-induced dysfunction of the cerebral white matter. The neuropsychological changes were found to be reversible, since cognitive function returned to baseline on reevaluation 3 mo after returning to sea level.

Many of the responses to hypoxia and altitude exposure occur in both individuals who develop symptoms and those who remain free of AMS. To address the discrepancy in symptomatic illness, the “tight fit” hypothesis was proposed. This theory suggests that the development of AMS/HACE is the result of a lack of intracranial space to accommodate increasing volume from brain swelling and edema that develop at altitude. The adequacy of the intracranial and intraspinal space to buffer changes in brain and cerebrospinal fluid (CSF) volume is the central concept. Buffering occurs as the intracranial CSF is displaced by the foramen magnum into the space available in the spinal canal, followed by increased CSF absorption and decreased CSF production. Individuals with less CSF buffering capacity have less compliance and are hypothesized to become more symptomatic (develop AMS).

**Prevention**

A comprehensive approach to travel to high altitude with children should focus on 3 phases: planning the ascent and assessment of risk, recognition and management of altitude-associated illness, and follow-up of any illness relative to future travel or diagnostic testing necessary.

**Planning for travel to high altitude with children** should consider rate of ascent, formulation of an emergency plan for communication and evacuation, and availability of medical care at the high-altitude destination. The availability of medical care and evacuation from altitude will influence the degree of personal preparation necessary. *Slow ascent with time for acclimatization is the best prevention for all forms of altitude illness*. Residing for a few days at moderate altitudes (2,000-3,100 m, 6,600-10,200 ft) followed by graded ascent before arriving at high altitude. One extra night of acclimatization (at the same sleeping altitude) should be taken for every 1,000 m (~3,300 ft) gained. Rapid ascent by air may be avoidable through alternate routes or alternate means of transportation. Exposure to hypobaric hypoxia (reduced barometric pressure with maintained $O_2$ of 20.9%) decreases end-tidal $CO_2$ and AMS score, while increasing $SaO_2$ and exercise endurance on exposure to higher altitude. Staying over in Denver, Colorado, for 1 or 2 days before traveling to higher alpine
destinations is an example of such a strategy and has been an effective technique of acclimatization; it has the advantage of reducing the likelihood of developing AMS, HACE, or HAPE. A similar trend in preacclimatization was found with preexposure to normobaric hypoxia (maintained barometric pressure with O₂ <20.9%) using commercially available low-O₂ tents or hypoxia breathing masks, although not as effective as preacclimatization with hypobaric hypoxia. Slow, gradual ascent is another effective means of acclimatization. The altitude at which someone sleeps is considered more important than the highest altitude reached during waking hours. Guidelines recommend that above 3,000 m (~9,800 ft), one should not increase sleeping elevation by >500 m (1,600 ft) per day and should include a rest day every 3-4 days with no ascent to a higher sleeping elevation. Acclimatization and slow ascent are by far the best ways to avoid AMS. The first few days at altitude, individuals should limit their activity and maintain adequate hydration.

**Medical risk assessment** encompasses consideration of age, previous altitude-associated illness, and possible predisposing circumstances to altitude illness. Very young infants (<4-6 wk) may not have completed the postnatal circulatory transition and may be more vulnerable to altitude-associated desaturation with periodic breathing, right-to-left shunting across the foramen ovale, and hypoxic pulmonary vasoconstriction. Infants who required supplemental oxygen during the neonatal period, especially for pulmonary hypertension, may be at risk for hypoxemia with prolonged altitude exposure. History and physical examination are useful to identify conditions predisposing to HAPE, including recent viral infections, cardiac malformations, or obstructive sleep apnea. Children are known to have greater pulmonary vascular reactivity than adults. Thus, respiratory illnesses such as otitis media, pneumonia, or bronchiolitis that cause release of inflammatory mediators will increase capillary permeability; although normally tolerated at sea level, when superimposed on hypoxia at high elevations, it may predispose children to serious altitude illness. If a child has had a recent upper or lower respiratory infection or otitis media, careful consideration should be given to rapid ascent above 2,000 m (~6,600 ft).

Children with chronic lung disease (e.g., cystic fibrosis, bronchopulmonary dysplasia) and obstructive sleep apnea (OSA) are at increased risk of hypoxia at altitude and development of HAPE. Therefore they should undergo SO₂ monitoring during altitude travel. Similarly, children with cardiac lesions involving an increase in pulmonary blood flow or pulmonary hypertension are at greater risk of developing HAPE. Children with trisomy 21 have increased
pulmonary vascular reactivity and a higher risk of pulmonary hypertension, and are also more likely to have OSA and hypoventilation. Children with sickle cell anemia who live at sea level should reconsider travel to altitude, or else ascend carefully because sickle cell crisis may occur at as low as 1,500 m (~5,000 ft). Those with sickle cell trait may become symptomatic at altitudes above 2,500 m (~8,200 ft).

**Acetazolamide** is commonly prescribed as prophylaxis against AMS because of its ability to stimulate respiration and increase alveolar and arterial oxygenation. It acts as a carbonic anhydrase inhibitor that induces a renal bicarbonate diuresis, causing a metabolic acidosis that increases ventilation and arterial oxygenation. However, prophylactic pharmacologic therapy with acetazolamide in children is generally not recommended because preacclimatization with slow ascent achieves the same effect. Exceptions include children with previous susceptibility to AMS and an unavoidably rapid ascent, such as flying to La Paz, Bolivia (3,700 m, 12,100 ft), or Cusco, Peru (3,400 m, 11,200 ft), from sea level. The pediatric dose of acetazolamide is 2.5 mg/kg (maximum, 125 mg/dose) every 12 hr (Table 90.1). In adults, it is recommended that prophylaxis begin 24 hr before arriving at altitude and be continued for 48 hr at altitude, or until the final destination high altitude is reached. The respiratory stimulation caused by acetazolamide also improves sleep by eradicating periodic breathing. Side effects are common and include paresthesias, polyuria, lightheadedness, dry mouth, and metallic taste with carbonated beverages. Acetazolamide is a nonbacteriostatic sulfonamide drug, so a history of anaphylactic reaction to sulfa medications is a contraindication to its use. Acetazolamide should be avoided in breastfeeding mothers and pregnant women. **Dexamethasone** is another agent that has been used for AMS prophylaxis in the adult population. However, it should not be used for prophylaxis in children because of the potential for side effects; pancreatitis, pseudotumor cerebri, and interference with normal growth. Low-risk children should not need medications for prophylaxis and should use gradual ascent to prevent illness.

* AMS prophylaxis is not routinely recommended in children. It is indicated when rapid ascent profile is unavoidable or with previous altitude illness in child about to undergo similar ascent profile. Doses as low as 1.25 mg/kg every 12 hr have been successful in some children.

† Use not warranted due to risk of adverse effects. Use slow, graded ascent or acetazolamide.

‡ Oxygen and descent are the treatment of choice for severe AMS. If acetazolamide is not tolerated, dexamethasone may be used. Oxygen, descent, and dexamethasone should be used in HACE.

§ In emergency settings where oxygen and descent are not an option, nifedipine is indicated.

¶ In emergency settings where oxygen and descent are not an option, if nifedipine is not well tolerated, sildenafil may provide an alternative.

**Diagnosis**

AMS is easily identified in older children and adolescents using the **Self-Report Lake Louise AMS Scoring System**. The criteria require that the individual be in the setting of a recent gain in altitude, be at the new altitude for at least several hours, and report a headache plus at least 1 of the following symptoms: gastrointestinal (GI) upset (anorexia, nausea, or vomiting), general weakness or fatigue, dizziness or lightheadedness, or difficulty sleeping. Shortness of breath...
on exertion may also be a part of the clinical picture, although if occurring at rest, the presence of HAPE should be considered in the absence of other causes. The headache may vary from mild to severe; anorexia and nausea, with or without vomiting, are common. Sleep disturbance caused by periodic breathing is common in all visitors to high altitudes but is exacerbated in the setting of AMS. All the symptoms of AMS can range in severity from mild to incapacitating. Symptoms develop within a few hours after ascent and generally reach maximum severity between 24 and 48 hr, followed by gradual resolution. Most adults become symptom free by the 3rd or 4th day. The vague nature of this presentation has resulted in many misdiagnoses and morbidity among adults. In the setting of recent altitude exposure, these symptoms warrant a presumptive diagnosis of AMS and limitation of further ascent. Any evidence of CNS dysfunction, such as mild ataxia or altered mentation, is early evidence of HACE.

In nonverbal young children and infants, recognition of AMS symptoms is more challenging. AMS is often a diagnosis of exclusion and is characterized by nonspecific signs: fussiness, lack of playfulness, anorexia, nausea, vomiting, and disordered sleep. In most cases of AMS in nonverbal young children and infants, all these symptoms are present. *Fussiness* is defined as a state of irritability that is not easily explained by a cause, such as tiredness, wet diaper, hunger, teething, or pain from an injury. Fussy behavior may include crying, restlessness, or muscular tension. Decreased playfulness may be profound. Alterations of appetite may progress to frank vomiting. Sleep disturbance can manifest with either increased or decreased sleep compared to normal patterns. Most often, decreased sleep and the inability to nap are noted.

The **Children’s Lake Louise Score (CLLS)** has been successfully tested in preverbal children <4 yr old by parents briefed on the use of the scoring system. The CLLS combines a score for the amount and intensity of unexplained fussiness with a symptom score of how well the child has eaten, played, and slept in the past 24 hr. Evaluating for headache is done by asking if the head hurts or by using a “faces” pain scale. GI symptoms are evaluated by asking children if they are “hungry” rather than trying to evaluate their appetite. A combined score of ≥7 is indicative of AMS (**Fig. 90.1**). Many of the symptoms manifested by AMS in children may also result from the disruption of normal routine with travel. A change in environment, sleeping accommodation, or eating options can result in a fussy child. The threshold scores for AMS diagnostic criteria are modified to account for these baseline variations. Supplemental
oxygen may serve as a diagnostic aid; 2-4 L/min by nasal cannula (27–33% O₂) for 15-20 min should significantly improve headache and other symptoms.

If symptoms occur >2 days after arrival at altitude and headache and dyspnea at rest are absent, and if the child fails to improve with supplemental oxygen, an

**CLLS = FS + E + P + S**

The CLLS must be ≥7 with both the FS ≥4 and E+P+S ≥3 to confirm acute mountain sickness.

**FIG. 90.1** Children's Lake Louise Score (CLLS). Fussiness is defined as a state of irritability that is not easily explained by a cause, such as tiredness, hunger, teething, or pain from an injury. Fussy behavior may include crying, restlessness, or muscular tension. Please rate your child's typical fussy behavior during the last 24 hr without the benefit of your intervention.
alternative diagnosis should be sought. It must be emphasized that altered mental status, neurologic abnormalities, breathing difficulty, or cyanosis are not part of uncomplicated AMS. **Any of these signs warrants immediate medical attention.** If serious bacterial illness, a surgical condition, or another problem meriting specific intervention is suspected in a child, descent to lower altitude is recommended to eliminate the confounding variable of altitude illness.

**Periodic Breathing**

Periodic breathing at altitude is common at all ages during sleep, resulting in brief, repeated episodes of oxyhemoglobin desaturation. Prepubertal children (9-12 yr old) have similar nighttime oxygen desaturation as their parents but have somewhat more stable breathing patterns with less periodicity. Periodic breathing is not a sign of AMS, but the exacerbation of hypoxia during sleep plays a role in AMS development. Newborn infants normally have periodicity in their respiratory pattern, which is increased by high-altitude exposure and sleep. \( \text{SaO}_2 \) of awake neonates born in Colorado at 3,100 m ranges from 88–91%. During sleep with increased periodic breathing, \( \text{SaO}_2 \) may drop to 81% during the 1st wk of life. The amount and magnitude of respiratory periodicity decrease as the child matures, and \( \text{SaO}_2 \) during sleep increases to 86% after 2 mo. A stable, mature pattern is usually reached by 6 mo of age. Preterm babies may demonstrate marked periodicity with prolonged desaturation as a result of their immaturity. Acute ascent with a child born preterm is best delayed until maturity, when normal pulmonary function and respiratory drive can be demonstrated. Parents of normal healthy babies may become distressed by the marked periodic breathing pattern in their child after ascent to moderate altitude. Clinicians can reassure parents that this is generally not a precursor of true apnea; however, desaturation can occur with periodic breathing in sleep, especially at higher altitudes.

**Management**

*The management of AMS must include strict adherence to the principle that further ascent to a higher sleeping altitude is contraindicated after the symptoms of altitude illness occur.* Halting ascent or activity to allow further acclimatization may reverse the symptoms. However, the ascent exacerbates the underlying pathologic processes and may lead to disastrous results. Stopping
further ascent and waiting for acclimatization treats most AMS in 1-4 days. Mild cases of AMS may be treated without descent if monitoring by a reliable caregiver is available. Conservative treatment may be provided, including rest, analgesics for headache, and antiemetics for nausea. Ibuprofen and acetaminophen are useful for the treatment of high-altitude headache; for nausea and vomiting, ondansetron dissolving tablets may be used.

More moderate symptoms may require acetazolamide and/or oxygen when conservative measures have proved inadequate. Oxygen is effective in the treatment of moderate AMS, titrated to maintain \( \text{Sao}_2 > 94\% \). Although no studies have formally assessed its use in pediatric patients, anecdotal reports have demonstrated efficacy of acetazolamide in treating mild AMS in this population. AMS that becomes worse or does not respond to maintenance of altitude, rest, and pharmacologic intervention after 48 hr mandates descent. Descent (500-1,000 m, ~1,600-3,300 ft) is effective treatment for all forms of altitude illness and should be tailored to the individual response. The presence of neurologic abnormalities (ataxia or altered mentation) or evidence of pulmonary edema (dyspnea at rest) mandates descent because these signs indicate a progression of AMS to severe altitude illness.

High-Altitude Cerebral Edema

The incidence of HACE is very low and practically unheard of below 4,000 m (~13,100 ft), but it is rapidly fatal if unrecognized. Generally seen in adults with prolonged stays above 4,000 m, HACE is usually associated with concurrent AMS or HAPE but can occur on its own.

HACE is regarded as the extreme expression of the same pathophysiology underlying AMS. The etiology is believed to be secondary to increased cerebral blood flow leading to increased intracranial pressure (ICP). Cerebral venous congestion caused by compression and/or elevated central venous pressure may be an underappreciated mechanism of the increased ICP. In patients with HACE, MRI reveals white matter changes consistent with vasogenic edema that correlate with symptoms; evidence of cytotoxic edema has also been described.

HACE is frequently preceded by AMS, but it is differentiated from severe AMS by the presence of neurologic signs, most often ataxia and altered mental status, including confusion, progressive decrease in responsiveness, and eventually coma. Less common signs are focal cranial nerve palsies, motor and
sensory deficits, and seizures. The CT scan is consistent with edema and increased ICP. MRI shows a high T2 signal in the white matter, specifically in the splenium of the corpus callosum, with diffusion-weighted technique.

**Descent remains the most effective treatment for HACE.** If available, supplemental oxygen is useful, especially when descent is not possible or delayed. Portable hyperbaric treatment is beneficial, but its use should not delay descent. Dexamethasone should be administered at a dose of 0.15 mg/kg orally every 6 hr. The few children reported with mild cases of HACE have recovered with dexamethasone and descent.

## High-Altitude Pulmonary Edema

### Epidemiology and Risk Factors

HAPE is a **noncardiogenic pulmonary edema** caused by intense pulmonary vasoconstriction and subsequent high capillary pressure, secondary to hypoxia, resulting in altered permeability of the alveolocapillary membrane and the extravasation of intravascular fluid into the extravascular space of the lung. **HAPE is the deadliest of the high-altitude illnesses**; its reported incidence is 0.5%, without an underlying predisposition, and typically requires recent ascent above 3,000 m. The development of HAPE depends on genetic factors typically affecting pulmonary vasoreactivity, rate of ascent, altitude achieved, and time spent at that altitude. Among children, HAPE occurs in 2 distinct settings. **Type I** HAPE (or simply HAPE) occurs in a child who resides at low altitude who travels to high altitude. **Type II** HAPE (also termed reentry or reascent HAPE) affects children who reside at high altitude but become ill on their return home after descent to lower altitudes. HAPE may also occur in children who develop acute respiratory illnesses that exacerbate hypoxia at high altitude. Fatal outcomes of HAPE in children have been reported. Most mild and moderate cases resolve without difficulty; however, if unrecognized and untreated, rapid progression to death can occur, especially when infection or cardiac conditions complicate the illness.

HAPE affects male and female children more equally than adults, among whom the observed male predominance appears to result from strenuous sport activities and military assignments. The occurrence and even the pathophysiology of HAPE may vary by population and genetic background. Individuals of Tibetan ancestry, resident on the Himalayan plateau and having
minimal admixture with other populations, represent the extreme of adaptation to high altitude and rarely experience HAPE. Other native populations residing at high altitude, such as Andeans, do not appear to be protected from HAPE, and certain populations may have genetic polymorphisms associated with pulmonary edema.

A number of conditions may predispose a child to HAPE (Table 90.2). Preexisting viral respiratory infections have been linked to HAPE, especially in children. Cardiorespiratory conditions associated with pulmonary hypertension, such as atrial and ventricular septal defects, pulmonary vein stenosis, congenital absence of a pulmonary artery, and OSA, also predispose to HAPE. Down syndrome is a risk factor for HAPE development, as are previously repaired congenital heart defects and the presence of hypoplastic lungs. Undiagnosed structural cardiopulmonary abnormalities may result in severe hypoxia and/or altitude illness once ascent occurs.

Pulmonary

Chronic lung disease
  Bronchopulmonary dysplasia
  Pulmonary hypoplasia
  Supplemental oxygen requirement at sea level
Pulmonary hypertension
Perinatal respiratory distress
  Persistent pulmonary hypertension of the newborn
  Perinatal asphyxia or depression
Sleep apnea

Infectious

Upper respiratory tract infection
Bronchitis/bronchiolitis
Pneumonitis
Otitis media

Pharmacologic

Any medication causing central nervous system and respiratory depression
  Alcohol
  Sympathomimetics

Systemic

  Down syndrome (trisomy 21)
  History of premature birth or low birthweight

Pathophysiology

Alveolar hypoxia results in vasoconstriction of pulmonary arterioles just proximal to the alveolar capillary bed. Hypoxic pulmonary vasoconstriction is a normal physiologic response to optimize ventilation/perfusion (V/Q) matching
by redistributing regional pulmonary blood flow to areas of highest ventilation, thereby optimizing arterial oxygenation. Under conditions that result in widespread alveolar hypoxia, extensive pulmonary vasoconstriction will lead to significant elevations in pulmonary arterial pressure; uneven pulmonary vasoconstriction can result in localized overperfusion, increased capillary pressures, distention, and leakage in the remaining vessels. This explains the patchy and heterogeneous edema that is classically observed in HAPE. The combination of pulmonary hypertension and uneven pulmonary vasoconstriction appears to be necessary in the pathogenesis of HAPE. Children and adolescents acutely exposed to high-altitude hypoxia demonstrated pulmonary hypertension, with increases in pulmonary artery pressure inversely related to age. Once the vascular leak occurs and alveolar fluid accumulates, a defect in transepithelial sodium transport impairs the clearance of alveolar fluid and contributes to HAPE.

**Diagnosis**

The diagnosis of HAPE is based on clinical findings and their evolution in the context of recent ascent from lower elevation. There is no single diagnostic test or constellation of laboratory findings. Symptoms usually develop within 24-96 hr, with onset of symptoms the 1st or 2nd night at altitude, when hypoxia may be exacerbated during sleep. HAPE generally is not observed beyond 5 days after ascent to altitude (unless additional ascent occurs) because pulmonary vascular remodeling and acclimatization have taken place. The minimum criteria to diagnose HAPE include recent exposure to altitude, dyspnea at rest, radiographic evidence of alveolar infiltrates, and near-complete resolution of both clinical and radiographic signs within 48 hr after descent or institution of oxygen therapy. Portable ultrasound is useful to diagnose HAPE through the finding of *comet tails*, artifacts created by microreflections of the ultrasound beam within interlobular septa thickened by interstitial and alveolar edema.

Frequently, patients first exhibit general malaise that may progress to more specific signs of dyspnea at rest, then cardiopulmonary distress. In preverbal toddlers and infants, HAPE may manifest as worsening respiratory distress over 1-2 days, pallor, depressed consciousness, increased fussiness, decreased playfulness, crying, decreased appetite, poor sleep, and sometimes vomiting. Young children may show agitation and general debility. Older children and adolescents may complain of headache and orthopnea and present with cough,
dyspnea not relieved by rest or out of proportion to effort, and production of frothy, rust-colored sputum. Physical exam findings include tachypnea, cyanosis, elevated jugular venous pressure, and diffuse crackles on lung auscultation. Dyspnea at rest, orthopnea, cyanosis, tachycardia, and chest pain herald worsening compromise, which may advance within hours to production of pink-tinged sputum.

Findings on physical examination frequently are less severe than the patient's chest radiograph and hypoxemia on pulse oximetry would predict. Children often appear pale, with or without visible cyanosis. Low-grade fever (<38.5°C [101.3°F]) is common, and respiratory rate is generally increased. Auscultation typically reveals rales, usually greater in the right lung than the left on presentation. Chest radiograph reveals diffuse interstitial changes typical of noncardiogenic pulmonary edema, with central interstitial edema associated with peribronchial cuffing, poorly defined vessels, enlargement of the pulmonary artery silhouette with dilation of more peripheral pulmonary arteries, and patchy air space consolidation; Kerley lines may be present. In severe cases, air space consolidation may become confluent and involve the entire lung (Fig. 90.2). Often the right lung shows more radiographic changes of edema than the left. Cardiomegaly is an uncommon finding, but enlargement of the pulmonary artery is a frequent finding. Significant arterial oxygen desaturation, as measured by pulse oximetry, is a consistent finding, with \( \text{SpO}_2 \) frequently below 75%. A complete blood count often reveals a leukocytosis with a left shift of the granulocyte series.

**FIG. 90.2** Acute mountain sickness (AMS) and high-altitude pulmonary edema (HAPE). A healthy 15 yr old boy flew from Buffalo, NY, to Denver, CO, and immediately drove with his school group from the airport to a ski resort at 9,300 ft in the Rocky Mountains. The following day he felt dizzy and complained of headache. Symptoms of headache
and dizziness continued along with emesis daily for 2 days. A snowboarding coach brought the patient to the local emergency facility the next day because of dyspnea, cough, headache, emesis, and fatigue. Pulse oximetry showed an arterial oxygen saturation of 51%. Chest radiograph showed diffuse pulmonary edema (A). The patient was transported to Denver (5,280 ft) by ambulance with 15 L/min oxygen via a non-rebreathing mask. SaO₂ improved with descent and was 94% on arrival at the Children's Hospital Colorado emergency department. Breath sounds remained coarse, and the patient was tachycardic and tachypneic. Oxygen flow was weaned to 1 L/min shortly after admission. Two days after presentation, lung exam was improved, without crackles. Repeat chest radiograph showed clearing of edema pattern (B). The patient maintained adequate SaO₂ without supplemental oxygen and was discharged.

(Courtesy of the Department of Radiology, Children's Hospital of Colorado.)

The differential diagnosis of HAPE includes pneumonia, bronchitis/bronchiolitis, asthma, and other forms of cardiogenic and noncardiogenic pulmonary edema, as well as pulmonary embolism. HAPE is most frequently misdiagnosed as pneumonia or a viral respiratory illness, especially when suspicion of altitude-associated pathology is not appropriately high. The presenting signs of cough, dyspnea, and orthopnea, followed by sputum production, can easily be misinterpreted as pneumonia, an impression reinforced by the frequent low-grade fever. Respiratory viral infections increase the risk of developing HAPE, which may lead to further confusion in diagnosis.

Complications of HAPE in children often relate to underlying, sometimes undiagnosed, cardiopulmonary pathology or coexisting viral infections that potentiate the severity of pulmonary edema and pulmonary hypertension. Acute altitude exposure in such circumstances may lead to severe presentations that progress rapidly to extreme hypoxemia or cardiac failure and death. Children with trisomy 21, with or without structural cardiac anomalies, show increased susceptibility to HAPE and rapid symptom progression. Neonatal respiratory distress with pulmonary hypertension has been linked to exaggerated hypoxic pulmonary vasoreactivity in early adulthood and thereby a theoretical predisposition to HAPE. Other conditions related to pulmonary overcirculation, small cross-sectional area of the pulmonary vascular bed, obstruction to pulmonary venous return, or left-sided obstruction potentiate HAPE. Inflammatory processes, such as viral infection, predispose to HAPE and may worsen hypoxemia.

Management

Descent with supplemental oxygen is the treatment of choice for HAPE in children. Unlike AMS, HAPE does not respond to rest and oxygen alone. When feasible, or in the absence of medical care, rapid descent of at least 1,000 m
(~3,300 ft) usually results in rapid recovery. As with all altitude illness, the magnitude of the descent is tailored to the resolution of symptoms. Those affected should exert themselves as little as possible on descent and prevent exposure to cold, to avoid exacerbation of pulmonary artery pressure and pulmonary edema. Oxygen and bed rest without descent can be safe and effective treatment for mild HAPE in children where careful medical observation is available. Mild HAPE in children and young adults at 3,750 m (~12,300 ft) has been treated with bed rest alone, although clinical recovery may be slower than with supplemental oxygen therapy.

Supplemental oxygen at altitude is administered at 2-6 L/min by nasal cannula for 48-72 hr to maintain an $\text{SaO}_2$ of at least 90%. Oxygen flow can be weaned with improvement in symptoms and $\text{SaO}_2$; at flow rates <2-4 L/min, children may be sufficiently stable and comfortable to continue treatment at home under family monitoring. Most children experience complete resolution of mild HAPE within 24-72 hr of oxygen therapy when treated at the altitude of symptom onset.

Pharmacotherapy for pediatric HAPE is rarely needed since oxygen and descent are so effective. However, in emergency situations without the option of descent or oxygen, pharmacotherapy should be considered for treatment of HAPE. In adults, nifedipine, a calcium channel blocker, is the preferred drug. Although its use has not been studied in children for treatment of HAPE, nifedipine is indicated for treatment of pulmonary hypertension. Extrapolated dosing for children is 0.5 mg/kg orally every 4-8 hr and titrated to response (maximum, 10 mg/dose). Liquid-filled capsules of nifedipine (10 mg/0.34 mL) can be punctured to obtain doses for children <20 kg. Patients should be monitored for hypotension during nifedipine administration. Alternatively, diltiazem can be given at 0.5-1.0 mg/kg/dose every 8 hr in tablet form or compounded oral suspension (12 mg/mL). Phosphodiesterase-5 inhibitors reduce pulmonary pressure at high altitude in adults through vasodilation and may be used if a calcium channel blocker is not available or poorly tolerated. However, concurrent use of multiple pulmonary vasodilators is not recommended. Pulmonary hypertension guidelines for children cite level I evidence for sildenafil in treatment of pulmonary hypertension.

$\beta$-Adrenergic agonists upregulate the clearance of alveolar fluid through transepithelial sodium transport and therefore could have a positive effect on HAPE. A single randomized controlled study in adults susceptible to HAPE exposed to very high altitude found that those receiving inhaled salmeterol had a 50% decreased incidence of HAPE compared to those who received placebo.
Prevention of pulmonary edema using salmeterol was not associated with a decrease in pulmonary pressure, underscoring the clearance of alveolar fluid and improved hypoxia, which is believed to have accounted for the improved AMS score in these patients compared with the placebo group.

**Special Considerations**

**Reentry HAPE**

Children residing at high altitude may also experience HAPE of the type termed reentry or reascent HAPE. Reentry HAPE occurs on reascent to the altitude of residence after a sojourn to low altitude. Most cases occur after several days at lower altitude, and probability of recurrence may justify pharmacologic prophylaxis.

**Travel With Young Infants**

Newborn infants retain some of the circulatory characteristics of recent fetal life, and these can pose a unique risk for altitude exposure. The fetal circulation has high pulmonary resistance, low pulmonary blood flow, and both intra- and extracardiac shunts that optimize oxygenation through the placenta rather than the fetal lungs. After birth, a transition begins that closes fetal shunts and establishes normal pulmonary circulation and oxygen transport. *Exposure to marked hypoxia (3,000-5,000 m) can result in reversion to fetal shunting patterns despite the absence of a placenta.* Therefore, prolonged exposure to high altitude should be avoided for infants <6 mo old who normally live at low altitude, or whose gestation occurred at low altitude. Normal infants at sea level complete these changes in 4-6 wk, although for infants born at moderate or high altitude, changes may last ≥3 mo. Travel to high altitude with young infants is generally safe after 4-6 wk, when circulatory changes have occurred, breastfeeding is established, and congenital abnormalities may have been detected. Infants between 6 wk and 1 yr of age may have a higher incidence of pulmonary hypertension with hypoxia, patent ductus arteriosus (PDA), and patent foramen ovale (PFO) with prolonged exposure to high altitudes. Hypoxic exposure induces medial hypertrophy of pulmonary arteries and pulmonary arterioles, together with dilation of the pulmonary trunk and impressive hypertrophy and dilation of the right ventricle.
Infants residing at an altitude above 2,400 m (~8,000 ft) are at an increased risk of sudden infant death syndrome (SIDS), possibly from greater hypoxia. Altitude may be an independent risk factor for SIDS. Similar to low altitude, infants should be placed on their backs for sleeping, and parents should be counseled on the potential elevated risk of SIDS at altitude.

**Sickle Trait and Sickle Cell Disease**

Children with sickle cell disease or sickle trait should avoid travel to altitude, because hypoxemia may trigger sickling and painful crises, including splenic crises. Up to 20% of pediatric patients with sickle cell and sickle-thalassemia disease may experience a vasoocclusive crisis at moderate altitude. Although the majority of children with sickle trait remain asymptomatic, children can experience splenic ischemia or infarction, with severe left upper quadrant pain.

Drowning is one of the leading causes of childhood morbidity and mortality in the world. Prevention is the most important step to reducing the impact of drowning injury, followed by early initiation of cardiopulmonary resuscitation (CPR) at the scene.

Etiology

Children are at risk of drowning when they are exposed to a water hazard in their environment. The World Congress of Drowning definition of drowning is “the process of experiencing respiratory impairment from submersion/immersion in liquid.” The term drowning does not imply the final outcome—death or survival; the outcome should be denoted as fatal or nonfatal drowning. Use of this terminology should improve consistency in reporting and research; the use of confusing descriptive terms such as “near,” “wet,” “dry,” “secondary,” “silent,” “passive,” and “active” should be abandoned. The injury following a drowning event is hypoxia.

Epidemiology

From 2005 to 2014, an average 3,536 people per year were victims of fatal drowning, and an estimated 6,776 persons per year were treated in U.S. hospital emergency departments (EDs) for nonfatal drowning. Compared with other types of injuries, drowning has one of the highest case fatality rates and is in the top-10 causes of death related to unintentional injuries for all pediatric age-groups. From 2010 to 2015, the highest drowning death rates were seen in
children age 1-4 yr and 15-19 yr (crude rates of 2.56 and 1.2 per 100,000, respectively). In children age 1-4 yr, drowning was the number-one cause of death from *unintentional injury* in the United States in 2014. Pediatric hospitalization rates associated with drowning ranged from 4.7 to 2.4 per 100,000 between 1993 and 2008. Rates of fatal drowning hospitalization declined from 0.5 to 0.3 deaths per 100,000 during the same period. Morbidity following nonfatal drowning is poorly studied.

The risk of drowning and the circumstances leading to it vary by age (*Fig. 91.1*). Drowning risk also relates to other host factors, including male gender, alcohol use, a history of seizures, and swimming lessons. Environmental risk factors include exposure to water and varying supervision. These factors are embedded in the context of geography, climate, socioeconomic status, and culture.

**FIG. 91.1** Death rates from unintentional drowning* by age-group and sex—United States,† 2011. A total of 3,961 deaths from unintentional drowning were reported in the United States in 2011; the overall death rate for males was 2.05 per 100,000 population, almost 4 times the rate for females (0.52). In each age-group except for infants (i.e., those age <1 yr), the drowning death rate was higher for males. Males age 1-4 yr had the highest rate (3.67); for males and females, death rates increased with age after age 5-24 yr. *Unintentional drowning as the underlying cause of death includes codes for accidental drowning and submersion (W65-74), watercraft causing drowning and submersion (V90), and water-transport–related drowning and submersion without accident to watercraft (V92) in the *International Classification of Diseases, 10th Revision*. † U.S. residents only. ‡ Includes decedents whose ages were not reported. (From National Vital Statistics System: Mortality public use data file for 2011. [http://www.cdc.gov/nchs/data_access/vitalstatsonline.htm](http://www.cdc.gov/nchs/data_access/vitalstatsonline.htm).)
Most (71%) drowning deaths in children younger than 1 yr occur in the bathtub, when an infant is left alone or with an older sibling. Infant tub seats or rings may exacerbate the risk by giving caregivers a false sense of security that the child is safe in the tub. The next major risk to children <1 yr is the large (5-gallon) household bucket, implicated in 16% of infant drowning deaths. These buckets are approximately 30 cm (1 ft) tall and designed not to tip over when half-full. The average 9 mo old child tends to be top-heavy and thus can easily fall headfirst into a half-full bucket, become stuck, and drown within minutes.

**Children 1-4 Yr Old**

Drowning rates are consistently highest in 1-4 yr old children, likely because of their curious but unaware nature, coupled with the rapid progression of their physical capabilities. From 1999 to 2015, U.S. rates are highest in the southern regions, in some areas as high as 3.8 per 100,000. A common factor in many of these deaths is a lapse in adult supervision, often reportedly <5 min. Most U.S. drownings occur in residential swimming pools. Usually, the child is in the child's own home, and the caregiver does not expect the child to be near the pool.

In rural areas, children 1-4 yr old often drown in irrigation ditches or nearby ponds and rivers. The circumstances are similar to those noted previously, in a body of water that is near the house. Drowning is one of the leading causes of farm injury–related deaths in children.

**School-Age Children**

School-age children are at increased risk of drowning in natural bodies of water such as lakes, ponds, rivers, and canals. Although swimming pools account for most nonfatal drownings across all ages, natural waterways account for a higher death rate in children 10-19 yr old. Unlike for preschool children, swimming or boating activities are important factors in drowning injuries in school-age children.

**Adolescents**

The 2nd major peak in drowning death rates occurs in older adolescents, age 15-19 yr. Almost 90% drown in open water. In this age-group particularly, striking
disparities in drowning deaths exist in gender and race. From 1999 to 2015, adolescent males fatally drowned at a rate of 2.4/100,000 compared to 0.3/100,000 in adolescent females. The gender disparity may likely be related to males’ greater risk-taking behavior, greater alcohol use, less perception about risks associated with drowning, and greater confidence in their swimming ability than females.

**Dangerous underwater breath-holding behaviors (DUBBs)** are often performed by experienced healthy swimmers or fitness enthusiasts (hypoxic training) or when teenagers hold breath-holding contests during horseplay. DUBBs have been primarily reported in regulated swimming facilities. Behaviors include intentional hyperventilation before submersion, static apnea, and extended periods of underwater distance swimming or breathhold intervals. Swimmers are found motionless and submerged; resuscitation is often unsuccessful.

There is also significant racial disparity seen across drowning rates and causes. In 2015, as in previous years, drowning rates for black males age 15-19 yr were double those for white males of the same age. Non-Caucasian children are 4 times more likely to have a nonfatal drowning across all age-groups through 19 yr old. Black children are more likely to drown in unguarded public or apartment pools; white children are more likely to drown in private residential pools. Hispanic and foreign-born children have lower rates of drowning than their white counterparts. Those with private insurance have lower rates of nonfatal drowning. Other factors include differences in exposure to swimming lessons, cultural attitudes, and fears about swimming, as well as experience around water, all of which may contribute to overall drowning risk.

**Underlying Conditions**

Several underlying medical conditions are associated with drowning at all ages. A number of studies have found an increased risk, up to 19-fold, in individuals with epilepsy. Drowning risk for children with seizures is greatest in bathtubs and swimming pools. Cardiac etiologies, including arrhythmias, myocarditis, and prolonged QT syndromes, have been found in some children who die suddenly in the water, particularly in those with a family history of syncope, cardiac arrest, prior drowning, or QT prolongation. Some children with long QT syndrome are misdiagnosed as having seizures (see Chapter 462.5).

Drowning may also be an intentional injury. A history of the event that
changes or is inconsistent with the child's developmental stage is the key to recognition of intentional drowning. Physical examination and other physical injuries rarely provide clues. **Child abuse** is more often recognized in bathtub-related drownings. **Suicide** usually occurs in lone swimmers in open water.

### Alcohol Use

The use of alcohol and drugs greatly increases the risk of drowning. Of teenagers and adults who die, up to 70% are associated with alcohol use. Alcohol can impair judgment, leading to riskier behavior, decreased balance and coordination, and blunted ability to self-rescue. Furthermore, an intoxicated adult may provide less effective supervision of children around water.

### Sports and Recreation

Most U.S. drowning deaths occur during recreational activities. Drowning is the leading cause of *noncardiac sports-related deaths*. Surveys confirm that alcohol use is common during water recreation, as is not using a personal flotation device (PFD) during boating activities. In 2015 the U.S. Coast Guard reported that 85% of those who drowned in boating accidents were not wearing a PFD.

### Global Impact of Drowning

Drowning injury is the 3rd leading cause of unintentional death worldwide, with the majority (90%) of fatalities occurring in low- and middle-income countries. More than half of the global drowning occurs in the World Health Organization (WHO) Western Pacific and Southeast Asia regions. Global drowning rates are vastly underestimated, since many drowning deaths in this region go unreported, and many immediate fatalities are unrecognized. In addition, these data exclude any cases of drowning as the result of intentional harm or assault, accidents of watercraft or water transport, and drowning related to forces of nature or cataclysmic storms, which usually claim large numbers of lives per incident; thus, true numbers of fatal drowning are likely much higher.

Some patterns of pediatric drowning are similar in all countries. By most accounts, the highest rates are seen in males and in children 1-4 yr old.

Whereas bathtubs and places of recreation (i.e., pools, spas) are significant locations for drowning in U.S. children, these are virtually unreported locations
for drownings in developing countries. Instead, the predominant locations are near or around the home, involving bodies of water used for activities of daily living. These include water-collecting systems, ponds, ditches, creeks, and watering holes. In tropical areas, death rates increase during monsoon season, when ditches and holes rapidly fill with rain, and are highest during daylight hours, when caregivers are busy with daily chores.

Drowning during natural disasters such as storms and floods is important in all areas of the world. The largest numbers of reported flood-related deaths occur in developing nations; most are drownings that occur during the storm surge. In the United States and much of Europe, advances in weather monitoring and warning systems have reduced such deaths. U.S. flooding incidents, including hurricanes Katrina and Sandy, showed that drowning caused the most deaths, particularly when people became trapped in their vehicles, were unable or refused to evacuate homes, or attempted to rescue others.

Pathophysiology

Drowning victims drown silently and do not signal distress or call for help. Vocalization is precluded by efforts to achieve maximal lung volume to keep the head above the water or by aspiration leading to laryngospasm. Young children can struggle for only 10-20 sec and adolescents for 30-60 sec before final submersion. A swimmer in distress is vertical in the water, pumping the arms up and down. This splashing or efforts to breathe are often misconstrued by nearby persons as merely playing in the water, until the victim sinks.

Anoxic-Ischemic Injury

After experimental submersion, a conscious animal initially panics, trying to surface. During this stage, small amounts of water enter the hypopharynx, triggering laryngospasm. There is a progressive decrease in arterial blood oxyhemoglobin saturation (Sao₂), and the animal soon loses consciousness from hypoxia. Profound hypoxia and medullary depression lead to terminal apnea. At the same time, the cardiovascular response leads to progressively decreasing cardiac output and oxygen delivery to other organs. By 3-4 min, myocardial hypoxia leads to abrupt circulatory failure. Ineffective cardiac contractions with electrical activity may occur briefly, without effective perfusion (pulseless electrical activity). With early initiation of CPR, spontaneous circulation may
initially be successfully restored. The extent of the global hypoxic-ischemic injury determines the final outcome and becomes more evident over subsequent hours.

With modern intensive care, the cardiorespiratory effects of resuscitated drowning victims are usually manageable and are less often the cause of death than irreversible hypoxic-ischemic central nervous system (CNS) injury (see Chapter 85). CNS injury is the most common cause of mortality and long-term morbidity. Although the duration of anoxia before irreversible CNS injury begins is uncertain, it is probably on the order of 3-5 min. Submersions <5 min are associated with a favorable prognosis, whereas those >25 min are generally fatal.

Several hours after cardiopulmonary arrest, cerebral edema may occur, although the mechanism is not entirely clear. Severe cerebral edema can elevate intracranial pressure (ICP), contributing to further ischemia; intracranial hypertension is an ominous sign of profound CNS damage.

All other organs and tissues may exhibit signs of hypoxic-ischemic injury. In the lung, damage to the pulmonary vascular endothelium can lead to acute respiratory distress syndrome (see Chapter 89). Aspiration may also compound pulmonary injury. Myocardial dysfunction (so-called stunning), arterial hypotension, decreased cardiac output, arrhythmias, and cardiac infarction may also occur. Acute kidney injury, cortical necrosis, and renal failure are common complications of major hypoxic-ischemic events (see Chapter 550.1). Vascular endothelial injury may initiate disseminated intravascular coagulation, hemolysis, and thrombocytopenia. Many factors contribute to gastrointestinal damage; bloody diarrhea with mucosal sloughing may be seen and often portends a fatal injury. Serum levels of hepatic transaminases and pancreatic enzymes are often acutely increased. Violation of normal mucosal protective barriers predisposes the victim to bacteremia and sepsis.

**Pulmonary Injury**

Pulmonary aspiration occurs in many drowning victims, but the amount of aspirated fluid is usually small (see Chapter 425). Aspirated water does not obstruct airways and is readily moved into the pulmonary circulation with positive pressure ventilation. More importantly, it can wash out surfactant and cause alveolar instability, ventilation-perfusion mismatch, and intrapulmonary shunting. In humans, aspiration of small amounts (1-3 mL/kg) can lead to
marked hypoxemia and a 10–40% reduction in lung compliance. The composition of aspirated material can also affect the patient's clinical course: Gastric contents, pathogenic organisms, toxic chemicals, and other foreign matter can injure the lung or cause airway obstruction. Clinical management is not significantly different in saltwater and freshwater aspirations, because most victims do not aspirate enough fluid volume to make a clinical difference.

**Cold Water Injury**

Drowning should be differentiated from cold water *immersion* injuries, in which the victim remains afloat, keeping the head above water without respiratory impairment in cold waters. The definition of cold water varies from <15 to 20°C (<59 to 68°F).

Heat loss through conduction and convection is more efficient in water than in air. Children are at increased risk for *hypothermia* because of their relatively high ratio of body surface area (BSA) to mass, decreased subcutaneous fat, and limited thermogenic capacity. Hypothermia can develop because of prolonged surface contact with cold water during immersion, while the airway is above water, or with submersion. Body temperature may also continue to fall because of cold air, wet clothes, hypoxia, and hospital transport. Hypothermia in pediatric drowning victims may be observed even after drowning in relatively warm water and in warm climates.

Immersion in cold water has immediate respiratory and cardiovascular effects. Victims experience *cold water shock*, a dynamic series of cardiorespiratory physiologic responses that can cause drowning. In adults, immersion in icy water results in intense involuntary reflex hyperventilation and to a decrease in breath-holding ability to <10 sec, which leads to fluid aspiration. Severe bradycardia, the *diving reflex*, occurs in adults but is transient and rapidly followed by supraventricular and ectopic tachycardia and hypertension. There is *no evidence* that the diving reflex has any protective effect.

Even after surviving the chaotic minutes of cold water shock, after an additional 5-10 min of cold water immersion, the victim can become incapacitated. Cooling of large and small muscles disables the victim's ability to grab hold, swim, or perform other self-rescue maneuvers. Depending on water and air temperature, insulation, BSA, thermogenic capacity, physical condition, swimming efforts, or high-water flow rates, heat loss with continued immersion can significantly decrease core temperature to hypothermic levels within 30-60
The symptoms and severity of hypothermia are categorized based on body temperature. The victim with mild hypothermia has a temperature of 34-36°C (93.2-96.8°F) with intact thermogenic mechanisms (shivering and nonshivering thermogenesis, vasoconstriction) and active movements. Compensatory mechanisms usually attempt to restore normothermia at body temperatures >32°C (89.6°F). Lower core temperatures lead to impaired cognition, coordination, and muscle strength and with it, less ability to self-rescue. Thermoregulation may fail and spontaneous rewarming will not occur. With moderate hypothermia (30 to <34°C [86 to <93.2°F]), loss of consciousness leads to water aspiration. Progressive bradycardia, impaired myocardial contractility, and loss of vasomotor tone contribute to inadequate perfusion, hypotension, and possible shock. At body temperatures <28°C (82.4°F), extreme bradycardia is usually present with decreases in cardiac output, and the propensity for spontaneous ventricular fibrillation or asystole is high. Central respiratory center depression with moderate to severe hypothermia results in hypoventilation and eventual apnea. A deep coma, with fixed and dilated pupils and absence of reflexes at very low body temperatures (<25-29°C [77-84.2°F]), may give the false appearance of death.

If the cooling process is quick—and cardiac output lasts long enough for sufficient heat loss to occur before the onset of severe hypoxia—the brain can cool to a level that may be considered in the neuroprotective range, approximately 33°C (91.4°F) in controlled, experimental conditions. However, if submersion leading to drowning occurs before development of a neuroprotective level of hypothermia, severe anoxia devastates tissue organs. The theoretical benefits, implications, and consequences of hypothermia in drowning victims are areas of controversy. Known adverse effects are associated with hypothermia, and these must be balanced against the potential benefits observed in experimental data. One should clearly differentiate among controlled hypothermia, such as that used in the operating room before the onset of hypoxia or ischemia; accidental hypothermia, such as occurs in drowning, which is uncontrolled and variable, with onset during or shortly after hypoxia-ischemia; and therapeutic hypothermia, involving the purposeful and controlled lowering and maintenance of body (or brain) temperature after a hypoxic-ischemic event.

In drowning victims with uncontrolled accidental hypothermia associated with icy water submersion, there are a few case reports of good neurologic recovery
after prolonged (10-150 min) cardiopulmonary arrest. Almost all these rare survivors have been in freezing water (<5°C [41°F]) and had core body temperatures <30°C (86°F), often much lower. Presumably, very rapid and sufficiently deep hypothermia developed in these fortunate survivors before irreversible hypoxic-ischemic injury occurred.

Most often, hypothermia is a poor prognostic sign, and a neuroprotective effect has not been demonstrated A 2014 study from Washington State found that submersion duration <6 min is most strongly related to good outcome, not water temperature. In another study of comatose drowning patients admitted to pediatric intensive care unit (PICU), 65% of hypothermic patients (body temperature <35°C [95°F]) died, compared with a 27% observed mortality rate in nonhypothermic victims. Similarly, in Finland (where the median water temperature was 16°C [60.9°F]) and in the United States, a beneficial effect of drowning-associated hypothermia was not seen in pediatric submersion victims; submersion duration <10 min was most strongly related to good outcome, not water temperature.

**Management**

Duration of submersion, speed of the rescue, effectiveness of resuscitative efforts, and clinical course determine the outcome in submersion victims. Two groups may be identified on the basis of responsiveness at the scene. The **first group** consists of children who require minimal resuscitation at the scene and quickly regain spontaneous respiration and consciousness. They have good outcomes and minimal complications. These victims should be transported from the scene to the ED for further evaluation and observation. The **second group** comprises children in cardiac arrest who require aggressive or prolonged resuscitation and have a high risk of multiple–organ system complications, major neurologic morbidity, or death. Compared with cardiac arrest from other causes, cardiac arrest from drowning has a higher survival rate.

Initial management of drowning victims requires coordinated and experienced prehospital care following the ABCs (airway, breathing, circulation) of emergency resuscitation. CPR of drowning victims must include providing ventilation. Children with severe hypoxic injury and symptoms often remain comatose and lack brainstem reflexes despite the restoration of oxygenation and circulation. Subsequent ED and PICU care often involve advanced life support (ALS) strategies and management of multiorgan dysfunction with discussions
about end-of-life care.

Initial Evaluation and Resuscitation

See Chapter 81.

Once a submersion has occurred, immediate institution of CPR efforts at the scene is imperative. The goal is to reverse the anoxia from submersion and limit secondary hypoxic injury after submersion. Every minute that passes without the reestablishment of adequate breathing and circulation dramatically decreases the possibility of a good outcome. When safe for the victim and the rescuer, institution of in-water resuscitation for nonbreathing victims by trained personnel may improve the likelihood of survival. Victims usually need to be extricated from the water as quickly as possible so that effective CPR can be provided. Common themes in children who have good recovery are a short duration of event and initiation of CPR as soon as possible, before arrival of emergency medical services.

Initial resuscitation must focus on rapidly restoring oxygenation, ventilation, and adequate circulation. The airway should be clear of vomitus and foreign material, which may cause obstruction or aspiration. Abdominal thrusts should not be used for fluid removal, because many victims have a distended abdomen from swallowed water; abdominal thrusts may increase the risk of regurgitation and aspiration. In cases of suspected airway foreign body, chest compressions or back blows are preferable maneuvers.

The cervical spine should be protected in anyone with potential traumatic neck injury (see Chapters 82 and 85). Cervical spine injury is a rare concomitant injury in drowning; only approximately 0.5% of submersion victims have C-spine injuries, and history of the event and victim's age should guide suspicion of C-spine injury. Drowning victims with C-spine injury are usually preteens or teenagers whose drowning event involved diving, a motor vehicle crash, a fall from a height, a water sport accident, child abuse, or other clinical signs of serious traumatic injury. In such cases, the neck should be maintained in a neutral position and protected with a well-fitting cervical collar. Patients rescued from unknown circumstances may also warrant C-spine precautions. In low-impact submersions, spinal injuries are exceedingly rare, and routine spinal immobilization is not warranted.

If the victim has ineffective respiration or apnea, ventilatory support must be initiated immediately. Mouth-to-mouth or mouth-to-nose breathing by trained
bystanders often restores spontaneous ventilation. As soon as it is available, supplemental oxygen should be administered to all victims. Positive pressure bag-mask ventilation with 100% inspired oxygen should be instituted in patients with respiratory insufficiency. If apnea, cyanosis, hypoventilation, or labored respiration persists, trained personnel should perform endotracheal intubation as soon as possible. Intubation is also indicated to protect the airway in patients with depressed mental status or hemodynamic instability. Hypoxia must be corrected rapidly to optimize the chance of recovery.

Concurrent with securing of airway control, oxygenation, and ventilation, the child's cardiovascular status must be evaluated and treated according to the usual resuscitation guidelines and protocols. Heart rate and rhythm, blood pressure, temperature, and end-organ perfusion require urgent assessment. CPR should be instituted immediately in pulseless, bradycardic, or severely hypotensive victims. Continuous monitoring of the electrocardiogram (ECG) allows appropriate diagnosis and treatment of arrhythmias. Slow capillary refill, cool extremities, and altered mental status are potential indicators of shock (see Chapter 88).

Recognition and treatment of hypothermia are the unique aspects of cardiac resuscitation in the drowning victim. Core temperature must be evaluated, especially in children, because moderate to severe hypothermia can depress myocardial function and cause arrhythmias. Wet clothing should be removed to prevent ongoing heat losses, although in the hemodynamically stable patient, rewarming should be initiated in the controlled environment of the receiving ED or PICU. Unstable patients (i.e., arrhythmias) should be warmed to 34°C (93.2°F), taking care not to overheat. Trials are investigating if therapeutic hypothermia might be helpful, or if avoiding hyperthermia is the key element to long-term neurologic survival.

Often, intravenous (IV) fluids and vasoactive medications are required to improve circulation and perfusion. Vascular access should be established as quickly as possible for the administration of fluids or pressors. Intraosseous catheter placement is a potentially lifesaving vascular access technique that avoids the delay usually associated with multiple attempts to establish IV access in critically ill children. Epinephrine is usually the initial drug of choice in victims with bradyasystolic cardiopulmonary arrest (IV dose is 0.01 mg/kg using the 1 : 10,000 [0.1 mg/mL] solution given every 3-5 min, as needed). Epinephrine can be given intratracheally (endotracheal tube dose is 0.1-0.2 mg/kg of 1 : 1,000 [1 mg/mL] solution) if no IV access is available. An
intravascular bolus of lactated Ringer solution or 0.9% normal saline (10-20 mL/kg) is often used to augment preload; repeated doses may be necessary. Hypotonic or glucose-containing solutions should not be used for intravascular volume administration of drowning victims.

**Hospital-Based Evaluation and Treatment**

Most pediatric drowning victims should be observed for at least 6-8 hr, even if they are asymptomatic on presentation to the ED. At a minimum, serial monitoring of vital signs (respiratory rate, heart rate, blood pressure, and temperature) and oxygenation by pulse oximetry, repeated pulmonary examination, and neurologic assessment should be performed in all drowning victims. Other studies may also be warranted, depending on the specific circumstances (possible abuse or neglect, traumatic injuries, or suspected intoxication). Almost half of asymptomatic or minimally symptomatic alert children (those who do not require ALS in the prehospital setting or who have an initial ED **Glasgow Coma Scale** [GCS] score of ≥13) experience some level of respiratory distress or hypoxemia progressing to pulmonary edema, usually during the 1st 4-8 hr after submersion. Most alert children with early respiratory symptoms respond to oxygen and, despite abnormal initial radiographs, become asymptomatic with a return of normal room-air pulse oximetry oxyhemoglobin saturation (SpO₂) and pulmonary examination by 4-6 hr. Subsequent delayed respiratory deterioration is extremely unlikely in such children. Selected low-risk patients who are alert and asymptomatic with normal physical findings and oxygenation levels may be considered for discharge after 6-8 hr of observation if appropriate follow-up can be ensured.

**Cardiorespiratory Management**

For children who are not in cardiac arrest, the level of respiratory support should be appropriate to the patient's condition and is a continuation of prehospital management. Frequent assessments are required to ensure that adequate oxygenation, ventilation, and airway control are maintained (see Chapter 89 ). Hypercapnia should generally be avoided in potentially brain-injured children. Patients with actual or potential hypoventilation or markedly elevated work of breathing should receive mechanical ventilation to avoid hypercapnia and decrease the energy expenditures of labored respiration.

   Measures to stabilize cardiovascular status should also continue. Conditions
contributing to myocardial insufficiency include hypoxic-ischemic injury, ongoing hypoxia, hypothermia, acidosis, high airway pressures during mechanical ventilation, alterations of intravascular volume, and electrolyte disorders. Heart failure, shock, arrhythmias, or cardiac arrest may occur. Continuous ECG monitoring is mandatory for recognition and treatment of arrhythmias (see Chapter 462).

The provision of adequate oxygenation and ventilation is a prerequisite to improving myocardial function. Fluid resuscitation and inotropic agents are often necessary to improve heart function and restore tissue perfusion (see Chapter 81). Increasing preload with IV fluids may be beneficial through improvements in stroke volume and cardiac output. Overzealous fluid administration, however, especially in the presence of poor myocardial function, can worsen pulmonary edema.

For patients with persistent cardiopulmonary arrest on arrival in the ED after non–icy water drowning, the decision to withhold or stop resuscitative efforts can be addressed by review of the history and the response to treatment. Because there are reports of good outcome following ongoing CPR in the ED, most drowning victims should be treated aggressively on presentation. However, for children who do not show ready response to aggressive resuscitative efforts, the need for prolonged ongoing CPR after non–icy water submersion almost invariably predicts death or persistent vegetative state. Consequently, in most cases, discontinuation of CPR in the ED is probably warranted for victims of non–icy water submersion who do not respond to resuscitation within 25-30 min. Final decisions regarding whether and when to discontinue resuscitative efforts must be individualized, with the understanding that the possibility of good outcome is generally very low with protracted resuscitation efforts.

**Neurologic Management**

Drowning victims who present to the hospital awake and alert usually have normal neurologic outcomes. In comatose victims, irreversible CNS injury is highly likely. The most critical and effective neurologic intensive care measures after drowning are rapid restoration and maintenance of adequate oxygenation, ventilation, and perfusion. Core body temperature and glucose management may also be important modulators of neurologic injury after hypoxia-ischemia.

Comatose drowning patients are at risk for intracranial hypertension. There is little evidence that ICP monitoring and therapy to reduce intracranial hypertension improve outcomes for drowning victims. Patients with elevated
ICP usually have poor outcomes—either death or persistent vegetative state. Children with normal ICP can also have poor outcomes, although less frequently. Conventional neurologic intensive care therapies, such as fluid restriction, hyperventilation, and administration of muscle relaxants, osmotic agents, diuretics, barbiturates, and corticosteroids, have not been shown to benefit the drowning victim, either individually or in combination. There is some evidence that these therapies may reduce overall mortality but increase the number of survivors with severe neurologic morbidity.

Seizures after hypoxic brain injury are common, although detection is often difficult in the ICU because these patients are frequently sedated, thus masking clinical signs. Continuous electroencephalographic (EEG) monitoring in critically ill patients revealed a 13% incidence of seizures, 92% of which were exclusively nonconvulsive. However, EEG monitoring has only limited value in the management of drowning victims, except to detect seizures or as an adjunct in the clinical evaluation of brain death (see Chapter 86). Seizures should be treated if possible to stabilize cerebral oxygen use, although benefits are inconclusive. Fosphenytoin or phenytoin (loading dose of 10-20 mg of phenytoin equivalents/kg, followed by maintenance dosing with 5-8 mg of phenytoin equivalents/kg/day in 2-3 divided doses; levels should be monitored) may be considered as an anticonvulsant; it may have some neuroprotective effects and may mitigate neurogenic pulmonary edema. Benzodiazepines, barbiturates, and other anticonvulsants may also have some role in seizure therapy, although no conclusive studies have shown improved neurologic outcome.

With optimal management, many initially comatose children can have impressive neurologic improvement, but usually do so within the 1st 24-72 hr. Unfortunately, half of deeply comatose drowning victims admitted to the PICU die of their hypoxic brain injury or survive with severe neurologic damage. Many children become brain dead. Deeply comatose drowning victims who do not show substantial improvement on neurologic examination after 24-72 hr and whose coma cannot be otherwise explained should be seriously considered for limitation or withdrawal of support.

Other Management Issues
A few drowning victims may have traumatic injury (see Chapter 82), especially if their drowning event involved participation in high-energy water sports such
as personal watercraft, boating, diving, or surfing. A high index of suspicion for such injury is required. *Spinal precautions should be maintained in victims with altered mental status and suspected traumatic injury.* Significant anemia suggests trauma and internal hemorrhage.

Hypoxic-ischemic injury can have multiple systemic effects, although protracted organ dysfunction is uncommon in the absence of severe CNS injury. Hyperglycemia is associated with a poor outcome in critically ill pediatric drowning victims. Its etiology is unclear, but hyperglycemia is possibly a stress response. Glucose control in patients after drowning should be focused on avoiding hypoglycemia, hyperglycemia, and wide or rapid fluctuations in serum glucose, to prevent further harm.

Manifestations of acute kidney injury may be seen after hypoxic-ischemic injury (see Chapter 550). Diuretics, fluid restriction, and dialysis are occasionally needed to treat fluid overload or electrolyte disturbances; renal function usually normalizes in survivors. **Rhabdomyolysis** after drowning has been reported.

Profuse bloody diarrhea and mucosal sloughing usually portend a grim prognosis; conservative management includes bowel rest, nasogastric suction, and gastric pH neutralization. Nutritional support for most drowning victims is usually not difficult, because the majority of children either die or recover quickly and resume a normal diet within a few days. Enteral tube feeding or parenteral nutrition is occasionally indicated in children who do not recover quickly.

*Hyperthermia after drowning or other types of brain injury may increase the risk of mortality and exacerbate hypoxic-ischemic CNS damage.* Almost half of drowning victims have a fever during the 1st 48 hr after submersion. Hyperthermia is usually not caused by infection and resolves without antibiotics in approximately 80% of patients. Generally, prophylactic antibiotics are not recommended. However, there is general consensus that fever or hyperthermia (core body temperature >37.5°C [99.5°F]) in comatose drowning victims resuscitated from cardiac arrest should be prevented at all times in the acute recovery period (at least the 1st 24-48 hr).

**Psychiatric and psychosocial sequelae** in the family of a pediatric drowning victim are common. Grief, guilt, and anger are typical among family members, including siblings. Divorce rates increase within a few years of the injury, and parents often report difficulties with employment or substance abuse. Friends and family may blame the parents for the event. Professional counseling,
pastoral care, or social work referral should be initiated for drowning victims and their families.

**Hypothermia Management**

Attention to core body temperature starts in the field and continues during transport and in the hospital. The goal is to prevent or treat moderate or severe hypothermia. Damp clothing should be removed from all drowning victims. Rewarming measures are generally categorized as passive, active external, or active internal (see Chapter 93). **Passive rewarming measures** can be applied in the prehospital or hospital setting and include the provision of dry blankets, a warm environment, and protection from further heat loss. These should be instituted as soon as possible for hypothermic drowning victims who have not had a cardiac arrest.

Full CPR with chest compressions is indicated for hypothermic victims if no pulse can be found or if narrow complex QRS activity is absent on ECG (see Chapters 81 and 93). When core body temperature is <30°C (86°F), resuscitative efforts should proceed according to the American Heart Association guidelines for CPR, but IV medications may be given at a lower frequency in moderate hypothermia because of decreased drug clearance. When ventricular fibrillation is present in severely hypothermic victims (core temperature <30°C [86°F]), defibrillation should be initiated but may not be effective until the core temperature is ≥30°C (86°F), at which time successful defibrillation may be more likely.

Significant controversy surrounds the discontinuation of prolonged resuscitative efforts in hypothermic drowning victims. Body temperature should be taken into account before resuscitative efforts are terminated. Other considerations include whether the victim may have been immersed before submerged, whether water was icy, or the cooling was very rapid with fast-flowing cold water. Victims with profound hypothermia may appear clinically dead, but full neurologic recovery is possible, although rare. Attempts at lifesaving resuscitation should not be withheld based on initial clinical presentation unless the victim is obviously dead (dependent lividity or rigor mortis). Rewarming efforts should usually be continued until the temperature is 32-34°C (89.6-93.2°F); if the victim continues to have no effective cardiac rhythm and remains unresponsive to aggressive CPR, resuscitative efforts can be discontinued.
Complete rewarming is not indicated for all arrest victims before resuscitative efforts are abandoned. Discontinuing resuscitation in victims of non–icy water submersion who remain asystolic despite 30 min of CPR is probably warranted. Physicians must use their individual clinical judgment about deciding to stop resuscitative efforts, taking into account the unique circumstances of each incident.

Once a drowning victim has undergone successful CPR after a cardiac arrest, temperature management should be carefully considered and body temperature continuously monitored. In victims in whom resuscitation duration was brief and who are awake soon after resuscitation, attempts to restore and maintain normothermia are warranted. Careful monitoring is necessary to prevent unrecognized worsening hypothermia, which can have untoward consequences.

For drowning victims who remain comatose after successful CPR, more contentious issues include rewarming of hypothermic patients and controlled application of therapeutic hypothermia. Although there is no evidence basis or opinion consensus, many investigators cautiously recommend that hypothermic drowning victims who remain unresponsive because of hypoxic-ischemic encephalopathy after restoration of adequate spontaneous circulation should not be actively rewarmed to normal body temperatures. Active rewarming should be limited to victims with core body temperatures <32°C (89.6°F), but temperatures 32-37.5°C (89.6-99.5°F) should be allowed without further rewarming efforts.

More controversial is the induction of therapeutic hypothermia in drowning victims who remain comatose because of hypoxic-ischemic encephalopathy after CPR for cardiac arrest. A specific recommendation for therapeutic hypothermia, especially in children, is not yet generally accepted. The Advanced Life Support Task Force of the International Liaison Committee on Resuscitation (2002) did not recommend therapeutic hypothermia in drowned children resuscitated after cardiopulmonary arrest, citing insufficient evidence and older studies demonstrating a potential deleterious effect in pediatric drowning victims. Several subsequent studies evaluating extracorporeal membrane circulation, rewarming, and therapeutic hypothermia in pediatric and adult drowning patients have shown no significant improvement in neurologic outcome or mortality.

The Therapeutic Hypothermia After Out-of-Hospital Pediatric Cardiac Arrest (THAPCA) randomized controlled trial (RCT) investigators analyzed post hoc the findings of targeted temperature management (TTM) in pediatric comatose survivors of out-of-hospital cardiac arrest due to drowning. Drowning comprised 28% of the landmark pediatric TTM (33°C vs 36.8°C) RCT, and the authors’
principal observation is that targeting hypothermia, compared with targeting normothermia, did not result in better survival.

**Prognosis**

The outcomes for drowning victims are remarkably bimodal: The great majority of victims either have a good outcome (intact or mild neurologic sequelae) or a poor outcome (severe neurologic sequelae, persistent vegetative state, or death), with very few exhibiting intermediate neurologic injury at hospital discharge. Subsequent evaluation of good outcome survivors may identify significant persistent cognitive deficits. Of hospitalized pediatric drowning victims, 15% die and as many as 20% survive with severe permanent neurologic damage.

Strong predictors of outcome are based on the incident and response to treatment at the scene. Intact survival or mild neurologic impairment has been seen in 91% of children with submersion duration <5 min and in 87% with resuscitation duration <10 min. Children with normal sinus rhythm, reactive pupils, or neurologic responsiveness at the scene virtually always had good outcomes (99%). Poor outcome is highly likely in patients with deep coma, apnea, absence of papillary responses, and hyperglycemia in the ED, with submersion durations >10 min, and with failure of response to CPR given for 25 min. In one comprehensive case series, all children with resuscitation durations >25 min either died or had severe neurologic morbidity, and all victims with submersion durations >25 min died. Long-term health-related quality of life and school performance in those who had received either bystander- or emergency medical service personnel–initiated CPR was high if their submersion duration was <5 min. Higher morbidity, mortality, and lower quality of life were reported in patients with >10 min submersion duration. In several studies of pediatric drowning, submersion duration was the best predictor of outcome, and water temperature was not. However, there are rare case reports of intact recovery following non–icy water drowning with longer submersion or resuscitation duration.

The GCS score has some limited utility in predicting recovery. Children with a score ≥6 on hospital admission generally have a good outcome, whereas those with a score ≤5 have a much higher probability of poor neurologic outcome. Occasionally, children with a GCS score of 3 or 4 in the ED have complete recovery. Improvement in the GCS score during the 1st several hr of hospitalization may indicate a better prognosis. Overall, early GCS assessments
fail to adequately distinguish children who will survive intact from those with major neurologic injury.

Neurologic examination and progression during the 1st 24-72 hr are the best prognosticators of long-term CNS outcome. Children who regain consciousness within 48-72 hr, even after prolonged resuscitation, are unlikely to have serious neurologic sequelae. On the contrary, several studies have shown that patients with minimal improvement during this initial period rarely show significant subsequent neurologic recovery despite aggressive resuscitation efforts and remain in a persistent vegetative state or die. Laboratory and technologic methods to improve prognostication have not yet proved superior to neurologic examination. Serial neurologic evaluations after CPR should be performed over the ensuing 48-72 hr, with consideration given to limitation or withdrawal of support in patients who do not have significant neurologic recovery, even though this may occur before absolute prognostic certainty is achieved.

Prevention

The most effective way to decrease the injury burden of drowning is prevention. Drowning is a multifaceted problem, but several evidence-based preventive strategies are effective. The pediatrician has a prime opportunity to identify and inform families at risk of these strategies through anticipatory guidance. Advocacy should focus on anticipatory guidance regarding the appropriate supervision of children, access to swim lessons, presence of lifeguards, barriers to swimming pools, and use of personal floatation devices (PFDs). A family-centered approach to anticipatory guidance for water safety helps explore and identify the water hazards that each family is exposed to in their environment. The practitioner can then discuss the best tools and strategies for prevention that are relevant for the family. It is important to identify the risk both in and around the home and in other locations they may frequent, often when vacationing, such as vacation or relatives’ homes. For some families the focus may be on bathtubs and bucket safety; for others, home pools or hot tubs may be the major hazards. If the family recreates near or on open water, they also need to learn about safety around boats and open water. In a rural environment, water collection systems and natural bodies of water may pose great risk.

Parents must build layers of water protection around their children. Table 91.1 provides an approach to the hazards and preventive strategies relevant to the most common sources of water involved in childhood drowning. A common
preventive strategy for exposure to all water types and all ages is ensuring **appropriate supervision**. Pediatricians should define for parents what constitutes appropriate supervision at the various developmental levels of childhood. Many parents either underestimate the importance of adequate supervision or are simply unaware of the risks associated with water. Even parents who say that constant supervision is necessary will often admit to brief lapses while their child is alone near water. Parents also overestimate the supervisory abilities of older siblings; many bathtub drownings occur when an infant or toddler is left with a child <5 yr old.

Supervision of infants and young children means that a responsible adult should be with the child every moment. The caregiver must be alert, must not be
consuming alcohol or other drugs or socializing, and must be attentive and focused entirely on watching the child. Even a brief moment of inattention, such as to answer a phone, get a drink, or hold a conversation, can have tragic consequences. If the child does not swim, *touch supervision* is required, meaning that the caregiver should be within arm's reach at all times. Adolescents require active adult supervision and avoidance of alcohol or drug use during water activities.

**Learning to swim** offers another layer of protection. Children may start swim lessons at an early age that are developmentally appropriate and aimed at the individual child's readiness and skill level. Swim lessons are beneficial and provide some level of protection to young children. A study from Bangladesh, where drowning accounts for 20% of all deaths in children ages 1-4 yr, showed that swim lessons and water safety curricula are cost-effective and led to a decrease in mortality from drowning. As with any other water safety intervention, parents need to know that swimming lessons and acquisition of swim skills cannot be solely relied on to prevent drowning. *No child can be drown-proof.* A supervising caretaker should be aware of where and how to get help and know how to safely rescue a child in trouble. Because only those trained in water rescue can safely attempt it, families should be encouraged to swim in designated areas only when and where a lifeguard is on duty.

Children and adolescents should never swim alone regardless of their swimming abilities. Even as they become more independent and participate in recreational activities without their parents, they should be encouraged to seek areas that are watched by *lifeguards*. In 2015, lifeguards rescued 940,000 Americans from drowning, and they probably prevent millions more drownings through verbal warnings and prompt interventions when needed. It is important to emphasize that even if the child is considered a strong swimmer, the ability to swim in a pool does not translate to being safe in open water, where water temperature, currents, and underwater obstacles can present additional and unfamiliar challenges. For swimmers, supervision by lifeguards reduces drowning risk, because lifeguards monitor risk behaviors and are trained in the difficult and potentially dangerous task of rescuing drowning victims.

Two of the preventive strategies listed in Table 91.1 deserve special mention. The most vigorously evaluated and effective drowning intervention applies to swimming pools. *Isolation fencing* that surrounds a pool with a secure, self-locking gate could prevent up to 75% of swimming pool–related drowning. Guidelines for appropriate fencing, provided by the U.S. Consumer Product
Safety Commission, are very specific; they were developed through testing of active toddlers in a gymnastics program on their ability to climb barriers of different materials and heights, and recent studies show them to be effective in preventing drowning in young children. In families who have a pool on their property, caregivers often erroneously believe that if a child falls into the water, there will be a loud noise or splash to alert them. Unfortunately, these events are usually silent, delaying timely rescue. This finding highlights the need for a fence that separates the pool from the house, not just surrounds the entire property.

The use of U.S. Coast Guard–approved lifejackets or PFDs should be advised with all families spending time around open water, not just those who consider themselves boaters. This issue is also particularly important for families who will participate in aquatic activities on a vacation. A PFD should be chosen with respect to the weight of the child and the proposed activity. Young children should wear PFDs that will float their head up. Parents should be urged to wear PFDs as well, since their use of PFDs is associated with greater use by their children. Toys such as water wings and “floaties” should not be relied on as drowning prevention measures.

Effective preventive efforts must also consider cultural practices. Different ethnic groups may have certain attitudes, beliefs, dress, or other customs that may affect their water safety. The higher drowning risk of minority children needs to be addressed by community-based prevention programs.

In addition to anticipatory guidance, pediatricians can play an active role in drowning prevention by participating in advocacy efforts to improve legislation for pool fencing, PFD use, and alcohol consumption in various water activities. Several counties in the United States, Australia, and New Zealand have laws requiring isolation fencing for pools. Their effectiveness has been limited by a lack of enforcement. Similarly, all states have boating-under-the-influence laws but, similarly, rarely enforce them. Furthermore, efforts at the community level may be needed to ensure the availability of swimming lessons for underserved populations and lifeguarded swim areas.

Bibliography

Quan L, Bierens JJ, Lis R, et al. Predicting outcome of

Burns are a leading cause of unintentional injury in children, second only to motor vehicle crashes. There has been a decline in the incidence of burn injury requiring medical care that has coincided with a stronger focus on burn treatment and prevention, increased fire and burn prevention education, greater availability of regional treatment centers, widespread use of smoke detectors, greater regulation of consumer products and occupational safety, and societal changes such as reductions in smoking and alcohol abuse.

Epidemiology

Approximately 2 million people in the United States require medical care for burn injuries each year. Approximately 50% of these patients are younger than 5 yr, with an average age of 32 mo. The principal cause of the burn is scald; one of the causes of scald burn is heating liquids in the microwave. The leading cause of burn in children 5-14 yr old is flame injury. In children 5-10 yr old, burns are usually a result of match play, whereas for older children, it is usually a result of gasoline ignition. Fires are a major cause of mortality in children, accounting for up to 34% of fatal injuries in those <16 yr old.

Scald burns account for 85% of total injuries and are most prevalent in children <4 yr old. Although the incidence of hot water scalding has been reduced by legislation requiring new water heaters to be preset at 48.9°C (120°F), scald injury remains the leading cause of hospitalization for burns. Steam inhalation used as a home remedy to treat respiratory infections is another potential cause of burns. Flame burns account for 13%; the remaining are electrical and chemical burns. Clothing ignition events have declined since passage of the Federal Flammable Fabric Act requiring sleepwear to be flame-
retardant; however, the U.S. Consumer Product Safety Commission has voted to relax the existing children's sleepwear flammability standard. Polyester is the fabric most resistant to ignition by small flame source. Polyester does burn deeply as it melts, but it self-extinguishes when the flame source is removed. Cotton, on the other hand, continues to burn after the flame source has been removed, resulting in large, deep burns. Polyester melts downward, sparing the face and respiratory tract; cotton burns upward toward the face. Pellet stove, glass front stoves, and flat top stoves are becoming frequent sources of hand burns in children. Approximately 18% of burns are the result of child abuse (usually scalds), making it important to assess the pattern and site of injury and their consistency with the patient history (see Chapter 16). Friction burns from treadmills are also a problem. Hands are the most commonly injured sites, with deep 2nd-degree friction injury sometimes associated with fractures of the fingers. Anoxia, not the actual burn, is a major cause of morbidity and mortality in house fires.

Review of the history usually shows a common pattern: scald burns to the side of the face, neck, and arm if liquid is pulled from a table or stove; burns in the pant leg area if clothing ignites; burns in a splash pattern from cooking; and burns on the palm of the hand from contact with a hot stove. However, glove or stocking burns of the hands and feet; single-area deep burns on the trunk, buttocks, or back; and small, full-thickness burns (e.g., cigarette burns) in young children should raise the suspicion of child abuse.

Burn care involves a range of activities: prevention, acute care and resuscitation, wound management, pain relief, reconstruction, rehabilitation, and psychosocial adjustment. Children with massive burns require early and appropriate psychological and social support as well as resuscitation. Surgical debridement, wound closure, and rehabilitative efforts should be instituted concurrently to promote optimal rehabilitation. In order to maximize survival, the clinical approach includes aggressive surgical removal of devitalized tissue, infection control, and judicious use of antibiotics; life support with endotracheal intubation and mechanical ventilation; and use of early nutrition. Children who have sustained burn injuries differ in appearance from their peers, necessitating supportive efforts for reentry to school and social and sporting activities.

**Prevention**

The aim of burn prevention is a continuing reduction in the number of serious
burn injuries (Table 92.1). Effective first aid and triage can decrease both the extent (area) and the severity (depth) of injuries. The use of flame-retardant clothing and smoke detectors, control of hot water temperature (thermostat settings) to 48.9°C (120°F) within buildings, and prohibition of cigarette smoking have been partially successful in reducing the incidence of burn injuries. Treatment of children with significant burn injuries in dedicated burn centers facilitates medically effective care, improves survival, and leads to greater cost efficiency. Survival of at least 80% of patients with burns of 90% of the body surface area (BSA) is possible; the overall survival rate of children with burns of all sizes is 99%. Death is more likely in children with irreversible anoxic brain injury sustained at the time of the burn. It is well known that burns occur in predictable patterns. Sources of burns include, by season:

**Table 92.1**

**Burn Prophylaxis**

**Prevent Fires**

- Install and use smoke detectors.
- Control the hot water thermostat; in public buildings, maximum water temperature should be 48.9°C (120°F).
- Keep fire, matches, and lighters out of the reach of children.
- Avoid cigarette smoking, especially in bed.
- Do not leave lit candles unattended.
- Use flame retardant–treated clothing.
- Use caution when cooking, especially with oil.
- Keep cloth items off heaters.

**Prevent Injury**

- Roll, but do not run, if clothing catches fire; wrap in a blanket.
- Practice escape procedures.
- Crawl beneath smoke if a fire occurs indoors.
- Use educational materials.*
Winter:
◆ Glass front fireplaces/pellet stoves and radiators increase hand burns.
◆ Treadmill injuries as more people exercise inside—child imitates adults or young child touches belt.

Summer:
◆ Fireworks, sparkler—temperatures reach 537.8°C (1,000°F).
◆ Burn contact with hot grill; hand/feet burn from hot embers.
◆ Lawnmowers

Spring/Fall:
◆ Burning leaves
◆ Gasoline burns
◆ Tap water scalds are essentially preventable through a combination of behavioral and environmental changes.

Pediatricians can play a major role in preventing the most common burns by educating parents and healthcare providers. Simple, effective, efficient, and cost-effective preventive measures include the use of appropriate clothing and smoke detectors and the planning of routes for emergency exit from the home. The National Fire Protection Association (NFPA) recommends replacing smoke detector batteries annually and the smoke detector alarm every 10 yr (or earlier, if indicated on the device). Child neglect and abuse must be seriously considered when the history of the injury and the distribution of the burn do not match.

Acute Care, Resuscitation, and Assessment

Indications for Admission
Burns covering >10% of total body surface area (BSA), burns associated with smoke inhalation, burns resulting from high-tension (voltage) electrical injuries, and burns associated with suspected child abuse or neglect should be treated as emergencies and the child hospitalized (Table 92.2). Small 1st- and 2nd-degree burns of the hands, feet, face, perineum, and joint surfaces also require
admission if close follow-up care is difficult to provide. Children who have been in enclosed-space fires and those who have face and neck burns should be hospitalized for at least 24 hr for observation for signs of central nervous system (CNS) effects of anoxia from carbon monoxide (CO) poisoning and pulmonary effects from smoke inhalation.

BSA, Body surface area.

**First Aid Measures**

Acute care should include the following measures:

1. Extinguish flames by rolling the child on the ground; cover the child with a blanket, coat, or carpet.
2. After determining that the airway is patent, remove smoldering clothing or clothing saturated with hot liquid. Jewelry, particularly rings and bracelets, should be removed or cut away to prevent constriction and vascular compromise during the edema phase in the first 24-72 hr after burn injury.
3. In cases of **chemical injury**, brush off any remaining chemical, if
powdered or solid; then use copious irrigation or wash the affected area with water. Call the local poison control center for the neutralizing agent to treat a chemical ingestion.

4. Cover the burned area with clean, dry sheeting and apply cold (not iced) wet compresses to small injuries. Significant large-burn injury (>15% of BSA) decreases body temperature control and contraindicates the use of cold compresses.

5. If the burn is caused by **hot tar**, use mineral oil to remove the tar.

6. Administer analgesic medications.

**Emergency Care**

Supportive measures are as follows (Table 92.3 and Table 92.4)

1. Rapidly review the cardiovascular and pulmonary status and document preexisting or physiologic lesions (asthma, congenital heart disease, renal or hepatic disease).

2. Ensure and maintain an adequate airway, and provide humidified oxygen by mask or endotracheal intubation (Fig. 92.1). The latter may be needed in children who have facial burns or a burn sustained in an enclosed space, before facial or laryngeal edema becomes evident. If hypoxia or CO poisoning is suspected, 100% oxygen should be used (see Chapters 81 and 89).
3. Children with burns >15% of BSA require intravenous (IV) fluid resuscitation to maintain adequate perfusion. In an emergency situation if IV access is unattainable, an intraosseous line should be placed. When inserting central lines to provide high-volume fluid, special attention should be paid to use a very-small-caliber catheter in small children to avoid injury to the vascular lining, which may predispose to formation of clots. All inhalation injuries, regardless of the extent of BSA burn, require venous access to control fluid intake. All high-tension and
electrical injuries require venous access to ensure forced alkaline diuresis in case of muscle injury to avoid myoglobinuric renal damage. Lactated Ringer solution, 10-20 mL/kg/hr (normal saline may be used if lactated Ringer solution is not available), is initially infused until proper fluid replacement can be calculated. Consultation with a specialized burn unit should be made to coordinate fluid therapy, the type of fluid, the preferred formula for calculation, and preferences for the use of colloid agents, particularly if transfer to a burn center is anticipated.

4. Evaluate the child for associated injuries, which are common in patients with a history of high-tension electrical burn, especially if there has also been a fall from a height. Injuries to the spine, bones, and thoracic or intraabdominal organs may occur (see Chapter 82). Cervical spine precautions should be observed until this injury is ruled out. There is a very high risk of cardiac abnormalities, including ventricular tachycardia and ventricular fibrillation, resulting from conductivity of the high electric voltage. Cardiopulmonary resuscitation (CPR) should be instituted promptly at the scene and cardiac monitoring started on the patient's arrival at the emergency department (ED) (see Chapter 81).

5. Children with burns of >15% of BSA should not receive oral fluids (initially) because gastric distention may develop. These children require insertion of a nasogastric tube in the ED to prevent aspiration.

6. A Foley catheter should be inserted into the bladder to monitor urine output in all children who require IV fluid resuscitation.

7. All wounds should be wrapped with sterile dressings until it is decided whether to treat the patient on an outpatient basis or refer to an appropriate facility.

8. A CO measurement (carboxyhemoglobin [HbCO]) should be obtained for fire victims and 100% oxygen administered until the result is known.

9. Review child immunization. Burns <10% BSA do not require tetanus prevention, whereas burns >10% need tetanus immunization. Use diphtheria, tetanus toxoids, and acellular pertussis (DTaP) for tetanus prophylaxis for children <11 yr old, and use tetanus, diphtheria, and pertussis (TdaP) for children >11 yr old (see Chapter 238).

**Classification of Burns**

Proper triage and treatment of burn injury require assessment of the extent and
depth of the injury (Table 92.5 and Fig. 92.2). 1st-degree burns involve only the epidermis and are characterized by swelling, erythema, and pain (similar to mild sunburn). Tissue damage is usually minimal, and there is no blistering. Pain resolves in 48-72 hr; in a small percentage of patients, the damaged epithelium peels off, leaving no residual scars.

</table>

**FIG. 92.2** Diagram of different burn depths. (From Hettiaratchy S, Papini R: Initial
A 2nd-degree burn involves injury to the entire epidermis and a variable portion of the dermal layer (vesicle and blister formation are characteristic). A superficial 2nd-degree burn is extremely painful because many remaining viable nerve endings are exposed. Superficial 2nd-degree burns heal in 7-14 days as the epithelium regenerates in the absence of infection. Mid-level to deep 2nd-degree burns also heal spontaneously if wounds are kept clean and infection free. Pain is less with these burns than in more superficial burns because fewer nerve endings remain viable. Fluid losses and metabolic effects of deep dermal (2nd-degree) burns are essentially the same as those of 3rd-degree burns.

Full-thickness, or 3rd-degree, burns involve destruction of the entire epidermis and dermis, leaving no residual epidermal cells to repopulate the damaged area. The wound cannot epithelialize and can heal only by wound contraction or skin grafting. The absence of painful sensation and capillary filling demonstrates the loss of nerve and capillary elements.

Technologies are being used to help accurately determine the depth of burns. Laser Doppler imaging can be used from 48 hr to 5 days after the burn. It produces a color map of the affected tissue; yellow indicates second-degree burns, reflecting the presence of capillaries, arterioles, and venules, and blue reflects very low or absence of blood flow, which indicates third-degree burns. Its accuracy is up to 95%, and with accurate assessment, the proper treatment can be applied without delay. Doppler imaging can be used in both outpatients and inpatients.

Another technology called reflectance confocal microscopy (RCM), can be combined with optical coherence tomography (OCT) to visualize tissue morphology at the subcellular level. It determines if the cells are damaged and enables detection of skin morphologic changes up to 1 mm in depth. It provides accurate determination of the depth of the burn, allowing for the appropriate treatment.

**Estimation of Body Surface Area for a Burn**

Appropriate burn charts for different childhood age-groups should be used to accurately estimate the extent of BSA burned. The volume of fluid needed in resuscitation is calculated from the estimation of the extent and depth of burn surface. Mortality and morbidity also depend on the extent and depth of the
burn. The variable growth rate of the head and extremities throughout childhood makes it necessary to use BSA charts, such as that modified by Lund and Brower or the chart used at the Shriners Hospital for Children in Boston (Fig. 92.3). The rule of nines used in adults may be used only in children >14 yr old or as a rough estimate to institute therapy before transfer to a burn center. In small burns, <10% of BSA, the rule of palm may be used, especially in outpatient settings; the area from the wrist crease to the finger crease (the palm) in the child equals 1% of the child's BSA.

**FIG. 92.3** Chart to determine developmentally related percentage of body surface area affected by burn injury. ANT, Anterior; POST, posterior; R., right; L., left. (Courtesy of Shriners Hospital for Crippled Children, Burn Institute, Boston Unit.)

**Treatment**

**Outpatient Management of Minor Burns**

A patient with 1st- and 2nd-degree burns of <10% BSA may be treated on an
outpatient basis unless family support is judged inadequate or there are issues of child neglect or abuse. These outpatients do not require a tetanus booster (unless not fully immunized) or prophylactic penicillin therapy. Blisters should be left intact and dressed with *bacitracin* or *silver sulfadiazine* cream (Silvadene). Dressings should be changed once daily, after the wound is washed with lukewarm water to remove any cream left from the previous application. Very small wounds, especially those on the face, may be treated with bacitracin ointment and left open. **Debridement** of the devitalized skin is indicated when the blisters rupture. A variety of wound dressings and wound membranes (e.g., AQUACEL Ag dressing [ConvaTec USA, Skillman, NJ] in soft felt-like material impregnated with silver ion) may be applied to 2nd-degree burns and wrapped with a dry sterile dressing. Similar wound membranes provide pain control, prevent wound desiccation, and reduce wound colonization (*Table 92.6*). These dressings are usually kept on for 7-10 days but are checked twice a week.

Burns to the palm with large blisters usually heal beneath the blisters; they should receive close follow-up on an outpatient basis. The great majority of superficial burns heal in 10-20 days. Deep 2nd-degree burns take longer to heal and may benefit from enzymatic debridement ointment (collagenase) applied daily on the wound, which aids in the removal of the dead tissue. These ointments should not be applied to the face, to avoid the risk of getting into the eyes.

The depth of scald injuries is difficult to assess early; conservative treatment is appropriate initially, with the depth of the area involved determined before grafting is attempted (*Fig. 92.4*). This approach obviates the risk of anesthesia.
and unnecessary grafting.

**Fluid Resuscitation**

Fluid resuscitation should begin soon after the injury has occurred, in the ED before transferring to a burn center. For most children, the *Parkland formula* is an appropriate starting guideline for fluid resuscitation (4 mL lactated Ringer solution/kg/% BSA burned). Half the fluid is given over the 1st 8 hr, calculated from the time of onset of injury; the remaining fluid is given at an even rate over the next 16 hr. The rate of infusion is adjusted according to the patient's response to therapy. Pulse and blood pressure should return to normal, and an adequate urine output (>1 mL/kg/hr in children; 0.5-1.0 mL/kg/hr in adolescents) should be accomplished by varying the IV infusion rate. Vital signs, acid-base balance, and mental status reflect the adequacy of resuscitation. Because of interstitial edema and sequestration of fluid in muscle cells, patients may gain up to 20% over baseline (preburn) body weight. Patients with burns of 30% BSA require a large venous access (central venous line) to deliver the fluid required over the critical 1st 24 hr. Patients with burns of >60% BSA may require a multilumen central venous catheter; these patients are best cared for in a specialized burn
In addition to fluid resuscitation, children should receive standard maintenance fluids (see Chapter 69).

During the 2nd 24 hr after the burn, patients begin to reabsorb edema fluid and to experience diuresis. Half the 1st day’s fluid requirement is infused as lactated Ringer solution in 5% dextrose. Children <5 yr old may require the addition of 5% dextrose in the 1st 24 hr of resuscitation. Controversy surrounds whether colloid should be provided in the early period of burn resuscitation. One preference is to use colloid replacement concurrently if the burn is >85% of total BSA. Colloid is usually instituted 8-24 hr after the burn injury. In children <12 mo old, sodium tolerance is limited; the volume and sodium concentration of the resuscitation solution should be decreased if the urinary sodium level is rising. The adequacy of resuscitation should be constantly assessed by means of vital signs as well as urine output, blood gas, hematocrit, and serum protein measurements. Some patients require arterial and central venous lines, particularly those undergoing multiple excision and grafting procedures, as needed, for monitoring and replacement purposes. Central venous pressure monitoring may be indicated to assess circulation in patients with hemodynamic or cardiopulmonary instability. Femoral vein cannulation is a safe access for fluid resuscitation, especially in infants and children. Burn patients who require frequent blood gas monitoring benefit from radial or femoral arterial catheterization.

Oral supplementation may start as early as 48 hr after the burn. Milk formula, artificial feedings, homogenized milk, or soy-based products can be given by bolus or constant infusion through a nasogastric or small bowel feeding tube. As oral fluids are tolerated, IV fluids are decreased proportionately in an effort to keep the total fluid intake constant, particularly if pulmonary dysfunction is present.

A 5% albumin infusion may be used to maintain the serum albumin levels at a desired 2 g/dL. The following rates are effective: for burns of 30–50% of total BSA, 0.3 mL of 5% albumin/kg/% BSA burn is infused over 24 hr; for burns of 50–70% of total BSA, 0.4 mL/kg/% BSA burn is infused over 24 hr; and for burns of 70–100% of total BSA, 0.5 mL/kg/% BSA burn is infused over 24 hr. Infusion of packed red blood cells is recommended if the hematocrit falls to <24% (hemoglobin = 8 g/dL). Some authorities recommend treatment for hematocrit <30% or hemoglobin <10 g/dL in patients with systemic infection, hemoglobinopathy, cardiopulmonary disease, anticipated (or ongoing) blood loss, and if repeated excision and grafting of full-thickness burns are needed.
Fresh-frozen plasma (FFP) is indicated if clinical and laboratory assessment shows a deficiency of clotting factors, a prothrombin level >1.5 times control, or a partial thromboplastin time >1.2 times control in children who are bleeding or are scheduled for an invasive procedure or a grafting procedure that could result in an estimated blood loss of more than half of blood volume. FFP may be used for volume resuscitation within 72 hr of injury in patients <2 yr old with burns >20% BSA and associated inhalation injury.

Sodium supplementation may be required for children with burns of >20% BSA if 0.5% silver nitrate solution is used as the topical antibacterial burn dressing. Sodium losses with silver nitrate therapy are regularly as high as 350 mEq/m² burn surface area. Oral sodium chloride supplement of 4 g/m² burn area/24 hr is usually well tolerated, divided into 4-6 equal doses to avoid osmotic diarrhea. The aim is to maintain serum sodium levels >130 mEq/L and urinary sodium concentration >30 mEq/L. Young children <5 yr are especially susceptible to hyponatremic and cerebral edema. IV potassium supplementation is supplied to maintain a serum potassium level >3 mEq/dL. Potassium losses may be significantly increased when 0.5% silver nitrate solution is used as the topical antibacterial agent or when aminoglycoside, diuretic, or amphotericin therapy is required.

Prevention of Infection and Surgical Management of the Burn Wound

Controversy surrounds the use of prophylactic penicillin for all patients hospitalized with acute burn injury and the periodic replacement of central venous catheters to prevent infection. In some units, a 5-day course of penicillin therapy is used for all patients with acute burns; standard-dose crystalline penicillin is given orally or intravenously in 4 divided doses. Erythromycin may be used as an alternative in penicillin-allergic children. Other units have discontinued prophylactic use of penicillin therapy without an increase in the infection rate. Similarly, there is conflicting evidence as to whether relocation of the IV catheter every 48-72 hr decreases or increases the incidence of catheter-related sepsis. Some recommend that the central venous catheter be replaced and relocated every 5-7 days, even if the site is not inflamed and there is no suspicion of catheter-related sepsis.

Mortality related to burn injury is associated not with the toxic effect of thermally injured skin, but with the metabolic and bacterial consequences of a
large open wound, reduction of the patient's host resistance, and malnutrition. These abnormalities set the stage for life-threatening bacterial infection originating from the burn wound. Wound treatment and prevention of wound infection also promote early healing and improve aesthetic and functional outcomes. Topical treatment of the burn wound with 0.5% silver nitrate solution, silver sulfadiazine cream, or mafenide acetate (Sulfamylon) cream or topical solution at a concentration of 2.5–5% to be used for wounds with multidrug-resistant bacteria aims at prevention of infection (Table 92.7). These 3 agents have tissue-penetrating capacity. Regardless of the choice of topical antimicrobial agent, it is essential that all 3rd-degree burn tissue be fully excised before bacterial colonization occurs, and that the area is grafted as early as possible to prevent deep wound sepsis. Children with a burn of >30% BSA should be housed in a bacteria-controlled nursing unit to prevent cross-contamination and to provide a temperature- and humidity-controlled environment to minimize hypermetabolism.

Deep 3rd-degree burns of >10% BSA benefit from early excision and grafting. To improve outcome, sequential excision and grafting of 3rd-degree and deep 2nd-degree burns is required in children with large burns. Prompt excision with immediate wound closure is achieved with autografts, which are often meshed to increase the efficiency of coverings. Alternatives for wound closure, such as
allografts, xenografts, and Integra (Integra LifeSciences, York, PA) and other synthetic skin coverings (bilaminate membrane composed of a porous lattice of crosslinked chondroitin-6-sulfate engineered to induce neovascularization as it is biodegraded), may be important for wound coverage in patients with extensive injury to limit fluid, electrolyte, and protein losses and to reduce pain and minimize temperature loss. Epidermal cultured cells (autologous keratinocytes) are a costly alternative and are not always successful. An experienced burn team can safely perform early-stage or total excision while burn fluid resuscitation continues. Important keys to success are: (1) accurate preoperative and intraoperative determination of burn depth; (2) the choice of excision area and appropriate timing; (3) control of intraoperative blood loss; (4) specific instrumentation; (5) the choice and use of perioperative antibiotics; and (6) the type of wound coverage chosen. This process can accomplish early wound coverage without the use of recombinant human growth hormone.

**Nutritional Support**

Supporting the increased energy requirements of a patient with a burn is a high priority. The burn injury produces a hypermetabolic response characterized by both protein and fat catabolism. Depending on the time lapse since the burn, children with a burn of 40% of total BSA require basal energy expenditure (oxygen consumption) approximately 50–100% higher than predicted for their age. Early excision and grafting can decrease the energy requirement. Pain, anxiety, and immobilization increase the physiologic demands. Additional energy expenditure is caused by cold stress if environmental humidity and temperature are not controlled; this is especially true in young infants, in whom the large BSA:mass ratio allows proportionately greater heat loss than in adolescents and adults. Providing environmental temperatures of 28-33°C (82.4-91.4°F), adequate covering during transport, and liberal use of analgesics and anxiolytics can decrease caloric demands. Special units to control ambient temperature and humidity may be necessary for children with large surface area burns. Appropriate sleep intervals are necessary and should be part of the regimen. Sepsis increases metabolic rates, and early enteral nutrition, initially with high-carbohydrate, high-protein caloric support (1,800 kcal/m²/24 hr maintenance plus 2,200 kcal/m² of burn/24 hr) reduces metabolic stress.

The objective of **caloric supplementation** programs is to maintain body weight and minimize weight loss by meeting metabolic demands. This reduces
the loss of lean body mass. Calories are provided at approximately 1.5 times the basal metabolic rate, with 3-4 g/kg of protein/day. The focus of nutritional therapy is to support and compensate for the metabolic needs. Multivitamins, particularly the B vitamin group, vitamin C, vitamin A, and zinc, are also necessary.

**Alimentation** should be started as soon as is practical, both enterally and parenterally, to meet all the caloric needs and keep the gastrointestinal (GI) tract active and intact after the resuscitative phase. Patients with burns of >40% of total BSA need a flexible nasogastric or small bowel feeding tube to facilitate continuous delivery of calories without the risk of aspiration. To decrease the risk of infectious complications, parenteral nutrition is discontinued as soon as is practical, after delivery of sufficient enteral calories are established. Continuous GI feeding is essential, even if feeding is interrupted, causing frequent visits to the operating room, until full grafting takes place. The use of anabolic agents (growth hormone, oxandrolone, low-dose insulin) or anticatabolic agents (propranolol) remains controversial, although β-blocking agents may reduce metabolic stress. Burn centers caring for large burns (>50% BSA, 3rd-degree) in patients who might be malnourished have used the anabolic steroid oxandrolone, at a dose of 0.1-0.2 mg/kg/day orally, to promote better protein synthesis while the nutritional support by nasogastric feeding and IV hyperalimentation continues.

**Topical Therapy**

Topical therapy is widely used and is effective against most burn wound pathogens (see Table 92.7). A number of topical agents are used: 0.5% silver nitrate solution, sulfacetamide acetate cream or solution, silver sulfadiazine cream, and Accuzyme ointment or AQUACEL Ag⁺. Accuzyme is an enzymatic debridement agent and may cause a stinging feeling for 15 min after application. Preferences vary among burn units. Each topical agent has advantages and disadvantages in application, comfort, and bacteriostatic spectrum. *Mafenide acetate* is a very effective broad-spectrum agent with the ability to diffuse through the burn eschar; it is the treatment of choice for injury to cartilaginous surface, such as the ear. Mafenide acetate solution at a concentration of 5% is useful for the treatment of burn wounds that are heavily colonized with multidrug-resistant bacteria (use should be limited to 5 days). The carbonic anhydrase inhibition activity of mafenide acetate may cause acid-base imbalance.
if large surface areas are treated, and adverse reactions to the sulfur-containing agents may produce transient **leukopenia**. This latter reaction is mostly noted with the use of silver sulfadiazine cream when applied over large surface areas in children <5 yr old. This phenomenon is transient, self-limiting, and reversible. No sulfa-containing agent should be used if the child has a history of sulfa allergies.

**Inhalalional Injury**

Inhalational injury is serious in the infant and child, particularly if preexisting pulmonary conditions are present (see **Chapter 89**). Inhalation injury should be suspected in a patient confined to a closed space (building), with a history of an explosion or a decreased level of consciousness, or with evidence of carbon deposits in the oropharynx or nose, singed facial hair, and carbonaceous sputum. Mortality estimates vary, depending on the criteria for diagnosis, but are 45–60% in adults; exact figures are not available in children. Evaluation aims at early identification of inhalation airway injuries, which may result from (1) direct heat (greater problems with steam burns); (2) acute asphyxia; (3) CO poisoning; and (4) toxic fumes, including cyanides from combustible plastics. Sulfur and nitrogen oxides and alkalis formed during the combustion of synthetic fabrics produce corrosive chemicals that may erode mucosa and cause significant tissue sloughing. Exposure to smoke may cause degradation of surfactant and decrease its production, resulting in atelectasis. Inhalation injury and burn injury are synergistic, and the combined effect can increase morbidity and mortality.

The pulmonary complications of burns and inhalation can be divided into 3 syndromes that have distinct clinical manifestations and temporal patterns:

1. Early complications include CO and/or cyanide poisoning, airway obstruction, and pulmonary edema.
2. Acute respiratory distress syndrome (ARDS) usually becomes clinically evident later, at 24-48 hr, although it can occur even later (see **Chapter 89**).
3. Late complications (days to weeks) include pneumonia and pulmonary emboli.

Inhalation injury should be assessed from the evidence of obvious injury (swelling or carbonaceous material in the nasal passages), wheezing, crackles or
poor air entry, and laboratory determinations of HbCO and arterial blood gases.

Treatment is initially focused on establishing and maintaining a patent airway through prompt and early nasotracheal or orotracheal intubation and adequate ventilation and oxygenation. **Wheezing** is common, and β-agonist aerosols or inhaled corticosteroids are useful. Aggressive pulmonary toilet and chest physiotherapy are necessary in patients with prolonged nasotracheal intubation or in the rare patient with a tracheotomy. An endotracheal tube can be maintained for months without the need for tracheostomy. If tracheotomy must be performed, it should be delayed until burns at and near the site have healed, and then it should be performed electively, with the child under anesthesia with optimal tracheal positioning and hemostasis. In children with inhalation injury or burns of the face and neck, upper airway obstruction can develop rapidly; endotracheal intubation becomes a lifesaving intervention. Extubation should be delayed until the patient meets the accepted criteria for maintaining the airway.

Signs of CNS injury from hypoxemia caused by asphyxia or **carbon monoxide poisoning** vary from irritability to depression. CO poisoning may be **mild** (<20% HbCO), with slight dyspnea, headache, nausea, and decreased visual acuity and higher cerebral functions; **moderate** (20–40% HbCO), with irritability, agitation, nausea, dimness of vision, impaired judgment, and rapid fatigue; or **severe** (40–60% HbCO), producing confusion, hallucination, ataxia, collapse, acidosis, and coma. Measurement of HbCO is important for diagnosis and treatment. The PaO₂ value may be normal and the HbCO saturation values misleading because HbCO is not detected by the usual tests of oxygen saturation. CO poisoning is assumed until the tests are performed, and it is treated with 100% oxygen. Significant CO poisoning requires hyperbaric oxygen therapy (see Chapter 77). **Cyanide poisoning** should be suspected if a metabolic acidosis persists despite adequate fluid resuscitation, and in environments containing synthetic polymers. Unless specifically suspected, most burn centers do not routinely screen for cyanide poisoning.

Patients with severe inhalation injury or with other causes of respiratory deterioration that lead to ARDS who do not improve with conventional pressure-controlled ventilation (progressive oxygenation failure, as manifested by oxygen saturation <90% while receiving FiO₂ of 0.9-1.0 and positive end-expiratory pressure of at least 12.5 cm H₂O) may benefit from high-frequency ventilation or nitric oxide inhalation treatment. Nitric oxide usually is administered through the ventilator at 5 parts per million (ppm) and increased to 30 ppm. This method of therapy reduces the need for extracorporeal membrane oxygenation (see
Pain Relief and Psychologic Adjustment

See Chapter 76.

It is important to provide adequate analgesia, anxiolytics, and psychologic support to reduce early metabolic stress, decrease the potential for posttraumatic stress disorder (PTSD), and allow future stabilization as well as physical and psychologic rehabilitation. Patients and family members require team support to work through the grieving process and accept long-term changes in appearance.

Children with burn injury show frequent and wide fluctuations in pain intensity. Appreciation of pain depends on the depth of the burn; the stage of healing; the patient's age, stage of emotional development, and cognition; the experience and efficiency of the treating team; the use of analgesics and other drugs; the patient's pain threshold; and interpersonal and cultural factors. From the onset of treatment, preemptive pain control during dressing changes is crucial. The use of a variety of nonpharmacologic interventions as well as pharmacologic agents must be reviewed throughout the treatment period. Opiate analgesia, prescribed in an adequate dose and timed to cover dressing changes, is essential to comfort management. A supportive person who is consistently present and knows the patient profile can integrate and encourage patient participation in burn care. The problem of undermedication is most prevalent in adolescents, in whom fear of drug dependence may inappropriately influence treatment. A related problem is that the child's specific pain experience may be misinterpreted; for anxious patients, those who are confused and alone, or those with preexisting emotional disorders, even small wounds may illicit intense pain. Anxiolytic medication added to the analgesic is usually helpful and has more than a synergistic effect. Equal attention is necessary to decrease stress in the intubated patient. Other modalities of pain and anxiety relief (relaxation techniques) can decrease the physiologic stress response.

Oral morphine sulfate (immediate release) is recommended at a consistent schedule at a dose of 0.3-0.6 mg/kg every 4-6 hr initially and until wound cover is accomplished. Morphine sulfate IV bolus is administered at a dose of 0.05-0.1 mg/kg (maximum, 2-5 mg) every 2 hr. Morphine sulfate rectal suppositories may be useful at a dose of 0.3-0.6 mg/kg every 4 hr when oral administration is not possible. The use of codeine preparation should be limited to children >6 yr old because of the ultrarapid metabolizers of codeine into morphine. For anxiety,
**lorazepam** is given on a consistent schedule, 0.05-0.1 mg/kg/dose every 6-8 hr. To control pain during a procedure (dressing change or debridement), oral morphine, (0.3-0.6 mg/kg) is given 1-2 hr before the procedure, supplemented by a morphine IV bolus (0.05-0.1 mg/kg) given immediately before the procedure. Lorazepam, 0.04 mg/kg, is given orally or intravenously, if necessary, for anxiety before the procedure. **Midazolam** is also very useful for conscious sedation at a dose of 0.01-0.02 mg/kg for nonintubated patients and 0.05-0.1 mg/kg for intubated patients, as an IV infusion or bolus, and may be repeated in 10 min. During the process of weaning from analgesics, the dose of oral opiates is reduced by 25% over 1-3 days, sometimes with the addition of acetaminophen as opiates are tapered. When weaning off antianxiety medications, the approach involves reducing the dose of benzodiazepines, at 25–50% per dose, daily over 1-3 days. **Risperidone**, up to 2.5 mg/day, is being used in children with severe burns.

For ventilated patients, pain control is accomplished by using morphine sulfate intermittently as an IV bolus at 0.05-0.1 mg/kg every 2 hr. Doses may need to be increased gradually, and some children may need continuous infusion; a starting dose of 0.05 mg/kg/hr as an infusion is increased gradually as the need of the child changes. Naloxone is rarely needed but should be immediately available to reverse the effect of morphine, if necessary; if needed for an airway crisis, it should be given in a dose of 0.1 mg/kg up to a total of 2 mg, either intramuscularly or intravenously. For patients undergoing assisted respiration who require treatment of anxiety, midazolam is used as an intermittent IV bolus (0.04 mg/kg by slow push every 4-6 hr) or as a continuous infusion. For intubated patients, opiates do not need to be discontinued during the process of weaning from the ventilator. Benzodiazepine should be reduced to approximately half the dose over 24-72 hr before extubation; too-rapid weaning from a benzodiazepine can lead to seizures.

There is a growing use of **psychotropic medication** in the care of children with burns, including prescription of selective serotonin reuptake inhibitors as antidepressants, the use of haloperidol as a neuroleptic in the critical care setting, and the treatment of PTSD with benzodiazepines. Conscious sedation using ketamine or propofol may be used for major dressing changes.

**Reconstruction and Rehabilitation**

To ensure maximum cosmetic and functional outcome, occupational and
physical therapy must begin on the day of admission, continue throughout hospitalization, and for some patients, continue after discharge. Physical rehabilitation involves body and limb positioning, splinting, exercises (active and passive movement), assistance with activities of daily living, and gradual ambulation. These measures maintain adequate joint and muscle activity with as normal a range of movement as possible after healing or reconstruction. **Pressure therapy** is necessary to reduce hypertrophic scar formation; a variety of prefabricated and custom-made garments are available for use in different body areas. These custom-made garments deliver consistent pressure on scarred areas, shorten the time of scar maturation, and decrease scar thickness, redness, and associated itching. Continued adjustments to scarred areas (scar release, grafting, rearrangement) and multiple minor cosmetic surgical procedures are necessary to optimize long-term function and improve appearance. Replacement of areas of alopecia and scarring has been achieved with the use of tissue-expander techniques. The use of ultrapulse laser for reduction of scarring is an adjunct in scar management.

**School Reentry and Long-Term Outcome**

It is best for the child to return to school immediately after discharge. Occasionally, a child may need to attend a few half-days (because of rehabilitation needs). It is important for the child to return to the normal routine of attending school and being with peers. Planning for a return to home and school often requires a **school reentry program** that is individualized to each child's needs. For a school-age child, planning for the return to school occurs simultaneously with planning for discharge. The hospital schoolteacher contacts the local school and plans the program with the school faculty, nurses, social workers, recreational/child-life therapists, and rehabilitation therapists. This team should work with students and staff to ease anxiety, answer questions, and provide information. Burns and scars evoke fears in those who are not familiar with this type of injury and can result in a tendency to withdraw from or reject the burned child. A school reentry program should be appropriate to a child’s development and changing educational needs.

Major advances have made it possible to save the lives of children with massive burns. Although some children have had lingering physical difficulties, most have a satisfactory quality of life. The comprehensive burn care that includes experienced multidisciplinary aftercare plays an important role in
recovery. Table 92.8 lists the long-term disabilities and complications of burns.

**Table 92.8**

**Common Long-Term Complications and Disabilities in Patients With Burn Injuries**

**Complications Affecting the Skin and Soft Tissue**

- Hypertrophic scars
- Susceptibility to minor trauma
- Dry skin
- Contractures
- Itching and neuropathic pain
- Alopecia
- Chronic open wounds
- Skin cancers

**Orthopedic Disabilities**

- Amputations
- Contractures
- Heterotopic ossification
- Temporary reduction in bone density

**Metabolic Disabilities**

- Heat sensitivity
- Obesity

**Psychiatric and Neurologic Disabilities**

- Sleep disorders
- Adjustment disorders
- Posttraumatic stress disorder
- Depression
Body image issues
Neuropathy and neuropathic pain
Long-term neurologic effects of carbon monoxide poisoning
Anoxic brain injury

**Long-Term Complications of Critical Care**

Deep vein thrombosis, venous insufficiency, or varicose veins
Tracheal stenosis, vocal cord disorders, or swallowing disorders
Renal or adrenal dysfunction
Hepatobiliary or pancreatic disease
Cardiovascular disease
Reactive airway disease or bronchial polyposis

**Preexisting Disabilities That Contributed to the Injuries**

Risk-taking behavior
Untreated or poorly treated psychiatric disorder

**Electrical Burns**

There are 3 types of electrical burns: extension cord (minor), high-tension wire, and lightning. **Minor electrical burns** usually occur as a result of biting on an extension cord. These injuries produce localized burns to the mouth, which usually involve the portions of the upper and lower lips that come in contact with the extension cord. The injury may involve or spare the corners of the mouth. Because these are nonconductive injuries (do not extend beyond the site of injury), hospital admission is not necessary, and care is focused on the area of the injury visible in the mouth, ensuring it is low voltage and does not cause entry or exit wounds or cardiac issues. Treatment with topical antibiotic creams
is sufficient until the patient is seen in a burn unit outpatient department or by a plastic surgeon.

A more serious category of electrical burn is the **high-tension electrical wire burn**, for which children must be admitted for observation, regardless of the extent of the surface area burn. Deep muscle injury is typical and cannot be readily assessed initially. These injuries result from high voltage (>1,000 V) and occur particularly at high-voltage installations, such as electric power stations or railroads; children climb an electric pole and touch an electric box out of curiosity or accidentally touch a high-tension electrical wire. Such injuries have a mortality rate of 3–15% for children who arrive at the hospital for treatment. Survivors have a high rate of morbidity, including major limb amputations.

Points of entry of current through the skin and the exit site show characteristic features consistent with current density and heat. The majority of entrance wounds involve the upper extremity, with small exit wounds in the lower extremity. The electrical path, from entrance to exit, takes the shortest distance between the 2 points and may produce injury in any organ or tissue in the path of the current. Multiple exit wounds in some patients attest to the possibility of several electrical pathways in the body, placing virtually any structure in the body at risk (Table 92.9). Damage to the abdominal viscera, thoracic structures, and the nervous system (confusion, coma, paralysis) in areas remote from obvious extremity injury occurs and must be sought, particularly in injuries with multiple current pathways or those in which the victim falls from a high pole.

Sometimes an **ignition** occurs and results in concurrent flame burn and clothing fire. **Cardiac abnormalities**, manifested as ventricular fibrillation or cardiac arrest, are common; patients with high-tension electrical injury need an initial electrocardiogram and cardiac monitoring until they are stable and have been fully assessed. Higher-risk patients have abnormal electrocardiographic findings and a history of loss of consciousness. Renal damage from **deep muscle necrosis** and subsequent myoglobinuria is another complication; such patients need forced alkaline diuresis to minimize renal damage. Soft tissue (muscle) injury of an extremity may produce a **compartment syndrome**. Aggressive removal of all dead and devitalized tissue, even with the risk of functional loss, remains the key to effective management of the electrically damaged extremity. Early debridement facilitates early closure of the wound. Damaged major vessels must be isolated and buried in a viable muscle to prevent exposure. Survival depends on immediate intensive care; functional result depends on long-term care and delayed reconstructive surgery.

**Lightning burns** occur when a high-voltage current directly strikes a person (most dangerous) or when the current strikes the ground or an adjacent (in-contact) object. A *step voltage burn* is observed when lightning strikes the ground and travels up one leg and down the other (the path of least resistance). Lightning burns depend on the current path, the type of clothing worn, the presence of metal, and cutaneous moisture. Entry, exit, and path lesions are possible; the prognosis is poorest for lesions of the head or legs. Internal organ injury along the path is common and does not relate to the severity of the cutaneous burn. Linear burns, usually 1st or 2nd degree, are in the locations where sweat is present. *Feathering*, or an arborescent pattern, is characteristic of lightning injury. Lightning may ignite clothing or produce serious cutaneous burns from heated metal in the clothing. Internal complications of lightning burns include cardiac arrest caused by asystole, transient hypertension, AST, Aspartate transaminase; ALT, alanine transaminase; BUN, blood urea nitrogen.

premature ventricular contractions, ventricular fibrillation, and myocardial ischemia. Most severe cardiac complications resolve if the patient is supported with CPR (see Chapter 81). CNS complications include cerebral edema, hemorrhage, seizures, mood changes, depression, and paralysis of the lower extremities. Rhabdomyolysis and myoglobinuria (with possible renal failure) also occur. Ocular manifestations include vitreous hemorrhage, iridocyclitis, retinal tearing, or retinal detachment.

The involvement of children and youth in snowmobiling, mountain climbing, winter hiking, and skiing places them at risk for cold injury. Cold injury may produce either local tissue damage, with the injury pattern depending on exposure to damp cold (frostnip, immersion foot, or trench foot), dry cold (which leads to local frostbite), or generalized systemic effects (hypothermia).

**Pathophysiology**

Ice crystals may form between or within cells, interfering with the sodium pump, and may lead to rupture of cell membranes. Further damage may result from clumping of red blood cells or platelets, causing microembolism or thrombosis. Blood may be shunted away from an affected area by secondary neurovascular responses to the cold injury; this shunting often further damages an injured part while improving perfusion of other tissues. The spectrum of injury ranges from mild to severe and reflects the result of structural and functional disturbance in small blood vessels, nerves, and skin.

**Etiology**

Body heat may be lost by conduction from wet clothing or contact with metal or other solid conducting objects, convection from wind chill, evaporation, or radiation. Susceptibility to cold injury may be increased by dehydration, alcohol or drug use, impaired consciousness, exhaustion, hunger, anemia, impaired circulation from cardiovascular disease, and sepsis; very young or older persons also are more susceptible. Certain medications may contribute to
hypothermia, whereas others may cause reduced metabolism or clearance during hypothermia (Table 93.1).

**Hypothermia** occurs when the body can no longer sustain normal core temperature by physiologic mechanisms, such as vasoconstriction, shivering, muscle contraction, and nonshivering thermogenesis. When shivering ceases, the body is unable to maintain its core temperature; when the body core temperature falls to <35°C (95°F), the syndrome of hypothermia occurs. Wind chill, wet or inadequate clothing, and other factors increase local injury and may cause dangerous hypothermia, even in the presence of an ambient temperature that is not <17-20°C (50-60°F).

**Clinical Manifestations**

**Frostnip**

Frostnip results in the presence of firm, cold, white areas on the face, ears, or
extremities. Blistering and peeling may occur over the next 24-72 hr, occasionally leaving mildly increased hypersensitivity to cold for days or weeks. Treatment consists of warming the area with an unaffected hand or a warm object before the lesion reaches a stage of stinging or aching and before numbness supervenes. Rewarming in a water bath (40-42.2°C [104-108°F]) is effective.

**Immersion Foot (Trench Foot)**

Immersion foot occurs in cold weather when the feet remain in damp or wet, poorly ventilated boots. The feet become cold, numb, pale, edematous, and clammy. Tissue maceration and infection are likely, and prolonged autonomic disturbance is common. This autonomic disturbance leads to increased sweating, pain, and hypersensitivity to temperature changes, which may persist for years. Treatment includes drying the foot, gentle rewarming and nonsteroidal antiinflammatory drugs (NSAIDs) for pain. Prevention consists of using well-fitting, insulated, waterproof, nonconstricting footwear. Once damage has occurred, patients must choose clothing and footwear that are more appropriate, dry, and well fitting. The disturbance in skin integrity is managed by keeping the affected area dry and well ventilated and by preventing or treating infection. Only supportive measures are possible for control of autonomic symptoms.

**Frostbite**

With frostbite, initial stinging or aching of the skin progresses to cold, hard, white anesthetic and numb areas. Clear or hemorrhagic vesicles may develop over the exposed areas. On rewarming, the area becomes blotchy, itchy, and often red, swollen, and painful. The injury spectrum ranges from complete normality to extensive tissue damage, even gangrene, if early relief is not obtained.

Treatment consists of warming the damaged area. It is important not to cause further damage by attempting to rub the area with ice or snow. The area may be warmed against an unaffected hand, the abdomen, or an axilla during transfer of the patient to a facility where more rapid warming with a warm (and not hot) water bath is possible. If the skin becomes painful and swelling occurs, NSAIDs are helpful, and an analgesic agent is necessary. Freeze and rethawing cycles are most likely to cause permanent tissue injury, and it may be necessary to delay
definitive warming and apply only mild measures if the patient is required to walk on the damaged feet en route to definitive treatment. In the hospital the affected area should be immersed in warm water (approximately 42°C [107.6°F]), with care taken not to burn the anesthetized skin. Broken vesicles may be debrided, but intact vesicles should be left alone. Vasodilating agents, such as prazosin and phenoxybenzamine, may be helpful. Use of anticoagulants (e.g., heparin, dextran) has had equivocal results; results of chemical and surgical sympathectomy have also been equivocal. Oxygen is of help only at high altitudes. Meticulous local care, prevention of infection, and keeping the rewarmed area dry, open, and sterile provide optimal results.

Recovery can be complete, and prolonged observation with conservative therapy is justified before any excision or amputation of tissue is considered. Analgesia and maintenance of good nutrition are necessary throughout the prolonged waiting period.

**Hypothermia**

Hypothermia may occur in winter sports when injury, equipment failure, or exhaustion decreases the level of exertion, particularly if sufficient attention is not paid to wind chill. Immersion in frozen bodies of water and wet wind chill rapidly produce hypothermia. As the core temperature of the body falls, insidious onset of extreme lethargy, fatigue, incoordination, and apathy occurs, followed by mental confusion, clumsiness, irritability, hallucinations, and finally, bradycardia. A number of medical conditions, such as cardiac disease, diabetes mellitus, hypoglycemia, sepsis, β-blocking agent overdose, and substance abuse, may need to be considered in a differential diagnosis. The decrease in rectal temperature to <34°C (93°F) is the most helpful diagnostic feature. Hypothermia associated with drowning is discussed in Chapter 91.

Prevention is a high priority. Of extreme importance for those who participate in winter sports is wearing layers of warm clothing, gloves, socks within insulated boots that do not impede circulation, and a warm head covering, as well as application of adequate waterproofing and protection against the wind. Thirty percent of heat loss for infants occurs from the head. Ample food and fluid must be provided during exercise. Those who participate in sports should be alert to the presence of cold or numbing of body parts, particularly the nose, ears, and extremities, and they should review methods to produce local warming and know to seek shelter if they detect symptoms of local cold injury.
Application of petrolatum (Vaseline) to the nose and ears helps protect against frostbite.

Treatment at the scene aims at prevention of further heat loss and early transport to adequate shelter (Table 93.2). Dry clothing should be provided as soon as practical, and transport should be undertaken if the victim has a pulse. If no pulse is detected at the initial review, cardiopulmonary resuscitation is indicated (Fig. 93.1) (see Chapter 81). During transfer, jarring and sudden motion should be avoided because of the risk of ventricular arrhythmia. It is often difficult to attain a normal sinus rhythm during hypothermia.

| Table 93.2 |

**Management of Hypothermia**

**History and Physical Examination**

Gentle handling of the patient to prevent arrhythmias  
ABCDE: cardiopulmonary resuscitation for ventricular fibrillation and asystole  
Underlying disease diagnosis and treatment  
Vital signs, pulse oximetry, electrocardiogram  
Wet or cold clothing removed and patient placed in warm environment

**Laboratory Tests**

Arterial blood gas analysis corrected for temperature  
Electrolytes, BUN, creatinine, Ca, Mg, P  
CBC with differential, PT/PTT, fibrinogen  
Glucose, amylase/lipase  
Liver function tests  
Additional lab tests, if appropriate, such as toxicology screen

**Passive Rewarming**

≥32°C (89.6°F) in patients who are capable of spontaneous thermogenesis

**Active Rewarming**
<32°C (89.6°F), cardiovascular instability, patients at risk for developing hypothermia
Close monitoring for core-temperature afterdrop
Acute: external and/or core rewarming
Chronic (<32°C [89.6°F] for >24 hr): core rewarming
Extracorporeal membrane oxygenation
Availability of rapid deployment

ABCDE, A irway and possibly a ntibiotics, b reathing, c irculation, d isability or neurologic and possible d extrose, e xtracorporeal support if all else fails; BUN, blood urea nitrogen; Ca, calcium; CBC, complete blood count; Mg, magnesium; P, phosphorus; PT, prothrombin time; PTT, partial thromboplastin time.

FIG. 93.1 Recommendations for out-of-hospital evaluation and treatment of accidental hypothermia. AED, Automatic external defibrillator; CPR, cardiopulmonary resuscitation; ECC, extracorporeal circulation; ECG, electrocardiogram; ETCO₂, end-tidal carbon dioxide; HPMK, Hypothermia Prevention Management Kit; ICU, intensive care unit.
If the patient is conscious, mild muscle activity should be encouraged and a warm drink offered. If the patient is unconscious, external warming should be undertaken initially with use of blankets and a sleeping bag; wrapping the patient in blankets or sleeping bag with a warm companion may increase the efficiency of warming. On arrival at a treatment center, while a warming bath of 45-48°C (113-118°F) water is prepared, the patient should be warmed through inhalation of warm, moist air or oxygen or with heating pads or thermal blankets. Monitoring of serum chemistry values and an electrocardiogram are necessary until the core temperature rises to >35°C (95°F) and can be stabilized. Control of fluid balance, pH, blood pressure, and arterial partial pressure of oxygen (Pao₂) is necessary in the early phases of the warming period and resuscitation. In severe hypothermia, there may be a combined respiratory and metabolic acidosis. Hypothermia may falsely elevate pH; nonetheless, most authorities recommend warming the arterial blood gas specimen to 37°C (98.6°F) before analysis and regarding the result as one from a normothermic patient. In patients with marked abnormalities, warming measures, such as gastric or colonic irrigation with warm saline or peritoneal dialysis, may be considered, but the effectiveness of these measures in treating hypothermia is unknown. In accidental deep hypothermia (core temperature 28°C [82.4°F]) with circulatory arrest, rewarming with cardiopulmonary bypass may be lifesaving for previously healthy young individuals. If rewarming is not successful despite appropriate measures, one should suspect infection, drug overdose, endocrine disorders, or a futile resuscitation.

**Chilblain (Pernio)**

Chilblain (pernio) is a form of cold injury in which erythematous, vesicular, or ulcerative lesions occur. The lesions are presumed to be of vascular or vasoconstrictive origin. They are often itchy, may be painful, and result in swelling and scabbing. The lesions are most often found on the ears, the tips of the fingers and toes, and exposed areas of the legs. The lesions last for 1-2 wk but may persist for longer. Treatment consists of prophylaxis: avoiding prolonged chilling and protecting potentially susceptible areas with a cap,
gloves, and stockings. Prazosin and phenoxybenzamine may be helpful in improving circulation if this is a recurrent problem. For significant itching, local corticosteroid preparations may be helpful.

**Familial chilblain lupus**, an autosomal dominant variant of lupus, is caused by mutations in the *TREX1*, *SAMHD1*, and *STING* genes. Patients develop cold-induced erythematous peripheral skin lesions and also manifest systemic disease typical of lupus (Chapter 183). In addition, fever and arthralgias may be present. Those with the *STING* mutation may develop a necrotizing acral vasculitis.

**Cold-Induced Fat Necrosis (Panniculitis)**

A common, usually benign injury, cold-induced fat necrosis occurs on exposure to cold air, snow, or ice and manifests in exposed (or less often covered) surfaces as red (or less often purple to blue) macular, papular, or nodular lesions. Treatment is with NSAIDs. The lesions may last 10 days to 3 wk but may persist for longer. Severe coagulopathy may be associated with poor outcome in some severe cold injuries, thus meriting anticoagulation therapy (see Chapter 680.1).

Integration of Genetics Into Pediatric Practice

Brendan Lee

Genetic testing involves analyzing genetic material to obtain information related to a person's health status using chromosomal (cytogenetic) analysis (see Chapter 98) or DNA-based testing.

Diagnostic Testing

Diagnostic genetic testing helps explain a set of signs and symptoms of a disease. The list of disorders for which specific genetic tests are available is extensive. The website http://www.ncbi.nlm.nih.gov/gtr/ provides a database of available tests that is provider driven, so claims are not validated by the site's host, the National Institutes of Health (NIH).

Single-gene disorders can be tested by at least 3 different approaches: linkage analysis (though this is now rarely used), array comparative genomic hybridization (aCGH), and direct mutation analysis, usually by DNA sequencing (Table 94.1). Linkage analysis is used if the responsible gene is mapped but not yet identified, or if it is impractical to find specific mutations, usually because of the large size and larger number of different mutations in some genes. Array CGH can be used to detect large, multigene deletions or duplications (copy number variations). In addition, with increasing resolution, single-gene or smaller intragenic deletions or duplications can be detected by aCGH, although it is important to note that coverage of each gene may vary from different providers. Direct DNA mutation analysis is preferred and is possible with the availability of the complete human genome sequence. An emerging feature is the increasing recognition of oligogenic disease where more
than one disease gene contributes to a complex, or “blended,” phenotype. The ability to sequence hundreds to thousands of genes at once has provided insight into this added layer of complexity in disease pathogenesis.

### Table 94.1

Approaches for Genetic Testing

<table>
<thead>
<tr>
<th>TYPE OF MUTATION TESTING</th>
<th>RESOLUTION</th>
<th>ADVANTAGES</th>
<th>DISADVANTAGES</th>
<th>SAMPLE REQUIREMENTS</th>
</tr>
</thead>
<tbody>
<tr>
<td>Linkage analysis</td>
<td>Depends on location of polymorphic markers near putative disease gene</td>
<td>Possible when specific disease-causing genetic mutation is not identifiable or found</td>
<td>Can give only diagnostic probability based on likelihood of genetic recombination between presumed DNA mutation and polymorphic markers</td>
<td>Requires multiple family members with documented mendelian pattern of inheritance within family</td>
</tr>
<tr>
<td>Array comparative genomic hybridization (aCGH)</td>
<td>Several hundred base pairs to several hundreds of kilobases</td>
<td>Able to detect small deletion or duplications within 1 or more genes</td>
<td>Can miss small deletions or insertions depending on resolution of the array used</td>
<td>Single patient sample sufficient, but having sample from biological parents can help with interpretation</td>
</tr>
<tr>
<td>Direct DNA-based testing (e.g., DNA sequencing)</td>
<td>Single–base-pair changes</td>
<td>High specificity if previously described deleterious mutation is found</td>
<td>Can miss deletion or duplication of a segment of gene</td>
<td>Single patient sample sufficient, but having sample from biological parents can help with interpretation</td>
</tr>

**Linkage testing** involves tracking a genetic trait through a family using closely linked polymorphic markers as a surrogate for the trait (Fig. 94.1). It requires testing an extended family and is vulnerable to several pitfalls, such as genetic recombination, genetic heterogeneity, and incorrect diagnosis in the proband. **Genetic recombination** occurs between any pair of loci, the frequency being proportional to the distance between them. This problem can be ameliorated by using very closely linked markers and, if possible, using markers that flank the specific gene. **Genetic heterogeneity** can be problematic for a linkage-based test if there are multiple distinct genomic loci that can cause the same phenotype, resulting in the risk that the locus tested for is not the one responsible for disease in the family. **Incorrect diagnosis** in the proband also leads to tracking the wrong gene. Linkage testing remains useful for several genetic conditions, but it is increasingly being superseded by the availability of direct DNA sequencing of either single genes or of the whole collection of genes that encode all proteins. It is critically important that genetic counseling be provided to the family to explain the complexities of interpretation of test
Use of linkage analysis in prenatal diagnosis of an autosomal recessive disorder. Both parents are carriers, and they have 1 affected son. The numbers below the symbols indicate alleles at 3 polymorphic loci: A, B, and C. Locus B resides within the disease gene. The affected son inherited the 1-2-2 chromosome from his father and the 2-1-2 chromosome from his mother. The fetus has inherited the same chromosome from the father, but the 3-2-4 chromosome from the mother and therefore is most likely to be a carrier.

**Array comparative genomic hybridization** can detect copy number variation in a patient's DNA by comparing it to a standard control DNA (see Chapter 98). In so doing, aCGH provides a level of genetic resolution between that available with DNA sequencing and that available with chromosome analysis. Whereas earlier technologies could only identify large deletions or duplications that might encompass multiple genes, aCGH can resolve deletions or duplications of several kilobases within 1 gene. In theory, this approach can detect deletion and duplication mutations that would be missed by either chromosome analysis or direct mutation testing by DNA sequencing. However, because the specific resolution and coverage of different aCGH platforms can vary tremendously for different gene regions, the sensitivity for detecting deletions and duplications can vary for different diseases and laboratories. The highest resolution is what would be detection of on average deletion or duplication at the single exon level.

**Direct DNA-based mutation testing** avoids the pitfalls of linkage testing by detecting the specific gene mutation (i.e., sequence change). The specific approach used is customized to the biology of the gene being tested. In some
disorders, 1 or a few distinct mutations occur in all affected individuals. This is the case in sickle cell anemia, in which the same single-base substitution occurs in everyone with the disorder. In other conditions, many possible mutations may account for the disorder in different individuals. In cystic fibrosis, for example, >1,000 distinct mutations have been found in the CFTR gene. Mutation analysis is challenging because no single technique can detect all possible mutations. However, with the completion of the human genome sequence and high-throughput DNA sequencing technology, the approach of choice is to directly sequence DNA that is generated by polymerase chain reaction (PCR) amplification of DNA isolated from peripheral blood white blood cells. The limitation of this approach is that only DNA that is amplified is sequenced, and usually this is restricted to the coding or exonic regions of a gene. Because mutations sometimes occur in the noncoding intronic regions, failure to detect a mutation does not exclude the diagnosis. Whole genome sequencing should identify mutations in the noncoding regions. In addition, genes in a deleted region will not be detected. Although DNA sequencing can be highly specific, it is not completely sensitive because of practical limitations of what is commercially available. Gene sequencing techniques may not be able to identify diseases caused by triplet repeat sequences; specific tests are needed.

The most useful development in clinical DNA diagnosis is application of next-generation sequencing technology to testing panels of genes that target disease symptoms (e.g., seizures, ataxia syndromes) or the whole exome (whole exome sequencing [WES]). Soon, whole genome sequencing (WGS), where both coding and noncoding sequences are identified, will provide even more information, although initial clinical interpretation will still be limited to the coding sequences of the approximately 20,000 human genes, the so-called digital exome, as it is extracted electronically from the whole genome data. The challenge is not so much the generation of DNA sequence, but the interpretation of enormous genetic variation within a single sample. Direct sequencing of tens to hundreds of genes in next-generation sequencing panels offer a potentially higher sensitivity because the “depth” of read is higher without complicating high discovery rate of variants of unknown sequences (VUS). WES and WGS also offer the potential for identifying new disease-gene associations as well as phenotypes caused by more than one disease gene (i.e., oligogenic phenotypes).

An important ethical consideration is the reporting of incidental findings, whether medically actionable or not medically actionable in a patient. WES and WGS may identify mutations that cause aminoglycoside-sensitive hearing loss,
which would be medically actionable. At the same time, the discovery of apolipoprotein E variants in a child that increase Alzheimer disease risk susceptibility may not be medically actionable. Therefore, counseling for patients undergoing these tests is important so that only wanted results are reported back to the patient. Guidelines are currently evolving for reporting of incidental findings for WES by the American College of Medical Genetics (www.acmg.net). Practice varies among institutions and recommendations vary among international genetic organizations about the approach for revealing incidental findings from WES/WGS to patients; many leave the choice up to the patient and family. Most require revealing to the patient and/or family significant diseases (actionable) with a specific and successful treatment or prevention strategy (Table 94.2).

* “Medically actionable” refers to a variant in a gene in which knowledge of the particular variant will affect medical decision-making, such as initiation of a treatment or family planning.

† “Not medically actionable” refers to variants that increase the individual's risk for a disease in which no treatment is proven to significantly change medical decision-making.

Genetic testing is interpreted by 3 factors: analytic validity, clinical validity, and clinical utility. **Analytical validity** is test accuracy: Does the test correctly detect the presence or absence of mutation? Most genetic tests have a very high analytical validity, assuming that human error, such as sample mix-up, has not occurred. Human errors are possible, and unlike most medical tests, a genetic test is unlikely to be repeated, because it is assumed that the result will not change over time. Therefore, human errors can go undetected for long periods of time. However, it may be reinterpreted over time as our knowledge base of what are disease-causing mutations and genes increases over time. **Clinical validity** is the degree to which the test correctly predicts presence or absence of disease. False-positive and false-negative test results can occur.
False-positive results are more likely for predictive tests than for diagnostic tests. An important contributing factor is nonpenetrance: an individual with an at-risk genotype might not clinically express the condition. Another factor is the finding of a genetic variant of unknown significance (VUS). Detection of a base sequence variation in an affected patient does not prove that it is the cause of the patient's disorder. In WES there may be more than 30,000 VUS; in WGS there may be more than 3,000,000 VUS. Various lines of evidence are used to establish pathogenicity. These include finding the variant only in affected individuals, inferring that the variant alters the function of the gene product, determining whether the amino acid altered by the mutation is conserved in evolution, and determining whether the mutation segregates with disease in the family. In some cases, it is possible to be certain whether the variant is pathogenic or incidental, but in other cases it might be impossible to definitively assign causality with 100% confidence.

False-negative results reflect an inability to detect a mutation in an affected patient. This occurs principally in disorders where genetic heterogeneity—allelic (different mutations occur in 1 causative gene) or locus (>1 gene can cause a disease) heterogeneity—is the rule. It is difficult to detect all possible mutations within a gene, because mutations can be varied in location within the gene and in the type of mutation. Direct sequencing may miss gene deletions or rearrangements (i.e. structural variants), and mutations may be found within noncoding sequences such as introns or the promoter; a negative DNA test does not necessarily exclude a diagnosis.

Clinical utility is the degree to which the results of a test guide clinical management. For genetic testing, clinical utility includes establishing a diagnosis that obviates the need for additional workup or guiding surveillance or treatment. Test results may also be used as a basis for genetic counseling. For some disorders, genetic testing is possible, but the test results do not add to the clinical assessment. If the diagnosis and genetic implications are already clear, it might not be necessary to pursue genetic testing.

**Predictive Testing**

Predictive genetic testing involves performing a test in a person who is at risk for developing a genetic disorder (presymptomatic), usually on the basis of family history, yet who does not manifest signs or symptoms. This is usually done for disorders that display age-dependent penetrance; the likelihood of manifesting
signs and symptoms increases with age, as in cancer or Huntington disease.

A major caution with predictive testing is that the presence of a gene mutation does not necessarily mean that the disease will develop. Many of the disorders with age-dependent penetrance display incomplete penetrance. A person who inherits a mutation might never develop signs of the disorder. There is concern that a positive DNA test could result in stigmatization of the person and might not provide information that will guide medical management. Stigmatization might include psychological stress, but it could also include discrimination, including denial of health, life, or disability insurance, or employment (see Chapter 95).

It is generally agreed that predictive genetic tests should be performed for children only if the results of the test will benefit the medical management of the child. Otherwise, the test should be deferred until the child has an understanding of the risks and benefits of testing and can provide informed consent. Individual states offer varying degrees of protection from discrimination on the basis of genetic testing. A major milestone in the prevention of genetic discrimination was the passage of the Genetic Information Nondiscrimination Act (GINA) in 2008, which is a U.S. federal law that prohibits discrimination in health coverage or employment based on genetic information; it does not protect against refusal of life insurance.

**Predispositional Testing**

It is expected that genetic tests will become available that will predict risk of disease. Common disorders are multifactorial in etiology; many different genes may contribute to risk of any specific condition (see Chapter 99). Most of the genetic variants that have been found to correlate with risk of a common disease add small increments of relative risk, probably in most cases too little to guide management. It is possible that further discovery of genes that contribute to common disorders will reveal examples of variants that convey more significant levels of risk. It is also possible that testing several genes together will provide more information about risk than any individual gene variant would confer.

The rationale for predispositional testing is that the results would lead to strategies aimed at risk reduction as part of a *personalized approach* to healthcare maintenance. This might include avoidance of environmental exposures that would increase risk of disease (cigarette smoking and $\alpha_1$-
Pharmacogenetic Testing

Polymorphisms in drug metabolism genes can result in distinctive patterns of drug absorption, metabolism, excretion, or effectiveness (see Chapters 72 and 99). Knowledge of individual genotypes will guide pharmacologic therapy, allowing customization of choice of drug and dosage to avoid toxicity and provide a therapeutic response. An example is testing for polymorphisms within the methylenetetrahydrofolate reductase (MTHFR) gene for susceptibility of potentially increased toxicity to methotrexate antimetabolite therapy for acute lymphoblastic leukemia.

94.1 Genetic Counseling

Brendan Lee, Pilar L. Magoulas

Genetic counseling is a communication process in which the genetic contribution to health, specific risks of transmission of a trait, and options to manage the condition are explained to individuals and their family members (Table 94.3). Genetic counselors are specialized healthcare providers trained in the psychosocial aspects of counseling and the science of medical genetics who may serve as members of medical teams in many different specialties. The genetic counselor is expected to present information in a neutral, nondirective manner while providing resources and psychosocial support to the individual and family to cope with decisions that are made.
## Indications for Genetic Counseling

- **Advanced parental age**
  - Maternal age ≥35 yr
  - Paternal age ≥40 yr

- **Previous child with or family history of:**
  - Congenital abnormality
  - Dysmorphology
  - Intellectual disability
  - Isolated birth defect
  - Metabolic disorder
  - Chromosome abnormality
  - Single-gene disorder

- **Adult-onset genetic disease (presymptomatic testing)**
  - Cancer
  - Huntington disease

- **Pharmacogenomics**

- **Consanguinity**

- **Teratogen exposure (occupational, abuse)**

- **Repeated pregnancy loss or infertility**

- **Pregnancy screening abnormality**
  - Maternal serum α-fetoprotein

- **Maternal 1st-trimester screen**
  - Maternal triple or quad screen or variant of this test
  - Fetal ultrasonography

- **Noninvasive prenatal testing (NIPT)**
  - Fetal karyotype

- **Heterozygote screening based on ethnic risk**
  - Sickle cell anemia
  - Tay-Sachs, Canavan, and Gaucher diseases
  - Thalassemias

- **Universal carrier screening panels**

- **Follow-up to abnormal neonatal genetic testing**

- **Prior to whole genome or exome sequencing**

- **Prior to preimplantation genetic testing**
 Genetic counseling has evolved from a model of care that was developed in the context of prenatal diagnosis and pediatrics into a multidisciplinary approach to medicine that factors into all aspects of healthcare (Table 94.3). In the prenatal setting, a common indication for genetic counseling is to assess risk of occurrence or recurrence of having a child with a genetic condition and to discuss management or treatment options that might be available before, during, or after the pregnancy, such as preimplantation genetic diagnosis, prenatal diagnosis or fetal intervention, and perinatal management. In pediatrics and adult genetics practices, the goals of genetic counseling are to help establish a diagnosis in an individual, provide longitudinal care and psychosocial support to the family, and discuss the genetic basis and inheritance of the condition as it relates to immediate and distant family members.

The genetic counseling role has expanded, particularly with advances in understanding the genetics of adult-onset or common and rare disease therapeutics. In the former context, genetic counseling has a major role in risk assessment for cancer, especially breast, ovarian, or colon cancer, for which well-defined risk models and genetic tests are available to assess risk to an individual. In the latter, the genetic counselor may discuss developments in rare disease therapeutics and make appropriate referral for medical therapies.

**Talking to Families**

The type of information provided to a family depends on the urgency of the situation, the need to make decisions, and the need to collect additional information. There are 4 situations in which genetic counseling plays a particularly important role in this process.

The 1st situation is the **prenatal diagnosis** of a congenital anomaly or genetic disease. The need for information is urgent because a family must often make time-sensitive decisions about treatment and management options, such as fetal intervention or continuation of a pregnancy in the context of fetal anomalies. Risks to the mother must also be considered. The 2nd type of situation occurs when a child is born with a life-threatening **congenital anomaly** or suspected **genetic disease**. Decisions must be made immediately with regard to how much support should be provided for the child and whether certain types of therapy should be attempted. The 3rd situation arises when there are concerns about a **genetic condition** affecting one later in life. For example, this may occur in an adolescent or young adult with a family history of an adult-onset genetic
disorder (e.g., Huntington disease, hereditary breast/ovarian cancer), in an individual with a suspected yet undiagnosed genetic condition, or if a couple with a personal or family history of a genetic condition (or a carrier) is planning a family. In these situations it is often necessary to have several meetings with a family to discuss possible testing, screening, and management options. Urgency is not as much of an issue as being sure that they have as much information and as many options as are available. The 4th situation is genetic counseling before genome sequencing, where the family is given options of what they want reported back to them (actionable/nonactionable incidental findings vs a specific diagnosis).

Genetic Counseling
Providing accurate information to families requires the following:

◆ Taking a careful family history and constructing a pedigree that lists the patient's relatives (including miscarriages, abortions, stillbirths, deceased persons) with their sex, age, ethnicity, and state of health, up to and including third-degree relatives.
◆ Gathering information from hospital records about the affected individual and, in some cases, about other family members.
◆ Documenting prenatal, pregnancy, and delivery histories.
◆ Reviewing the latest available medical, laboratory, and genetic information concerning the disorder.
◆ Performing a careful physical examination of the affected individual (photographs, measurements) and of apparently unaffected individuals in the family
(this is usually performed by a physician rather than a genetic counselor).
◆ Establishing or confirming the diagnosis by the diagnostic tests available.
◆ Giving the family information about support groups and local and national resources.
◆ Providing new information to the family as it becomes available (a mechanism for updating needs to be established).

Counseling sessions must include the specific condition, knowledge of the diagnosis of the particular condition, natural history of the condition, genetic aspects of the condition and risk of recurrence, prenatal diagnosis and reproductive options, therapies and referrals, support groups, and nondirective counseling.

Specific Condition or Conditions
If a specific diagnosis is made and confirmed, this should be discussed with the family and information provided in writing. Often, however, the disorder fits into a spectrum (e.g., one of many types of arthrogryposis) or the diagnosis is clinical rather than laboratory based. In these situations the family needs to understand the limits of present knowledge, and that additional research will probably lead to better information in the future.

Knowledge of the Diagnosis of the Particular Condition
Although it is not always possible to make an exact diagnosis, having a diagnosis as accurate as possible is important. Estimates of recurrence risk for various family members depend on an accurate diagnosis, that considers the likelihood that a particular finding is isolated, associated with a syndrome, or nonsyndromic (e.g., isolated cleft lip and palate). When a specific diagnosis
cannot be made (as in many cases of multiple congenital anomalies), the various possibilities in the differential diagnosis should be discussed with the family and empirical information provided. If available, specific diagnostic tests should be discussed. Often, empirical recurrence risks can be given even without a specific laboratory-based diagnosis. At the same time, even negative laboratory testing can further modify this risk.

Natural History of the Condition

It is important to discuss the natural history of the specific genetic disorder in the family. Affected persons and their families have questions regarding the prognosis and potential management or therapy that can be answered only with knowledge of the natural history. If there are other possible diagnoses, their natural history may also be discussed. If the disorder is associated with a spectrum of clinical outcomes or complications, the range of possible outcomes and variability of the condition, as well as treatment and referral to the appropriate specialist, should be addressed.

Genetic Aspects of the Condition and Recurrence Risk

The genetic aspects and risk of recurrence are important because all family members should be informed of their reproductive choices. The genetic basis of the disorder can be explained with visual aids (e.g., diagrams of chromosomes and inheritance patterns). It is important to provide accurate occurrence and recurrence risks for various members of the family, including unaffected individuals. If a definite diagnosis cannot be made, it is necessary to use empirical recurrence risks. Genetic counseling gives patients the necessary information to understand the various options and to make their own informed decisions regarding pregnancy, adoption, artificial insemination, prenatal diagnosis, screening, carrier detection, or termination of pregnancy. It may be necessary to have more than one counseling session.

Prenatal Diagnosis and Prevention

Many different methods of prenatal diagnosis are available, depending on the specific genetic disorder (see Chapter 115 ). The use of ultrasonography allows
prenatal screening of anatomic abnormalities such as congenital heart defects. Amniocentesis and chorionic villus sampling are used to obtain fetal tissue for analysis of chromosomal abnormalities, biochemical disorders, and DNA studies. Maternal blood or serum sampling is used for some types of screening, including noninvasive prenatal screening by direct analysis of fetal DNA fragments found in maternal blood. This has gained widespread use for screening of conditions such as trisomy 21. In addition, this source of cell free fetal DNA has also been used clinically for DNA sequencing for dominant de novo conditions in the fetus that may occur with increased frequency with increasing paternal age. In the research arena, intact fetal cells can also be retrieved from maternal blood (though this is not yet readily available compared to free fetal DNA) for testing, and this may potentially offer higher resolution testing including whole exome or whole genome testing. Importantly, current tests of fetal DNA from maternal blood should be considered screening tests, and invasive testing like amniocentesis or chorionic villus sampling should be considered for confirmatory diagnostic testing.

**Therapies and Referral**

A number of genetic disorders require the care of multiple specialists. Many genetic conditions now have diagnosis and management guidelines to aid in the treatment and management of these complex patients. Prevention of known complications is a priority, so close follow-up with the necessary specialists involved in the child's care is essential to identify any potentially concerning issues early. The psychological adjustment of the family might also require specific intervention. Some challenges may involve when to discuss the diagnosis of a chronic disease with the patient, siblings, and other family members or friends. The decision to do so should always involve the parents and an assessment of the maturity and capacity of the child or adolescent.

Alternative medicines or nontraditional therapies are often brought to attention by parents after exhaustive internet searches. Such treatments should not necessarily be dismissed out of hand because the physician and genetic counselor should serve as an important resource for helping parents navigate the maze of nonstandard treatments. Instead, the relative merits of treatments should be framed in the context of cost and benefit, scientific rationale, evidence from controlled and observational studies, the placebo effect, safety of the treatment, and the gaps in our own scientific knowledge base.
Support Groups

A large number of community and online lay support groups have been formed to provide information and to fund research on specific genetic and nongenetic conditions. An important part of genetic counseling is to give information about these groups to patients and to suggest a contact person for the families. Many groups have established websites with very helpful information. With the rise of social media and its ability to connect families with rare syndromes from around the world, it is important to stress to families that their individual disease course will be unique.

Follow-up

Families should be encouraged to continue to ask questions and keep up with new information about the specific disorder. New developments often influence the diagnosis and therapy of specific genetic disorders. Lay support groups are a good source of new information.

Nondirective Counseling

Genetic counseling is usually nondirective; choices about reproduction are left to the family to decide what is right for them. The role of the counselor (physician, genetic counselor, nurse, medical geneticist) is to provide information in understandable terms and outline the range of options available.

94.2

Management and Treatment of Genetic Disorders

Brendan Lee, Nicola Brunetti-Pierri
Genetic conditions are often chronic disorders; few are amenable to curative therapies, although there has been a rapid increase in the number available in recent years. All patients and families should be provided information about the disorder, genetic counseling, anticipatory guidance, and appropriate medical surveillance. Surgical management is available for many conditions that are associated with congenital anomalies or predisposition to tumors.

Resources for patients include the National Organization of Rare Disorders (www.rarediseases.org), the Genetic Alliance (www.geneticalliance.org), the National Library of Medicine (www.nlm.nih.gov/medlineplus/geneticdisorders.html), and a large number of disease-specific websites. A current listing of federally and privately funded clinical trials, including many for genetic diseases, is available at www.ClinicalTrials.gov.

Specific medical therapies for genetic disorders can be classified into physiologic and replacement therapies. Another approach corrects protein misfolding induced by missense mutations through use of small molecules that specifically bind to mutant proteins stabilizing their conformation, thereby preventing early degradation and allowing proper cellular trafficking and localization. This strategy has found successful applications for therapy of cystic fibrosis caused by specific CFTR mutations, including the F508del (see Chapter 432).

**Physiologic Therapies**

Physiologic therapies attempt to ameliorate the phenotype of a genetic disorder by modifying the physiology of the affected individual. The underlying defect itself is not altered by treatment. Physiologic therapies are used in the treatment of inborn errors of metabolism (see Chapter 102). These include dietary manipulation, such as avoiding phenylalanine by persons with phenylketonuria; coenzyme supplementation for some patients with methylmalonic acidemia and mitochondrial diseases; stimulation of alternative pathways to excrete ammonia for those with urea cycle disorders; phototherapy to increase excretion of neurotoxic unconjugated bilirubin in Crigler-Najjar syndrome; bisphosphonate treatment for those with osteogenesis imperfecta to reduce bone fractures; and avoiding cigarette smoking by persons with α₁-antitrypsin deficiency or specific foods and drugs by persons with glucose-6-phosphate dehydrogenase deficiency.
or acute intermittent porphyria. Physiologic treatments can be highly effective, but they usually need to be maintained for a lifetime because they do not affect the underlying genetic disorder. Many of these treatments are most effective when begun early in life, before irreversible damage has occurred. This is the rationale for comprehensive newborn screening for inborn errors of metabolism.

Many physiologic therapies use small-molecule pharmaceuticals (e.g., to remove ammonia in those with urea cycle disorders). Pharmacologic treatments directly target a defective cellular pathway that is altered by an abnormal or a missing gene product. However, there are relatively few such therapies. One example is the inhibition of an enzyme reaction that is upstream of the deficient enzyme, to prevent accumulation of the toxic metabolites, such as the nitisinone (NTBC) for therapy of tyrosinemia type I. A similar approach focuses on partially reducing the synthesis of the substrate of the mutant enzyme or its precursors in lysosomal storage disorders (see Chapter 104.4).

Replacement Therapies

Replacement therapies include replacement of a missing metabolite, an enzyme, an organ, or even a specific gene.

Enzyme Replacement

Enzyme replacement therapy is a component of the treatment of cystic fibrosis to manage intestinal malabsorption. Pancreatic enzymes are easily administered orally, because they must be delivered to the gastrointestinal tract. Recombinant alkaline phosphatase coupled to bone targeting motif is available for intravenous therapy of hypophosphatasia, a skeletal disorder caused by alkaline-phosphatase deficiency.

Enzyme replacement strategies are effective for several lysosomal storage disorders. Enzymes are targeted for the lysosome by modification with mannose-6-phosphate, which binds to a specific receptor. This receptor is also present on the cell surface, so lysosomal enzymes with exposed mannose-6-phosphate residues can be infused into the blood and are taken into cells and transported to lysosomes. Enzyme replacement therapies are available for Gaucher disease and Fabry disease, some mucopolysaccharidoses (MPS I, II, IVA, VI), acid lipase deficiency, and Pompe disease, and are being tested for MPS IIIA, MPS VII, metachromatic leukodystrophy, α-mannosidosis, Niemann-Pick disease type B,
and neuronal ceroid lipofuscinosis, late infantile (CLN2). Other examples include enzyme replacement therapy for hypophosphatasia.

One complication of enzyme replacement therapy is antibody response to the infused recombinant enzyme. The magnitude of this response is not always predictable and varies depending on the enzyme preparation and the disease. In most cases, the patient's antibody response does not affect the treatment's efficacy (e.g., Gaucher disease), but in other situations it may be a significant hurdle (e.g., Pompe disease and phenylketonuria).

**Transplantation**

Cell transplantation and organ transplantation are potentially effective approaches to replacement of a defective gene. Aside from transplantation to replace damaged tissues, transplantation of stem cells, liver, or bone marrow is also used for several diseases, mainly inborn errors of metabolism, and hematologic or immunologic disorders. A successful transplant is essentially curative, although there may be significant risks and side effects (see Chapters 161-165). Cell and tissue transplantation is effective in many clinical scenarios, but there is always short-term morbidity, often associated with either surgical (liver) or preparative (bone marrow) regimens, and long-term morbidity related to chronic immunosuppression and graft failure. Bone marrow transplantation is the best example of stem cell therapy, but much effort also is focused on identifying, characterizing, expanding, and using other tissue stem cells for regenerative therapies.

Alternatively, research has focused on replacing a defective gene (gene therapy). In theory, if one can target the specific tissue that has a deficiency in the gene or gene product, this can offer a less invasive means of achieving a cure for a genetic disorder. Ultimately, gene therapy depends on the unique interaction of the disease pathophysiology, which is specific to the patient, and the gene delivery vehicle.

Gene-transfer vehicles include viral and nonviral vectors administered through ex vivo or in vivo approaches. In ex vivo approaches the patient's cells are removed and after gene correction are infused into the patient. An example of this is the FDA approved CAR-T cell therapy for non-Hodgkin lymphoma. In the in vivo approaches the gene therapy vector is directly injected into the body by either systemic (e.g., intravenous) or localized (e.g., intramuscular, intracerebral, intraocular) injections. Most human clinical trials have used viral vectors
because of their efficiency of tissue transduction. In some diseases, such as X-linked and adenosine deaminase–deficient severe combined immunodeficiency, chronic granulomatous disease, and Wiskott-Aldrich syndrome, clinical gene therapy is a viable and effective option (see Chapter 152.1). Ex vivo gene transfer of hematopoietic stem cells can now be considered at least as effective to allogenic hematopoietic stem cells transplantation in presymptomatic patients with X-linked adrenoleukodystrophy and metachromatic leukodystrophy. In vivo gene therapy is also promising for Leber congenital amaurosis by intraocular delivery, lipoprotein lipase deficiency by intramuscular injections, and hemophilia B by systemic intravenous injection. The first ever human in vivo gene therapy was recently approved in the United States by the FDA for treatment of a specific RPE65-deficient form of retinitis pigmentosa using adenoassociated virus (AAV)-mediated expression of the normal RPE65 gene via intraretinal injection.

**Gene editing** with direct correction of a pathologic mutation is a possible approach to genetic therapy. **CRISPR/Cas9** (clustered regularly interspaced short palindromic repeats/CRISPR-associated system) is a mechanism that permits permanent gene modification of genes in cells. CRISPR genes are bacterial DNA sequences used as a defense mechanism to destroy DNA from viral infections. Combined with related Cas nuclease proteins, the foreign RNA or DNA is recognized, excised, and digested. In gene editing, a complex of the nuclease enzyme and a complementary RNA sequence recognizes the base sequence in the mutated gene. Once bound to the targeted sequence, the nuclease excises both strands and inserts the corrected (nonmutated) sequence. The CRISPR system has corrected the gene defect in a mouse model of Duchenne muscular dystrophy and reduced the tumor burden in explanted human prostate cancer cells in mice. CRISPR-edited T cells can be modified to target and kill tumor cells. CRISPR/Cas9 has been employed to correct the mutation in **MYBPC3** (hypertrophic cardiomyopathy) in an experimental human embryo model. Clinical trials are now in progress applying this approach in somatic tissue. Currently, germline and/or embryonic gene editing studies in humans have not been approved.

Prevention of genetic disease has been accomplished by **preimplantation genetic diagnosis**. This procedure requires in vitro fertilization and single–embryo cell genetic testing of the known families' mutation and is performed with PCR amplification of the affected gene. To avoid recurrent disease, only the unaffected embryos are used for implantation.
In addition, mitochondrial DNA mutations may be avoided by using mitochondrial replacement therapies. In one technique the mutation carrier mother's nuclear DNA is removed from the unfertilized oocyte and transferred to the unaffected mitochondrial donor oocyte (minus that cell's nuclear DNA). In another approach the pronucleus from the mutation-carrier mother's fertilized oocyte is transferred to the unaffected mitochondrial donor's fertilized oocyte (minus the pronucleus).

These different and promising methodologies have many technical and ethical considerations that are being discussed by medical, ethical, legal, and policymaking organizations.

Since the completion of the Human Genome Project, we have seen an unprecedented expansion in our understanding of how human health is impacted by variations in genomic sequence and epigenetic, non-sequence-based, changes that affect gene expression. This period has also seen the development and implementation of new clinical tests that have made it easier for physicians to detect such changes. In addition, there has been a dramatic increase in the availability of information about the genetic aspects of pediatric diseases, particularly on the internet (Table 95.1).

The Burden of Genetic Disorders in Childhood

Medical problems associated with genetic disorders can appear at any age, with the most obvious and serious problems typically manifesting in childhood. It has been estimated that 53/1,000 children and young adults can be expected to have diseases with an important genetic component. If congenital anomalies are included, the rate increases to 79/1,000. In 1978 it was estimated that just over half of admissions to pediatric hospitals were for a genetically determined condition. By 1996, because of changes in healthcare delivery and a greater understanding of the genetic basis of many disorders, that percentage rose to 71%, in one large pediatric hospital in the United States, with 96% of chronic disorders leading to admission having an obvious genetic component or being influenced by genetic susceptibility.

Major categories of genetic disorders include single-gene, genomic, chromosomal, and multifactorial conditions.

Individually, each single-gene disorder is rare, but collectively they represent an important contribution to childhood disease. The hallmark of a single-gene disorder is that the phenotype is overwhelmingly determined by changes that affect an individual gene. The phenotypes associated with single-gene disorders can vary from one patient to another based on the severity of the change affecting the gene and additional modifications caused by genetic, environmental, and stochastic factors. This feature of genetic disease is termed variable expressivity. Common single-gene disorders include sickle cell anemia and cystic fibrosis. Some identifiable syndromes and diseases can be caused by more than one gene (e.g., Noonan syndrome by RAF1, NF1, NRAS, PTPN11, SOS1, SOS2, KRAS, BRAF, SOC2, LZTR1, and RIT1). In addition, mutations affecting a single gene may produce different phenotypes (e.g., SCN5A and Brugada syndrome, long QT syndrome 3, dilated cardiomyopathy, familial atrial fibrillation, and congenital sick sinus syndrome).

Single-gene disorders tend to occur when changes in a gene have a profound
effect on the quantity of the gene product produced, either too much or too little, or the function of the gene product, either a loss of function or a harmful gain of function. Single-gene disorders can be caused by de novo sequence changes that are not found in the unaffected parents of the affected individual, or they may be caused by inherited changes. When a single-gene disorder is known to be caused by changes in only 1 gene, or a small number of individual genes, searching for deleterious changes is most often performed by directly sequencing that gene and, in some cases, looking for small deletions and/or duplications. When multiple genes can cause a particular disorder, it is sometimes more efficient and cost-effective to screen large numbers of disease-causing genes using a disease-specific panel that takes advantage of next-generation sequencing technology than to screen genes individually. When such panels are not available, or when the diagnosis is in question, physicians may consider screening the protein-coding regions of all genes by whole exome sequencing (WES) on a clinical basis. In many circumstances, WES is less expensive than sequencing multiple individual genes. In the future, whole genome sequencing, in which an individual's entire genome is sequenced, may become a valid clinical option as the cost of such tests fall and our ability to interpret the clinical consequences of the thousands of changes identified in such tests improves (see Chapter 94).

The risk of having a child with a particular single-gene disorder can vary from one population to another. In some cases, this is the result of a founder effect, in which a specific change affecting a disease-causing gene becomes relatively common in a population derived from a small number of founders. This high frequency is maintained when there is relatively little interbreeding with persons outside that population because of social, religious, or physical barriers. This is the case for Tay-Sachs disease in Ashkenazi Jews and French Canadians. Other changes may be subject to positive selection when found in the heterozygous carrier state. In this case, individuals who carry a single copy of a genetic change (heterozygotes) have a survival advantage over noncarriers. This can occur even when individuals who inherit 2 copies of the change (homozygotes) have severe medical problems. This type of positive selection is evident among individuals in sub-Saharan Africa who carry a single copy of a hemoglobin mutation that confers relative resistance to malaria but causes sickle cell anemia in homozygotes.

Genomic disorders are a group of diseases caused by alterations in the genome, including deletions (copy number loss), duplications (copy number gain), inversions (altered orientation of a genomic region), and chromosomal...
rearrangements (altered location of a genomic region). Contiguous gene disorders are caused by changes that affect 2 or more genes that contribute to the clinical phenotype and are located near one other on a chromosome. DiGeorge syndrome, which is caused by deletions of genes located on chromosome 22q11, is a common example. Some genomic disorders are associated with distinctive phenotypes whose pattern can be recognized clinically. Other genomic disorders do not have a distinctive pattern of anomalies but can cause developmental delay, cognitive impairment, structural birth defects, abnormal growth patterns, and changes in physical appearance.

Fluorescent in situ hybridization (FISH) can provide information about the copy number and location of a specific genomic region. Array-based copy number detection assays can be used to screen for chromosomal deletions (large and small) and duplications across the genome, but do not provide information about the orientation or location of genomic regions. A chromosome analysis (karyotype) can detect relatively large chromosomal deletions and duplications and can also be useful in identifying inversions and chromosomal rearrangements even when they are copy number neutral changes that do not result in a deletion or duplication of genomic material.

Deletions, duplications, and chromosomal rearrangements that affect whole chromosomes, or large portions of a chromosome, are typically referred to as chromosomal disorders. One of the most common chromosomal disorders is Down syndrome, most often associated with the presence of an extra copy, or trisomy, of an entire chromosome 21. When all or a part of a chromosome is missing, the disorder is referred to as monosomy. Translocations are a type of chromosomal rearrangement in which a genomic region from one chromosome is transferred to a different location on the same chromosome or on a different (nonhomologous) chromosome. Translocations can be balanced, meaning that no genetic material has been lost or gained, or they can be unbalanced, in which some genetic material has been deleted or duplicated.

In some cases, only a portion of cells that make up a person's body are affected by a single-gene defect, a genomic disorder, or a chromosomal defect. This is referred to as mosaicism and indicates that the individual's body is made up of 2 or more distinct cell populations.

Polygenic disorders are caused by the cumulative effects of changes or variations in more than 1 gene. Multifactorial disorders are caused by the cumulative effects of changes or variations in multiple genes and/or the combined effects of both genetic and environmental factors. Spina bifida and
isolated cleft lip or palate are common birth defects that display multifactorial inheritance patterns. Multifactorial inheritance is seen in many common pediatric disorders, such as asthma and diabetes mellitus. These traits can cluster in families but do not have a mendelian pattern of inheritance (see Chapter 97 ). In these cases the genetic changes or variations that are contributing to a particular disorder are often unknown, and genetic counseling is based on empirical data.

The Changing Paradigm of Genetics in Medicine

Genetic testing is increasingly available for a wide variety of both rare and relatively common genetic disorders. Genetic testing is typically used in pediatric medicine to resolve uncertainty regarding the underlying etiology of a child's medical problems and provides a basis for improved genetic counseling and possibly a specific therapy. Even in cases where a specific treatment is not available, identifying a genetic cause can aid physicians in providing individuals and family with accurate prognostic and recurrence risk information and usually helps to relieve unfounded feelings of guilt and stem the tide of misdirected blame.

Genetic tests will ultimately come to underlie a high proportion of medical decisions and will be seamlessly incorporated into routine medical care. Although most genetic testing is presently aimed at identifying or confirming a diagnosis, in the future, genetic testing may find wider application as a means of determining if an individual is predisposed to develop a particular disease. Another area in which genetic testing could make a significant impact is on individualized drug treatment. It has long been known that genetic variation in the enzymes involved in drug metabolism underlies differences in the therapeutic effect and toxicity of some drugs. As the genetic changes that underlie these variations are identified, new genetic tests are being developed that allow physicians to tailor treatments based on individual variations in drug metabolism, responsiveness, and susceptibility to toxicity (see Chapter 72 ). It is likely that the expansion of such testing will depend, at least in part, on the extent to which such tests can be linked to strategies to prevent disease or improve outcome (see Chapter 94 ). As such links are made, we will enter into a new era of personalized medical treatment.
Long-standing and highly successful carrier screening programs have existed for disorders such as Tay-Sachs disease and many other rare, single-gene disorders that are prevalent in specific populations. Couples are usually offered screening for a variety of conditions, in part based on ancestry (Tay-Sachs disease, hemoglobinopathies, cystic fibrosis). Couples found to be at increased risk for such disorders can be offered preconception or prenatal testing aimed at detecting specific disease-causing mutations.

Prenatal screening is routinely offered for chromosomal disorders such as trisomy 13, trisomy 18, and Down syndrome. An increasing number of pregnancies affected by these and other genetic disorders are being recognized by noninvasive screening tests targeting fetal cell-free DNA in maternal blood and by fetal ultrasound. When genetic disorders are suspected, chorionic villus sampling at 10-12 wk of gestation or amniocentesis at 16-18 wk of gestation can provide material for genetic testing. When a couple are at risk for a specific genetic defect, preimplantation genetic diagnosis can sometimes be used to select unaffected early embryos, which are then implanted as part of an in vitro fertilization procedure.

Although prenatally obtained genetic material can be used to identify single-gene disorders, genomic disorders, and chromosomal anomalies, the information obtained on any pregnancy depends on the tests that are ordered. It is important that physicians select the most appropriate prenatal tests, and that couples understand the limitations of these tests. No amount of genetic testing can guarantee the birth of a healthy child.

Specific treatments are not available for the majority of genetic disorders, although some important exceptions exist (Chapter 94). Inborn errors of metabolism were the first genetic disorders to be recognized, and many are amenable to treatment by dietary manipulation (see Chapter 102). These conditions result from genetically determined deficiency of specific enzymes, leading to the buildup of toxic substrates and/or deficiency of critical end products.

Individual metabolic disorders tend to be very rare, but their combined impact on the pediatric population is significant. Tandem mass spectrometry has made it relatively inexpensive to screen for a large number of these disorders in the newborn period. Use of this technology not only dramatically increases the number of metabolic disorders identified within a population, but also allows treatment to be initiated at a much earlier stage in development.

Another area showing progress in genetic therapies is the treatment of
lysosomal storage disorders (see Chapter 104.4). These metabolic diseases are caused by defects in lysosomal function. Lysosomes are cellular organelles that contain specific digestive enzymes. Some of these disorders that were characterized by early lethal or intractable chronic illness can now be treated using specially modified enzymes administered by intravenous infusion. These enzymes are taken up by cells and incorporated into lysosomes. Conditions such as Gaucher disease and Fabry disease are routinely treated using enzyme replacement, and similar therapies are being developed for other lysosomal disorders.

Therapeutic advances are also being made in the treatment of nonmetabolic genetic disorders. Improvements in surgical techniques and intensive care medicine are extending the survival of children with life-threatening birth defects such as congenital diaphragmatic hernia and severe cardiac defects. In many cases the life expectancy of children with debilitating genetic disorders is also increasing. For example, in cystic fibrosis, improvements in nutrition and the management of chronic pulmonary disease allow an increasing percentage of affected patients to survive into adulthood, creating a need to transition care from pediatric to adult providers.

Gene replacement therapies have long been anticipated and are starting to show some benefit (see Chapter 94). Stem cell–based therapies have also been touted as a potential treatment for a number of intractable disorders, but clear evidence that such therapies are effective has yet to materialize.

Ethics Issues

As with all medical care, genetic testing, diagnosis, and treatment should be performed confidentially. Nothing is as personal as one's genetic information, and all efforts should be made to avoid any stigma for the patient. Many people worry that results of genetic testing will put them, or their child, at risk for genetic discrimination. Genetic discrimination occurs when people are treated unfairly because of a difference in their DNA that suggests they have a genetic disorder or they are at an increased risk of developing a certain disease. In the United States the Genetic Information Nondiscrimination Act of 2008 protects individuals from genetic discrimination at the hands of health insurers and employers, but does not extend protection against discrimination from providers of life, disability, or long-term care insurance.

As in all medical decision-making, the decisions about genetic testing should
be based on a careful evaluation of the potential benefits and risks. In the pediatric setting, these decisions may be more difficult because physicians and parents are often called on to make decisions for a child who cannot directly participate in discussions about testing. Molecular diagnostic tests are often used to diagnose malformation syndromes, cognitive delay, or other disabilities in which there is a clear benefit to the child. In other cases, such as genetic testing for susceptibility to adult-onset diseases, it is appropriate to wait until the child or adolescent is mature enough to weigh the potential risks and benefits and make his or her own decisions about genetic testing.

Policies regarding genetic testing of children have been developed collaboratively by the American Academy of Pediatrics (AAP) and the American College of Medical Genetics and Genomics (ACMG; Pediatrics 131[3]:620–622, 2013). These recommendations are outlined next.

**General Recommendations**
1. Decisions about whether to offer genetic testing and screening should be driven by the best interest of the child.
2. Genetic testing is best offered in the context of genetic counseling. Genetic counseling can be performed by clinical geneticists, genetic counselors, or any other health care provider with appropriate training and expertise. AAP and ACMG support the expansion of educational opportunities in human genomics and genetics for medical students, residents, and practicing pediatric primary care providers.

**Diagnostic Testing**
3. In a child with symptoms of a genetic condition, the rationale for genetic testing is similar to that of other medical diagnostic evaluations. Parents or guardians should be informed about the risks and benefits of testing, and their permission should be obtained. Ideally, and when appropriate, the assent of the child should be obtained.
4. When performed for therapeutic purposes, pharmacogenetic testing of children is acceptable, with permission of parents or guardians and, when appropriate, the child's assent. If a pharmacogenetic test result carries implications beyond drug targeting or dose responsiveness, the broader implications should be discussed before testing.

**Newborn Screening**
5. AAP and ACMG support the mandatory offering of newborn screening for all children. After education and counseling about the substantial
benefits of newborn screening, its remote risks, and the next steps in the event of a positive screening result, parents should have the option of refusing the procedure, and an informed refusal should be respected.

**Carrier Testing**
6. AAP and ACMG do not support routine carrier testing in minors when such testing does not provide health benefits in childhood. The AAP and ACMG advise against school-based testing or screening programs, because the school environment is unlikely to be conducive to voluntary participation, thoughtful consent, privacy, confidentiality, or appropriate counseling about test results.

7. For pregnant adolescents or for adolescents considering reproduction, genetic testing and screening should be offered as clinically indicated, and the risks and benefits should be explained clearly.

**Predictive Genetic Testing**
8. Parents or guardians may authorize predictive genetic testing for asymptomatic children at risk of childhood-onset conditions. Ideally, the assent of the child should be obtained.

9. Predictive genetic testing for adult-onset conditions generally should be deferred unless an intervention initiated in childhood may reduce morbidity or mortality. An exception might be made for families for whom diagnostic uncertainty poses a significant psychosocial burden, particularly when an adolescent and the parents concur in their interest in predictive testing.

10. For ethical and legal reasons, healthcare providers should be cautious about providing predictive genetic testing to minors without the involvement of their parents or guardians, even if a minor is mature. Results of such tests may have significant medical, psychological, and social implications, not only for the minor but also for other family members.

**Histocompatibility Testing**
11. Tissue compatibility testing of minors of all ages is permissible to benefit immediate family members but should be conducted only after thorough exploration of the psychosocial, emotional, and physical implications of the minor serving as a potential stem cell donor. A donor advocate or similar mechanism should be in place from the outset to avert coercion and safeguard the interests of the child.

**Adoption**
12. The rationale for genetic testing of children in biological families should apply for adopted children and children awaiting placement for adoption. If a child has a known genetic risk, prospective adoptive parents must be made aware of this possibility. In rare cases, it may be in a child's best interest to undergo predictive genetic testing for a known risk before adoption, to ensure the child's placement with a family capable of and willing to accept the child's potential medical and developmental challenges. In the absence of such indications, genetic testing should not be performed as a condition of adoption.

Disclosure

13. At the time of genetic testing, parents or guardians should be encouraged to inform their child of the test results at an appropriate age. Parents or guardians should be advised that, under most circumstances, a request by a mature adolescent for test results should be honored.

14. Results from genetic testing of a child may have implications for the parents and other family members. Healthcare providers have an obligation to inform parents and the child, when appropriate, about these potential implications. Healthcare providers should encourage patients and families to share this information and offer to help explain the results to the extended family or refer them for genetic counseling.

15. Misattributed paternity, use of donor gametes, adoption, or other questions about family relationships may be uncovered “incidentally” whenever genetic testing is performed, particularly when testing multiple family members. This risk should be discussed, and a plan about disclosure or nondisclosure should be in place before testing.

Direct-to-Consumer Testing

16. AAP and ACMG strongly discourage the use of direct-to-consumer and home-kit genetic testing of children because of the lack of oversight on test content, accuracy, and interpretation.

Qasim W, Gaspar HB, Thrasher AJ. Update on clinical gene
The human genome has approximately 20,000 genes that encode the wide variety of proteins found in the human body. Reproductive or germline cells contain 1 copy (N) of this genetic complement and are haploid, whereas somatic (nongermline) cells contain 2 complete copies (2N) and are diploid. Genes are organized into long segments of deoxyribonucleic acid (DNA), which, during cell division, are compacted into intricate structures together with proteins to form chromosomes. Each somatic cell has 46 chromosomes: 22 pairs of autosomes, or nonsex chromosomes, and 1 pair of sex chromosomes (XY in a male, XX in a female). Germ cells (ova or sperm) contain 22 autosomes and 1 sex chromosome, for a total of 23. At fertilization, the full diploid chromosome complement of 46 is again realized in the embryo.

Most of the genetic material is contained in the cell's nucleus. The mitochondria (the cell's energy-producing organelles) contain their own unique genome. The mitochondrial chromosome consists of a double-stranded circular piece of DNA, which contains 16,568 base pairs (bp) of DNA and is present in multiple copies per cell. The proteins that occupy the mitochondria are produced either in the mitochondria, using information contained in the mitochondrial genome, or are produced outside of the mitochondria, using information contained in the nuclear genome, and then transported into the organelle. Sperm do not usually contribute mitochondria to the developing embryo, so all mitochondria are maternally derived, and a child's mitochondrial genetic makeup derives exclusively from the child's biological mother (see Chapter 106).

**Fundamentals of Molecular Genetics**

DNA consists of a pair of chains of a sugar-phosphate backbone linked by
pyrimidine and purine bases to form a **double helix** (Fig. 96.1). The sugar in DNA is deoxyribose. The pyrimidines are cytosine (C) and thymine (T); the purines are guanine (G) and adenine (A). The bases are linked by hydrogen bonds such that A always pairs with T and G with C. Each strand of the double helix has polarity, with a free phosphate at one end (5′) and an unbonded hydroxyl on the sugar at the other end (3′). The 2 strands are oriented in opposite polarity in the double helix.

![DNA double helix](image)

**FIG. 96.1** DNA double helix, with sugar-phosphate backbone and nitrogenous bases. (From Jorde LB, Carey JC, Bamshad MJ, et al, editors: Medical genetics, ed 2, St Louis, 1999, Mosby, p 8.)

The replication of DNA follows the pairing of bases in the parent DNA strand. The original 2 strands unwind by breaking the hydrogen bonds between base pairs. Free nucleotides, consisting of a base attached to a sugar-phosphate chain, form new hydrogen bonds with their complementary bases on the parent strand;
new phosphodiester bonds are created by enzymes called DNA polymerases. Replication of chromosomes begins simultaneously at multiple sites, forming replication bubbles that expand bidirectionally until the entire DNA molecule (chromosome) is replicated. Errors in DNA replication, or mutations induced by environmental mutagens such as irradiation or chemicals, are detected and potentially corrected by DNA repair systems.

The central tenet of molecular genetics is that information encoded in DNA, predominantly located in the cell nucleus, is transcribed into messenger ribonucleic acid (mRNA), which is then transported to the cytoplasm, where it is translated into protein. A prototypical gene consists of a regulatory region, segments called exons that encode the amino acid sequence of a protein, and intervening segments called introns (Fig. 96.2).

**FIG. 96.2** Flow of information from DNA to RNA to protein for a hypothetical gene with 3 exons and 2 introns. Within the exons, colored regions indicate coding sequences. Steps include transcription, RNA processing and splicing, RNA transport from the nucleus to the cytoplasm, translation, and protein assembly. (From Nussbaum RL, McInnis RR, Willard HF, Hamosh A, editors: Thompson & Thompson genetics in medicine, ed 7, Philadelphia, 2007, Saunders/Elsevier, p 31.)
Transcription is initiated by attachment of ribonucleic acid (RNA) polymerase to the promoter site upstream of the beginning of the coding sequence. Specific proteins bind to the region to repress or activate transcription by opening up the chromatin, which is a complex of DNA and histone proteins. It is the action of these regulatory proteins (transcription factors) that determines, in large part, when a gene is turned on or off. Some genes are also turned on and off by methylation of cytosine bases that are adjacent to guanine bases (cytosine-phosphate-guanine bases, CpGs). Methylation is an example of an epigenetic change, meaning a change that can affect gene expression, and possibly the characteristics of a cell or organism, but that does not involve a change in the underlying genetic sequence. Gene regulation is flexible and responsive, with genes being turned on or off during development and in response to internal and external environmental conditions and stimuli.

Transcription proceeds through the entire length of the gene in a 5′ to 3′ direction to form an mRNA transcript whose sequence is complementary to that of one of the DNA strands. RNA, like DNA, is a sugar-phosphate chain with pyrimidines and purines. In RNA the sugar is ribose, and uracil replaces the thymine found in DNA. A “cap” consisting of 7-methylguanosine is added to the 5′ end of the RNA in a 5′-5′ bond and, for most transcripts, several hundred adenine bases are enzymatically added to the 3′ end after transcription.

mRNA processing occurs in the nucleus and consists of excision of the introns and splicing together of the exons. Specific sequences at the start and end of introns mark the sites where the splicing machinery will act on the transcript. In some cases, there may be tissue-specific patterns to splicing, so that the same primary transcript can produce multiple distinct proteins.

The processed transcript is next exported to the cytoplasm, where it binds to ribosomes, which are complexes of protein and ribosomal RNA (rRNA). The genetic code is then read in triplets of bases, each triplet corresponding with a specific amino acid or providing a signal that terminates translation. The triplet codons are recognized by transfer RNAs (tRNAs) that include complementary anticodons and bind the corresponding amino acid, delivering it to the growing peptide. New amino acids are enzymatically attached to the peptide. Each time an amino acid is added, the ribosome moves 1 triplet codon step along the mRNA. Eventually a stop codon is reached, at which point translation ends and the peptide is released. In some proteins, there are posttranslational modifications, such as attachment of sugars (glycosylation); the protein is then
delivered to its destination within or outside the cell by trafficking mechanisms that recognize portions of the peptide.

Another mechanism of genetic regulation is noncoding RNAs, which are RNAs transcribed from DNA but not translated into proteins. Noncoding RNAs function in mediating splicing, the processing of coding RNAs in the nucleus, and the translation of coding mRNAs in ribosomes. The roles of large noncoding RNAs (>200 bp) and short noncoding RNAs (<200 bp) extend beyond these processes to impact a diverse set of biologic functions, including the regulation of gene expression. For example, micro RNAs (miRNAs) are a class of small RNAs that control gene expression in the cell by directly targeting specific sets of coding RNAs by direct RNA–RNA binding. This RNA–RNA interaction can lead to degradation of the target-coding RNA or inhibition of translation of the protein specified by that coding RNA. miRNAs, in general, target and regulate several hundred mRNAs.

Genetic Variation

The process of producing protein from a gene is subject to disruption at multiple levels because of alterations in the coding sequence (Fig. 96.3). Changes in the regulatory region can lead to altered gene expression, including increased or decreased rates of transcription, failure of gene activation, or activation of the gene at inappropriate times or in inappropriate cells. Changes in the coding sequence can lead to substitution of one amino acid for another (missense variant or nonsynonymous variant) or creation of a stop codon in the place of an amino acid codon. Overall, missense or nonsense variants are the most common (56% of variants); small deletions or insertions represent approximately 24% of variants (Table 96.1). Some single-base changes do not affect the amino acid (silent, wobble, or synonymous variants), because there may be several triplet codons that correspond to a single amino acid. Amino acid substitutions can have a profound effect on protein function if the chemical properties of the substituted amino acid are markedly different from the usual one. Other substitutions can have a subtle or no effect on protein function, particularly if the substituted amino acid is chemically similar to the original one.
FIG. 96.3 Various types of intragenic sequence variants. Promoter variants alter rate of transcription or disrupt gene regulation. Base changes within exons can have various effects, as shown. Variants within introns can lead to inclusion of some intronic sequence in the final processed mRNA, or it can lead to exon skipping.

* Some have been shown to cause aberrant splicing.

Genetic changes can also include **insertions** or **deletions**. Insertions or deletions of a nonintegral multiple of 3 bases into the coding sequence leads to a **frameshift**, altering the grouping of bases into triplets. This leads to translation of an incorrect amino acid sequence and often a premature stop to translation. Insertion or deletion of an integral multiple of 3 bases into the coding sequence will insert or delete a corresponding number of amino acids from the protein, leading to **in-frame** alterations that maintain the amino acid sequence outside the deleted or duplicated amino acids. Larger-scale insertions or deletions can disrupt a coding sequence or result in complete deletion of an entire gene or group of genes.

Pathogenic variants usually can be classified as causing a loss of function or a gain of function. **Loss-of-function variants** cause a reduction in the level of protein function as a result of decreased expression or production of a protein that does not work as efficiently. In some cases, loss of protein function from 1 gene is sufficient to cause disease. **Haploinsufficiency** describes the situation in which maintenance of a normal phenotype requires the proteins produced by both copies of a gene, and a 50% decrease in gene function results in an abnormal phenotype. Thus, haploinsufficient phenotypes are, by definition, dominantly inherited. Loss-of-function variants can also have a dominant negative effect when the abnormal protein product actively interferes with the function of the normal protein product. Both these situations lead to diseases inherited in a dominant fashion. In other cases, loss-of-function variants must be present in both copies of a gene before an abnormal phenotype results. This situation typically results in diseases inherited in a recessive fashion (see **Chapter 97**).

**Gain-of-function variants** typically cause dominantly inherited diseases. These variants can result in production of a protein molecule with an increased ability to perform a normal function or can confer a novel property on the protein. The gain-of-function variant in **achondroplasia**, the most common of
the disproportionate, short-limbed short stature disorders, exemplifies the enhanced function of a normal protein. Achondroplasia results from a mutation in the fibroblast growth factor (FGF) receptor 3 gene (\textit{FGFR3}), which leads to activation of the receptor, even in the absence of FGF. In \textit{sickle cell disease} an amino acid is substituted into the hemoglobin molecule and has little effect on the ability of the protein to transport oxygen. However, sickle hemoglobin chains have a novel property. Unlike normal hemoglobin, sickle hemoglobin chains aggregate under conditions of deoxygenation, forming fibers that deform the red cells.

Other gain-of-function mutations result in overexpression or inappropriate expression of a gene product. Many cancer-causing genes (\textit{oncogenes}) are normal regulators of cellular proliferation during development. However, expression of these genes in adult life and/or in cells in which they usually are not expressed can result in neoplasia.

In some cases, changes in gene expression are caused by changes in the number of copies of a gene that are present in the genome (\textit{Fig. 96.4}). Although some \textit{copy number variations} are common and do not appear to cause or predispose to disease, others are clearly disease causing. \textit{Charcot-Marie-Tooth disease type 1A}, the most common inherited form of chronic peripheral neuropathy of childhood, is caused by duplications of the gene for peripheral myelin protein 22, resulting in overexpression as a result of the existence of 3 active copies of this gene (see \textit{Chapter 631.1}). Deletions of this same gene leaving only 1 active copy are responsible for a different disorder, hereditary neuropathy with liability to pressure palsies.
FIG. 96.4 Array comparative genomic hybridization. Test and reference DNA samples are differentially labeled, mixed, and passed over a target array of probes (e.g., bacterial artificial chromosome clones or oligonucleotides) containing DNA fragments from across the whole human genome. The experiment is often repeated with reversal of the test and reference dyes to detect dye effects or identify spurious signals. DNA samples hybridize with their corresponding probe, and the ratio of fluorescence from each probe (test:reference) is used to detect regions that vary in copy number between the test and the reference sample (red line, original hybridization; blue line, dye-swapped hybridization). Equal copy number for both the test and the reference DNA is identified by equal binding, resulting in a ratio of 1:1. Duplication in a genomic region of the test sample is identified by an increased ratio, and a deletion is identified by a decreased ratio, but a deletion in the test sample is indistinguishable from a duplication in the reference sample. These ratios are usually converted to log2 scale for further analysis. (Adapted from Feuk L, Carson AR, Scherer SW: Structural variation in the human genome, Nat Rev Genet 7:85–97, 2006, with permission from Nature Reviews Genetics.)

Deletions and duplications can vary in their extent and can involve several genes, even when they are not visible on a traditional chromosome analysis. Such changes are commonly called microdeletions and microduplications. When deletion or duplication of 2 or more genes in the same chromosomal region each play a role in the resulting clinical features, the condition can also be referred to as a contiguous gene disorder.

In some cases the recognition of a specific constellation of features leads the
clinician to suspect a specific microdeletion or microduplication syndrome. Examples of such disorders include Smith-Magenis, DiGeorge, and Williams syndromes. In other cases the clinician may be alerted to this possibility by an unusually diverse array of clinical features in one patient or the presence of unusual features in a person with a known condition. Because of the close physical proximity of a series of genes, different deletions involving the short arm of the X chromosome can produce individuals with various combinations of ichthyosis, Kallmann syndrome, ocular albinism, intellectual disability, chondrodysplasia punctata, and short stature.

DNA rearrangements can also take place in somatic cells (cells that do not go on to produce ova or sperm). Rearrangements that occur in lymphoid cells are required for the formation of functional immunoglobulin in B cells and antigen-recognizing receptors on T cells. Large segments of DNA, which code for the variable and the constant regions of either immunoglobulin or the T-cell receptor (TCR), are physically joined at a specific stage in the development of an immunocompetent lymphocyte. These rearrangements take place during development of the lymphoid cell lineage in humans and result in the extensive diversity of immunoglobulin and TCR molecules. Because of this postgermline DNA rearrangement, no 2 individuals, not even identical twins, are really identical, because mature lymphocytes from each will have undergone random DNA rearrangements at these loci.

Studies of the human genome sequence reveal that any 2 individuals differ in about 1 base in 1,000. Some of these differences are silent; some result in changes that explain phenotypic differences (hair or eye color, physical appearance); some have medical significance, causing single-gene disorders such as sickle cell anemia or explaining susceptibility to common pediatric disorders such as asthma. Genetic variants in a single gene that occur at a frequency of >1% in a population are often referred to as polymorphisms. These variations may be silent or subtle or may have significant phenotypic effects.

**Genotype-Phenotype Correlations in Genetic Disease**

The term *genotype* is used to signify the internally coded, heritable information of an individual and can also be used to refer to which particular alternative
version (allele) of a gene is present at a specific location (locus) on a chromosome. A phenotype is the observed structural, biochemical, and physiologic characteristics of an individual, determined by the genotype, and can also refer to the observed structural and functional effects of a variant allele at a specific locus. Many sequence variants result in predictable phenotypes. In these cases, physicians can predict clinical outcomes and plan appropriate treatment strategies based on a patient's genotype. Increasingly, there is phenotypic expansion where multiple alleles (variants) within a gene can be associated with often diverse and distinct clinical presentations.

The long QT syndrome exemplifies a disorder with predictable associations between a patient's genotype and his or her phenotype (see Chapter 462.5). Long QT syndrome is genetically heterogeneous, meaning that pathogenic variants in several different genes can cause the same disorder. The risk for cardiac events (syncope, aborted cardiac arrest, or sudden death) is higher in patients with long QT syndrome involving the KCNQ1 gene (63%) or KCNH2 (46%) than in those with pathogenic variants in SCN5A (18%). In addition, those with KCNQ1 variants experience most of their episodes during exercise and rarely during rest or sleep. In contrast, individuals with pathogenic variants in KCNH2 and SCN5A are more likely to have episodes during sleep or rest and rarely during exercise. Therefore, variants in specific genes (genotype) are correlated with specific manifestations (phenotype) of long QT syndrome. These types of relationships are commonly referred to as genotype-phenotype correlations.

Pathogenic variants in the fibrillin-1 gene associated with Marfan syndrome represent another example of predictable genotype-phenotype correlations (see Chapter 722). Marfan syndrome is characterized by the combination of skeletal, ocular, and aortic manifestations, with the most devastating outcome being aortic root dissection and sudden death. The fibrillin-1 gene consists of 65 exons, and mutations have been found in almost all these. The location of the mutation within the gene (genotype) might play a significant role in determining the severity of the condition (phenotype). Neonatal Marfan syndrome is caused by mutations in exons 24-27 and in exons 31 and 32, whereas milder forms are caused by mutations in exons 59-65 and in exons 37 and 41.

Genotype-phenotype correlations have also been observed in some complications of cystic fibrosis (CF; see Chapter 432). Although pulmonary disease is the major cause of morbidity and mortality, CF is a multisystem disorder that affects not only the epithelia of the respiratory tract but also the
exocrine pancreas, intestine, male genital tract, hepatobiliary system, and exocrine sweat glands. CF is caused by pathologic variants in the CF transmembrane conductance regulator (CFTR) gene; >1,600 different pathogenic variants have been identified. The most common is a deletion of 3 nucleotides that removes the amino acid phenylalanine (F) at the 508th position on the protein (ΔF508 variant), which accounts for approximately 70% of all pathogenic CF variants and is associated with severe disease. The best genotype-phenotype correlations in CF are seen in the context of pancreatic function, with most common mutations being classified as either pancreatic sufficient or pancreatic insufficient. Persons with pancreatic sufficiency usually have either 1 or 2 pancreatic-sufficient alleles, indicating that pancreatic-sufficient alleles are dominant. In contrast, the genotype-phenotype correlation in pulmonary disease is much weaker, and persons with identical genotypes have wide variations in the severity of their pulmonary disease. This finding may be accounted for in part by genetic modifiers or environmental factors.

In many disorders the effects of variants on phenotype can be modified by changes in the other allele of the same gene, by changes in specific modifier genes, and/or by variations in a number of unspecified genes (genetic background). When sickle cell anemia is co-inherited with the gene for hereditary persistence of fetal hemoglobin, the sickle cell phenotypic expression is less severe. Modifier genes in CF can influence the development of congenital meconium ileus, or colonization with Pseudomonas aeruginosa. Modifier genes can also affect the manifestations of Hirschsprung disease, neurofibromatosis type 2, craniosynostosis, and congenital adrenal hyperplasia. The combination of genetic variants producing glucose-6-phosphate dehydrogenase deficiency and longer versions of the TATAA element in the uridine diphosphate-glucuronosyltransferase gene promoter exacerbates neonatal physiologic hyperbilirubinemia.

**Human Genome Project**

A rudimentary genetic map can be made using genetic linkage, which is based on the principle that alleles at 2 genetic loci that are located near each other segregate together in a family unless they are separated by genetic recombination. The frequency of recombination between the loci can be used to estimate the physical distance between points. Some of the first maps of the human genome were linkage maps based on a set of polymorphic genetic loci.
located along the entire human genome. Linkage analysis is still used to map the location of genetic changes responsible for phenotypic traits and genetic disorders that are inherited in a mendelian fashion.

In contrast to linkage maps, which are based on recombination frequencies, physical maps rely on overlapping DNA fragments to determine the location of loci with respect to one another. Several strategies can be used to create physical maps of a chromosomal region. In one strategy, segments of the region of interest with lengths from hundreds or thousands to a few million base pairs are isolated and placed in microorganisms such as bacteria or yeast. Common regions contained in different organisms can then be identified and this information used to piece together a map composed of overlapping DNA pieces, each contained in a different microorganism. The pieces contained in each organism can then be sequenced to obtain the DNA sequence of the entire region. An alternative strategy involves breaking the entire genome into random fragments, sequencing the fragments, and then using a computer to order the fragments based on overlapping segments. This whole genome approach in combination with new next-generation sequencing technologies has resulted in a dramatic reduction in the cost of sequencing an individual's entire genome.

Analysis of the human genome has produced some surprising results. The number of genes appears to be about 20,000. This is fewer than had been expected and is in the same range as many simpler organisms. *The number of protein products encoded by the genome is greater than the number of genes.* This is a result of the presence of alternative promoter regions, alternative splicing, and posttranslational modifications, which can allow a single gene to encode a number of protein products.

It is also apparent that most of the human genome does not encode protein, with <5% being transcribed and translated, although a much larger percentage may be transcribed without translation. Many transcribed sequences are not translated but represent genes that encode RNAs that serve a regulatory role. A large fraction of the genome consists of repeated sequences that are interspersed among the genes. Some of these are transposable genetic elements that can move from place to place in the genome. Others are static elements that were expanded and dispersed in the past during human evolution. Other repeated sequences might play a structural role. There are also regions of genomic duplications. Such duplications are substrate for evolution, allowing genetic motifs to be copied and modified to serve new roles in the cell. Duplications can also play a role in chromosomal rearrangement, permitting nonhomologous chromosome
segments to pair during meiosis and exchange material. This is another source of evolutionary change and a potential source of chromosomal instability leading to congenital anomalies or cancer. Low copy repeats also play an important role in causing genomic disorders. When low copy repeats flank unique genomic segments, these regions can be duplicated or deleted through a process known as nonallelic homologous recombination.

Availability of the entire human genomic sequence permits the study of large groups of genes, looking for patterns of gene expression or genome alteration. Microarrays permit the expression of thousands of genes to be analyzed on a small glass chip. Increasingly, studies of gene expression are being performed using next generation sequencing techniques to obtain information about all of the RNA transcripts in a tissue sample. In some cases the patterns of gene expression provide signatures for particular disease states, such as cancer, or change in response to therapy (Fig. 96.5).

**FIG. 96.5** Microarray containing 36,000 oligonucleotides. The microarray was exposed to RNA from normal fibroblasts (labeled in red; see arrows) and fibroblasts from a
patient with Niemann-Pick disease, type C (labeled green). Arrows point to regions in which there was a strong hybridization signal with either normal or disease RNA. This microarray was used to search for genes that are highly expressed in the fibroblasts of patients. Family History and Pedigree Notation

The family history remains the most important screening tool for pediatricians in identifying a patient's risk for developing a wide range of diseases, from multifactorial conditions such as diabetes and attention-deficit/hyperactivity disorder, to single-gene disorders such as sickle cell anemia and cystic fibrosis. Through a detailed family history, the physician can often ascertain the mode of genetic transmission and the risks to family members. Because not all familial clustering of disease is caused by genetic factors, a family history can also identify common environmental and behavioral factors that influence the occurrence of disease. The main goal of the family history is to identify genetic susceptibility, and the cornerstone of the family history is a systematic and standardized pedigree.

A pedigree provides a graphic depiction of a family's structure and medical history. It is important when taking a pedigree to be systematic and use standard symbols and configurations so that anyone can read and understand the information (Figs. 97.1 to 97.4). In the pediatric setting, the proband is typically the child or adolescent who is being evaluated. The proband is designated in the pedigree by an arrow.
### Instructions:
- Key should contain all information relevant to interpretation of pedigree (e.g., define fill/shading)
- For clinical (non-published) pedigrees include:
  - name of proband/consultant
  - family names/initials of relatives for identification, as appropriate
  - name and title of person recording pedigree
  - historian (person relaying family history information)
  - date of intake/update
  - reason for taking pedigree (e.g., abnormal ultrasound, familial cancer, developmental delay, etc.)
  - ancestry of both sides of family
- Recommended order of information placed below symbol (or to lower right)
  - age: can note year of birth (e.g., b. 1978) and/or death (e.g., d. 2007)
  - evaluation (see Figure 75-4)
  - pedigree number (e.g., I-1, I-2, I-3)
- Limit identifying information to maintain confidentiality and privacy

**Instructions:**
- D represents egg or sperm donor
- S represents surrogate (gestational carrier)
- If the woman is both the ovum donor and a surrogate, in the interest of genetic assessment, she will only be referred to as a donor (e.g., 4 and 5); the pregnancy symbol and its line of descent are positioned below the woman who is carrying the pregnancy
- Available family history should be noted on the gamete donor and/or gestational carrier
A 3 to 4-generation pedigree should be obtained for every new patient as an initial screen for genetic disorders segregating within the family. The pedigree can provide clues to the inheritance pattern of these disorders and can aid the clinician in determining the risk to the proband and other family members. The closer the relationship of the proband to the person in the family with the genetic
disorder, the greater is the shared genetic complement. First-degree relatives, such as a parent, full sibling, or child, share one-half their genetic information on average; first cousins share one-eighth. Sometimes the person providing the family history may mention a distant relative who is affected with a genetic disorder. In such cases a more extensive pedigree may be needed to identify the risk to other family members. For example, a history of a distant maternally related cousin with intellectual disability caused by fragile X syndrome can still place a male proband at an elevated risk for this disorder.

**Mendelian Inheritance**

There are 3 classic forms of genetic inheritance: autosomal dominant, autosomal recessive, and X-linked. These are referred to as mendelian inheritance forms, after Gregor Mendel, the 19th-century monk whose experiments led to the laws of segregation of characteristics, dominance, and independent assortment. These remain the foundation of single-gene inheritance.

**Autosomal Dominant Inheritance**

Autosomal dominant inheritance is determined by the presence of one abnormal gene on one of the autosomes (chromosomes 1-22). Autosomal genes exist in pairs, with each parent contributing 1 copy. In an autosomal dominant trait, a change in 1 of the paired genes affects the phenotype of an individual, even though the other copy of the gene is functioning correctly. A phenotype can refer to a physical manifestation, a behavioral characteristic, or a difference detectable only through laboratory tests.

The pedigree for autosomal dominant disorders demonstrates certain characteristics. These disorders show a vertical transmission (parent-to-child) pattern and can appear in multiple generations. In Fig. 97.5, this is illustrated by individual I.1 passing on the changed gene to II.2 and II.5. An affected individual has a 50% (1 in 2) chance of passing on the deleterious gene in each pregnancy and, therefore, of having a child affected by the disorder. This is referred to as the recurrence risk for the disorder. Unaffected individuals (family members who do not manifest the trait and do not harbor a copy of the deleterious gene) do not pass the disorder to their children. Males and females are equally affected.
FIG. 97.5  Autosomal dominant pedigree. Pedigree showing typical inheritance of a form of achondroplasia (FGFR3) inherited as an autosomal dominant trait. Black, Affected patients.

Although not a characteristic per se, the finding of male-to-male transmission essentially confirms autosomal dominant inheritance. Vertical transmission can also be seen with X-linked traits. However, because a father passes on his Y chromosome to a son, male-to-male transmission cannot be seen with an X-linked trait. Therefore, male-to-male transmission eliminates X-linked inheritance as a possible explanation. Although male-to-male transmission can occur with Y-linked genes as well, there are very few Y-linked disorders, compared with thousands having the autosomal dominant inheritance pattern.

Although parent-to-child transmission is a characteristic of autosomal dominant inheritance, many patients with an autosomal dominant disorder have no history of an affected family member, for several possible reasons. First, the patient may have the disorder due to a de novo (new) mutation that occurred in the DNA of the egg or sperm that formed that individual. Second, many autosomal dominant conditions demonstrate incomplete penetrance, meaning that not all individuals who carry the mutation have phenotypic manifestations. In a pedigree this can appear as a skipped generation, in which an unaffected individual links 2 affected persons (Fig. 97.6). There are many potential reasons that a disorder might exhibit incomplete penetrance, including the effect of modifier genes, environmental factors, gender, and age. Third, individuals with the same autosomal dominant variant can manifest the disorder to different degrees. This is termed variable expression and is a characteristic of many autosomal dominant disorders. Fourth, some spontaneous genetic mutations occur not in the egg or sperm that forms a child, but rather in a cell in the developing embryo. Such events are referred to as somatic mutations, and because not all cells are affected, the change is said to be mosaic. The phenotype caused by a somatic mutation can vary but is usually milder than if all
cells were affected by the mutation. In **germline mosaicism** the mutation occurs in cells that populate the germline that produces eggs or sperm. An individual who is germline mosaic might not have any manifestations of the disorder but may produce multiple eggs or sperm that are affected by the mutation.

**FIG. 97.6** Incomplete penetrance. This family segregates a familial cancer syndrome, familial adenomatous polyposis. Individual II.3 is an obligate carrier, but there are no findings to suggest the disorder. This disorder is nonpenetrant in this individual. **Black,** Affected patients.

**Autosomal Recessive Inheritance**

Autosomal recessive inheritance requires deleterious variants in both copies of a gene to cause disease. Examples include cystic fibrosis and sickle cell disease. Autosomal recessive disorders are characterized by **horizontal transmission**, the observation of multiple affected members of a kindred in the same generation, but no affected family members in other generations (Fig. 97.7). They are associated with a recurrence risk of 25% for carrier parents who have had a previous affected child. Male and female offspring are equally likely to be affected, although some traits exhibit differential expression between sexes. The offspring of consanguineous parents are at increased risk for rare, autosomal recessive traits due to the increased chance that both parents may carry a gene affected by a deleterious mutation that they inherited from a common ancestor. **Consanguinity** between parents of a child with a suspected genetic disorder implies, but certainly does not prove, autosomal recessive inheritance. Although consanguineous unions are uncommon in Western society, in other
parts of the world (southern India, Japan, and the Middle East) as high as 50% of all children may be conceived in consanguineous unions. The risk of a genetic disorder for the offspring of a first-cousin union (6–8%) is about double the risk in the general population (3–4%).

Every individual probably has several rare, deleterious recessive pathogenic sequence variants. Because most pathogenic variants carried in the general population occur at a very low frequency, it does not make economic sense to screen the entire population in order to identify the small number of persons who carry these variants. As a result, these variants typically remain undetected unless an affected child is born to a couple who both carry pathogenic variants affecting the same gene.

However, in some genetic isolates (small populations isolated by geography, religion, culture, or language), certain rare recessive pathogenic variants are much more common than in the general population. Even though there may be no known consanguinity, couples from these genetic isolates have a greater chance of sharing pathogenic alleles inherited from a common ancestor. Screening programs have been developed among some such groups to detect persons who carry common disease-causing variants and therefore are at increased risk for having affected children. A variety of autosomal recessive conditions are more common among Ashkenazi Jews than in the general population. Couples of Ashkenazi Jewish ancestry should be offered prenatal or
preconception screening for Gaucher disease type 1 (carrier rate 1 : 14), cystic fibrosis (1 : 25), Tay-Sachs disease (1 : 25), familial dysautonomia (1 : 30), Canavan disease (1 : 40), glycogen storage disease type 1A (1 : 71), maple syrup urine disease (1 : 81), Fanconi anemia type C (1 : 89), Niemann-Pick disease type A (1 : 90), Bloom syndrome (1 : 100), mucolipidosis IV (1 : 120), and possibly neonatal familial hyperinsulinemic hypoglycemia.

The prevalence of carriers of certain autosomal recessive variants in some larger populations is unusually high. In such cases, heterozygote advantage is postulated. The carrier frequencies of sickle cell disease in the African population and of cystic fibrosis in the northern European population are much higher than would be expected from the rate of new mutations. In these populations, heterozygous carriers may have had an advantage in terms of survival and reproduction over noncarriers. In sickle cell disease the carrier state is thought to confer some resistance to malaria; in cystic fibrosis the carrier state has been postulated to confer resistance to cholera or enteropathogenic Escherichia coli infections. Population-based carrier screening for cystic fibrosis is recommended for persons of northern European and Ashkenazi Jewish ancestry; population-based screening for sickle cell disease is recommended for persons of African ancestry.

If the frequency of an autosomal recessive disease is known, the frequency of the heterozygote or carrier state can be calculated from the Hardy-Weinberg formula:

\[ p^2 + 2pq + q^2 = 1 \]

where \( p \) is the frequency of one of a pair of alleles and \( q \) is the frequency of the other. For example, if the frequency of cystic fibrosis among white Americans is 1 in 2,500 (\( p^2 \)), then the frequency of the heterozygote (2pq) can be calculated: If \( p^2 = 1/2,500 \), then \( p = 1/50 \) and \( q = 49/50 \); \( 2pq = 2 \times (1/50) \times (49/50) = 98/2500 \), or 3.92%.

Pseudodominant Inheritance

Pseudodominant inheritance refers to the observation of apparent dominant (parent to child) transmission of a known autosomal recessive disorder (Fig. 97.8). This occurs when a homozygous affected individual has a partner who is a
heterozygous carrier. This is most likely to occur for relatively common recessive traits within a population, such as sickle cell anemia or nonsyndromic autosomal recessive hearing loss caused by deleterious mutations in the $GJB2$, the gene that encodes connexin 26.

![FIG. 97.8 Pseudodominant inheritance. Black, Affected (deaf); central dot shows carrier who is asymptomatic (unaffected).](image)

**X-Linked Inheritance**

X-linked inheritance describes the inheritance pattern of most disorders caused by deleterious changes in genes located on the X chromosome (Fig. 97.9). In X-linked disorders, males are more commonly affected than females. Female carriers of these disorders are generally unaffected, or if affected, they are affected more mildly than males. In each pregnancy, female carriers have a 25% chance of having an affected son, a 25% chance of having a carrier daughter, and a 50% chance of having a child that does not inherit the mutated X-linked gene. Since affected males pass their X chromosome to all their daughters and their Y chromosome to all their sons, they have a 50% chance of having an unaffected son that does not carry the disease gene and a 50% chance of having a daughter who is a carrier. Male-to-male transmission excludes X-linked inheritance but is seen with autosomal dominant and Y-linked inheritance.
A female occasionally exhibits signs of an X-linked trait similar to a male. This occurs rarely from homozygosity for an X-linked trait or the presence of a sex chromosome abnormality (45,X or 46,XY female) or skewed or nonrandom X-inactivation. X chromosome inactivation occurs early in development and involves the random and irreversible inactivation of most genes on one X chromosome in female cells (Fig. 97.10). In some cases, a preponderance of cells inactivates the same X chromosome, resulting in phenotypic expression of an X-linked pathogenic variant if it resides on the active chromosome. This can occur because of chance, selection against cells that have inactivated the X chromosome carrying the normal gene, or an X chromosome abnormality that results in inactivation of the X chromosome carrying the normal gene.
In some X-linked disorders, both hemizygous males and heterozygous females who carry an affected X–linked gene have similar phenotypic manifestations. In these cases, an affected male will have a 50% chance of having an affected daughter and a 50% chance of having an unaffected son in each pregnancy, whereas half the male and female offspring of an affected woman will be affected (Fig. 97.11). Some X-linked conditions are lethal in a high percentage of males, such as incontinentia pigmenti (see Chapter 614.7). In such cases the pedigree typically shows only affected females and an overall female/male ratio of 2 : 1, with an increased number of miscarriages (Fig. 97.12).
FIG. 97.11 Pedigree pattern demonstrating X-linked dominant inheritance. Black, Affected patients. Note there is no father-to-son transmission in this situation, and hemizygosity (i.e., X-linked gene in a male) is not lethal. In some X-linked dominant conditions, X-linked males have a more severe phenotype and might not survive. In that case, only females manifest the disease (see Fig. 97.12).

FIG. 97.12 Pedigree of an X-linked dominant disorder with male lethality, such as incontinentia pigmenti. Black, Affected patients.

Y-Linked Inheritance

There are few Y-linked traits. These demonstrate only male-to-male transmission, and only males are affected (Fig. 97.13). Most Y-linked genes are
related to male sex determination and reproduction and are associated with infertility. Therefore, it is rare to see familial transmission of a Y-linked disorder. However, advances in assisted reproductive technologies might make it possible to have familial transmission of male infertility.

**FIG. 97.13** Y-linked inheritance. *Black, Affected patients.*

### Inheritance Associated With Pseudoautosomal Regions

Of special note are the pseudoautosomal regions on the X and Y chromosomes. Since these regions are made up of homologous sequences of nucleotides, genes that are located in these regions are present in equal numbers among both males and females. *SHOX* is one of the best-characterized disease genes located in these regions. Heterozygous *SHOX* mutations cause Leri-Weil *dyschondrostosis*, a rare skeletal dysplasia that involves bilateral bowing of the forearms with dislocations of the ulna at the wrist and generalized short stature. Homozygous *SHOX* mutations cause the much more severe Langer *mesomelic dwarfism*.

### Digenic Inheritance

Digenic inheritance explains the occurrence of *retinitis pigmentosa (RP)* in children of parents who each carry a pathogenic variant in a different RP-associated gene (Fig. 97.14). Both parents have normal vision, as would be
expected, but their offspring who are **double heterozygotes**—having inherited both mutations—develop RP. Digenic pedigrees can exhibit characteristics of both autosomal dominant (vertical transmission) and autosomal recessive inheritance (1 in 4 recurrence risk). A couple in which the 2 unaffected partners are carriers for mutation in 2 different RP-associated genes that show digenic inheritance have a 1 in 4 risk of having an affected child, similar to what is seen in autosomal recessive inheritance. However, their affected children, and affected children in subsequent generations, have a 1 in 4 risk of transmitting both mutations to their offspring, who would be affected (vertical transmission).

![Digenic pedigree](image)

**FIG. 97.14** Digenic pedigree. Here, the disease alleles are $a$ and $b$ and they reside on distinct genetic loci or genes. For a person to have the disease, heterozygosity for mutant alleles in both genes $(A/a; B/b)$ is required. **Black**, Affected patients.

**Pseudogenetic Inheritance and Familial Clustering**

Sometimes nongenetic reasons for the occurrence of a particular disease in multiple family members can produce a pattern that mimics genetic transmission. These nongenetic factors can include identifiable environmental factors, teratogenic exposures, or as yet undetermined or undefined factors. Examples of identifiable factors might include multiple siblings in a family having asthma because of exposure to cigarette smoke from their parents or having failure to thrive, developmental delay, and unusual facial appearance
caused by exposure to alcohol during pregnancy.

In some cases the disease is sufficiently common in the general population that some familial clustering occurs simply by chance. Breast cancer affects 11% of all women, and it is possible that several women in a family will develop breast cancer even in the absence of a genetic predisposition. However, hereditary breast cancer associated with mutations in \textit{BRCA1} and \textit{BRCA2} should be suspected in any individual who has a personal history of breast cancer with onset before age 50, early-onset breast and ovarian cancer at any age, bilateral or multifocal breast cancer, a family history of breast cancer or breast and ovarian cancer consistent with autosomal dominant inheritance, or a personal or family history of male breast cancer.

Nonetheless, such clustering within families may be caused by as yet undefined genetic factors or unidentified pathogenic sequence variants (nuclear or mitochondrial).

\textbf{Nontraditional Inheritance}

Some genetic disorders are inherited in a manner that does not follow classical mendelian patterns. Nontraditional inheritance is seen in mitochondrial disorders, triplet repeat expansion diseases, and imprinting defects.

\textbf{Mitochondrial Inheritance}

An individual's mitochondrial genome is entirely derived from the mother because sperm contain relatively few mitochondria, and these are degradated after fertilization. It follows that \textit{mitochondrial inheritance} is essentially \textit{maternal inheritance}. A woman with a mitochondrial genetic disorder can have affected offspring of either sex, but an affected father cannot pass on the disease to his offspring (\textit{Fig. 97.15 }). Mitochondrial DNA mutations are often deletions or point mutations; overall, 1 person in 400 has a maternally inherited pathogenic mitochondrial DNA mutation (see \textit{Chapter 106 }). In individual families, mitochondrial inheritance may be difficult to distinguish from autosomal dominant or X-linked inheritance, but in many cases, the sex of the transmitting and nontransmitting parents can suggest a mitochondrial basis (\textit{Table 97.1 }).

mtDNA, Mitochondrial DNA; rRNA, ribosomal RNA; tRNA, transfer RNA.

The mitochondria are the cell's suppliers of energy, and it is not surprising that the organs that are most affected by the presence of abnormal mitochondria are those that have the greatest energy requirements, such as the brain, muscle, heart, and liver (see Chapters 105.4, 388, 616.2, and 629.4) (Fig. 97.16). Common manifestations include developmental delay, seizures, cardiac dysfunction, decreased muscle strength and tone, and hearing and vision problems.
Mitochondrial diseases can be highly variable in clinical manifestation. This is partly because cells can contain multiple mitochondria, each bearing several copies of the mitochondrial genome. Thus a cell can have a mixture of normal and abnormal mitochondrial genomes, which is referred to as \textbf{heteroplasmy}. In contrast, \textbf{homoplasmy} refers a state in which all copies of the mitochondrial genome carry the same sequence variant. Unequal segregation of mitochondria carrying normal and abnormal genomes and replicative advantage can result in varying degrees of heteroplasmy in the cells of an affected individual, including the individual ova of an affected female. Because of this, a mother may be
asymptomatic yet have children who are severely affected. The level of heteroplasmy at which disease symptoms typically appear can also vary based on the type of mitochondrial variant. Detection of mitochondrial genome variants can require sampling of the affected tissue for DNA analysis. In some tissues, such as blood, testing for mitochondrial DNA variants may be inadequate because the variant may be found primarily in affected tissues such as muscle (Fig. 97.17).

Growth and differentiation factor 15 (GDF-15) and blood lactate levels are
screening tests for mitochondrial disorders.

**Triplet Repeat Expansion Disorders**

Triplet repeat expansion disorders are distinguished by the special dynamic nature of the disease-causing variant. Triplet repeat expansion disorders include fragile X syndrome, myotonic dystrophy, Huntington disease, and spinocerebellar ataxias (Table 97.2 and Fig. 97.18). These disorders are caused by expansion in the number of 3-bp repeats. The fragile X gene, *FMR1*, normally has 5-40 CGG triplets. An error in replication can result in expansion of that number to a level in the gray zone between 41 and 58 repeats, or to a level referred to as **premutation**, which comprises 59-200 repeats. Some premutation carriers, more often males, develop fragile X–associated tremor/ataxia syndrome (FXTAS) as adults. Female premutation carriers are at risk for fragile X–associated primary ovarian insufficiency (*FXPOI*). Persons with a premutation are also at risk for having the repeat expand further in subsequent meiosis, thus crossing into the range of a **full mutation** (>200 repeats) in offspring. With this number of repeats, the *FMR1* gene becomes hypermethylated, and protein production is lost.

</table>

Some triplet expansions associated with other genes can cause disease through a mechanism other than decreased protein production. In Huntington disease the expansion causes the gene product to have a new, toxic effect on the neurons of the basal ganglia. For most triplet repeat disorders, there is a clinical correlation to the size of the expansion, with a greater expansion causing more severe symptoms and having an earlier age of disease onset. The observation of increasing severity of disease and early age at onset in subsequent generations is termed genetic anticipation and is a defining characteristic of many triplet repeat expansion disorders (Fig. 97.19).
Myotonic dystrophy pedigree illustrating genetic anticipation. In this case the age at onset for family members affected with an autosomal dominant disease is lower in more recent generations. Black, Affected patients.

Genetic Imprinting

The 2 copies of most autosomal genes are functionally equivalent. However, in some cases, only 1 copy of a gene is transcribed and the 2nd copy is silenced. This gene silencing is typically associated with methylation of DNA, which is an epigenetic modification, meaning it does not change the nucleotide sequence of the DNA (Fig. 97.20). In imprinting, gene expression depends on the parent of origin of the chromosome (see Chapter 98.8). Imprinting disorders result from an imbalance of active copies of a given gene, which can occur for several reasons. Prader-Willi and Angelman syndromes, two distinct disorders associated with developmental impairment, are illustrative. Both can be caused by microdeletions of chromosome 15q11-12. The microdeletion in Prader-Willi syndrome is always on the paternally derived chromosome 15, whereas in Angelman syndrome it is on the maternal copy. UBE3A is the gene responsible for Angelman syndrome. The paternal copy of UBE3A is transcriptionally silenced in the brain, and the maternal copy continues to be transcribed. If an individual has a maternal deletion, an insufficient amount of UBE3A protein is produced in the brain, resulting in the neurologic deficits seen in Angelman syndrome.
Uniparental disomy (UPD), the rare occurrence of a child inheriting both copies of a chromosome from the same parent, is another genetic mechanism that can cause Prader-Willi and Angelman syndromes. Inheriting both chromosomes 15 from the mother is functionally the same as deletion of the paternal 15q12 and results in Prader-Willi syndrome. Approximately 30% of cases of Prader-Willi syndrome are caused by maternal UPD15, whereas paternal UPD15 accounts for only 3% of Angelman syndrome (see Chapter 98.8).

A mutation in an imprinted gene is another cause. Pathologic variants in UBE3A account for almost 11% of patients with Angelman syndrome and also result in familial transmission. The most uncommon cause is a mutation in the imprinting center, which results in an inability to correctly imprint UBE3A. In a woman, inability to reset the imprinting on her paternally inherited chromosome 15 imprint results in a 50% risk of passing on an incorrectly methylated copy of UBE3A to a child, who would then develop Angelman syndrome.

Besides 15q12, other imprinted regions of clinical interest include the short arm of chromosome 11, where the genes for Beckwith-Wiedemann syndrome...
and nesidioblastosis map, and the long arm of chromosome 7 with maternal UPD of 7q, which has been associated with some cases of idiopathic short stature and Russell-Silver syndrome.

Imprinting of a gene can occur during gametogenesis or early embryonic development (reprogramming). Genes can become inactive or active by various mechanisms including DNA methylation or demethylation or histone acetylation or deacetylation, with different patterns of (de)methylation noted on paternal or maternal imprintable chromosome regions. Some genes demonstrate tissue-specific imprinting (see Fig. 97.20). Several studies suggest a small but significantly increased incidence of imprinting disorders, specifically Beckwith-Wiedemann and Angelman syndrome, associated with assisted reproductive technologies such as in vitro fertilization and intracytoplasmic sperm injection. However, the overall incidence of these disorders in children conceived using assisted reproductive technologies is likely to be <1%.

**Multifactorial and Polygenic Inheritance**

**Multifactorial inheritance** refers to traits that are caused by a combination of inherited, environmental, and stochastic factors (Fig. 97.21). Multifactorial traits differ from **polygenic inheritance**, which refers to traits that result from the additive effects of multiple genes. Multifactorial traits segregate within families but do not exhibit a consistent or recognizable inheritance pattern. Characteristics include the following:

![The progressive decrease in the genetic load contributing to Multifactorial and Polygenic Inheritance](image)

**FIG. 97.21** The progressive decrease in the genetic load contributing to
the development of a disease creates a smooth transition in the distribution of illnesses on an etiologic diagram. In theory, no diseases are completely free from the influence of both genetic and environmental factors. (From Bomprezzi R, Kovanen PE, Martin R: New approaches to investigating heterogeneity in complex traits, J Med Genet 40:553–559, 2003. Reproduced with permission from the BMJ Publishing Group.)

◆ There is a similar rate of recurrence among all first-degree relatives (parents, siblings, offspring of affected child). It is unusual to find a substantial increase in risk for relatives related more distantly than second degree to the index case.
◆ The risk of recurrence is related to the incidence of the disease.
◆ Some disorders have a sex predilection, as indicated by an unequal male:female incidence. Pyloric stenosis, for example, is more common in males, whereas congenital dislocation of the hips is more common in females. With an altered sex ratio, the risk is higher for the relatives of an index case whose gender is less often affected than relatives of an index case of the more frequently affected gender. For example, the risk to the son of an affected female with infantile pyloric stenosis is 18%, compared with the 5% risk for the son of an affected male. An affected female presumably has a greater genetic susceptibility, which she can then pass on to her offspring.
◆ The likelihood that both identical twins will be
affected with the same malformation is <100% but much greater than the chance that both members of a nonidentical twin pair will be affected. This contrasts with the pattern seen in mendelian inheritance, in which identical twins almost always share fully penetrant genetic disorders.

◆ The risk of recurrence is increased when multiple family members are affected. A simple example is that the risk of recurrence for unilateral cleft lip and palate is 4% for a couple with 1 affected child and increases to 9% with 2 affected children. It is sometimes difficult to distinguish between a multifactorial and mendelian etiology in families with multiple affected individuals.

◆ The risk of recurrence may be greater when the disorder is more severe. For example, an infant who has long-segment Hirschsprung disease has a greater chance of having an affected sibling than the infant who has short-segment Hirschsprung disease.

There are two types of multifactorial traits. One exhibits continuous variation, with “normal” individuals falling within a statistical range—often defined as having a value 2 standard deviations (SDs) above and/or below the mean—and “abnormals” falling outside that range. Examples include such traits as intelligence, blood pressure, height, and head circumference. For many of these traits, offspring values can be estimated based on a modified average of their parental values, with nutritional and environmental factors playing an important role.

With other multifactorial traits, the distinction between normal and abnormal is based on the presence or absence of a particular trait. Examples include
pyloric stenosis, neural tube defects, congenital heart defects, and cleft lip and cleft palate. Such traits follow a **threshold model** (see Fig. 97.15). A distribution of liability because of genetic and nongenetic factors is postulated in the population. Individuals who exceed a threshold liability develop the trait, and those below the threshold do not.

The balance between genetic and environmental factors is demonstrated by neural tube defects. Genetic factors are implicated by the increased recurrence risk for parents of an affected child compared with the general population, yet the recurrence risk is about 3%, less than what would be expected if the trait was caused by a single, fully penetrant mutation. The role of nongenetic environmental factors is shown by the recurrence risk decreasing up to 87% if the mother-to-be takes 4 mg of folic acid daily starting 3 mo before conception.

Many adult-onset diseases behave as if caused by multifactorial inheritance. Diabetes, coronary artery disease, and schizophrenia are examples.

**Bibliography**

Clinical cytogenetics is the study of chromosomes: their structure, function, inheritance, and abnormalities. Chromosome abnormalities are very common and occur in approximately 1–2% of live births, 5% of stillbirths, and 50% of early fetal losses in the 1st trimester of pregnancy (Table 98.1). Chromosome abnormalities are more common among individuals with intellectual disability and play a significant role in the development of some neoplasias.

* Recent studies show the prevalence is currently 1:580.

Chromosome analyses are indicated in persons presenting with multiple congenital anomalies, dysmorphic features, and/or intellectual disability. The specific indications for studies include advanced maternal age (>35 yr), multiple abnormalities on fetal ultrasound (prenatal testing), multiple congenital anomalies, unexplained growth restriction in the fetus, postnatal problems in growth and development, ambiguous genitalia, unexplained intellectual disability with or without associated anatomic abnormalities, primary amenorrhea or infertility, recurrent miscarriages (≥3) or prior history of stillbirths and neonatal deaths, a first-degree relative with a known or suspected structural chromosome abnormality, clinical findings consistent with a known anomaly, some malignancies, and chromosome breakage syndromes (e.g., Bloom syndrome, Fanconi anemia).

98.1

Methods of Chromosome Analysis

*Carlos A. Bacino, Brendan Lee*

Cytogenetic studies are usually performed on peripheral blood lymphocytes, although cultured fibroblasts obtained from a skin biopsy may also be used. Prenatal (fetal) chromosome studies are performed with cells obtained from the amniotic fluid (amniocytes), chorionic villus tissue, and fetal blood or, in the case of preimplantation diagnosis, by analysis of a blastomere (cleavage stage)
biopsy, polar body biopsy, or blastocyst biopsy. Cytogenetic studies of bone marrow have an important role in tumor surveillance, particularly among patients with leukemia. These are useful to determine induction of remission and success of therapy or in some cases the occurrence of relapses.

Chromosome anomalies include abnormalities of number and structure and are the result of errors during cell division. There are 2 types of cell division: mitosis, which occurs in most somatic cells, and meiosis, which is limited to the germ cells. In \textbf{mitosis}, 2 genetically identical daughter cells are produced from a single parent cell. DNA duplication has already occurred during \textbf{interphase} in the S phase of the cell cycle (DNA synthesis). Therefore, at the beginning of mitosis the chromosomes consist of 2 double DNA strands joined together at the centromere, known as \textit{sister chromatids}. Mitosis can be divided into 4 stages: prophase, metaphase, anaphase, and telophase. \textbf{Prophase} is characterized by condensation of the DNA. Also during prophase, the nuclear membrane and the nucleolus disappear and the mitotic spindle forms. In \textbf{metaphase} the chromosomes are maximally compacted and are clearly visible as distinct structures. The chromosomes align at the center of the cell, and spindle fibers connect to the centromere of each chromosome and extend to centrioles at the 2 poles of the mitotic figure. In \textbf{anaphase} the chromosomes divide along their longitudinal axes to form 2 daughter chromatids, which then migrate to opposite poles of the cell. \textbf{Telophase} is characterized by formation of 2 new nuclear membranes and nucleoli, duplication of the centrioles, and cytoplasmic cleavage to form the 2 daughter cells.

\textbf{Meiosis} begins in the female oocyte during fetal life and is completed years to decades later. In males it begins in a particular spermatogonial cell sometime between adolescence and adult life and is completed in a few days. Meiosis is preceded by DNA replication so that at the outset, each of the 46 chromosomes consists of 2 chromatids. In meiosis, a \textbf{diploid cell} (2n = 46 chromosomes) divides to form 4 \textbf{haploid cells} (n = 23 chromosomes). Meiosis consists of 2 major rounds of cell division. In \textbf{meiosis I}, each of the homologous chromosomes pair precisely so that \textbf{genetic recombination}, involving exchange between 2 DNA strands (\textit{crossing over}), can occur. This results in reshuffling of the genetic information for the recombined chromosomes and allows further genetic diversity. Each daughter cell then receives 1 of each of the 23 homologous chromosomes. In oogenesis, one of the daughter cells receives most of the cytoplasm and becomes the egg, whereas the other smaller cell becomes the first polar body. \textbf{Meiosis II} is similar to a mitotic division but without a
preceding round of DNA duplication (replication). Each of the 23 chromosomes divides longitudinally, and the homologous chromatids migrate to opposite poles of the cell. This produces 4 spermatagonia in males, or an egg cell and a 2nd polar body in females, each with a haploid ($n = 23$) set of chromosomes. Consequently, meiosis fulfills 2 crucial roles: It reduces the chromosome number from diploid (46) to haploid (23) so that on fertilization a diploid number is restored, and it allows genetic recombination.

Two common errors of cell division may occur during meiosis or mitosis, and either can result in an abnormal number of chromosomes. The 1st error is **nondisjunction**, in which 2 chromosomes fail to separate during meiosis and thus migrate together into one of the new cells, producing 1 cell with 2 copies of the chromosome and another with no copy. The 2nd error is **anaphase lag**, in which a chromatid or chromosome is lost during mitosis because it fails to move quickly enough during anaphase to become incorporated into 1 of the new daughter cells (Fig. 98.1).
For chromosome analysis, cells are cultured (for varying periods depending on cell type), with or without stimulation, and then artificially arrested in mitosis during metaphase (or prometaphase), later subjected to a hypotonic solution to allow disruption of the nuclear cell membrane and proper dispersion of the chromosomes for analysis, fixed, banded, and finally stained. The most
commonly used banding and staining method is the **GTG banding** (G-bands trypsin Giemsa), also known as **G banding**, which produces a unique combination of dark (G-positive) and light (G-negative) bands that permits recognition of all individual 23 chromosome pairs for analysis.

Metaphase chromosome spreads are first evaluated microscopically, and then their images are photographed or captured by a video camera and stored on a computer for later analysis. Humans have 46 chromosomes or 23 pairs, which are classified as **autosomes** for chromosomes 1-22, and the **sex chromosomes**, often referred as **sex complement**: XX for females and XY for males. The homologous chromosomes from a metaphase spread can then be paired and arranged systematically to assemble a karyotype according to well-defined standard conventions such as those established by International System for Human Cytogenetic Nomenclature (ISCN), with chromosome 1 being the largest and 22 the smallest. According to nomenclature, the description of the karyotype includes the total number of chromosomes followed by the sex chromosome constitution. A normal karyotype is 46,XX for females and 46,XY for males (**Fig. 98.2**). Abnormalities are noted after the sex chromosome complement.

**Fig. 98.2** Karyotype of a normal male at the 550-600 band level. The longer the chromosomes are captured at metaphase or sometimes prometaphase, the more bands that can be visualized.
Although the internationally accepted system for human chromosome classification relies largely on the length and banding pattern of each chromosome, the position of the centromere relative to the ends of the chromosome also is a useful distinguishing feature (Fig. 98.3). The centromere divides the chromosome in 2, with the short arm designated the p arm and the long arm designated the q arm. A plus or minus sign before the number of a chromosome indicates that there is an extra or missing chromosome, respectively. Table 98.2 lists some of the abbreviations used for the descriptions of chromosomes and their abnormalities. A metaphase chromosome spread usually shows 450-550 bands. Prophase and prometaphase chromosomes are longer, are less condensed, and often show 550-850 bands. High-resolution analysis may detect small chromosome abnormalities although has been mostly replaced by chromosome microarray studies (array CGH or aCGH).

![Figure 98.3](image-url)

**Figure 98.3** Example of different chromosome types according to the position of the centromere. On the left is a chromosome 1 pair with the centromere equidistant from the short and long arm (also known as metacentric). In the center is a chromosome 11 pair that is submetacentric. On the right is a chromosome 13 pair that is an example of an acrocentric chromosome. Acrocentric chromosomes contain a very small short arm, stalks, and satellite DNA. The black arrow indicates the position of the centromere. The blue arrow shows the long arm of a chromosome. The red arrow shows the short arm of a chromosome. The green arrow highlights the satellite region, which is made of DNA repeats. The light area between the short arm and the satellite is known as the stalk.

of cells | Mosaicism in Klinefelter syndrome with 12 normal cells and 10 cells with an extra X chromosome
---|---
cen | Centromere

del | Deletion | 46,XY,del(5p) | Male with deletion of chromosome 5 short arm

der | Derivative | 46,XX,der(2),t(2p12;7q13) | Female with a structurally rearranged chromosome 2 that resulted from a translocation between chromosomes 2 (short arm) and 7 (long arm)
dup | Duplication | 46,XY,dup(15)(q11-q13) | Male with interstitial duplication in the long arm of chromosome 15 in the Prader-Willi/Angelman syndrome region

ins | Insertion | 46,XY,ins(3)(p13q21q26) | Male with an insertion within chromosome 3

inv | Inversion | 46,XY,inv(2)(p21q31) | Male with pericentric inversion of chromosome 2 with breakpoints at bands p21 and q31

ish | Metaphase FISH | 46,XX,ish del(7) (q11.23q11.23) | Female with deletion in the Williams syndrome region detected by in situ hybridization

nuc ish | Interphase FISH | nuc ish(DXZ1 × 3) | Interphase in situ hybridization showing 3 signals for the X chromosome centromeric region

mar | Marker | 47,XY,+mar | Male with extra, unidentified chromosome material

mos | Mosaic | mos 45,X[14]/46,XX[16] | Turner syndrome mosaicism (analysis of 30 cells showed that 14 cells were 45,X and 16 cells were 46,XX)
p | Short arm | 46,XY,del(5)(p12) | Male with a deletion on the short arm of chromosome 5, band p12 (short nomenclature)

q | Long arm | 46,XY,del(5)(q14) | Male with a deletion on the long arm of chromosome 5, band 14

r | Ring chromosome | 46,X,r(X)(p21q27) | Female with 1 normal X chromosome and a ring X chromosome

t | Translocation | t(2;8)(q33;q24.1) | Interchange of material between chromosomes 2 and 8 with breakpoints at bands 2q33 and 8q24.1

ter | Terminal | 46,XY,del(5)(p12-pter) | Male with a deletion of chromosome 5 between p12 and the end of the short arm (long nomenclature)

/ | Slash | 45,X/46,XY | Separate lines or clones

+ | Gain of | 47,XX,+21 | Female with trisomy 21

− | Loss of | 45,XY,−21 | Male with monosomy 21

Molecular techniques (e.g., FISH, CMA, aCGH) have filled a significant void for the diagnosing cryptic chromosomal abnormalities. These techniques identify subtle abnormalities that are often below the resolution of standard cytogenetic studies. **Fluorescence in situ hybridization (FISH)** is used to identify the presence, absence, or rearrangement of specific DNA segments and is performed with gene- or region-specific DNA probes. Several FISH probes are used in the clinical setting: unique sequence or single-copy probes, repetitive-sequence probes (alpha satellites in the pericentromeric regions), and multiple-copy probes (chromosome specific or painting) (Fig. 98.4A and B). FISH involves using a unique, known DNA sequence or probe labeled with a fluorescent dye that is complementary to the studied region of disease interest. The labeled probe is exposed to the DNA on a microscope slide, typically metaphase or interphase
chromosomal DNA. When the probe pairs with its complementary DNA sequence, it can then be visualized by fluorescence microscopy (Fig. 98.5). In metaphase chromosome spreads, the exact chromosomal location of each probe copy can be documented, and often the number of copies (deletions, duplications) of the DNA sequence as well. When the interrogated segments (as in genomic duplications) are close together, only interphase cells can accurately determine the presence of 2 or more copies or signals since in metaphase cells, some duplications might falsely appear as a single signal.
FIG. 98.4  A, FISH analysis of interphase peripheral blood cells from a patient with Down syndrome using a chromosome 21–specific probe. The 3 red signals mark the presence of 3 chromosomes 21. B, FISH analysis of a metaphase chromosome spread from a clinically normal individual using a whole chromosome paint specific for chromosome 5. Both chromosomes 5 are completely labeled (yellow) along their entire length. C, FISH on metaphase cells using a unique sequence probe that hybridizes to the elastin gene on chromosome 7q11.23, inside the Williams syndrome critical region. The elastin probe is labeled in red, and a control probe on chromosome 7 is labeled in green. The left image shows normal hybridization to chromosome 7, with 2 signals for the elastin region and 2 for the control probe. The right image shows a normal chromosome on the right with control and elastin signals, and a deleted chromosome 7 on the left, evidenced by a single signal for the control probe. This image corresponds to a patient with a Williams syndrome region deletion. D, FISH in interphase cells using DNA probes that hybridize to repetitive α-satellite sequences in the pericentromeric region for the sex chromosomes. Left, interphase cells with 2 signals, 1 labeled in red for the X chromosome and green for the Y chromosome, consistent with a normal male chromosome complement. Right, interphase cell showing 2 red signals for the X chromosome, compatible with a normal female chromosome complement.
FIG. 98.5  FISH involves denaturation of double-stranded DNA as present in metaphase chromosomes or interphase nuclei on cytogenetic slide preparations (A) into single-stranded DNA (B). The slide-bound (in situ) DNA is then renatured or reannealed in the presence of excess copies of a single-stranded, fluorochrome-labeled DNA base-pair sequence or probe (C). The probe anneals or “hybridizes” to sites of complementary DNA sequence (D) within the chromosomal genome. Probe signal is visualized and imaged on the chromosome by fluorescent microscopy. (From Lin RL, Cherry AM, Bangs CD, et al: FISHing for answers: the use of molecular cytogenetic techniques in adolescent medicine practice. In Hyme HE, Greydanus D, editors: Genetic disorders in adolescents: state of the art reviews. Adolescent medicine, Philadelphia, 2002, Hanley and Belfus, pp. 305–313.)

Chromosome rearrangements <5 million bp (5 Mbp) cannot be detected by conventional cytogenetic techniques. FISH was initially used to detect deletions as small as 50-200 kb of DNA and facilitated the early clinical characterization of a number of microdeletion syndromes. Some FISH probes hybridize to repetitive sequences located in the pericentromeric regions. Pericentromeric probes are still widely used for the rapid identification of certain trisomies in interphase cells of blood smears, or even in the rapid analysis of prenatal samples from cells obtained through amniocentesis. Such probes are available
for chromosomes 13, 18, and 21 and for the sex pair X and Y (see Fig. 98.4C and D). With regard to the detection of genomic disorders, FISH is no longer the first line of testing, and its role has also mostly changed to the confirmation of microarray findings. In summary, FISH is reserved for (1) confirmation studies of abnormalities detected by CMA, (2) rapid prenatal screening on interphase amniotic fluid cells, and (3) interphase blood smear for sex assignment of newborns who present with ambiguous genitalia.

**Array comparative genomic hybridization (aCGH) and chromosomal microarray (CMA)** are molecular-based techniques that involve differentially labeling the patient's DNA with a fluorescent dye (green fluorophore) and a normal reference DNA with a red fluorophore (Fig. 98.6). Oligonucleotides (short DNA segments) encompassing the entire genome are spotted onto a slide or microarray grid. Equal amounts of the 2-label DNA samples are mixed, and the green:red fluorescence ratio is measured along each tested area. Regions of amplification of the patient's DNA display an excess of green fluorescence, and regions of loss show excess red fluorescence. If the patient's and the control DNA are equally represented, the green:red ratio is 1 : 1, and the tested regions appear yellow (see Chapter 96, Fig. 96.5). The detection is currently possible at the single-exon resolution level, depending on the arrays used. In the near future, copy number detections may further evolve to be detected by next generation sequencing in the context of whole genome sequencing.
FIG. 98.6 Example of a cryptic microdeletion at a translocation breakpoint of an apparently balanced translocation in a patient with developmental delay (dd) and growth defect. A, Partial karyotype shows t(15;22)(q26.1;q11.2). B, FISH with clones 2O19 (green) and 354M14 (red) at 15q26.1; arrows indicate signals only present on the normal chromosome 15, suggesting a deletion on the der(15). C, Two-color aCGH with dye swap with 244 K oligo probes; arrowhead indicates a 3.3-Mbp deletion at chromosome 15q26.1-q26.2, arrow points to the close-up view of the deletion. (From Li MM, Andersson HC: Clinical application of microarray-based molecular cytogenetics: an emerging new era of genomic medicine, J Pediatr 155:311–317, 2009, with permission of the authors and publisher.)

The many advantages of aCGH include its ability to test all critical disease-causing regions in the genome at once, detect duplications and deletions not currently recognized as recurrent disease-causing regions probed by FISH, and detect single-gene and contiguous gene deletion syndromes. Also, aCGH does
not always require cell culture to generate sufficient DNA, which may be important in the context of prenatal testing because of timing. Limitations of aCGH are that it does not detect balanced translocations or inversions and may not detect low levels of chromosomal mosaicism. Among different types of aCGH, some are more targeted than others. **Targeted aCGH** can be an efficient way to detect clinically known cryptic chromosomal aberrations, which are typically associated with known disease phenotypes. **Whole genome arrays** target the entire genome and allow better and denser coverage in evenly spaced genomic regions. Its disadvantage is that interpretation of deletions or duplications may be difficult if it involves areas not previously known to be involved in disease.

A frequently used array in the clinical setting is the **single nucleotide polymorphism (SNP)**. SNPs are polymorphic variations between 2 nucleotides, and when analyzed in massive parallel fashion, they can provide valuable clinical information. Several million SNPs normally occur in the human genome. SNP arrays can help with the detection of **uniparental disomies** (i.e., genetic information derived from only 1 parent), as well as consanguinity in the family. Many arrays currently used in clinical practice combine the use of oligonucleotides for the detection of **copy number variations** in conjunction with SNPs. There are many copy number variations causing deletion or duplication in the human genome. Thus, most detected genetic abnormalities, unless associated with well-known clinical phenotypes, require **parental investigations** because a detected copy number variation that is inherited could be benign or an incidental polymorphic variant. A **de novo** abnormality (i.e., one found only in the child and not the parents) is often more significant if it is associated with an abnormal phenotype found only in the child, and if it involves genes with important functions.

aCGH is a very valuable technology alone or when combined with FISH and conventional chromosome studies (Fig. 98.7).
FIG. 98.7 aCGH in a female patient with Down syndrome. Each black dot represents a piece of DNA segment specific for different chromosome location. Most of the dots displayed between the 0.0 and 0.2 axis are considered within normal range. Exceptions are often a result of polymorphic variations. A group of dots colored in green clusters on chromosome 21 and above 0.5. These represent a gain in copy number of DNA segments for chromosome 21, as seen in Down syndrome and consistent with trisomy 21.

Down Syndrome and Other Abnormalities of Chromosome Number

Brendan Lee

Aneuploidy and Polyploidy

Human cells contain a multiple of 23 chromosomes (n = 23). A haploid cell (n) has 23 chromosomes (typically in the ovum or sperm). If a cell's chromosomes are an exact multiple of 23 (46, 69, 92 in humans), those cells are referred to as euploid. Polyploid cells are euploid cells with more than the normal diploid
number of 46 (2n) chromosomes: 3n, 4n. Polyploid conceptions are usually not viable, but the presence of mosaicism with a karyotypically normal cell line can allow survival. Mosaicism is an abnormality defined as the presence of 2 or more cell lines in a single individual. Polyploidy is a common abnormality seen in 1st-trimester pregnancy losses. Triploid cells are those with 3 haploid sets of chromosomes (3n) and are only viable in a mosaic form. Triploid infants can be liveborn but do not survive long. Triploidy is often the result of fertilization of an egg by 2 sperm (dispermy). Failure of 1 of the meiotic divisions, resulting in a diploid egg or sperm, can also result in triploidy. The phenotype of a triploid conception depends on the origin of the extra chromosome set. If the extra set is of paternal origin, it results in a partial hydatidiform mole (excessive placental growth) with poor embryonic development, but triploid conceptions that have an extra set of maternal chromosomes results in severe embryonic restriction with a small, fibrotic placenta (insufficient placental development) that is typically spontaneously aborted.

Abnormal cells that do not contain a multiple of haploid number of chromosomes are termed aneuploid cells. Aneuploidy is the most common and clinically significant type of human chromosome abnormality, occurring in at least 3–4% of all clinically recognized pregnancies. Monosomies occur when only 1, instead of the normal 2, of a given chromosome is present in an otherwise diploid cell. In humans, most autosomal monosomies appear to be lethal early in development, and survival is possible in mosaic forms or by means of chromosome rescue (restoration of the normal number by duplication of single monosomic chromosome). An exception to this rule is monosomy for the X chromosome (45,X), seen in Turner syndrome; the majority of 45,X conceptuses are believed to be lost early in pregnancy for as yet unexplained reasons.

The most common cause of aneuploidy is nondisjunction, the failure of chromosomes to disjoin normally during meiosis (see Fig. 98.1). Nondisjunction can occur during meiosis I or II or during mitosis, although maternal meiosis I is the most common nondisjunction in aneuploidies (e.g., Down syndrome, trisomy 18). After meiotic nondisjunction, the resulting gamete either lacks a chromosome or has 2 copies instead of 1 normal copy, resulting in a monosomic or trisomic zygote, respectively.

Trisomy is characterized by the presence of 3 chromosomes, instead of the normal 2, of any particular chromosome. Trisomy is the most common form of aneuploidy. Trisomy can occur in all cells or it may be mosaic. Most individuals
with a trisomy exhibit a consistent and specific phenotype depending on the chromosome involved.

FISH is a technique that can be used for rapid diagnosis in the prenatal detection of common fetal aneuploidies, including chromosomes 13, 18, and 21, as well as sex chromosomes (see Fig. 98.4C and D). Direct detection of fetal cell-free DNA from maternal plasma for fetal trisomy is a safe and highly effective screening test for fetal aneuploidy. The most common numerical abnormalities in liveborn children include trisomy 21 (Down syndrome), trisomy 18 (Edwards syndrome), trisomy 13 (Patau syndrome), and sex chromosomal aneuploidies: Turner syndrome (usually 45,X), Klinefelter syndrome (47,XXY), 47,XXX, and 47,XYY. By far the most common type of trisomy in liveborn infants is trisomy 21 (47,XX,+21 or 47,XY,+21) (see Table 98.1). Trisomy 18 and trisomy 13 are relatively less common and are associated with a characteristic set of congenital anomalies and severe intellectual disability (Table 98.3). The occurrence of trisomy 21 and other trisomies increases with advanced maternal age (≥35 yr). Because of this increased risk, women who are ≥35 yr old at delivery should be offered genetic counseling and prenatal diagnosis (including serum screening, ultrasonography, and cell-free fetal DNA detection, amniocentesis, or chorionic villus sampling; see Chapter 115).

</tr>
</tbody>
</table>
Down Syndrome

Trisomy 21 is the most common genetic etiology of moderate intellectual disability. The incidence of Down syndrome in live births is approximately 1 in 733; the incidence at conception is more than twice that rate; the difference is accounted for by early pregnancy losses. In addition to cognitive impairment, Down syndrome is associated with congenital anomalies and characteristic dysmorphic features (Figs. 98.8 and 98.9 and Table 98.4). Although there is variability in the clinical features, the constellation of phenotypic features is fairly consistent and permits clinical recognition of trisomy 21. Affected individuals are more prone to congenital heart defects (50%) such as atrioventricular septal defects, ventricular septal defects, isolated secundum atrial septal defects, patent ductus arteriosus, and tetralogy of Fallot. Pulmonary complications include recurrent respiratory infections, sleep-disordered breathing, laryngo- and tracheobronchomalacia, tracheal bronchus, pulmonary hypertension, and asthma. Congenital and acquired gastrointestinal anomalies (celiac disease) and hypothyroidism are common (Table 98.5). Other abnormalities include megakaryoblastic leukemia, immune dysfunction, diabetes mellitus, seizures, alopecia, juvenile idiopathic arthritis, and problems with hearing and vision. Alzheimer disease–like dementia is a known complication that occurs as early as the 4th decade and has an incidence 2-3 times higher than sporadic Alzheimer disease. Most males with Down syndrome are sterile, but some females have been able to reproduce, with a 50% chance of having trisomy 21 pregnancies. Two genes (DYRK1A, DSCR1) in the putative critical region of chromosome 21 may be targets for therapy.
FIG. 98.8  A, Face of a child with Down syndrome. B, Karyotype of a male with trisomy 21 as seen in Down syndrome. This karyotype reveals 47 chromosomes instead of 46, with an extra chromosome in pair 21.

- Hip dysplasia
- Slipped capital femoral epiphyses
- Avascular hip necrosis
- Recurrent joint dislocations (shoulder, knee, elbow, thumb)

**Endocrine**

- Congenital or acquired hypothyroidism
- Diabetes mellitus
- Infertility
- Obesity
- Hyperthyroidism

**Hematologic**

- Transient myeloproliferative syndrome
- Acute lymphocytic leukemia
- Acute myelogenous leukemia

**Gastrointestinal**

- Celiac disease
- Delayed tooth eruption
Respiratory
Obstructed sleep apnea
Frequent infections (sinusitis, nasopharyngitis, pneumonia)

Cutaneous
Hyperkeratosis
Seborrhea
Xerosis
Perigenital folliculitis

Developmental delay is universal (Tables 98.6 and 98.7 and Fig. 98.10). Cognitive impairment does not uniformly affect all areas of development. Social development is often relatively spared, but autism spectrum disorder can occur. Children with Down syndrome have considerable difficulty using expressive language. Understanding the individual developmental strengths and challenges is necessary to maximize the educational process. Persons with Down syndrome often benefit from programs aimed at cognitive training, stimulation, development, and education. Children with Down syndrome also benefit from anticipatory guidance, which establishes the protocol for screening, evaluation, and care for patients with genetic syndromes and chronic disorders (Table 98.8). Up to 15% of children with Down syndrome have misalignment of the 1st cervical vertebra (C1), which places them at risk for spinal cord injury with neck hyperextension or extreme flexion. Special Olympics recommends sports participation and training but requires x-ray examination (full extension and flexion views) of the neck before participation in sports that may result in hyperextension or radical flexion or pressure on the neck or upper spine. Such sports include diving starts in swimming, butterfly stroke, diving, pentathlon, high jump, equestrian sports, gymnastics, football, soccer, alpine skiing, and warm-up exercises placing stress on the head and neck. If atlantoaxial instability is diagnosed, Special Olympics will permit participation if the parents or guardians request so and only after obtaining written certification from a physician and acknowledgment of the risks by the parent or guardian.

IgA, Immunoglobulin A; IgG, immunoglobulin G.

Compared with the general population, children with Down syndrome are at increased risk for behavior problems; psychiatric comorbidity is an estimated 18–38% in this population. Common behavioral difficulties that occur in children with Down syndrome include inattentiveness, stubbornness, and a need for routine and sameness. Aggression and self-injurious behavior are less common in this population than other children with similar degrees of intellectual disability from other etiologies. All these behaviors can respond to educational, behavioral, or pharmacologic interventions.

The life expectancy for children with Down syndrome is reduced and is approximately 50-55 yr. Little prospective information about the secondary medical problems of adults with Down syndrome is known. Retrospective studies have shown premature aging and an increased risk of Alzheimer disease in adults with Down syndrome. These studies have also shown unexpected negative (protective) associations between Down syndrome and comorbidities. Persons with Down syndrome have fewer-than-expected deaths caused by solid tumors and ischemic heart disease. This same study reported increased risk of adult deaths from congenital heart disease, seizures, and leukemia. In one large study, leukemias accounted for 60% of all cancers in people with Down syndrome and 97% of all cancers in children with Down syndrome. There was decreased risk of solid tumors in all age-groups with Down syndrome, including
neuroblastomas and nephroblastomas in children and epithelial tumors in adults.

Most adults with Down syndrome are able to perform activities of daily living. However, most have difficulty with complex financial, legal, or medical decisions, and a guardian may be appointed.

The risk of having a child with trisomy 21 is highest in women who conceive after age 35 yr. Even though younger women have a lower risk, they represent half of all mothers with babies with Down syndrome because of their higher overall birth rate. *All women should be offered screening for Down syndrome* in their 2nd trimester by means of 4 maternal serum tests (free β-human chorionic gonadotropin [β-hCG], unconjugated estriol, inhibin, and α-fetoprotein). This is known as the *quad screen*; it can detect up to 80% of Down syndrome pregnancies vs 70% in the triple screen. Both tests have a 5% false-positive rate. There is a method of screening during the 1st trimester using fetal nuchal translucency (NT) thickness that can be done alone or in conjunction with maternal serum β-hCG and pregnancy-associated plasma protein-A (PAPP-A). In the 1st trimester, NT alone can detect ≤70% of Down syndrome pregnancies, but with β-hCG and PAPP-A, the detection rate increases to 87%. If both 1st- and 2nd-trimester screens are combined using NT and biochemical profiles (integrated screen), the detection rate increases to 95%. If only 1st-trimester quad screening is done, maternal serum α-fetoprotein (which is decreased in affected pregnancies) is recommended as a 2nd-trimester follow-up.

Detection of cell-free fetal DNA in maternal plasma is also diagnostic and replacing conventional 1st- and 2nd-trimester screens. The noninvasive detection of fetal trisomy 21 by analyzing cell-free fetal DNA in maternal serum is an important advance in prenatal diagnosis of Down syndrome. Next-generation DNA sequencing has reduced the cost of this procedure, which has a high degree of accuracy (98% detection rate) and applicability. The prenatal screens are also useful for other trisomies, although the detection rates may be different from those given for Down syndrome. Current tests can detect microdeletions including 22q11.2 deletion syndrome, Angelman syndrome, Prader Willi syndrome deletion, cri du chat syndrome, Williams syndrome, and 1p36.3 deletion syndrome. Importantly, especially for microdeletions, cell-free noninvasive prenatal testing (NIPT) should be considered primarily for screening tests and follow-up invasive testing (e.g., amniocentesis) pursued for definitive diagnosis.

In approximately 95% of the cases of Down syndrome, there are 3 copies of chromosome 21. The origin of the supernumerary chromosome 21 is maternal in
97% of the cases as a result of errors in meiosis. The majority of these occur in maternal meiosis I (90%). Approximately 1% of persons with trisomy 21 are mosaics, with some cells having 46 chromosomes, and another 4% have a translocation that involves chromosome 21. The majority of translocations in Down syndrome are fusions at the centromere between chromosomes 13, 14, 15, 21, and 22, known as robertsonian translocations. The translocations can be de novo or inherited. Very rarely is Down syndrome diagnosed in a patient with only a part of the long arm of chromosome 21 in triplicate (partial trisomy).

Isochromosomes and ring chromosomes are other rarer causes of trisomy 21. Down syndrome patients without a visible chromosome abnormality are the least common. It is not possible to distinguish the phenotypes of persons with full trisomy 21 and those with a translocation. Representative genes on chromosome 21 and their potential effects on development are noted in Table 98.9. Patients who are mosaic tend to have a milder phenotype.

Chromosome analysis is indicated in every person suspected of having Down syndrome. If a translocation is identified, parental chromosome studies must be performed to determine whether one of the parents is a translocation carrier, which carries a high recurrence risk for having another affected child. That parent might also have other family members at risk. Translocation (21;21) carriers have a 100% recurrence risk for a chromosomally abnormal child, and other robertsonian translocations, such as t(14;21), have a 5–7% recurrence risk when transmitted by females. Genomic dosage imbalance contributes through direct and indirect pathways to the Down syndrome phenotype and its phenotypic variation.

Tables 98.10 and 98.11 provide more information on other aneuploidies and partial autosomal aneuploidies (Figs. 98.11 to 98.14).

### 98.3 Abnormalities of Chromosome Structure
Translocations

Translocations, which involve the transfer of material from one chromosome to another, occur with a frequency of 1 in 500 liveborn human infants. They may be inherited from a carrier parent or appear de novo, with no other affected family member. Translocations are usually reciprocal or robertsonian, involving 2 chromosomes (Fig. 98.15).

**FIG. 98.15**  A, Schematic diagram (left) and partial G-banded karyotype (right) of a reciprocal translocation between chromosome 2 (blue) and chromosome 8 (pink). The breakpoints are on the long (q) arm of both chromosomes at bands 2q33 and 8q24.1, with the reciprocal exchange of material between the derivative (der) chromosomes 2 and 8. This translocation is balanced, with no net gain or loss of material. The nomenclature for this exchange is t(2;8)(q33;q24.1). B, Schematic diagram
(left) and partial G-banded karyotype (right) of a robertsonian translocation between chromosomes 13 (blue) and 14 (pink). The breakpoints are at the centromere (band q10) of both chromosomes, with fusion of the long arms into a single derivative chromosome and loss of the short (p) arm material. The nomenclature for this exchange is der(13;14)(q10;q10).

**Reciprocal translocations** are the result of breaks in nonhomologous chromosomes, with reciprocal exchange of the broken segments. Carriers of a reciprocal translocation are usually phenotypically normal but are at an increased risk for miscarriage caused by transmission of unbalanced reciprocal translocations and for bearing chromosomally abnormal offspring. Unbalanced translocations are the result of abnormalities in the segregation or crossover of the translocation carrier chromosomes in the germ cells.

**Robertsonian translocations** involve 2 acrocentric chromosomes (chromosomes 13, 14, 15, 21, and 22) that fuse near the centromeric region with a subsequent loss of the short arms. Because the short arms of all 5 pairs of acrocentric chromosomes have multiple copies of genes encoding for ribosomal RNA, loss of the short arm of 2 acrocentric chromosomes has no deleterious effect. The resulting karyotype has only 45 chromosomes, including the translocated chromosome, which consists of the long arms of the 2 fused chromosomes. Carriers of robertsonian translocations are usually phenotypically normal. However, they are at increased risk for miscarriage and unbalanced translocations in phenotypically abnormal offspring.

In some rare instances, translocations can involve 3 or more chromosomes, as seen in complex rearrangements. Another, less common type is the insertional translocation. **Insertional translocations** result from a piece of chromosome material that breaks away and later is reinserted inside the same chromosome at a different site or inserted in another chromosome.

**Inversions**

An inversion requires that a single chromosome break at 2 points; the broken piece is then inverted and joined into the same chromosome. Inversions occur in 1 in 100 live births. There are 2 types of inversions: pericentric and paracentric. In **pericentric inversions** the breaks are in the 2 opposite arms of the chromosome and include the centromere. They are usually discovered because they change the position of the centromere. The breaks in **paracentric inversions** occur in only 1 arm. Carriers of inversions are usually phenotypically
normal, but they are at increased risk for miscarriages, typically in paracentric inversions, and chromosomally abnormal offspring in pericentric inversions.

Deletions and Duplications

Deletions involve loss of chromosome material and, depending on their location, can be classified as *terminal* (at the end of chromosomes) or *interstitial* (within the arms of a chromosome). They may be isolated or may occur along with a duplication of another chromosome segment. The latter typically occurs in unbalanced reciprocal chromosomal translocation secondary to abnormal crossover or segregation in a translocation or inversion carrier.

A carrier of a deletion is monosomic for the genetic information of the missing segment. Deletions are usually associated with intellectual disability and malformations. The most commonly observed deletions in routine chromosome preparations include 1p−, 4p−, 5p−, 9p−, 11p−, 13q−, 18p−, 18q−, and 21q− (Table 98.12 and Fig. 98.16), all distal or terminal deletions of the short or the long arms of chromosomes. Deletions may be observed in routine chromosome preparations, and deletions and translocations larger than 5-10 Mbp are usually visible microscopically.

### Table 98.12

**Common Deletions and Their Clinical Manifestations**

<table>
<thead>
<tr>
<th>DELETION</th>
<th>CLINICAL ABNORMALITIES</th>
</tr>
</thead>
<tbody>
<tr>
<td>4p−</td>
<td>Wolf-Hirschhorn syndrome. The main features are a typical “Greek helmet” facies secondary to ocular hypertelorism, prominent glabella, and frontal bossing; microcephaly, dolichocephaly, hypoplasia of the orbits, ptosis, strabismus, nystagmus, bilateral epicanthic folds, cleft lip and palate, beaked nose with prominent bridge, hypospadias, cardiac malformations, and intellectual disability.</td>
</tr>
<tr>
<td>5p−</td>
<td>Cri du chat syndrome. The main features are hypotonia, short stature, characteristic shrill cry in the first few weeks of life (also called cat's cry syndrome), microcephaly with protruding metopic suture, hypertelorism, bilateral epicanthic folds, high arched palate, wide and flat nasal bridge, and intellectual disability.</td>
</tr>
<tr>
<td>9p−</td>
<td>The main features are craniofacial dysmorphic features with trigonocephaly, slanted palpebral fissures, discrete exophthalmos secondary to supraorbital hypoplasia, arched eyebrows, flat and wide nasal bridge, short neck with low hairline, genital anomalies, long fingers and toes with extra flexion creases, cardiac malformations, and intellectual disability.</td>
</tr>
<tr>
<td>13q−</td>
<td>The main features are low birthweight, failure to thrive, microcephaly, and severe intellectual disability. Facial features include high, wide nasal bridge; hypertelorism; ptosis; and micrognathia. Ocular malformations are common (retinoblastoma). The hands have hypoplastic or absent thumbs and syndactyly.</td>
</tr>
<tr>
<td>18p−</td>
<td>A few patients (15%) are severely affected and have cephalic and ocular malformations: holoprosencephaly, cleft lip and palate, ptosis, epicanthic folds, and varying degrees of intellectual disability.</td>
</tr>
</tbody>
</table>
disability. Most (80%) have only minor malformations and mild intellectual disability.

18q−
The main features are growth deficiency and hypotonia with a “froglike” position with the legs flexed, externally rotated, and in hyperabduction. The face is characteristic, with depressed midface and apparent protrusion of the mandible, deep-set eyes, short upper lip, and everted lower lip (“carplike” mouth); antihelix of the ears is very prominent. Varying degrees of intellectual disability and belligerent personality are present. Myelination abnormalities occur in the central nervous system.
High-resolution banding techniques, FISH, and molecular studies such as aCGH can reveal deletions that are too small to be seen in ordinary or routine chromosome spreads (see Fig. 98.7). Microdeletions involve loss of small chromosome regions, the largest of which are detectable only with prophase chromosome studies and molecular methods. For submicroscopic deletions, the missing piece can only be detected using molecular methodologies such as DNA-based studies (e.g., aCGH, FISH). The presence of extra genetic material from the same chromosome is referred to as duplication. Duplications can also be sporadic or result from abnormal segregation in translocation or inversion carriers.

Microdeletions and microduplications usually involve regions that include several genes, so the affected individuals can have a distinctive phenotype depending on the number of genes involved. When such a deletion involves more than a single gene, the condition is referred to as a contiguous gene deletion syndrome (Table 98.13). With the advent of clinically available aCGH, a large number of duplications, most of them microduplications, have been uncovered. Many of those microduplication syndromes are the reciprocal duplications of the known deletions or microdeletion counterparts and have distinctive clinical features (Table 98.14).

**Subtelomeric regions** are often involved in chromosome rearrangements that cannot be visualized using routine cytogenetics. Telomeres, which are the distal ends of the chromosomes, are gene-rich regions. The distal structure of the telomeres is essentially common to all chromosomes, but proximal to these are unique regions known as subtelomeres, which typically are involved in deletions and other chromosome rearrangements. Small subtelomeric deletions, duplications, or rearrangements (translocations, inversions) may be relatively common in children with nonspecific intellectual disability and minor anomalies. Subtelomeric rearrangements have been found in 3–7% of children with moderate to severe intellectual disability and 0.5% of those with mild intellectual disability and can be detected by aCGH studies.

Telomere mutations and length abnormalities have also been associated with dyskeratosis congenita and other aplastic anemia syndromes, as well as pulmonary or hepatic fibrosis. Both the subtelomeric rearrangements and the
microdeletion and microduplication syndromes are typically diagnosed by molecular techniques such as aCGH and multiple ligation-dependent primer amplification studies. Recent studies show that aCGH can detect 14–18% of abnormalities in patients who previously had normal chromosome studies.

**Insertions**

Insertions occur when a piece of a chromosome broken at 2 points is incorporated into a break in another part of a chromosome. A total of 3 breakpoints are then required, and they can occur between 2 or within 1 chromosome. A form of nonreciprocal translocation, insertions are rare. Insertion carriers are at risk of having offspring with deletions or duplications of the inserted segment.

**Isochromosomes**

Isochromosomes consist of 2 copies of the same chromosome arm joined through a single centromere and forming mirror images of one another. The most commonly reported autosomal isochromosomes tend to involve chromosomes with small arms. Some of the more common chromosome arms involved in this formation include 5p, 8p, 9p, 12p, 18p, and 18q. There is also a common isochromosome abnormality seen in long arm of the X chromosome and associated with Turner syndrome. Individuals who have 1 isochromosome X within 46 chromosomes are monosomic for genes in the lost short arm and trisomic for the genes present in the long arm of the X chromosome.

**Marker and Ring Chromosomes**

Marker chromosomes are rare and are usually chromosome fragments that are too small to be identified by conventional cytogenetics; they usually occur in addition to the normal 46 chromosomes. Most are sporadic (70%); mosaicism is often (50%) noted because of the mitotic instability of the marker chromosome. The incidence in newborn infants is 1 in 3,300, and the incidence in persons with intellectual disability is 1 in 300. The associated phenotype ranges from normal to severely abnormal, depending on the amount of chromosome material and number of genes included in the fragment.
Ring chromosomes, which are found for all human chromosomes, are rare. A ring chromosome is formed when both ends of a chromosome are deleted and the ends are then joined to form a ring. Depending on the amount of chromosome material that is lacking or in excess (if the ring is in addition to the normal chromosomes), a patient with a ring chromosome can appear normal or nearly normal or can have intellectual disability and multiple congenital anomalies.

Marker and ring chromosomes can be found in the cells of solid tumors of children the cells of whose organs do not contain this additional chromosomal material.

Abnormalities of Chromosome Structure

98.4
Sex Chromosome Aneuploidy

Carlos A. Bacino, Brendan Lee

About 1 in 400 males and 1 in 650 females have some form of sex chromosome abnormality. Considered together, sex chromosome abnormalities are the most common chromosome abnormalities seen in liveborn infants, children, and adults. Sex chromosome abnormalities can be either structural or numerical and can be present in all cells or in a mosaic form. Those affected with these abnormalities might have few or no physical or developmental problems (Table 98.15).

Turner Syndrome

Turner syndrome is a condition characterized by complete or partial monosomy
of the X chromosome and defined by a combination of phenotypic features (Table 98.16). Half the patients with Turner syndrome have a 45,X chromosome complement. The other half exhibit mosaicism and varied structural abnormalities of the X or Y chromosome. Maternal age is not a predisposing factor for children with 45,X. Turner syndrome occurs in approximately 1 in 5,000 female live births. In 75% of patients, the lost sex chromosome is of paternal origin (whether an X or a Y). 45,X is one of the chromosome abnormalities most often associated with spontaneous abortion. It has been estimated that 95–99% of 45,X conceptions are miscarried.

**Table 98.16**

**Signs Associated With Turner Syndrome**

- Short stature
- Congenital lymphedema
- Horseshoe kidneys
- Patella dislocation
- Increased carrying angle of elbow (cubitus valgus)
- Madelung deformity (chondrodysplasia of distal radial epiphysis)
- Congenital hip dislocation
- Scoliosis
- Widespread nipples
- Shield chest
- Redundant nuchal skin (in utero cystic hygroma)
- Low posterior hairline
- Coarctation of aorta
- Bicuspid aortic valve
- Cardiac conduction abnormalities
- Hypoplastic left heart syndrome and other left-sided heart abnormalities
- Gonadal dysgenesis (infertility, primary amenorrhea)
- Gonadoblastoma (increased risk if Y chromosome material is present)
- Learning disabilities (nonverbal perceptual motor and visuospatial skills)
  (in 70%)
- Developmental delay (in 10%)
- Social awkwardness
- Hypothyroidism (acquired in 15–30%)
- Type 2 diabetes mellitus (insulin resistance)
Strabismus
Cataracts
Red-green color blindness (as in males)
Recurrent otitis media
Sensorineural hearing loss
Inflammatory bowel disease
Celiac disease (increased incidence)

Clinical findings in the newborns can include small size for gestational age, webbing of the neck, protruding ears, and lymphedema of the hands and feet, although many newborns are phenotypically normal (Fig. 98.17). Older children and adults have short stature and exhibit variable dysmorphic features. Congenital heart defects (40%) and structural renal anomalies (60%) are common. The most common heart defects are bicuspid aortic valves, coarctation of the aorta, aortic stenosis, and mitral valve prolapse. The gonads are generally streaks of fibrous tissue (gonadal dysgenesis). There is primary amenorrhea and lack of secondary sex characteristics. These children should receive regular endocrinologic testing (see Chapter 604). Most patients tend to be of normal intelligence, but intellectual disability is seen in up to 6% of affected children. They are also at increased risk for behavioral problems and deficiencies in spatial and motor perception. Guidelines for health supervision for children with Turner syndrome are published by the American Academy of Pediatrics (AAP) and include pubertal induction, as well as treatment with growth hormone and oxandrolone.
Patients with 45,X/46,XY mosaicism can have Turner syndrome, although this form of mosaicism can also be associated with male pseudohermaphroditism, male or female genitalia in association with mixed gonadal dysgenesis, or a normal male phenotype. This variant is estimated to represent approximately 6% of patients with mosaic Turner syndrome. Some of the patients with Turner syndrome phenotype and a Y cell line exhibit masculinization. Phenotypic females with 45,X/46,XY mosaicism have a 15–30% risk of developing gonadoblastoma. The risk for the patients with a male phenotype and external testes is not so high, but tumor surveillance is nevertheless recommended. AAP has recommended the use of FISH analysis to
look for Y chromosome mosaicism in all 45,X patients. If Y chromosome material is identified, laparoscopic gonadectomy is recommended.

**Noonan syndrome** shares many clinical features with Turner syndrome and was formerly called pseudo-Turner syndrome, although it is an autosomal dominant disorder resulting from mutations in several genes involved in the RAS-MAPK (mitogen-activated protein kinase) pathway. The most common of these is *PTPN11* (50%), which encodes a protein-tyrosine phosphatase (SHP-2) on chromosome 12q24.1. Other genes include *SOS1* in 10–13%, *RAF1* in 3–17%, *RIT1* in 5%, *KRAS* <5%, *BRAF* <2%, *MAP2K* <2%, and *NRAS* (only few reported families). Overlapping phenotypes are seen in LEOPARD (lentigines, electrocardiographic abnormalities, ocular hypertelorism, pulmonary stenosis, abnormalities of genitalia, retardation of growth, deafness) syndrome, cardiofaciocutaneous (CFC) syndrome, and Costello syndrome; these are Noonan-related disorders. Features common to Noonan syndrome include short stature, low posterior hairline, shield chest, congenital heart disease, and a short or webbed neck (Table 98.17). In contrast to Turner syndrome, Noonan syndrome affects both sexes and has a different pattern of congenital heart disease, typically involving right-sided lesions.

### Table 98.17

**Signs Associated With Noonan Syndrome**

- Short stature
- Failure to thrive (best to use Noonan growth curve)
- Tall forehead
- Epicanthal folds
- Ptosis
- Blue-green irises
- Hypertelorism
- Low nasal bridge, upturned nose
- Downward-slanting palpebral fissures
- Myopia
- Nystagmus
- Low-set and posteriorly rotated auricles
- Dental malocclusion
- Low posterior hairline
- Short, webbed neck (excessive nuchal skin), cystic hygroma
Shield chest
Pectus carinatum superiorly
Scoliosis
Pigmented villonodular synovitis (polyarticular)
Cubitus valgus
Pulmonary valve stenosis (dysplastic valve)
Hypertrophic cardiomyopathy
Atrial septal defect, ventricular septal defect
Lymphedema
Nevi, lentigines, café au lait spots
Cryptorchidism
Small penis
Delayed puberty
Bleeding disorders, including thrombocytopenia and coagulation factor deficiencies
Leukemia, myeloproliferative disorders, other malignancies
Cognitive delay (KRAS mutation)

Klinefelter Syndrome

Persons with Klinefelter syndrome are phenotypically male; this syndrome is the most common cause of hypogonadism and infertility in males and the most common sex chromosome aneuploidy in humans (see Chapter 601). Eighty percent of children with Klinefelter syndrome have a male karyotype with an extra chromosome X-47,XXY. The remaining 20% have multiple sex chromosome aneuploidies (48,XXXY; 48,XXYY; 49,XXXXY), mosaicism (46,XY/47,XXY), or structurally abnormal X chromosomes; the greater the aneuploidy, the more severe the mental impairment and dysmorphism. Early studies showed a birth prevalence of approximately 1 in 1,000 males, but more recent studies suggest that the prevalence of 47,XXY appears has increased to approximately 1 in 580 liveborn males; the reasons for this are still unknown but hypothesized to be the result of environmental factors acting in spermatogenesis. Errors in paternal nondisjunction in meiosis I account for half the cases.

Puberty commences at the normal age, but the testes remain small. Patients develop secondary sex characters late, and 50% ultimately develop gynecomastia. They have taller stature. Because many patients with Klinefelter syndrome are phenotypically normal until puberty, the syndrome often goes
undiagnosed until they reach adulthood, when their infertility leads to identification. Patients with 46,XY/47,XXY have a better prognosis for testicular function. Their intelligence shows variability and ranges from above to below average. Persons with Klinefelter syndrome can show behavioral problems, learning disabilities, and deficits in language. Problems with self-esteem often occur in adolescents and adults. Substance abuse, depression, and anxiety have been reported in adolescents with Klinefelter syndrome. Those who have higher X chromosome counts show impaired cognition. It has been estimated that each additional X chromosome reduces the IQ by 10-15 points, when comparing these individuals with typical siblings. The main effect is seen in language skills and social domains.

### 47,XYY

The incidence of 47,XYY is approximately 1 in 800-1,000 males, with many cases remaining undiagnosed, because most affected individuals have a normal appearance and normal fertility. The extra Y is the result of nondisjunction at paternal meiosis II. Those with this abnormality have normal intelligence but are at risk for learning disabilities. Behavioral abnormalities, including hyperactive behavior, pervasive developmental disorder, and aggressive behavior, have been reported. Early reports that assigned stigmata of criminality to this disorder have long been disproved.

**98.5**

**Fragile Chromosome Sites**

Carlos A. Bacino, Brendan Lee
Fragile sites are regions of chromosomes that show a tendency for separation, breakage, or attenuation under particular growth conditions. They visually appear as a gap in the staining in chromosome studies. At least 120 chromosomal loci, many of them heritable, have been identified as fragile sites in the human genome (see Table 97.2).

A clinically significant fragile site is on the distal long arm of chromosome Xq27.3 associated with the **fragile X syndrome**. Fragile X syndrome accounts for 3% of males with intellectual disability. There is another fragile site on the X chromosome (FRAXE on Xq28) that has also been implicated in mild intellectual disability. The FRA11B (11q23.3) breakpoints are associated with **Jacobsen syndrome** (condition caused by deletion of the distal long arm of chromosome 11). Fragile sites can also play a role in tumorigenesis. In fragile X syndrome the CGG repeat expansion silences the gene producing **fragile X mental retardation protein (FMRP)** that regulates the translation of multiple mRNAs to specific proteins, thus affecting synaptic function. FMRP deficiency upregulates the metabotropic glutamate receptor (mGluR) 5 pathway. FMRP deficiency also alters the expression of matrix metalloproteinase (MMP) 9.

The main clinical manifestations of fragile X syndrome in affected males are intellectual disability, autistic behavior, postpubertal macroorchidism, hyperextensible finger joints, and characteristic facial features (Table 98.18). The facial features, which include a long face, large ears, and a prominent square jaw, become more obvious with age. Females affected with fragile X show varying degrees of intellectual disability and/or learning disabilities. Diagnosis of fragile X syndrome is possible by DNA testing that shows an expansion of a triplet DNA repeat inside the FMR1 gene on the X chromosome >200 repeats. The expansion involves an area of the gene that contains a variable number of trinucleotide (CGG) repeats (typically <50 in unaffected individuals). The larger the triplet repeat expansion, the more significant is the intellectual disability. In cases where the expansion is large, females can also manifest different degrees of intellectual disability. Males with premutation triple repeat expansions (55-200 repeats) have been found to have an adult, late-onset, progressive neurodegenerative disorder known as **fragile X–associated tremor/ataxia syndrome**. Females with premutation triple repeat expansions are at high risk for developing premature ovarian failure (POF).

Bibliography

Fragile Chromosome Sites

Raspa M, Wheeler AC, Riley C. Public health literature review

98.6 Mosaicism

Carlos A. Bacino, Brendan Lee

Mosaicism describes an individual or tissue that contains ≥2 different cell lines typically derived from a single zygote and the result of mitotic nondisjunction (see Fig. 98.1). Study of placental tissue from chorionic villus samples collected at or before the 10th wk of gestation has shown that ≥2% of all conceptions are mosaic for a chromosome abnormality. With the exception of chromosomes 13, 18, and 21, complete autosomal trisomies are usually nonviable; the presence of a normal cell line might allow these other trisomic conceptions to survive to term. Depending on the point at which the new cell line arises during early embryogenesis, mosaicism may be present in some tissues but not in others.

Germline mosaicism, which refers to the presence of mosaicism in the germ cells of the gonad, may be associated with an increased risk for recurrence of an affected child if the germ cells are affected with a chromosomal abnormality or with a specific gene mutation.

Pallister-Killian Syndrome

Pallister-Killian syndrome is characterized by coarse facies (prominent full
cheeks), abnormal ear lobes, localized alopecia (sparse hair in the temporal regions), pigmentary skin anomalies, diaphragmatic hernia, cardiovascular anomalies, supernumerary nipples, seizures, and profound intellectual disability. The syndrome is caused by mosaicism for an isochromosome 12p. The presence of the isochromosome 12p in cells gives 4 functional copies for the short arm of chromosome 12 in the affected cells. The isochromosome 12p is preferentially cultured from fibroblasts that can be readily obtained from a skin punch biopsy and is seldom present in lymphocytes. The abnormalities seen in affected persons probably reflect the presence of abnormal cells during early embryogenesis.

**Hypomelanosis of Ito**

Hypomelanosis of Ito is characterized by unilateral or bilateral macular hypopigmented or hyperpigmented whorls, streaks, and patches (see Chapter 672). Sometimes these pigmentary defects follow the lines of Blaschko. Hair and tooth anomalies are common. Abnormalities of the eyes, musculoskeletal system (growth asymmetry, syndactyly, polydactyly, clinodactyly), and central nervous system (microcephaly, seizures, intellectual disability) may also be present. Patients with hypomelanosis of Ito might have two genetically distinct cell lines. The mosaic chromosome anomalies that have been observed involve both autosomes and sex chromosomes and have been demonstrated in about 50% of clinically affected patients. The mosaicism might not be visible in lymphocyte-derived chromosome studies; it is more likely to be found when chromosomes are analyzed from skin fibroblasts. The distinct cell lines might not always be caused by observable chromosomal anomalies but might result from single-gene mutations or other mechanisms.

**98.7**

**Chromosome Instability Syndromes**

Carlos A. Bacino, Brendan Lee
Chromosome instability syndromes, formerly known as chromosome breakage syndromes, are characterized by an increased risk of malignancy and specific phenotypes. They display autosomal recessive inheritance and have an increased frequency of chromosome breakage and/or rearrangement, either spontaneous or induced. Chromosome instability syndromes result from specific defects in DNA repair, cell cycle control, and apoptosis. The resulting chromosomal instability leads to the increased risk of developing neoplasms. The classic chromosome instability syndromes are Fanconi anemia, ataxia telangiectasia, Nijmegen syndrome, ICF (immunodeficiency, centromere instability, facial anomalies) syndrome, Roberts syndrome, Werner syndrome, and Bloom syndrome.

98.8
Uniparental Disomy and Imprinting

Carlos A. Bacino, Brendan Lee

Uniparental Disomy

Uniparental disomy (UPD) occurs when both chromosomes of a pair or areas from one chromosome in any individual have been inherited from a single parent. UPD can be of 2 types: uniparental isodisomy or uniparental heterodisomy. Uniparental isodisomy means that both chromosomes or chromosomal regions are identical (typically the result of monosomy rescue by duplication). Uniparental heterodisomy means that the 2 chromosomes are different members of a pair, both of which were still inherited from 1 parent. This results from a trisomy that is later reduced to disomy, leaving 2 copies from 1 parent. The phenotypic result of UPD varies according to the chromosome involved, the parent who contributed the chromosomes, and whether it is isodisomy or heterodisomy. Three types of phenotypic effects are seen in UPD: those related to imprinted genes (i.e., the absence of a gene that is normally expressed only when inherited from a parent of a specific sex), those related to the uncovering of autosomal recessive disorders, and those related to a vestigial
aneuploidy producing mosaicism (see Chapter 97).

In uniparental isodisomy, both chromosomes or regions (and thus the genes) in the pair are identical. This is particularly important when the parent is a carrier of an autosomal recessive disorder. If the offspring of a carrier parent has UPD with isodisomy for a chromosome that carries an abnormal gene, the abnormal gene will be present in 2 copies, and the phenotype will be that of the autosomal recessive disorder; the child has an autosomal recessive disorder even though only 1 parent is a carrier of that recessive disorder. It is estimated that all humans carry approximately 20 abnormal autosomal recessive genes. Some autosomal recessive disorders, such as spinal muscular atrophy, cystic fibrosis, cartilage-hair hypoplasia, α- and β-thalassemias, and Bloom syndrome, have been reported in cases of UPD. The possibility of uniparental isodisomy should also be considered when a person is affected with >1 recessive disorder because the abnormal genes for both disorders could be carried on the same isodisomic chromosome. Uniparental isodisomy is a rare cause of recessively inherited disorders. Uniparental isodisomies can also be detected by SNP microarrays.

**Maternal UPD** involving chromosomes 2, 7, 14, and 15 and **paternal UPD** involving chromosomes 6, 11, 15, and 20 are associated with phenotypic abnormalities of growth and behavior. UPD of maternal chromosome 7 is associated with a phenotype similar to Russell-Silver syndrome with intrauterine growth restriction. These phenotypic effects may be related to imprinting (see later) (Fig. 98.18).
UPD for chromosome 15 is seen in some cases of Prader-Willi syndrome and Angelman syndrome. In Prader-Willi syndrome, approximately 25–29% of cases have maternal UPD (missing the paternal chromosome 15) (Fig. 98.19). In Angelman syndrome, paternal UPD of chromosome 15 is rarer and is observed in approximately 5% of the cases (missing the maternal chromosome 15). The phenotype for Prader-Willi syndrome and Angelman syndrome in cases of UPD is thought to result from the lack of the functional contribution from a particular parent of chromosome 15. In Prader-Willi syndrome the paternal contribution is missing, and the maternal contribution is missing in Angelman syndrome. Prader-Willi syndrome may be caused by paternal deficiency of HB11-85 small nucleolar RNAs (snoRNAs). These findings suggest that there are differences in
function of certain regions of chromosome 15, depending on whether it is inherited from the mother or from the father. Angelman syndrome is caused by absence of a maternally contributed gene known as \textit{UBE3A} and can be the result of maternal deletion, maternal \textit{UBE3A} mutation, paternal UPD, and abnormalities in the maternal imprinting center on chromosome 15q11-13 region.
UPD most frequently arises when a pregnancy starts off as a **trisomic**
conception followed by trisomy rescue. Because most trisomies are lethal, the fetus can only survive if a cell line loses 1 of the extra chromosomes to revert to the disomic state. One third of the time, the disomic cell line is uniparental. This is the typical mechanism for Prader-Willi syndrome, and it is often associated with advanced maternal age. The embryo starts off as trisomy 15 secondary to maternal meiosis I nondisjunction, followed by random loss of the paternal chromosome. In this case the disomic cell line becomes the more viable one and outgrows the trisomic cell line. When mosaic trisomy is found at prenatal diagnosis, care should be taken to determine whether UPD has resulted and whether the chromosome involved is one of the disomies known to be associated with phenotypic abnormalities. There must always be concern that some residual cells that are trisomic are present in some tissues, leading to malformations or dysfunction. The presence of aggregates of trisomic cells might account for the spectrum of abnormalities seen in persons with UPD.

Imprinting

Traditional genetics for many years has suggested that most genes are equally expressed when inherited from maternal vs paternal lineages. The only exception to this rule were genes on the X chromosome that are subject to inactivation, and the immunoglobulin genes subject to allelic exclusion, a phenomenon that results in monoallelic expression of a particular immunoglobulin chain by switching expression of parental alleles on and off. Genomic imprinting occurs when the phenotypic expression of a gene depends on the parent of origin for certain genes or in some cases entire chromosome regions. Whether the genetic material is expressed or not depends on the sex of the parent from whom it was derived. Genomic imprinting can be suspected in some cases on the basis of a pedigree. In these pedigrees the disease is always transmitted from one sex and could be passed on silently for several generations by the opposite sex (Figs. 98.20 and 98.21). Imprinting probably occurs in many different parts of the human genome and is thought to be particularly important in gene expression related to development, growth, cancer, and even behavior; >60 genes have been classified as imprintable. Imprinting disorders may arise from UPD, deletions or duplications, epigenetic aberrant methylation patterns, or point mutations in a specific gene.
In this hypothetical pedigree suggestive of imprinting, phenotypic effects occur only when the mutated gene is transmitted from the mother, but not when it is transmitted from the father, that is, maternal deficiency. Equal numbers of males and females can be affected and not affected phenotypically in each generation. A nonmanifesting transmitter gives a clue to the sex of the parent who passes the expressed genetic information; that is, in maternal deficiency disorders (also termed *paternal imprinting*), there are “skipped” nonmanifesting females. This is theoretical, because in most clinical scenarios of maternal deficiency, such as Angelman syndrome, affected persons do not reproduce.

In theoretical pedigrees suggestive of paternal deficiency (maternal imprinting), phenotypic effects occur only when the mutated gene is transmitted from the father, but not when transmitted from the mother. Equal numbers of males and females can be affected and not affected phenotypically in each generation. In a theoretical situation, a nonmanifesting transmitter gives a clue to the sex of the parent who passes on the expressed genetic information; that is, in paternal deficiency (also known as *maternal imprinting*), there are “skipped” nonmanifesting males. In real-life clinical cases of Prader-Willi syndrome, affected persons do not reproduce.
A classic example of imprinting disorder is seen in Prader-Willi syndrome and Angelman syndrome, 2 very different clinical conditions. These syndromes are usually associated with deletion of the same region in the proximal long arm of chromosome 15. A deletion on the paternally derived chromosome causes Prader-Willi syndrome, in which the maternally derived copy is still intact, but some of the imprinted genes within this region normally remain silent. Prader-Willi syndrome can be diagnosed clinically (Table 98.20) and confirmed with genetic testing. Additional clinical features and issues of weight gain are noted in Table 98.21. The weight gain is difficult to control, but treatment with growth hormone has resulted in improvements in height, lean body mass, decreased adipose tissue, and improvement in cognitive function.

A maternal deletion of the same region as in Prader-Willi syndrome causes Angelman syndrome, leaving intact the paternal copy that in this case has genes that are also normally silent. In other situations, UPD can lead to the same diagnosis (Table 98.22). Many other disorders are associated with this type of parent-of-origin effect, as in some cases of Beckwith-Wiedemann syndrome, Russell-Silver syndrome, and neonatal diabetes.

**Uniparental Disomy and Imprinting**

Eggermann T. Russell-Silver syndrome. *Am J Med Genet C*

Common pediatric diseases are usually multifactorial. The combination of many genes and environmental factors contribute to a complex sequence of events leading to disease. The complexity of the combination of contributing factors increases the challenge of finding genetic variants that cause disease. Genetic tools include the completed human genome sequence, public databases of genetic variants, and the human haplotype map. In addition to public genetic databases, dramatic reduction in the cost of genotyping and DNA sequencing has allowed very large numbers of genetic variants to be efficiently tested in large numbers of patients. Most of these studies focus on common variants (those with frequencies >5%). Technologies for DNA sequencing are allowing whole exome sequencing in many individuals at very low cost. This technology is being used to investigate the role of rare coding sequence variants in common diseases. The incorporation of these tools into large, well-designed population studies is the field of genetic epidemiology. Many new methods for analyzing genetic data have been developed, stimulating a renaissance in applied population genetics.
Millions of genetic variants are present in every person. Many of these variants have no impact on health, while others have a measurable influence. Sometimes, single-gene mutations consistently cause a disease, as with cystic fibrosis and sickle cell anemia. Other types of genetic variation, however, can contribute much less to the emergence of specific medical conditions, and these are best conceptualized as *modifiers* of disease risk. *Fig. 99.1* demonstrates the relationship between variant frequency and the relative medical impact of the allele. The spectrum of variant impact is logarithmic, ranging widely from a slightly increased risk of illness to predetermined fully expressed disease. Studies aimed at discovering rare variants with outsized health effects only require small sample populations to achieve statistical significance, while those studying common variants require much larger sample sizes because of the small anticipated impact of each variant.

*Fig. 99.1* Relationship between allele frequency and relative strength of genetic effect. Alleles with large effect tend to be very rare but can be studied with a small sample size because of the relative ease of allele detection when medical impact is high. Common variants tend to have a modest or low effect on health, requiring large datasets to visualize statistically small effects. The vast majority of disease-associated alleles...
The cumulative risk of many common variants determines genetic susceptibility. For common conditions, the genetic predisposition alone is not sufficient to cause disease. Everyone inherits a different degree of disease vulnerability, which is then augmented by exposure to certain environmental factors. Fig. 99.2 shows a model for the contribution of common genetic variants to individual health. One of the goals in medical genetics is to identify the genes that contribute to initial genetic susceptibility and to help prevent the occurrence of disease, either by avoiding inciting environmental factors or by instituting interventions that reduce risk. For persons who cross the threshold of disease, the goal is to better understand the pathogenesis in the hope that this will suggest better approaches to treatment. Common genetic variation can also influence response to medications and the risk of adverse drug reactions (see Chapter 72) and augment the health impacts of environmental toxins.

**FIG. 99.2** Model for the influence of gene-environment interaction on genetic susceptibility to common diseases. Everyone inherits common variants that determine initial genetic liability for disease risk. For multifactorial disorders, the initial genetic susceptibility is insufficient to produce disease on its own. Over time, exposure to environmental factors increases the likelihood of a disease state. Identifying the gene
variants responsible for risk can lead to prevention strategies or treatments.

Complex traits may be inherently difficult to study if the precision of clinical diagnosis (phenotype) is problematic, as often occurs with neurobehavioral traits. A starting point in the genetic analysis of a complex trait is to obtain evidence in support of a genetic contribution and to estimate the relative strength of genetic and environmental factors. Complex traits typically exhibit familial clustering but are not transmitted in a regular pattern as is autosomal dominant or recessive inheritance. Complex traits often show variation among different ethnic or racial groups, possibly reflecting the differences in gene variants among these groups.

Assessing the potential genetic contribution begins by determining whether the trait is seen among related individuals more often than in the general population. A common measure of **familiality** is the first-degree relative risk (usually designated by the symbol $\lambda_s$), which is equal to the ratio of the prevalence rate in siblings and/or parents to the prevalence rate in the general population. The $\lambda_s$ for type 1 diabetes is about 15. The relative strength of genetic and nongenetic risk factors can be estimated by variance components analysis. The **heritability** of a trait is the estimate of the fraction of the total variance contributed by genetic factors (Fig. 99.3).

![FIG. 99.3 Heritability concept. The phenotypic variance of a particular trait can be partitioned between the contributions of the genetic variance, environmental variance, and measurement variance. This is usually empirically determined. Heritability is defined by the proportion of the phenotypic variance that is accounted for by the genetic variance. One can estimate the heritability from correlation of a quantitative trait between relatives.](fig.png)

A minority of cases of common diseases such as diabetes may be caused by single-gene mutations (mendelian inheritance), chromosomal disorders, and other genomic disorders. These *less common* causes of the disease can often provide important insight into the most important molecular pathways involved. Chromosomal regions with genes that might contribute to disease susceptibility
could theoretically be located with **linkage mapping**, which locates regions of DNA that are inherited in families with the specific disease. In practical terms, however, this has become quite difficult for most complex traits either because of a dearth of families or because the effect of individual genetic loci is weak.

Genetic **association studies** are more powerful in identifying common gene variants (>5% in the population) that confer increased risk of disease, but they fail if the disease-causing gene variants are relatively rare. Detection of the modest effect of each variant and interactions with environmental factors requires well-powered studies that often include thousands of individuals. A number of parallel approaches for analyzing the aggregate effects of rare variants in genes have also been developed. Such rare variant association methods also seem to require large sample sizes because the gene effects have also proved to be relatively weak.

Linkage mapping and association studies require markers along the DNA that can be ascertained, or **genotyped**, with large-scale, high-throughput laboratory techniques. Markers that are typically used are in the forms of microsatellites and **single nucleotide polymorphisms (SNPs)**; Fig. 99.4). A sample of the same region of genome from 50 people will reveal that approximately 1 in every 200 bases varies from the more common form. Although most SNPs lack any obvious function, a few alter the amino acid sequence of the protein or affect regulation of gene expression. Some of these functional alterations directly affect susceptibility to disease. A complex clinical **phenotype** can be defined by the presence or absence of a disease as a **dichotomous trait**, or by selection of a clinically meaningful variable such as serum glucose in type 2 diabetes, which is a continuous or **quantitative trait**.
Different combinations of SNPs are found in different individuals. The locations of these SNPs can be pinpointed on maps of human genes. Subsequently, they can be used to create profiles that are associated with difference in response to a drug, such as efficacy and nonefficacy. (Adapted from Roses A: Pharmacogenetics and the practice of medicine, Nature 405:857–865, 2000. Copyright 2000. Reprinted by permission of Macmillan Publishers Ltd.)

Although it might not be possible to define subgroups of patients in advance based on common disease mechanisms, the more uniform the phenotype, the more likely that a genetic study will be successful. Locus heterogeneity refers to the situation in which a trait results from the independent action of more than 1 gene. Allelic heterogeneity indicates that more than 1 variant in a particular gene can contribute to disease risk. The development of a trait or disease from a nongenetic mechanism results in a phenocopy. These 3 factors often contribute to the difficulty in identifying individual disease susceptibility genes, because they reduce the effective size of the study population.

A person bearing any variant or allele (inherited unit, DNA segment, or chromosome) in a gene has a certain probability of being affected with a specific gene variant–associated disease. This is called the penetrance. Some diseases manifest signs only later in life (age-related penetrance), which could lead to misclassifying children who actually have the disease-producing gene as unaffected. Single-gene disorders are typically caused by mutations with
relatively high penetrance, but some common variants have very low penetrance because their overall contribution to the disease is small. Many such common variants can contribute to disease risk for a complex trait. Normal human height is influenced by >400 genes.

Ideally, important environmental exposures should be measured and accounted for in a population because there may be a dependent interaction between the environmental factor and specific genetic variant. An example is the likely requirement for a viral infection preceding onset of type 1 diabetes. Although gene-environment interactions are strongly suspected to play an important role in common diseases, it is difficult to identify and measure them. Very large studies with uniform collection of information about environmental exposures are rare. Methods, such as genome-wide analysis of DNA methylation, may show evidence of environmental effects—so-called developmental programming (see Chapter 100). This information might be used to discover and validate gene-environment interactions.

**Linkage Mapping**

Linkage studies were used in the past to isolate genes that cause rare genetic syndromes; modified methods have been used to identify chromosomal regions linked to more common diseases. Linkage studies involve tagging segments of a person's genome with markers that allow identification of segments that have been inherited through the family along with disease. The markers are typically microsatellites or SNPs that define and help to distinguish which type of an allele any person carries. Genotype refers to the combination of alleles at a locus in a diploid organism. Linkage analyses of common diseases have shown inconsistent results. Factors such as heterogeneity, pleiotropy, variable expressivity, and reduced penetrance, in addition to variability in environmental exposures, weaken the power of linkage studies in complex traits.

**Genetic Association**

For multifactorial common diseases, association analyses may be used to identify causally important genes. There are two types of association study: direct association, in which the causal variant itself is tested to see whether its presence correlates with disease, and indirect association, in which markers
that are physically close to the biologically important variant are used as proxies. The correlation of markers with other genetic variants in a small region of the genome is called **linkage disequilibrium**. Indirect association is enabled by the construction of a detailed genetic map in 3 reference populations (Europeans, Asians, West Africans) through the International HapMap Project. SNPs that tag most of the genome have been identified and can be genotyped at low cost using specially designed microarrays.

Three basic study designs are used for association testing. In a case control design, the frequency of an allele in the affected group is compared with the unaffected group. In a family-based control design, parents or siblings of an affected individual are used as the controls. In a cohort design, large numbers of people are ascertained and then followed for the onset of any number of diseases. The cohort analysis is very expensive, and there are few true cohort studies.

Family-based control study designs are somewhat attractive for pediatric diseases because it is usually possible to enroll parents. These studies solve a major problem in testing for association because the parents are perfectly matched for genetic background. When parents are collected, the statistical test used for these studies is called the **transmission disequilibrium test** (TDT). TDT compares the transmitted genotype with the inferred nontransmitted genotype. The success of all association analysis depends on the design of a well-powered study and an accurately measured trait to avoid phenotypic misclassification. In large, population-based studies, confounding by ethnicity or **population stratification** could distort results. Some genetic variants are more common in people from a particular ethnic group, which could cause an apparent association of a variant with a disease, when the disease rate happens to be higher in that group. This association would not be a true association between an allele and a disease, because the association would be confounded by genetic background. The family-based tests using the TDT are immune to population stratification. However, TDT and related study designs are inherently less efficient than case control studies. Newer methods for measuring subtle mismatching between cases and controls using many thousands of markers routinely genotyped in genome-wide association studies allow researchers to account for this effect.

Association studies should be a powerful tool to find genetic variation that confers risk to an individual; the effect of any 1 genetic variant will be a very small contribution to the complex disease pathway. Genetic variants have been found that implicate a novel gene in a process, motivating more in-depth
research into systems that will affect disease outcome. Associations such as the APOE ε4 variant with an increased risk of Alzheimer disease are noted by many studies. Many published association results are not reproducible; insufficient power and stratification might account for the inconsistencies. As of late 2016, 2,650 studies and 29,954 unique SNP-trait associations have been catalogued (https://www.ebi.ac.uk/gwas).

Low-cost methods for sequencing the complete exomes and genomes of individuals will allow a more comprehensive evaluation of the full range of genetic variants involved in common diseases. Rare genetic variants, including small insertions or deletions, could turn out to be extremely important in explaining the impact of genetic factors in important pediatric diseases such as autism, cardiovascular malformations, and other birth defects. Common traits such as obesity, diabetes, and autoimmune diseases might also be affected by rare variants. In common severe disorders such as intellectual disability and complex heart malformations, de novo mutations (i.e., mutations not present in either parent) are known to play an important role.

Bibliography

Pediatricians are asked to consider the possibility that certain conditions involve epigenetic mechanisms. The assumption is that epigenetic processes, generally defined as regulatory control of gene expression, are capable of overriding information encoded in the DNA sequence to increase or decrease the risk of a disease. Despite powerful genomic assays to test these regulators of gene expression, it has proved difficult to provide clear answers about how epigenetic mechanistic insights could improve patient care. Clarifying the fundamental concepts and definitions that underlie proposed epigenetic contributions to phenotypes should lead to valuable insights into their role in human health.

Epigenetic Mechanisms of Disease: Viable Yellow Mouse Model

The back-translated meaning of epigenetics (epi, above, upon; genetic, DNA sequence) implies that information encoded in the DNA sequence may be modifiable in some way by higher-order information that regulates the levels of activity of specific genes. Such a concept is attractive when trying to understand why monozygotic twins, who have identical DNA sequences, are sometimes discordant for certain heritable diseases, such as Alzheimer disease and type 1 diabetes mellitus. Genetic predisposition that fails to account fully for the development of a disease (or other) phenotype has been called “missing heritability,” a gap that epigenetic regulatory processes have been proposed to fill. Furthermore, because the environment influences the risk of certain disorders by modifying an underlying genetic predisposition, environmental
stimuli may act through epigenetic regulatory processes of gene expression.

The most compelling evidence for the epigenetic, higher-level regulation of genes and predisposition to disease was the viable yellow mouse model (Fig. 100.1). This mouse was found to have a mutation involving an endogenous retrovirus, a component of the genome that can replicate itself and move to a new location. In the case of the viable yellow mouse, the endogenous retrovirus was the type called an **intracisternal A particle (IAP)**, which inserted upstream from a gene called **a (nonagouti)**. The **nonagouti** gene encodes agouti-signaling protein precursor, which binds to and has a negative effect on melanocortin receptors. When it stimulates melanocytes in hair follicles, it causes the production of the yellow pheomelanin pigment rather than black eumelanin. Without the upstream IAP element, **nonagouti** would normally switch on for a very short burst of activity and stimulate a limited amount of yellow pigment production. The presence of the active IAP element upstream was found to create a new, constitutively active start site for the **nonagouti** gene, leading to the hair being produced with pheomelanin throughout its length, and a distinctive yellow fur phenotype. Because the agouti-signaling protein precursor is also expressed in other cell types, the extra activity of the **nonagouti** gene driven by the IAP element caused the yellow mice to become obese (due to actions on adipocytes), creating a syndrome comparable to human type 2 diabetes mellitus in these animals.
FIG. 100.1  The viable yellow mouse model of epigenetic modification of disease risk. The wild-type strain is depicted at the top; the brown coat color is caused by a band of yellow phaeomelanin within the shaft of the otherwise black hair, resulting from a pulse of expression during hair growth from the a (nonagouti) gene on chromosome 2. The lower examples represent what happens when the intracisternal A particle (IAP) transposable element inserts upstream from the nonagouti gene. These mice can be indistinguishable from wild-type mice when the IAP element is completely silenced (pseudoagouti phenotype), or the IAP element can be active in every cell (bottom), driving continuous transcription of the nonagouti gene and causing phaeomelanin to be expressed throughout the growth of the hair, causing the yellow color of the fur (viable yellow phenotype). These mice are also obese because of the effect of agouti-signaling protein on adipocytes. When some cells express and others silence the IAP element, an intermediate fur phenotype, often described as “mottled,” is generated, accompanied by a less pronounced obesity. This demonstrates how the same genetic mutation (the IAP insertion) is variable in its association with a phenotype, depending on differences in transcriptional regulation at a specific locus in the genome.

These mice became an intriguing model of a potential epigenetic role in disease risk because of the unexpected observation that pups from the same litter, all containing the same IAP insertion mutation, differed strikingly in their amount of yellow fur and associated adult obesity. Some of the mice had so little yellow fur that they had no visible evidence of having a mutation at all. The IAP element in these littermates was active in the cells of the yellow mice, as expected, but had undergone silencing in the mice with the brown fur. The inactive IAP element was distinctive for having acquired DNA methylation, the modification of cytosines located immediately before guanines (CG or CpG...
dinucleotides) to 5-methylcytosine. Methylation of cytosines at CG dinucleotides is the default state throughout the genome, but it is usually absent at the sites regulating expression of nearby genes, so its acquisition at these sites indicates that the gene has undergone silencing. This suggested that an influence on how genes are expressed overrode innate genetic susceptibility, modifying the risk of acquiring a disease. Further, researchers modified the diets of mothers pregnant with a litter of pups with the IAP insertion by supplementing folic acid, a single-carbon donor that increased the availability of a cofactor needed for DNA methylation. The outcome was a higher proportion of pups born with DNA methylation and inactivation of the IAP mutation (Fig. 100.2).

Therefore, a reason for the variability in whether the mice developed the yellow fur and obesity could be influences during pregnancy, such as maternal diet. This supported suggestions that intrauterine stresses were associated with increased risks of certain adult conditions, such as cardiovascular, renal, and metabolic diseases. This field of study is often known as the Developmental Origins of Health and Disease (DOHaD), which asks how someone's cells remember an intrauterine stress years or decades later. The viable yellow mouse model suggested that such memory could be mediated by regulators of gene expression and influenced by environmental factors such as maternal diet during pregnancy.
Epigenetics and Regulation of Gene Expression

Two examples of gene regulation provide a model for locking in a regulatory pattern early in development and maintaining it indefinitely thereafter. The first is X chromosome inactivation. Because males have only 1 X chromosome, it does not undergo inactivation. However, a person with 2 X chromosomes will inactivate 1, a person with trisomy for the X chromosome will inactivate 2, and so on. The result is that males and females have 1 active X chromosome per cell, despite starting with different numbers of X chromosomes, a process referred to as dosage compensation.

X chromosome inactivation is generally a random event, choosing the maternal X for inactivation in half the cells of the body and the paternal X in the other half. The inactivation occurs very early during development, when the blastocyst is implanting itself into the uterine wall. However, once established in this small number of pluripotent cells, the inactivation persists in all the cells of the individual throughout life.

The other relevant model of gene regulation is genomic imprinting (see Chapter 97). Gene activation in a specific cell type usually switches on the copies present on both the paternal and the maternal chromosomes. However, an imprinted locus is distinctive because only the copy on the paternal chromosome is switched on for some imprinted genes, while other imprinted genes are distinctive for only switching on the maternal copy. The timing of this inactivation event is even earlier than X chromosome inactivation, occurring during the formation of the male or female gametes. Again, these patterns of inactivation persist throughout life into old age.

Evolution of the Term “Epigenetics”

Because the 2 previous examples both involved a gene regulation event (silencing) that occurred early in development and was maintained into adulthood, they were described as “epigenetic,” emphasizing how a cell retains a memory of past regulatory processes. This highlights that epigenetics has long been held to have a 2nd property, mediating cellular memory.

In the 1950s, Nanney interpreted the epigenetic landscape to define epigenetics as the property of a cell to remember past events. In the 1970s, Riggs and Holliday both noted that DNA methylation patterns could be propagated
from parent to daughter cells, potentially providing a molecular mechanism of cellular memory, and described this as an “epigenetic property.” When DNA methylation was found to be a feature of the alleles silenced during X chromosome inactivation and genomic imprinting, this appeared to confirm the idea of a “heritable molecular mark” being involved in remembering a past silencing event during development, leading DNA methylation to be described as an “epigenetic regulator.” When the active and silenced alleles at X inactivated or imprinted loci were further studied, differences in chromatin states and long noncoding RNAs were found to distinguish the chromosomes, suggesting that they helped to mediate the long-term silencing at these loci.

There have been attempts to test whether chromatin states are heritable through cell division in the same way as DNA methylation. Despite the evidence for their heritability being less compelling, the field has tended to be inclusive rather than exclusive in labeling transcriptional regulators as epigenetic, but needed to redefine epigenetics as epi (above, upon) and genetics (DNA sequence), the back-translated definition. This definition is not only dissociated from the original ideas of cell fates and cellular memory, but now also encompasses all transcriptional regulatory processes. Because of the broadened definition of epigenetics, an experiment testing for differences in cellular memory is no different in design from an experiment testing for differences in transcriptional regulation, which may or may not mediate cellular memory.

**Pediatric Diseases Involving Epigenetic Processes**

Prime examples of epigenetics are those involving imprinted loci, exemplified by the Prader-Willi and Angelman syndromes (see Chapter 97). Each of these syndromes may be caused by the same deletion on chromosome 15, distinguished by the deletion occurring on the paternal chromosome 15 causing **Prader-Willi syndrome** and the maternal chromosome 15 causing **Angelman syndrome**. There are imprinted genes located within the 15q11-q13 region, some of which are expressed only on the paternal chromosome, some only on the maternal chromosome. When an individual is missing the region on the paternally inherited chromosome, the person still has a copy of the gene on the remaining maternal chromosome, but if it is silenced by imprinting, the individual effectively has no functional copy of the gene, leading to the Prader-
Willi phenotype. The converse happens for Angelman syndrome; a deletion of the maternal chromosome leaves a silenced copy of the gene on the paternal chromosome.

Although deletions cause these syndromes in the majority of affected individuals, a subset results from uniparental disomy (UPD), in which there are 2 intact chromosomes 15, but both are inherited from 1 parent. Maternal UPD has the same effect as a paternal deletion in that there is no contribution of a paternally inherited chromosome, causing Prader-Willi syndrome, with paternal UPD causing Angelman syndrome. UPD is thought to start with trisomy for that chromosome, with a 2nd event occurring early in development in which 1 of the 3 chromosomes is lost, occasionally leaving 2 chromosomes derived from the same parent. In a further, very small proportion of individuals, mutations within the 15q11-q13 region seem to affect the imprinted domain as a whole.

Prader-Willi and Angelman syndromes occur because of genetic mutations: large deletions, nondisjunction events leading to whole chromosomal gains or losses, or smaller DNA mutations. These mutations reveal the underlying pattern of genomic imprinting, a distinctive organization of gene regulation at chromosome 15q11-q13 that reflects a memory of the gamete of origin of each chromosome, described as epigenetic. What is not occurring in these individuals is an alteration of the normal epigenetic regulation of the locus, as exemplified by the yellow agouti mice. To find examples of altered epigenetic regulation associated with disease, researchers take advantage of assays that studied DNA methylation patterns throughout the genome. If we had never known about the IAP element insertion in the yellow agouti mice, for example, the locus would have revealed itself by having distinctive DNA methylation in the yellow, obese animals compared with the brown, lean, genetically identical littermates. This approach, referred to as an epigenome-wide association study (EWAS), was initially applied to study individuals who had intrauterine perturbations, environmental exposures, or various types of cancer, to look for cellular reprogramming events.

Epigenome-Wide Association Studies: DNA Methylation

Because of the availability of genome-wide assays and its demonstrated
heritability through mitosis, DNA methylation has been the primary focus for studies attempting to link altered epigenetic regulation with disease phenotypes. The genome-wide association study (GWAS) template was used for EWAS, but instead of linking variability in DNA sequences, the EWAS links variability in DNA methylation with the presence of a phenotype.

Interpretation of EWAS is more complex than foreseen partly because DNA methylation in a sample of cells reflects not only its reprogramming in these cells but also other influences. For example, if a sample of cells contains more than 1 subtype (each subtype of cells in the body has distinctive DNA methylation patterns), a change in proportion of cell subtypes between individuals will cause a change in the pattern of DNA methylation, at the loci where differences in DNA methylation distinguish the cell subtypes. In this way, DNA methylation changes can be found in an EWAS without any individual cells having altered their DNA methylation.

Another major influence, accounting for an estimated 22–80% of DNA methylation variation between individuals, is DNA sequence variability. Epigenetic regulation is defined as a level of information above that of DNA sequence, but the reciprocal influence of DNA sequence variation on DNA methylation is substantial. The typical EWAS to date has not taken genetic variation into account when interpreting its results, again suggesting misinterpretation of DNA methylation changes as reflective of reprogramming of cells, when in fact the differences in DNA methylation may reflect sequence differences in the individuals studied.

The typical design of an EWAS is cross-sectional: comparing a group of individuals with a condition against a group without the condition; by the time these people are studied, they have already developed the disorder of interest. This makes the study vulnerable to the effects of reverse causation, in which the condition studied alters DNA methylation, rather than reprogramming of DNA methylation causing the condition. This has been shown to occur in peripheral blood leukocytes in individuals with high body mass index. The results of all EWAS to date therefore should be interpreted with caution.

Cell Fate Variability as Model for Epigenetics and Disease

A universally held belief is that 1 or more cell types in the body undergo a
change in the regulation of gene expression, a type of cellular reprogramming that alters the properties of the cell to contribute to the disease. However, another model to consider is a reprogramming occurring earlier, during cell fate decision-making, and changing the repertoire of cells in the organ in such a way that it predisposes to disease.

Studies are guided by a mouse model characterized by maternal vitamin A deficiency during pregnancy. Vitamin A is the dietary precursor of retinoic acid, which binds to a retinoic acid receptor that then finds its way to specific locations in the genome to regulate the expression of groups of genes. When vitamin A was restricted in the diet of pregnant female mice from embryonic days 9.5-14.5, the period when most lung formation occurs, the mice were born with increased amounts of smooth muscle around the airways, later in their lives shown to be associated with increased airway resistance. The mice were thus showing a component of the reactive airways disease (asthma) phenotype caused solely by a micronutrient deficiency during fetal life (see Fig. 100.2). The change in a cell fate decision to alter the proportion of 1 or more cell types in the mature organ is a strikingly attractive mechanism for DOHaD and highly consistent with the original definition of epigenetic events based on cell fate decisions, but it is not considered the outcome of interest in current EWAS.

The same model can be considered for the epigenetic response to toxins, in particular endocrine disruptors, defined by their interaction with the endocrine system, for which links with epigenetic regulatory processes have been frequently sought. One interesting class of endocrine-disrupting chemical is the organotins, biocides used in different types of manufacturing. The organotin tributyltin was found to cause obesity and to direct tissue stem cells preferentially toward the production of adipocytes, signaling through a transcriptional pathway involving PPAR gamma. Again, this is not an outcome generally sought in a typical EWAS at present, but it represents a perturbation acting to change cell fate through transcriptional regulatory mechanisms and leading to an altered repertoire of cells in the exposed individual.

**Epigenetic Disease and Therapeutic Interventions**

The question arises whether interventions can ameliorate or reverse a disease phenotype when it is caused by epigenetic processes. In cancer, involving
somatic mutations that can target various mediators of transcriptional regulation, numerous therapeutic avenues have emerged that show promise. An interesting noncancer example is the genetic condition called Kabuki syndrome, which is caused by mutations in either a histone methyltransferase \((KMT2D)\) or a histone demethylase \((KDM6A)\) gene, each of which has a role in creating accessible chromatin to allow genes to be expressed appropriately (Fig. 100.3 and Table 100.1). With the idea that increasing the amount of histone acetylation could help to compensate for the inappropriate histone methylation, mice with Kabuki syndrome were placed on a ketogenic diet, which increases the amount of \(\beta\)-hydroxybutyrate, an endogenous inhibitor of histone deacetylases. Mice on this diet showed improved neurogenesis and memory, suggesting that such an intervention in children with Kabuki syndrome may also have beneficial effects.

Jirtle RL. The Agouti mouse: a biosensor for environmental

Rare and novel disorders often present in childhood and represent a diagnostic challenge that can be addressed using advanced genetic techniques. In the United States, rare disorders are defined as those affecting <200,000 people (about 1 in 1,500 persons), but no single definition has been agreed on internationally.

Scope of Genetic Disease

An estimated 8000 rare disorders are recognized, and the existence of approximately 23,000 human genes suggests that many more genetic diseases will be discovered in the future. Potential reasons patients may remain undiagnosed despite extensive prior investigation include:

- The genetic variant had not previously been associated with the disease phenotype.
- There is genetic pleiotropy (same gene but different variant producing a different phenotype).
- There is genetic heterogeneity (different genes producing similar phenotype).
- Presentation is known but atypical features for a known disease.
Multiple diseases are contributing to the presenting set of disease features.

Somatic mosaicism

**NIH Undiagnosed Diseases Program**

One approach toward investigating undiagnosed diseases was taken by the National Institutes of Health (NIH) Undiagnosed Diseases Program (UDP), which was expanded to a nationwide Undiagnosed Diseases Network (UDN). For the >4,000 patient applications to the UDP, prior investigations are recounted in a summary letter from the referring clinician and documented with medical records that include photos, videos, imaging, and histologic slides of biopsy material. Specialty consultants review the records, and the UDP directors determine the next steps. Accepted patients come to the NIH Clinical Center for a week-long inpatient admission. Approximately half the patients with undiagnosed diseases have neurologic disease; cardiovascular, rheumatology, immunology, and pulmonary problems are also common. Approximately 40% of accepted patients are children, who often have congenital anomalies and neurologic disorders.

**Clinical Evaluation**

Patients remain without a definitive diagnosis after an extensive workup in part because every individual has a unique genetic and environmental background, and diseases have variable expression. Undiagnosed conditions include those never before seen, unusual presentations of otherwise recognizable conditions, and combinations of conditions that obfuscate each other's identities. A thorough clinical investigation allows the clinician to broaden the differential diagnosis through research, consultation, and clinical testing. Extensive phenotyping, imaging, and other tests provide better documentation of the presentation and allow for association with diseases not yet discovered, genetic variants, and patient cohorts.

A complete history anchors the data and includes prenatal and neonatal findings, developmental milestones, growth pattern, onset and progression of symptoms and signs, precipitating influences, response to medications, and a pedigree to determine which family members are possibly affected. Pertinent
physical findings include dysmorphisms, organomegaly, neurologic impairment, bone involvement, and dermatologic findings. Because many rare and novel disorders are *multisystemic*, consultants play a critical role in every diagnostic evaluation. Typical studies performed to address possible diagnoses are listed in Table 101.1; neurodevelopmental or neurodegenerative phenotypes require even more extensive studies (Table 101.2).

Ophthalmology
Endocrinology
Immunology
Rheumatology
Dermatology
Cardiology
Neuropsychology
Nutrition
Rehabilitative medicine
  Physical therapy
  Occupational therapy
  Speech therapy

Procedures

Swallow study for aspiration
Abdominal ultrasound (hepatosplenomegaly)
Skeletal survey (dysostosis)
Bone density scan (nonambulatory or growth failure patients)
Bone age
Electroencephalogram, evoked responses, electroretinogram (ERG)
Muscle biopsy for electron transport chain function, histology, immunohistochemistry
Neuropsychometric testing
Nerve biopsy

Laboratory Evaluations

Complete blood count with differential and peripheral smear
Comprehensive metabolic panel
Prothrombin time/partial thromboplastin time (for anesthesia sedation)
Thyroid-stimulating hormone, thyroxine
Vitamins A and E, 1,25-dihydroxyvitamin D
Lactate, pyruvate
Ammonia
Amino acids (plasma and urine)
Organic acids (urine)
Acylcarnitine profile
Total and free carnitine
Lysosomal enzyme analysis in leukocytes/fibroblasts
White blood cell coenzyme Q
Purines and pyrimidines (urine)
α-Glucosidase (plasma and urine)
Peroxisomal panel
Oxysterols
Methylmalonic acid and homocysteine (plasma)
Copper/ceruloplasmin
Transferrin isoelectric focusing
N - and O -glycans (plasma)
Oligosaccharides and free glycans (urine)
Glycosaminoglycans (urine)

**Additional Testing if Clinically Indicated**

- Electron microscopy of white blood cell buffy coat for inclusion bodies
- Electron microscopy of skin biopsy for evidence of storage
- Stool for ova and parasites, occult blood, fecal fat, or fecal calprotectin
- Autoimmune antibodies
- Vaccine response titers
- C3/C4
- Quantitative immunoglobulins
- T-cell subsets
- Conjunctival or salivary gland biopsy

**Research Specimens**

- Cerebrospinal fluid
- Serum
- Plasma
- Skin biopsy for fibroblasts and/or melanocytes
- Isolated DNA/RNA
- Urine
**Studies Under Sedation**

- 3T MRI/magnetic resonance spectroscopy of brain (and spine if indicated)
- Skin biopsy
- Ophthalmologic exam
- Brainstem auditory evoked response
- Electroretinogram
- Lumbar puncture for biopterin, neopterin, neurotransmitters, folate, and inflammatory markers
- Dental exam
- Large blood draws
- Catheterization for urine
- Any part of the physical exam difficult to do in an awake child, including dysmorphology measurements and genital and rectal exam
- Electromyography and nerve conduction studies

An inpatient admission allows for close interaction among experts in different fields, informs the evaluation of complex cases, and often leads to new disease discovery. In the last situation, other family members require evaluation to ascertain whether they are affected with the disorder.

**Commercial Genetic Studies**

Once **phenotyping** is complete, a list of candidate genetic disorders can be compiled. Laboratory testing is available for an increasingly large number of molecular disorders. Examples of genetic panels include those for X-linked cognitive impairment, hereditary spastic paraplegia, spastic paraplegia and gait disorders, spinocerebellar ataxias, dystonias, and mitochondrial disorders. Some of these are expensive and may exceed the cost of **exome sequencing**. On the other hand, exome and genome sequencing are not useful for detecting diseases caused by many types of genetic disorder, including from DNA repeats. In addition, exome sequencing may provide less certainty for excluding genetic diseases than a disease-specific test panel.

**Single Nucleotide Polymorphism Arrays**
Single nucleotide polymorphism (SNP) arrays and next-generation sequencing (NGS) provide valuable genome-wide structural information. The human genome's 3.2 billion bases include many that are polymorphic, customarily defined as differing between any 2 people >1% of the time. In most human populations, about 4 million differences exist between any 2 unrelated individuals (about 1 polymorphism for every 1,000 bases in the genome on average). Within a single ethnic population, about 1 common SNP occurs per 3,000-7,000 bases, where common means a >10% chance that the base will differ between 2 unrelated people. Approximately 1 million of these common SNPs can be included on a DNA hybridization array and examined simultaneously, revealing copy number variants, mosaicism, and regions of identity by descent. These results complement NGS results; one example is the pairing of sequence variants detected by exome or genome sequencing with trans -oriented deletions detected by SNP assay.

**Exome Sequencing**

Technical advances have allowed for massive, inexpensive DNA sequencing, making it feasible to determine the sequence of the coding regions of almost all the human genes. Because this involves 1.9% of the 3.2 billion bases in the human genome, exome sequences comprise approximately 60,000,000 bases. Using current technology, clinical exome sequencing adequately sequences >80% of known genes and >90% of genes that have been associated with human disease. The average exome sequencing produces about 35,000 bases (0.06%) that differ from the “reference” sequence and from any other unrelated human sequence of the same ethnic group. These variants include some laboratory and computational errors. In practice, most variants are inconsequential polymorphisms and minor polynucleotide repeats that occur near intron/exon boundaries. However, each of the 35,000 variants of unknown significance is a potential disease-causing variant, yet only 1 (or 2 for compound heterozygous recessive cases) is the disease-causing mutation for a monogenic disorder (with perhaps 2 or 3 additional loci modifying severity). The clinician and bioinformatician must reduce the number of candidate variants to a tractable number, which is challenging. For instance, a variant causing an adult-onset disease may look just as damaging as a different variant causing congenital-onset disease. However, the likelihood of the presence of the associated diseases is much different in an adult vs a child.
Certain rules are used to separate *likely-interesting variants* from likely-uninteresting variants. For example, variants that segregate in a family consistent with a given inheritance model (e.g., dominant or recessive) are retained, while those that segregate in an inconsistent manner are set aside. This segregation filter requires careful clinical data collection and experimental design, since it depends on correct assignment of affected vs unaffected statuses in the family and collection of sequencing data for family members besides the proband.

A 2nd technique used to evaluate sequence variants is **pathogenicity assessment**. Bioinformaticians estimate the likelihood that a given DNA sequence variant will have biologic consequences (e.g., change protein function or gene expression). Factors such as nucleotide conservation and differences in coded amino acids are used to create a pathogenicity estimate, or score. Various software programs take different, often overlapping, approaches. PolyPhen-2, SIFT, and MutationTaster rate the pathogenicity of amino acid changes. Computer modeling programs such as CADD, Eigen, and M-CAP, trained on model genetic changes that are already validated, predict effects on gene expression of noncoding variants. These filters are very powerful because of large population datasets that are publically available, including the 1000Genomes project, ExAC, and the UK's 10K genome project. In the next 1 or 2 yr, datasets with genome populations in the 100,000 to 1 million range (e.g., GnomAD database) will further improve these filters and provide better subpopulation frequencies. Ultimately, a multiethnic, graph theory-based alignment should allow successful filtering of variants in currently incomplete genomic regions such as the HLA region. Overall, computational pathogenicity assessment has false-positive and false-negative rates of 10–20%.

Some filters compare variants to databases that contain previously measured or asserted properties of variants found in human populations, such as population frequency information (e.g., ExAC), or curated evidence for association with human disease (e.g., CLINVAR). The latter, while potentially useful, is quite incomplete for many genes, but this is improving. One common pitfall of database-derived filters is an inaccurate designation of certain variants as rare. This typically happens when the database is missing information from human populations in whom the variant is seen more often than in the included populations.

Several points need to be considered when employing genome-scale sequencing for clinical diagnostics. **Positive predictive value** gives the likelihood that a positive test is a true positive. This is higher in a population in
whom a disease is common and lower in a population in whom the disease is rare. A person being tested with exome sequencing will show no clinical signs or symptoms of most of the genetic diseases for which the exome sequencing tests. Therefore, many apparently positive findings will be *false positives*, variants associated with phenotypes that do not match the person being tested.

**Individual vs family** studies are relevant because family data allow for the proband's variants to be substantially filtered. This advantage must be weighed against the financial costs of studying families vs individuals. Furthermore, family studies are useless if an affected person is called unaffected, or vice versa. Therefore, *phenotyping family members is critical*. For later-onset conditions, younger siblings may not be suitable for inclusion in an exome sequencing study unless their affected status can be determined unambiguously. Datasets with large numbers of young individuals may have many pathologic variants that cause disease in elderly persons and are inappropriate for filtering variants in late-onset adult diseases or for prenatal counseling about late-onset disease inheritance risks.

**Data revisiting policies** must be addressed. Genome-scale sequencing generates data for many genes besides those involved in the current diagnostic effort; these data may be useful in the future care of the patient. Some unreported mutated genes, not currently associated with disease, may be implicated in the future as disease risk factors or even as protective factors. In the current testing environment, time-limited data reuse policies and storage and reuse fees are increasingly common. In fact, the storage of data is now becoming more expensive than the cost of re-generating the data.

**Early discussion with a genetic specialist is critical.** Genetic counseling should be sought before an exome sequencing study is sent. Proper consent for exome sequencing studies is an involved process, including discussions of disease risk factors, unrelated medical conditions, carrier states, and cancer susceptibility. Consented individuals should be asked which types of results they would like to receive.

**Anticipating findings that are difficult to use clinically is an important part of counseling.** Variants of unknown significance (VUS) are problematic, and genome-scale sequencing amplifies the problem by including variable numbers of results that are difficult to use for medical decision-making. Discussing such variants with families can be challenging; counseling families about the likelihood of receiving this type of result before testing is performed can help the family to cope when the report is returned (see Chapter 94).
When used as a gene panel, exome sequencing rules *in* but does not rule *out*. An exome study is a cost-effective way to test many genes simultaneously, but coverage of any given exon varies. Therefore, exome studies cannot always exclude variants in a panel of genes. With careful analysis involving laboratory validation performed on many similarly processed individuals, the exome coverage of any given gene can be assessed. However, commercial/clinical testing facilities may be unwilling to perform such an analysis when a large set of genes needs to be considered. Therefore, a gene panel can be useful when the index of suspicion is high for a disorder caused by a large group of genes. Cerebellar ataxia and hereditary spastic paraplegia are examples (see Chapters 615.1 and 631).

Providing information to the testing facility improves the chance of diagnosis. Exome sequencing interpretation benefits substantially from the incorporation of an accurate and detailed phenotype. The more clinical information provided to the testing lab, the more specific and useful will be the clinical report.

The role of whole genome sequencing (WGS) is not yet defined in clinical practice but remains a consideration when exome sequencing yields no diagnosis. The fundamental issue is whether the VUS findings in an exome will be more meaningful than any additional variants discovered by WGS, rather than a clinical conclusion that there is no germline genetic/molecular cause for the undiagnosed patient. WGS tools have less confidence because of net lower coverage, take more time to process, and generate variants in noncoding regions of the genome that are much more difficult to filter and interpret.

**Gene Function Studies**

Despite filtering for frequency and predicted deleteriousness, a variant identified by exome or genome sequencing cannot be interpreted as the cause of an individual's disease unless it has been previously demonstrated to cause a disease with a similar phenotype. To prove causality, medical genetics relies on association (the recurrence of mutations within a gene among individuals with a similar phenotype). For rare diseases, there may be too few affected patients to demonstrate a statistically significant association, and other evidence from phenotype ontologies, metabolomics, glycomics, proteomics, and lipidomics may be required. In addition, models (e.g., mice, zebrafish, fruit flies, yeast, cultured cells) can be developed to recapitulate the disease. The variant in
question can also be linked to a biologic process or pathway that is known to cause a similar phenotype when disturbed. Finally, standardized and correlated phenotypic and genomic data are deposited into a database to identify other individuals with a similar phenotype and mutations in the same gene.

Physicians may apply their past biases to a group of variants that could be disease causing, but this is often misleading. A standardized computational approach is preferable. For example, the Human Phenotype Ontology standardizes the description of a disease and, because the descriptors have been mapped to other human diseases and to mutant model organisms, identifies possible candidate genes and genetic networks for causing the disease. Similarly, untargeted laboratory screening tests provide an unbiased survey of patient cellular biology and physiology and a more informed prioritization of candidate variants.

The ultimate proof of causality is to ameliorate the disease process by correcting the genetic defect; this might be demonstrable in a model system that recapitulates the human disease. Alternatively, a search for other patients with a similar phenotype and mutations in the same gene can be performed using public databases established using strict statistical and biologic standards.

**Pediatric Issues**

Of the UDP's 1st 500 pediatric applications, >10% had more than 1 family member (usually a sibling) similarly affected. The age distribution had peaks at 4-5 yr (reflecting patients with congenital disorders) and at 16-18 yr (representing disorders with symptom onset at early school age). Most applicants had been on a diagnostic odyssey for >5 yr. Of the 200 pediatric cases accepted, 25% received a diagnosis; half were obtained using conventional diagnostic methods, including clinical suspicion, biochemical testing with molecular confirmation, or radiographic interpretation. Otherwise, SNP analysis and NGS yielded the diagnosis; all involved rare diseases.

Pediatric medical records require attention to what has and what has not been completed previously. The electronic medical record is an important tool, but “copy forward” functions can perpetuate errors, such as reports of normal testing when in fact the test was recommended or ordered but not performed. Repetitive copying also fosters sloppiness in critical thinking, failure to take an adequate history, and missing the nuances of symptom progression. A history and physical examination should be performed anew and all prior testing results confirmed
Considerations for Families of Undiagnosed Children

When a child comes to a genetics clinic for evaluation, the parents ask these questions:

◆ What does my child have? (diagnosis)
◆ Why did it happen? (etiology/inheritance)
◆ What will happen in the future? (natural history; prognosis)
◆ Is there a treatment? (therapy)
◆ Could the same thing happen to other family members? (recurrence risk)

The answers all require an accurate diagnosis. The lack of a diagnosis makes both the family and the physician uncomfortable, raises suspicion among relatives and acquaintances, and creates feelings of guilt about not having worked hard enough to obtain a diagnosis. Families often consult more and more specialists, becoming frustrated with the lack of coordination among providers. Families should save copies of every test and every visit from each institution in a binder for travel among institutions. A 2- to 3-page narrative summarizing the child's history, medications, list of healthcare providers with contact information, main medical issues, level of functioning on well days and sick days, and interventions that worked in the past can be invaluable in an emergency room setting. An electronic copy is easily updated. Parents can always be the best advocates for their child, particularly an undiagnosed child.

Recommendations to parents of an undiagnosed child are similar to those that apply to any child with chronic illness:
◆ Organize copies of all records, especially original reports from “send-out” laboratories.
◆ Carry an updated emergency letter.
◆ Establish a medical home even if you obtain many second opinions.
◆ Find a physiatrist (rehabilitation medicine physician) to coordinate rehabilitative care.
◆ Strongly advocate with the school system for needed services (see Chapter 48), using a legal advocate if necessary;
◆ Explore parent support groups for unknown disorders (Syndromes Without a Name, National Organization for Rare Disorders).
◆ Periodically check with providers (especially geneticists) for new diagnoses reported in the medical literature.
◆ Carve out time for yourselves as caregivers by engaging extended family members or respite care services.
◆ Work at supporting and being attentive to well children in the family.
◆ For the dying child, consider an autopsy to establish a diagnosis, especially when there is a possibility of future pregnancies.

The Diagnostic Spectrum

Rare and new genetic disorders can present at any age; a gene's “severe”
mutations may manifest early in life while “mild” mutations present later. Diagnoses of known disorders can have very different bases, such as the extent of recognition of a clinical entity, a molecular confirmation, or biochemical evidence. Some variants identified by SNP and exome sequencing analyses may represent new diseases.

One example of the use of these technologies to discover a new diagnosis involves 2 brothers whose parents were first cousins. The brothers had an early-onset spastic ataxia-neuropathy syndrome, with lower-extremity spasticity, peripheral neuropathy, ptosis, oculomotor apraxia, dystonia, cerebellar atrophy, and progressive myoclonic epilepsy. A homozygous missense mutation (c.1847G>A; p.Y616C) in AFG3L2, which encodes a subunit of a mitochondrial protease, was identified by exome sequencing. The AFG3L2 protein can bind to another AFG3L2 molecule or to paraplegin. UDP collaborators in Germany used a yeast model system to demonstrate that the patients' mutation affects the specific amino acid involved in the formation of both these complexes. As a result, the brothers exhibited the signs and symptoms of a known AFG3L2 defect, autosomal dominant spinocerebellar ataxia type 28 (SCA28), and also deficits attributable to a paraplegin defect, hereditary spastic paraplegia type 7 (SPG7). Other features of a mitochondrial disorder (oculomotor apraxia, extrapyramidal dysfunction, myoclonic epilepsy) were also present. The 2 brothers represent the 1st such cases in the world and expand the phenotype of AFG3L2 disease.

A 2nd example involves 2 siblings ages 5 and 10 yr with hypotonia, developmental delays, facial dysmorphisms, hearing loss, nystagmus, seizures, and atrophy on brain MRI. In this case the leading clue was biochemical in nature, and genetic analysis confirmed the diagnosis. Urine thin-layer chromatography for oligosaccharides identified a strong band determined by mass spectrometry to consist of a tetrasaccharide containing 3 glucose and 1 mannose. This suggested a defect of glucosidase I, the 1st enzyme involved in endoplasmic reticulum trimming of N-linked glycoproteins from a high-mannose to a complex form. Mutation analysis confirmed compound heterozygous variants in the glucosidase I gene, establishing the diagnosis of congenital disorder of glycosylation IIb. The 2 siblings were the 2nd and 3rd patients in the world with this disorder.

Occasionally an autosomal dominant disorder, typically presenting in adulthood, can manifest as a completely different and more severe disorder when pathologic variants in the same gene are inherited from each parent; the child is a
compound heterozygote. This was the case in a 3 yr old child who inherited 2 variants in GARS, the gene causing autosomal dominant Charcot-Marie-Tooth disease (CMT) 2D. The child had severe intrauterine and postnatal growth retardation, microcephaly, developmental delay, optic nerve atrophy and retinal pigment changes, as well as an atrial septal defect. Neither parent was symptomatic at the time the child was evaluated; the parents had normal electromyography and nerve conduction studies. This case emphasizes the need to consent families before any genetic testing as to the possibility of receiving unexpected results in additional family members. In this case, genetic counseling was expanded to include possible CMT2D in the parents.

Chapter 110 The Porphyrias
Chapter 111 Hypoglycemia
Many childhood conditions are caused by single-gene mutations that encode specific proteins. These mutations can change primary protein structure or the amount of protein synthesized. The function of a protein, whether it is an enzyme, receptor, transport vehicle, membrane component, transcriptional co-regulator, or structural element, may be compromised or abolished. Hereditary diseases that disrupt normal biochemical processes are termed inborn errors of metabolism or inherited metabolic diseases.

Most genetic changes are clinically inconsequential and represent benign variants. However, pathogenic variants produce diseases that range in severity of presentation and time of onset. Severe metabolic disorders usually become clinically apparent in the newborn period or shortly thereafter, whereas milder forms may present later in childhood and even in adulthood. With some exceptions, the presenting symptoms of most metabolic conditions lack the specificity to enable a definitive diagnosis without further evaluation. The combination of low specificity of presenting symptoms and low prevalence of metabolic disorders makes determination of the diagnosis difficult. Progressive symptoms, the lack of plausible non-genetic diagnosis after detailed evaluation, history of overlapping symptoms in patient's relatives, or consanguinity should alert a pediatrician to seek a consultation with a geneticist and consider metabolic testing early in the evaluation.

Correct diagnosis is often only the beginning of a long medical journey for most families affected by metabolic conditions (see Chapter 95). Although each inherited metabolic disorder is individually rare, improved diagnosis and increasing survival of patients with metabolic conditions virtually ensure that a pediatrician will encounter and provide care to affected patients. Pediatricians
can play a critical role in establishing the continuity of care, managing some aspects of treatment, fostering adherence, and delivering routine pediatric interventions such as immunizations, referrals to specialists, and elements of genetic counseling (see Chapter 94.1).

The greater awareness of metabolic conditions, wider availability of biochemical laboratories, global metabolomic analysis, and routine application of exome sequencing dramatically increased the detection rate of the known disorders and contributed to the discovery of new metabolic disorders. Nonetheless, collection and analysis of family history remains a critical screening test that a healthcare provider can use to identify an infant or child at risk for a metabolic disorder. The identification of consanguinity or a particular ethnic background with an unusually high incidence of inborn errors of metabolism can be important to direct further studies. For example, tyrosinemia type 1 is more common among French-Canadians of Quebec, maple syrup urine disease is seen with higher frequency in the U.S. Amish population, and Canavan disease in patients of the Ashkenazi Jewish ancestry.

Newborn Screening

The individual rarity of inborn errors of metabolism, the importance of early diagnosis, and the ensuing genetic counseling ramifications make a strong argument for the universal screening all newborn infants. Tandem mass spectrometry of metabolites and digital microfluidics analysis of enzyme activities form the foundation of newborn screening today. Both methods require a few drops of blood to be placed on a filter paper and delivered to a central laboratory for assay. Many genetic conditions can be identified by these methods, and the list of disorders continues to grow (Tables 102.1 and 102.2). Pediatricians need to be aware of the general screening procedure and limitations of screening. As a screening method, a positive result may require a repeat newborn screen or confirmatory testing to secure the diagnosis. Time required to return the results vary from country to country and even within states in the same country. Some metabolic conditions can be severe enough to cause clinical manifestations before the results of the newborn screening become available. Conversely, diagnostic metabolites in milder forms of screened disorders may not reach a set threshold to trigger secondary studies, thus leading to a negative newborn screen results and delayed diagnosis. Therefore, negative newborn screening in a patient with symptoms suggestive of a metabolic disorder
warrants a referral to genetics center for further evaluation.

Congenital adrenal hyperplasia
Galactosemia
Hearing loss
Cystic fibrosis
Severe combined immunodeficiency (SCID) †
Critical congenital heart disease †

\[cbl\ A, \text{Cobalamin A defect;} \ cbl\ B, \text{cobalamin B defect;} \ CoA, \text{coenzyme A.}\]

* As of November 2014, there is state-to-state variation in newborn screening; a list of the disorders that are screened for by each state is available at [http://genes-r-us.uthscsa.edu/sites/genes-r-us/files/nbsdisorders.pdf](http://genes-r-us.uthscsa.edu/sites/genes-r-us/files/nbsdisorders.pdf).

† The inclusion of SCID and critical congenital heart disease received support of the American College of Medical Genetics and Genomics.

**Table 102.2**

**Secondary Conditions Recommended by American College of Medical Genetics* Task Force for Inclusion in Newborn Screening**

**Organic Acid Metabolism Disorders**
Methylmalonic acidemia (*cbl C and cbl D defects*)
- Malonic acidemia
- 2-Methyl-3-hydroxybutyric aciduria
- Isobutyryl-CoA dehydrogenase deficiency
- 2-Methylbutyryl-CoA dehydrogenase deficiency
- 3-Methylglutaconic aciduria

**Fatty Acid Oxidation Disorders**

- Short-chain acyl-CoA dehydrogenase deficiency
- Glutaric acidemia type 2
- Medium/short-chain 3-hydroxy-acyl-CoA dehydrogenase deficiency
- Medium-chain ketoacyl-CoA thiolase deficiency
- Carnitine palmitoyltransferase IA deficiency
- Carnitine palmitoyltransferase II deficiency
- Carnitine:acylcarnitine translocase deficiency
- Dienoyl-CoA reductase deficiency

**Amino Acid Metabolism Disorders**

- Hyperphenylalaninemia, benign (not classic phenylketonuria)
- Tyrosinemia type II
- Tyrosinemia type III
- Defects of biopterin cofactor biosynthesis
- Defects of biopterin cofactor regeneration
- Argininemia
- Hypermethioninemia
- Citrullinemia type II (citrin deficiency)

**Hemoglobinopathies**

- Hemoglobin variants (including hemoglobin E)

**Others**
Galactose epimerase deficiency
Galactokinase deficiency

cbl C, Cobalamin C defect; cbl D, cobalamin D defect; CoA, coenzyme A.

* The American College of Medical Genetics Newborn Screening Expert Group (May 2006) recommended reporting, in addition to the primary disorders, 25 disorders (“secondary targets”) that can be detected through screening but that do not meet the criteria for primary disorders (https://www.acmg.net/resources/policies/nbs/NBS_Main_Report_01.pdf).

Universal newborn screening may also identify mild forms of inherited metabolic conditions, some of which may never cause clinical manifestations in the lifetime of the individual. For example, short-chain acyl-CoA dehydrogenase deficiency has been identified with unexpectedly high frequency in screening programs using tandem mass spectrometry, but most of these children have remained asymptomatic. This highlights the need for an ongoing evaluation of metabolite cutoff values and approaches to confirmatory testing to maximize the diagnostic yield and minimize potential psychosocial and economic implications of such findings. Premature infants represent a special patient population in whom the incidence of false-positive or false-negative test results can be especially high.

With the advent of genetic therapy for spinal muscular atrophy (SMA) and enzyme replacement therapy for some lysosomal storage diseases (e.g., Pompe disease, Fabry disease, Gaucher disease, and mucopolysaccharidosis type 1), pilot newborn screening programs have demonstrated initial success in identifying SMA or lysosomal storage disorders, often before severe symptoms develop.

Clinical Manifestations of Genetic Metabolic Diseases

Physicians and other healthcare providers who care for children should familiarize themselves with early manifestations of genetic metabolic disorders,
because (1) severe forms of some of these conditions may cause symptoms before the results of screening studies become available, and (2) the current screening methods, although quite extensive, identify a small number of all inherited metabolic conditions. In the newborn period, the clinical findings are usually nonspecific and similar to those seen in infants with sepsis. A genetic disorder of metabolism should be considered in the differential diagnosis of a severely ill newborn infant, and special studies should be undertaken if the index of suspicion is high (Fig. 102.1).

![Diagram](image)

**FIG. 102.1** Initial clinical approach to a full-term newborn infant with a suspected genetic metabolic disorder. This schema is a guide to elucidate some of the metabolic disorders in newborn infants. Although some exceptions to this schema exist, it is appropriate for most cases affected by disorders or intermediate metabolism. CNS, Central nervous system; GI, gastrointestinal; HCO$_3^-$, bicarbonate.

Signs and symptoms such as lethargy, hypotonia, hypothermia, convulsions (Table 102.3), poor feeding, and vomiting may develop as early as a few hours after birth. Occasionally, vomiting may be severe enough to suggest the diagnosis of pyloric stenosis, which is usually not present, although it may occur
simultaneously in such infants. Lethargy, poor feeding, seizures, and coma may also be seen in infants with hypoglycemia (Table 102.4) (see Chapters 111 and 127), hypocalcemia (Chapters 64 and 589), and hyperammonemia (Table 102.5) (Chapter 103). Measurements of blood concentrations of glucose and calcium and response to intravenous injection of glucose or calcium help establish these diagnoses. Every organ system can be affected by metabolic disorders. However, *physical examination* usually reveals nonspecific findings; most signs are related to the central nervous system such as opisthotonus in the case of maple syrup urine disease (MSUD). Hepatomegaly is a common finding in a variety of inborn errors of metabolism (Table 102.6). Cardiomyopathy (Table 102.7), dysmorphology (Table 102.8), and fetal hydrops (Table 102.9) are additional potential manifestations of a metabolic disorder (Table 102.10). Occasionally, a peculiar odor may offer an invaluable aid to the diagnosis (Table 102.11).

In an increasing number of patients, a metabolic condition may be recognized months or years after birth. This is more typical in patients carrying milder autosomal recessive pathogenic variants, in mitochondrial disorders, in females affected by X-linked recessive conditions, and specific metabolic conditions that usually present later in life. *Clinical manifestations*, such as intellectual disability, motor deficits, developmental regression, seizures, psychosis, cardiomyopathy, myopathy, organomegaly, and recurrent emesis, in patients beyond the neonatal period should suggest an inherited metabolic disease (Table
There may be an episodic or intermittent pattern, with episodes of acute clinical manifestations separated by periods of seemingly disease-free states. The episodes are usually triggered by stress or nonspecific catabolic stress such as an infection. The child may die during one of these acute attacks. An inborn error of metabolism should be considered in any child with 1 or more of the following manifestations: unexplained developmental delay; intellectual disability; developmental regression; motor deficits or adventitious movements (e.g., dystonia, choreoathetosis, ataxia); seizures; catatonia; unusual odor (particularly during an acute illness); intermittent episodes of unexplained vomiting, acidosis, mental deterioration, psychosis, or coma; hepatomegaly; renal stones; renal dysfunction, especially Fanconi syndrome or renal tubular acidosis; muscle weakness; and cardiomyopathy (Table 102.12).

Diagnosis usually requires a variety of specific laboratory studies. Plasma amino acid analysis, plasma acylcarnitine profile, total and free carnitine profile,
and urine organic acid assay, while not exhaustive in their diagnostic scope, are useful as initial screening tests to evaluate for a suspected inborn error of metabolism. Measurements of plasma ammonia, lactate, bicarbonate, and pH are readily available in hospitals and very helpful initially in differentiating major causes of genetic metabolic disorders (Table 102.13; see Fig. 102.1). Elevation of blood ammonia is usually caused by defects of urea cycle enzymes, organic acidemias, and disorders of fatty acid oxidation. Infants with elevated blood ammonia levels from urea cycle defects tend to have normal serum pH and bicarbonate values; without measurement of blood ammonia, they may remain undiagnosed and succumb to their disease. In organic acidemias, elevated plasma ammonia is accompanied by severe acidosis caused by accumulation of organic acids, ketone bodies, and lactate in body fluids.

When blood ammonia, pH, and bicarbonate values are normal, other aminoacidopathies (e.g. hyperglycinemia) or galactosemia should be considered. Galactosemic infants may also manifest cataracts, hepatomegaly, ascites, and jaundice.

**Treatment**

The majority of patients with genetic disorders of metabolism respond to one or more of the following treatments:

1. Special diets play an important role in the treatment of affected children.
Dietary changes should be tailored to the pathophysiology of the condition and vary greatly among disorders.

2. Hemodialysis for expeditious removal of accumulated noxious compounds. This is a very effective modality for treatment of the acute phase of the condition.

3. Catabolic states in patients at risk for metabolic crisis can be treated with fluids containing dextrose and electrolytes.

4. Administration of the deficient metabolite.

5. Administration of the cofactor or coenzyme to maximize the residual enzyme activity.

6. Activation of alternate pathways to reduce the noxious compounds accumulated because of the genetic mutation.

7. Administration of the deficient enzyme.

8. Bone marrow transplantation.

The organ transplantation modalities may offer the best treatment modality to stabilize a metabolic patient and improve quality of life. To date, replacement of the mutant gene with a normal copy using gene therapy has been successful in only a few diseases.

Treatment of genetic disorders of metabolism is complex and requires medical and technical expertise. The therapeutic regimen often needs to be tailored to the individual patient because of large phenotypic variations in the severity of the disease, even within a single family. Providing education and support for the family is the key to successful long-term therapy. Even in patients with poor prognoses, every effort should be made to establish correct diagnoses premortem. Effective treatment is best achieved by a team of specialists—metabolic genetics specialist, nutritionist, neurologist, and psychologist—in a major medical center.

Andersson HC. Newborn screening for spinal muscular atrophy

Phenylalanine is an essential amino acid. Dietary phenylalanine not utilized for protein synthesis is normally degraded by way of the tyrosine pathway (Fig. 103.1). Deficiency of the enzyme phenylalanine hydroxylase (PAH) or of its cofactor tetrahydrobiopterin (BH₄) causes accumulation of phenylalanine in body fluids and in the brain.
Elevations of phenylalanine in the plasma depend on the degree of enzyme deficiency. In patients with severe PAH deficiency (previously referred to as classic phenylketonuria), plasma phenylalanine levels on unrestricted diet usually exceed 20 mg/dL (>1,200 µmol/L). Patients with milder PAH pathogenic variants have plasma phenylalanine levels between 10 mg/dL (600 µmol/L) and 20 mg/dL (1,200 µmol/L). Levels between 2 and 10 mg/dL (120-600 µmol/L) on unrestricted diet are observed in patients with mild hyperphenylalaninemia. In
affected infants with plasma concentrations >20 mg/dL, excess phenylalanine is metabolized to phenylketones (phenylpyruvate and phenylacetate; see Fig. 103.1) that are excreted in the urine, giving rise to the term \textit{phenylketonuria} (PKU).

These metabolites have no known role in pathogenesis of central nervous system (CNS) damage in PKU patients; their presence in the body fluids simply signifies the severity of the condition. The brain is the main organ damaged by PKU, but the exact mechanism of injury remains elusive. Both toxic levels of phenylalanine and insufficient tyrosine may play a role. Phenylalanine hydroxylase converts phenylalanine to \textit{tyrosine}, which is necessary for the production of neurotransmitters such as epinephrine, norepinephrine, and dopamine (Fig. 103.2). If the degree of enzymatic block is severe, tyrosine becomes an essential amino acid and may be deficient if intake is not adequate. On the other hand, observations that lower concentration of phenylalanine in plasma and brain tissue are associated with improved neurobehavioral outcomes support the view that toxic levels of phenylalanine are key to the mechanisms of the disease. High blood levels of phenylalanine can saturate the transport system across the blood-brain barrier and cause inhibition of the cerebral uptake of other large neutral amino acids such as branched-chain amino acids, tyrosine, and tryptophan, impairing brain protein synthesis.

\textbf{FIG. 103.2} Other pathways involving tyrosine metabolism. BH$_4$ * indicates hyperphenylalaninemia caused by tetrahydrobiopterin (BH$_4$) deficiency (see Fig. 103.1). HVA, Homovanillic acid; VMA, vanillylmandelic acid. Enzymes: (1) Tyrosine hydroxylase (TH), (2) aromatic L-amino acid decarboxylase (AADC), (3) dopamine β-hydroxylase (DβH), (4) phenylethanolamine-N-methyltransferase (PNMT), (5) catechol O-methyltransferase (COMT), (6) monoamine oxidase (MAO).
Severe Phenylalanine Hydroxylase Deficiency (Classic Phenylketonuria)

Elevations of plasma phenylalanine >20 mg/dL (>1,200 µmol/L), if untreated, invariably result in the development of signs and symptoms of classic PKU, except in uncommon and unpredictable cases.

Clinical Manifestations

The affected infant appears normal at birth. Profound intellectual disability develops gradually if the infant remains untreated. Cognitive delay may not be evident for the 1st few months. In untreated patients, 50–70% will have an IQ below 35, and 88–90% will have an IQ below 65. Only 2–5% of untreated patients may have normal intelligence. Vomiting, sometimes severe enough to be misdiagnosed as pyloric stenosis, may be an early symptom. Older untreated children become hyperactive with autistic behaviors, including purposeless hand movements, rhythmic rocking, and athetosis.

Untreated and undertreated infants are lighter in their complexion than unaffected siblings. Some may have a seborrheic or eczematoid rash, which is usually mild and disappears as the child grows older. These children have an odor of phenylacetic acid, which has been described as musty or “mousey.” Neurologic signs include seizures (approximately 25%), spasticity, hyperreflexia, and tremors; >50% have electroencephalographic (EEG) abnormalities. Microcephaly, prominent maxillae with widely spaced teeth, enamel hypoplasia, and growth retardation are other common findings in untreated children. Low bone mineral density and osteopenia have been reported in affected individuals of all ages. Although inadequate intake of natural proteins seems to be the major culprit, the exact pathogenesis of this sequela remains unclear. Long-term care of patients with PKU is best achieved by a team of experienced professionals (metabolic specialist, nutritionist, and psychologist) in a regional treatment center. The clinical manifestations of classic PKU are rarely seen in countries where neonatal screening programs for the detection of PKU are in effect.

Non-PKU Hyperphenylalaninemia

In any screening program for PKU, a group of infants will be identified in whom
Initial plasma concentrations of phenylalanine are above normal (i.e., >2 mg/dL, or 120 µmol/L) but <20 mg/dL (1,200 µmol/L). These infants typically do not excrete phenylketones. Patients with non-PKU hyperphenylalaninemia may still require dietary therapy, depending on their untreated plasma phenylalanine level. Attempts have been made to classify these patients in different subgroups depending on the degree of hyperphenylalaninemia, but such a practice has little clinical or therapeutic advantage. The possibility of deficiency of BH₄ should be investigated in all infants with the milder forms of hyperphenylalaninemia.

Diagnosis

Because of the gradual and nonspecific nature of early clinical symptoms such as vomiting, developmental delay, or eczematoid rash, hyperphenylalaninemia is usually diagnosed through newborn screening in all developed countries. In infants with positive screening results, diagnosis should be confirmed by quantitative measurement of plasma phenylalanine concentration. Identification and measurement of phenylketones in the urine has no place in any screening program. In countries and places where such programs are not in effect, identification of phenylketones in the urine by ferric chloride may offer a simple test for diagnosis of infants with developmental and neurologic abnormalities. Once the diagnosis of hyperphenylalaninemia is established, additional studies for BH₄ metabolism should be performed to rule out BH₄ deficiency as the cause of hyperphenylalaninemia.

Neonatal Screening for Hyperphenylalaninemia

Effective and relatively inexpensive methods for mass screening of newborn infants are used in the United States and many other countries. A few drops of blood, which are placed on a filter paper and mailed to a central laboratory, are used for assay. The screening method of choice uses tandem mass spectrometry, which identifies all forms of hyperphenylalaninemia with a low false-positive rate and excellent accuracy and precision. The addition of the phenylalanine:tyrosine molar ratio has further reduced the number of false-positive results. Diagnosis must be confirmed by measurement of plasma phenylalanine concentration. Blood phenylalanine in affected infants with PKU may rise to diagnostic levels as early as 4 hr after birth, even in the absence of protein feeding. It is recommended that the blood for screening be obtained in the 1st 24-48 hr of life after feeding protein to reduce the possibility of false-
negative results, especially in the milder forms of the condition.

**Treatment**

The mainstay of treatment of PKU is a *low-phenylalanine diet*. The general consensus is to start diet treatment immediately in patients with blood phenylalanine levels >10 mg/dL (600 µmol/L). It is generally accepted that infants with persistent (more than a few days) plasma levels of phenylalanine ≥6 mg/dL (360 µmol/L) should also be treated with a phenylalanine-restricted diet similar to that in classic PKU. The goal of therapy is to reduce phenylalanine levels in the plasma and brain. Formulas free of, or low in, phenylalanine are commercially available. The diet should be started as soon as the diagnosis is established. Because phenylalanine is not synthesized endogenously, the diet should provide phenylalanine to prevent phenylalanine deficiency. Dietary phenylalanine tolerance is determined based on age and severity of the PAH deficiency. *Phenylalanine deficiency* is manifested by lethargy, failure to thrive, anorexia, anemia, rashes, diarrhea, and even death. Further, tyrosine becomes an essential amino acid in this disorder, and its adequate intake must be ensured. Special food items low in phenylalanine are commercially available for dietary treatment of affected children and adults.

There is no firm consensus concerning optimal levels of blood phenylalanine in affected patients either across different countries or among treatment centers in the United States. The current recommendation is to maintain blood phenylalanine levels between 2 and 6 mg/dL (120-360 µmol/L) throughout life. Discontinuation of therapy, even in adulthood, may cause deterioration of IQ and cognitive performance. Lifelong adherence to a low-phenylalanine diet is extremely difficult. Patients who maintain good control as children but discontinue the phenylalanine-restricted diet as teenagers or adults may experience significant difficulties with executive function, concentration, emotional liability, and depression. Executive dysfunction may also occur in early-treated children despite diet treatment.

Given the difficulty of maintaining a strict low-phenylalanine diet, there are continuing attempts to find other modalities for treatment of these patients. Administration of *large neutral amino acids* (LNAAs) is another approach to dietary therapy. LNAAs (tyrosine, tryptophan, leucine, isoleucine, valine, methionine, histidine, and phenylalanine) share the same transporter protein (LNAA type 1 or LAT-1) for transit through the intestinal cell membrane and
blood-brain barrier (BBB). Binding of LNAAAs to the transporter protein is a competitive process. The rationale for use of LNAA is that these molecules compete with phenylalanine for transport across the BBB; therefore, large concentrations of other LNAAAs in the intestinal lumen and in the blood reduce the uptake of phenylalanine into bloodstream and the brain. Large, controlled clinical trials are necessary to establish the efficacy of this treatment.

Oral administration of BH₄, the cofactor for PAH, may result in reduction of plasma levels of phenylalanine in some patients with PAH deficiency. Plasma levels of phenylalanine in these patients may decrease enough to allow for considerable modification of their dietary restriction. In very rare cases the diet may be discontinued because the phenylalanine levels remain under 6 mg/dL (360 µmol/L). The response to BH₄ cannot be predicted consistently based on the genotype alone, especially in compound heterozygous patients. Sapropterin dihydrochloride, a synthetic form of BH₄, which acts as a cofactor in patients with residual PAH activity, is approved by the U.S. Food and Drug Administration (FDA) to reduce phenylalanine levels in PKU. A sustained decrease of plasma phenylalanine by at least 30% is consistent with sapropterin responsiveness. Injectable PEGylated recombinant phenylalanine ammonia lyase is in development.

**Pregnancy in Women With PAH Deficiency (Maternal Phenylketonuria)**

Pregnant women with PAH deficiency who are not on a phenylalanine-restricted diet have a very high risk of having offspring with intellectual disability, microcephaly, growth retardation, congenital malformations, and congenital heart disease. These complications are directly correlated with elevated maternal blood phenylalanine levels during pregnancy. Prospective mothers who have been treated for PAH deficiency should be maintained on a phenylalanine-restricted diet before and during pregnancy. The best observed outcomes occur when strict control of maternal blood phenylalanine concentration is instituted before pregnancy. Plasma phenylalanine levels >6 mg/dL (360 µmol/L) after conception are associated with increased incidence of intrauterine growth restriction and congenital malformations, as well as lower IQ. However, there is strong evidence that phenylalanine control instituted after conception results in improved outcomes. The currently recommended phenylalanine concentration is
2-6 mg/dL (120-360 µmol/L) throughout the pregnancy, although some expert
groups advocate plasma phenylalanine levels <4 mg/dL (<240 µmol/L). All
women with PAH deficiency who are of childbearing age should be counseled
properly regarding the risk of congenital anomalies in their offspring.

**Hyperphenylalaninemia Caused by Deficiency of the Cofactor Tetrhydrobiopterin**

In 1-3% of infants with hyperphenylalaninemia, the defect resides in one of the
enzymes necessary for production or recycling of the cofactor BH₄ (see Fig.
103.1 ). If these infants are misdiagnosed as having PKU, they may deteriorate
neurologically despite adequate control of plasma phenylalanine. BH₄ is
synthesized from guanosine triphosphate (GTP) through several enzymatic
reactions (see Fig. 103.1 ). In addition to acting as a cofactor for PAH, BH₄ is
also a cofactor for tyrosine hydroxylase and tryptophan hydroxylase, which are
involved in the biosynthesis of dopamine (see Fig. 103.2 ) and serotonin (see
Fig. 103.5 ), respectively. Therefore, patients with hyperphenylalaninemia
resulting from BH₄ deficiency also manifest neurologic findings related to
deficiencies of these neurotransmitters. Four enzyme deficiencies leading to
defective BH₄ formation cause hyperphenylalaninemia with concomitant
deficiencies of dopamine and serotonin: autosomal recessive GTP
cyclohydrolase I deficiency, 6-pyruvoyl-tetrahydropterin synthase deficiency,
dihydropteridine reductase deficiency, and pterin-4-α-carbinolamine dehydratase
deficiency. More than half the reported patients have had a deficiency of 6-
pyruvoyl-tetrahydropterin synthase. Autosomal dominant forms of GTP
cyclohydrolase I deficiency and sepiapterin reductase deficiency result in
deficiencies of neurotransmitters without hyperphenylalaninemia (see Chapter
103.11 ).

**Clinical Manifestations**

Infants with cofactor BH₄ deficiency are identified during screening programs
for PKU because of evidence of hyperphenylalaninemia. Plasma phenylalanine
levels may be as high as those in classic PKU or may be in the milder range.
However, the clinical manifestations of the neurotransmitter disorders differ greatly from those of PKU. Neurologic symptoms of the neurotransmitter disorders often manifest in the 1st few months of life and include extrapyramidal signs (choreoathetotic or dystonic limb movements, axial and truncal hypotonia, hypokinesia), feeding difficulties, and autonomic abnormalities. Intellectual disability, seizures, hypersalivation, and swallowing difficulties are also seen. The symptoms are usually progressive and often have a marked diurnal fluctuation. Prognosis and outcome strongly depend on the age at diagnosis and at introduction of treatment, but also on the specific nature of the pathogenic variant and resulting enzyme defect.

**Diagnosis**

Despite the low incidence of BH₄ synthesis defects, all newborns with hyperphenylalaninemia detected through newborn screening must be screened for BH₄ synthesis defects. BH₄ deficiency and the responsible enzyme defect may be diagnosed by several studies.

**Measurement of Neopterin and Biopterin.**

Neopterin (oxidative product of dihydronopterin triphosphate) and biopterin (oxidative product of dihydrobiopterin and BH₄) are measured in body fluids, especially urine (see Fig. 103.1). In patients with GTP cyclohydrolase I deficiency, urinary excretion of both neopterin and biopterin is very low. In patients with 6-pyruvoyl-tetrahydropterin synthase deficiency, there is a marked elevation of neopterin excretion and a concomitant decrease in biopterin excretion. In patients with dihydropteridine reductase deficiency, the excretion of neopterin and biopterin is elevated. Excretion of biopterin increases in this enzyme deficiency because the quinonoid dihydrobiopterin cannot be recycled back to BH₄. Patients with pterin-4-α-carbinolamine dehydratase deficiency excrete 7-biopterin (an unusual isomer of biopterin) in their urine.

**Cerebrospinal Fluid Studies.**

Examination of cerebrospinal fluid (CSF) may reveal decreased levels of dopamine and serotonin metabolites (see Chapter 103.11).

**BH₄ Loading Test.**
An oral dose of BH₄ (20 mg/kg) normalizes plasma phenylalanine and phenylalanine:tyrosine ratio in patients with BH₄ deficiency within 4-12 hr. The blood phenylalanine should be elevated (>400 µmol/L) to enable interpretation of the results. This may be achieved by discontinuing diet therapy for 2 days before the test or by administering a loading dose of phenylalanine (100 mg/kg) 3 hr before the test. In BH₄ -responsive PKU caused by PAH deficiency, blood phenylalanine levels may decrease during the BH₄ loading test, but increase later even with BH₄ supplementation. Patients who demonstrate phenylalanine levels within normal range over at least 1 wk without a phenylalanine-restricted diet can continue BH₄ supplementation as the sole treatment for the hyperphenylalaninemia. However, it is imperative that plasma phenylalanine levels be monitored prospectively to ensure that phenylalanine levels remain within the normal range.

**Molecular Testing.**
Sequencing and deletion/duplication analysis are clinically available and play an increasingly more important role in confirming the biochemical diagnosis.

**Enzyme Assay.**
The activity of dihydropteridine reductase can be measured in the dry blood spots on the filter paper used for screening purposes. 6-Pyruvoyl-tetrahydropterin synthase activity can be measured in the liver, fibroblasts, and erythrocytes. Pterin-4-α-carbinolamine dehydratase activity can be measured in the liver and fibroblasts. GTP cyclohydrolase I activity can be measured in the liver and in cytokine (interferon-γ)–stimulated mononuclear cells or fibroblasts (the enzyme activity is normally very low in unstimulated cells).

**Treatment**
The goals of therapy are to correct hyperphenylalaninemia and to restore neurotransmitter deficiencies in the CNS. The control of hyperphenylalaninemia is important in patients with cofactor deficiency, because high levels of phenylalanine cause intellectual disability and interfere with the transport of neurotransmitter precursors (tyrosine and tryptophan) into the brain. Plasma phenylalanine should be maintained as close to normal as possible (<6 mg/dL or
<360 \mu mol/L). This can be achieved by oral supplementation of BH₄ (5-20 mg/kg/day). Sapropterin dihydrochloride, the synthetic form of BH₄, is commercially available but expensive.

Lifelong supplementation with neurotransmitter precursors such as \( \text{L}\) -dopa and 5-hydroxytryptophan, along with carbidopa to inhibit degradation of \( \text{L}\) -dopa before it enters the CNS, is necessary in most of these patients even when treatment with BH₄ normalizes plasma levels of phenylalanine. BH₄ does not readily enter the brain to restore neurotransmitter production. To minimize untoward side effects (especially \( \text{L}\) -dopa–induced dyskinesia), the treatment should be started with low doses of \( \text{L}\) -dopa/carbidopa and 5-hydroxytryptophan and should be gradually adjusted based on response to therapy and clinical improvement for each individual patient. Supplementation with folinic acid is also recommended in patients with dihydropteridine reductase deficiency. Unfortunately, attempting to normalize neurotransmitter levels using neurotransmitter precursors usually does not fully resolve the neurologic symptoms, because of the inability to attain normal levels of BH₄ in the brain. Patients often demonstrate intellectual disability, fluctuating abnormalities of tone, eye movement abnormalities, poor balance and coordination, decreased ability to ambulate, and seizures despite supplementation with neurotransmitter precursors.

**Hyperprolactinemia** occurs in patients with BH₄ deficiency and may be the result of hypothalamic dopamine deficiency. Measurement of serum prolactin levels may be a convenient method for monitoring adequacy of neurotransmitter replacement in affected patients.

Some drugs, such as trimethoprim/sulfamethoxazole, methotrexate, and other antileukemic agents, are known to inhibit dihydropteridine reductase enzyme activity and should be used with great caution in patients with BH₄ deficiency.

### Genetics and Prevalence

All defects causing hyperphenylalaninemia are inherited as autosomal recessive traits. The prevalence of PKU in the United States is estimated at 1 in 14,000 to 1 in 20,000 live births. The prevalence of non-PKU hyperphenylalaninemia is estimated at 1 in 50,000 live births. The condition is more common in whites and Native Americans and less prevalent in blacks, Hispanics, and Asians.

The gene for PAH is located on chromosome 12q23.2, and many disease-
causing mutations have been identified in different families. Most patients are compound heterozygotes for 2 different mutant alleles. The gene for 6-pyruvoyl-tetrahydropterin synthase (PTS), the most common cause of BH₄ deficiency, resides on chromosome 11q23.1, the gene for dihydropteridine reductase (QDPR) is located on chromosome 4p15.32, and those of pterin-4-α-carbinolamine dehydratase (PCBD1) and GTP cyclohydrolase I (GCH1) are on 10q22.1 and 14q22.2, respectively. Prenatal diagnosis is possible if causative mutations are known.

Tetrahydrobiopterin Defects Without Hyperphenylalaninemia

Tyrosine is derived from ingested proteins or is synthesized endogenously from phenylalanine. It is used for protein synthesis and is a precursor of dopamine, norepinephrine, epinephrine, melanin, and thyroxine. Excess tyrosine is metabolized to carbon dioxide and water (see Fig. 103.1). Hereditary causes of
hypertyrosinemia include deficiencies of the enzymes fumarylacetoacetate hydrolase (FAH), tyrosine aminotransferase, and 4-hydroxyphenylpyruvate dioxygenase (4-HPPD). Acquired hypertyrosinemia may occur in severe hepatocellular dysfunction (liver failure), scurvy (vitamin C is the cofactor for 4-HPPD), and hyperthyroidism. Hypertyrosinemia is common in blood samples obtained soon after eating and in premature infants.

**Tyrosinemia Type I (Fumarylacetoacetate Hydrolase Deficiency, Hepatorenal Tyrosinemia)**

Tyrosinemia type I is a severe multisystemic disease caused by FAH deficiency. Liver, kidney, and nerve damage is likely caused by metabolites of tyrosine degradation, especially fumarylacetoacetate and succinylacetone.

**Clinical Manifestations and Natural History**

Without treatment, affected infants appear normal at birth and develop symptoms in the 1st yr of life. Most patients present between 2 and 6 mo of age but rarely may become symptomatic in the 1st mo or appear healthy beyond the 1st yr of life. Earlier presentation confers poorer prognosis. The 1-yr mortality of untreated children, which is approximately 60% in infants developing symptoms before 2 mo of age, decreases to 4% in infants who become symptomatic after 6 mo.

An acute **hepatic crisis** typically heralds the onset of the disease and is usually precipitated by an intercurrent illness that produces a catabolic state. Fever, irritability, vomiting, hemorrhage, hepatomegaly, jaundice, elevated levels of serum transaminases, hypoglycemia, and neuropathy are common. An odor resembling boiled cabbage may be present, resulting from increased methionine metabolites. Hepatic crises may progress to liver failure and death. Between the crises, varying degrees of failure to thrive, hepatomegaly, and coagulation abnormalities often persist. Cirrhosis and eventually hepatocellular carcinoma occur with increasing age.

Episodes of acute **peripheral neuropathy** resembling acute porphyria occur in approximately 40% of affected children. These crises, often triggered by a minor infection, are characterized by severe pain, often in the legs, associated
with extensor hypertonia of the neck and trunk, vomiting, paralytic ileus, and occasionally self-induced injuries of the tongue or buccal mucosa. Marked weakness occurs in about 30% of episodes, which may lead to respiratory failure requiring mechanical ventilation. Crises typically last 1-7 days, but recuperation from paralytic crises can require weeks to months.

**Renal involvement** is manifested as a Fanconi-like syndrome with hyperphosphaturia, hypophosphatemia, normal–anion gap metabolic acidosis, and vitamin D–resistant rickets. Nephromegaly and nephrocalcinosis may be present on ultrasound examination. Glomerular failure may occur in adolescents and older patients.

Hypertrophic cardiomyopathy and hyperinsulinism are seen in some infants.

**Laboratory Findings**

Elevated levels of succinylacetone in serum and urine are diagnostic for tyrosinemia type I (see Fig. 103.1). Succinylacetone levels may fall below the diagnostic threshold in patients treated with nitisinone. In untreated patients, the blood level of α-fetoprotein is increased, often greatly, and liver-synthesized coagulation factors are decreased in most patients. Increased levels of α-fetoprotein are present in the cord blood of affected infants, indicating intrauterine liver damage. Serum transaminase levels are often increased, with marked increases possible during acute hepatic episodes. Serum concentration of bilirubin is usually normal but can be increased with liver failure. Plasma tyrosine levels are usually elevated at diagnosis, but this is a nonspecific finding and depends on dietary intake. Plasma levels of other amino acids, particularly methionine, may also be elevated in patients with liver damage. Hyperphosphaturia, hypophosphatemia, and generalized aminoaciduria may occur. The urinary level of 5-aminolevulinic acid (also known as delta aminolevulinic acid) is elevated because of inhibition of 5-aminolevulinate dehydratase by succinylacetone (see Fig. 110.1).

**Diagnosis** is usually established by demonstration of elevated levels of succinylacetone in urine or blood. Neonatal screening for hypertyrosinemia using tyrosine alone detects only a fraction of patients with tyrosinemia type I. Succinylacetone, which is assayed by many neonatal screening programs, has higher sensitivity and specificity than tyrosine and is the preferred metabolite for screening. Tyrosinemia type I should be differentiated from other causes of hepatitis and hepatic failure in infants, including galactosemia, hereditary
fructose intolerance, neonatal iron storage disease, giant cell hepatitis, and citrullinemia type II (see Chapter 103.12).

**Treatment and Outcome**

A diet low in phenylalanine and tyrosine can slow but does not halt the progression of the condition. The treatment of choice is nitisinone (NTBC), which inhibits 4-HPPD and reduces the flux of tyrosine metabolites to FAH, thus decreasing the production of the offending compounds, fumarylacetoacetate and succinylacetone (see Fig. 103.1). The dose of nitisinone is titrated to the lowest, most effective dose (usually targeting the blood range of 20-40 µmol/L) to suppress production of succinylacetone while maintaining plasma tyrosine level <400 µmol/L (7.2 mg/dL). This treatment prevents acute hepatic and neurologic crises. Although nitisinone greatly slows disease progression, some pretreatment liver damage is not reversible. Therefore, patients must be followed for development of cirrhosis or hepatocellular carcinoma. On imaging, the presence of even a single liver nodule usually indicates underlying cirrhosis. Most liver nodules in tyrosinemic patients are benign, but current imaging techniques do not accurately distinguish all malignant nodules. For patients with severe liver failure not responding to nitisinone, liver transplantation is an effective therapy, which can also alleviate the risk of hepatocellular carcinoma. The impact of nitisinone treatment on the need for liver transplantation is still under study, but the greatest effect is in patients treated early, such as children detected by neonatal screening, prior to developing clinical symptoms. In early-treated patients, nitisinone has greatly reduced the need for liver transplantation. Because nitisinone treatment increases plasma tyrosine, a low-tyrosine, low-phenylalanine diet is recommended. Rarely, nitisinone-treated patients develop corneal crystals, presumably of tyrosine, which are reversible by strict dietary compliance. This finding, combined with observations of developmental delay in some patients with tyrosinemia type II who chronically have elevated tyrosine levels, suggest that a diet low in phenylalanine and tyrosine should be continued in patients treated with nitisinone. The dietary treatment of patients with tyrosine and phenylalanine restriction necessitates surveillance of growth and development by ensuring adequate intakes of amino acids and other nutrients.

**Genetics and Prevalence**
Tyrosinemia type I is inherited as an autosomal recessive trait. The FAH gene maps to chromosome 15q25.1. DNA analysis is useful for molecular prenatal diagnosis if the familial pathogenic variants are known and for carrier testing in groups at risk for specific mutations, such as French-Canadians from the Saguenay-Lac Saint-Jean region of Quebec. The prevalence of the condition is estimated to be 1 in 1,846 live births in the Saguenay-Lac Saint-Jean region and approximately 1 in 100,000 live births worldwide. Prenatal screening can be performed by measurement of succinylacetone in amniotic fluid. Prenatal diagnosis is possible using DNA analysis of amniocytes or of chorionic villi, if the familial pathogenic variants are known.

**Tyrosinemia Type II (Tyrosine Aminotransferase Deficiency, Richner-Hanhart Syndrome, Oculocutaneous Tyrosinemia)**

Tyrosinemia type II is a rare autosomal recessive disorder caused by deficiency of cytosolic tyrosine aminotransferase and results in palmar and plantar hyperkeratosis, herpetiform corneal ulcers, and intellectual disability (see Fig. 103.1). *Ocular manifestations*, which may occur as early as 6 mo of age, include excessive tearing, redness, pain, and photophobia. Corneal lesions are presumed to be caused by tyrosine deposition. In contrast to herpetic ulcers, corneal lesions in tyrosinemia type II stain poorly with fluorescein and often are bilateral. *Skin lesions*, which may develop later in life, include painful, nonpruritic hyperkeratotic plaques on the soles, palms, and fingertips. Intellectual disability, which occurs in approximately 50% of patients, is usually mild to moderate. The contribution of consanguinity in this rare disorder is incompletely understood.

The principal **laboratory finding** in untreated patients is marked hypertyrosinemia, >500 µmol/L and may reach 1,100-2,750 µmol/L. Surprisingly, 4-hydroxyphenylpyruvic acid and its metabolites are also elevated in urine despite being downstream from the metabolic block (see Fig. 103.1). This is hypothesized to occur via the action of other transaminases in the presence of high tyrosine concentrations, producing 4-hydroxyphenylpyruvic acid in mitochondria, where it cannot be further degraded.
tyrosinemia type I, liver and kidney function are normal, as are serum concentrations of other amino acids and succinylacetone. Tyrosinemia type II is caused by tyrosine aminotransferase (TAT) gene pathogenic variants, causing deficiency of cytosolic TAT activity in liver. TAT maps to chromosome 16q22.

**Diagnosis** of type II tyrosinemia is established by assay of plasma tyrosine concentration in patients with suggestive findings. Molecular diagnosis is possible. Assay of liver TAT requires a liver biopsy and is rarely indicated.

**Treatment** with a diet low in tyrosine and phenylalanine aiming to achieve plasma tyrosine levels <500 µmol/L improves skin and eye manifestations. The claim that intellectual disability may be prevented by early diet therapy is reasonable and is consistent with some case reports.

**Tyrosinemia Type III (Primary Deficiency of 4-Hydroxyphenylpyruvate Dioxygenase)**

Only a few patients with tyrosinemia type III have been reported. Most were detected by amino acid chromatography performed for various neurologic findings; therefore ascertainment bias likely confounds our current understanding of this disorder. Apparently, asymptomatic infants with 4-HPPD deficiency have been identified by neonatal screening for hypertyrosinemia. Age at presentation has been from 1-17 mo. In symptomatic patients, developmental delay, seizures, intermittent ataxia, and self-injurious behavior have been reported. Liver and renal abnormalities are absent.

The role of 4-HPPD deficiency in the disease mechanisms needs further study. The **diagnosis** is suspected in children with sustained moderate increases in plasma levels of tyrosine (typically 350-700 µmol/L on a normal diet) and the presence of 4-hydroxyphenylpyruvic acid and its metabolites 4-hydroxyphenyllactic and 4-hydroxyphenylacetic acids in urine. Diagnosis may be refined by demonstrating the presence of pathogenic variants in the HPD gene encoding 4-HPPD, or rarely by demonstrating a low activity of 4-HPPD enzyme; the latter requires a liver biopsy and is not usually indicated.

Given the possible association with neurologic abnormalities, dietary reduction of plasma tyrosine levels is prudent. It is also logical to attempt a trial of vitamin C, the cofactor for 4-HPPD. The condition is inherited as an
autosomal recessive trait.

**Hawkinsinuria**

A missense variant c.722A>G (p.Asn241Ser) in *HPD* encoding 4-HPPD results in the uncoupling of normal oxidization of 4-hydroxyphenylpyruvate to homogentisic acid and premature release of quinolacetic acid. The abnormal enzyme, incapable of normally oxidizing 4-hydroxyphenylpyruvate to homogentisic acid, forms an intermediate that reacts with glutathione to form the unusual organic acid **hawkinsin** ([2-L-cystein-S-yl,1,4-dihydroxycyclohex-5-en-1-yl]acetic acid), named after the first affected family (see Fig. 103.1). As a result, secondary glutathione deficiency may ensue. Hawkinsinuria is inherited as an autosomal dominant trait. In one patient, compound heterozygosity for hawkinsuria and tyrosinemia type III alleles produced only biochemical features of hawkinsuria.

The clinical course of this rare disorder is incompletely understood. Individuals with hawkinsinuria may be symptomatic only during infancy. The symptoms usually appear in the 1st few months of life, typically after weaning from breastfeeding and with the introduction of a high-protein diet. Severe metabolic acidosis, ketosis, failure to thrive, anemia, mild hepatomegaly, renal tubular acidosis, and an unusual odor are reported manifestations of this disorder. Neurocognitive development is usually normal.

Symptomatic infants and asymptomatic affected children and adults excrete hawkinsin, 4-hydroxyphenylpyruvic acid, and its metabolites (4-hydroxyphenyllactic and 4-hydroxyphenylacetic acids), 4-hydroxycyclohexylacetic acid and 5-oxoproline (from secondary glutathione deficiency) in their urine. The plasma tyrosine level, which is moderately elevated in the symptomatic infants, may become normal in the asymptomatic affected individuals.

**Treatment** consists of a low-protein diet during infancy. Breastfeeding is encouraged. Avoidance of protein overrestriction is important because some patients may present with failure to thrive. Successful long-term use of *N*-acetyl-L-cysteine to treat secondary glutathione deficiency has been reported. A trial with vitamin C is recommended. The abnormal enzyme is susceptible to inhibition by nitisinone. Clinical studies showing the efficacy of this agent in symptomatic infants are lacking at this time, and the indications for its use are not known.
**Transient Tyrosinemia of the Newborn**

In a small number of newborn infants, plasma tyrosine may be as high as 3,300 µmol/L during the 1st 2 wk of life. Most affected infants are premature and are receiving a high-protein diet. Transient tyrosinemia is thought to result from delayed maturation of 4-HPPD (see Fig. 103.1). Lethargy, poor feeding, and decreased motor activity are noted in some patients. Most are asymptomatic and are identified by a high blood phenylalanine or tyrosine level on routine screening. Laboratory findings include marked elevation of plasma tyrosine with a moderate increase in plasma phenylalanine. The finding of hypertyrosinemia differentiates this condition from PKU. 4-Hydroxyphenylpyruvic acid and its metabolites are present in the urine. Hypertyrosinemia usually resolves spontaneously in the 1st 2 mo of life. It can be corrected by reducing dietary protein to below 2 g/kg/24 hr and by administering vitamin C. Mild intellectual deficits have been reported in some infants who had this condition, but the causal relationship to hypertyrosinemia is not conclusively established.

**Alkaptonuria**

Alkaptonuria is a rare (approximately 1 in 250,000 live births) autosomal recessive disorder caused by a deficiency of homogentisate 1,2-dioxigenase. Large amounts of homogentisic acid are formed (see Fig. 103.1), which are excreted in urine or deposited in tissues.

The main **clinical manifestations** of alkaptonuria consist of ochronosis and arthritis in adulthood. The only sign in children is blackening of the urine on standing, caused by oxidation and polymerization of homogentisic acid. A history of gray- or black-stained diapers should suggest the diagnosis. This sign may never be noted; thus diagnosis is often delayed until adulthood. *Ochronosis*, which is seen clinically as dark spots on the sclera or ear cartilage, results from the accumulation of the black polymer of homogentisic acid. *Arthritis* is another result of this deposition and can be disabling with advancing age. It involves the spine and large joints (shoulders, hips, and knees) and is usually more severe in males. As with rheumatoid arthritis, the alkaptonuric arthritis has acute exacerbations, but the radiologic findings are typical of osteoarthrosis, with characteristic narrowing of the joint spaces and calcification of the intervertebral disks. High incidence of heart disease (mitral and aortic valvulitis, calcification of heart valves, myocardial infarction) has been reported.
The diagnosis is confirmed by finding massive excretion of homogentisic acid on urine organic acid testing. Tyrosine levels are normal. The enzyme is expressed only in the liver and kidneys.

**Treatment** of the arthritis is symptomatic. Nitisinone efficiently reduces homogentisic acid production in alkaptonuria. If presymptomatic individuals are detected, treatment with nitisinone, combined with a phenylalanine- and tyrosine-restricted diet, seems reasonable, although no experience is available regarding long-term efficacy.

The gene for homogentisate 1,2-dioxygenase (*HGD*) maps to chromosome 3q13.3. Alkaptonuria is most common in the Dominican Republic and Slovakia.

**Tyrosine Hydroxylase Deficiency**

See Chapter 103.11.

**Albinism**

See also Chapters 640 and 672.

Albinism is caused by deficiency of melanin, the main pigment of the skin and eye (Table 103.1). Melanin is synthesized by melanocytes from tyrosine in a membrane-bound intracellular organelle, the melanosome. Melanocytes originate from the embryonic neural crest and migrate to the skin, eyes (choroid and iris), hair follicles, and inner ear. The melanin in the eye is confined to the iris stromal and retinal pigment epithelia, whereas in skin and hair follicles, it is secreted into the epidermis and hair shaft. Albinism can be caused by deficiencies of melanin synthesis, by some hereditary defects of melanosomes, or by disorders of melanocyte migration. Neither the biosynthetic pathway of melanin nor many facets of melanocyte cell biology are completely elucidated (see Fig. 103.2). The end products are 2 pigments: *pheomelanin*, which is a yellow-red pigment, and *eumelanin*, a brown-black pigment.

Clinically, primary albinism can be generalized or localized. Primary generalized albinism can be ocular or oculocutaneous. Some syndromes feature albinism in association with platelet, immunologic, or neurologic dysfunction. In generalized oculocutaneous albinism, hypopigmentation can be either complete or partial. Individuals with complete albinism do not develop either generalized (tanning) or localized (pigmented nevi) skin pigmentation.

The diagnosis of albinism is usually evident, but for some white children whose families are particularly light-skinned, normal variation may be a diagnostic consideration. Unlike patients with albinism, normal fair-skinned children progressively develop pigmentation with age, do not exhibit the eye manifestations of albinism, and have pigmentary development similar to other family members. The clinical diagnosis of oculocutaneous albinism, as opposed to other types of cutaneous hypopigmentation, requires the presence of characteristic eye findings.

The ocular manifestations of albinism include hypopigmentation of iris and retina with foveal hypoplasia, along with reduced visual acuity, refractive errors, nystagmus, alternating strabismus, and iris transillumination (diffuse reddish hue of iris produced during ophthalmoscopic or slit-lamp examination of eye). There is also an abnormality in routing of the optic fibers at the chiasm. Unlike in pigmented individuals, in patients with albinism the majority of the nerve fibers from the temporal side of the retina cross to the contralateral hemisphere of the brain. This results in lack of binocular (stereoscopic) vision and depth perception and in repeated switching of vision from eye to eye, causing alternating strabismus. This abnormality also causes a characteristic pattern of visual
evoked potentials. These findings are highly specific for albinism and can be used to enable the clinical diagnosis. Regular ophthalmologic follow-up is recommended for patients with oculocutaneous albinism. Correction of refractive errors can maximize visual function. Usually, the alternating strabismus does not result in amblyopia and does not require surgery.

Patients with albinism should be counseled to avoid ultraviolet (UV) radiation by wearing protective long-sleeved clothing and by using sunscreens with a sun protection factor (SPF) rating >30. Melanin is also present in the cochlea. Albino individuals may be more susceptible to ototoxic agents such as gentamicin.

Oculocutaneous albinism is inherited as autosomal recessive trait. Many clinical forms of albinism have been identified. Some of the seemingly distinct clinical forms are caused by different pathogenic variants of the same gene. Several genes located on different chromosomes are involved in melanogenesis (see Table 103.1 ). Attempts to differentiate types of albinism based on the mode of inheritance, tyrosinase activity, or extent of hypopigmentation have failed to yield a comprehensive classification. The classification outlined next is based on the distribution of albinism in the body and the affected genes.

Genetic analysis is clinically available for most albinism genes (see Table 103.1 ). Molecular diagnosis is of little use therapeutically in isolated albinism but can be helpful for precise genetic counseling of families.

**Oculocutaneous (Generalized) Albinism**

Lack of pigment is generalized, affecting skin, hair, and eyes. At least 4 genetically distinct forms of oculocutaneous albinism (OCA) have been identified: OCA_1, OCA_2, OCA_3, and OCA_4. The lack of pigment is complete in patients with OCA_1A; the other types may not be clinically distinguishable from one another. All affected individuals have ocular manifestations of albinism. All forms are inherited as autosomal recessive traits.

**OCA_1 (Tyrosinase-Deficient Albinism)**

The defect in patients with OCA_1 resides in the tyrosinase gene, TYR, located on chromosome 11q14.3. Many mutant alleles have been identified. Most affected individuals are compound heterozygotes. A clinical clue to the diagnosis of OCA_1 is complete lack of pigment at birth. The condition can be subdivided to OCA_1 A and OCA_1 B, based on enzyme activity and difference in clinical
manifestations as a function of age.

**OCA₁ A (Tyrosinase-Negative OCA)**

In patients with OCA₁ A, the most severe form of OCA, both TYR alleles have pathogenic variants that completely inactivate tyrosinase. Clinically, lack of pigment in the skin (milky white), hair (white hair), and eyes (red-gray irides) is evident at birth and remains unchanged throughout life. They do not tan and do not develop pigmented nevi or freckles.

**OCA₁ B**

Patients with OCA₁ B have TYR gene pathogenic variants that preserve some residual activity. Clinically, they completely lack pigment at birth, but with age become light blond with light-blue or hazel eyes. They develop pigmented nevi and freckles, and they may tan. OCA₁ B patients, depending on the degree of pigmentation, were once subdivided into different groups and thought to be genetically distinct.

**OCA₂ (Tyrosinase-Positive OCA)**

OCA₂ is the *most common form of generalized OCA*, particularly in patients of African ancestry. Clinically, the phenotype is highly variable; most patients demonstrate some pigmentation of the skin and eyes at birth and continue to accumulate pigment throughout life. The hair is yellow at birth and may darken with age. They have pigmented nevi and freckles, and some may tan. They may be clinically indistinguishable from OCA₁ B patients. Individuals with OCA₂, however, have normal tyrosinase activity in hair bulbs. The defect is in the OCA₂ gene, which is an orthologue of the *p* (pink-eyed dilution) gene in the mouse. This gene produces the P protein, a melanosome membrane protein. Patients with Prader-Willi and Angelman syndromes caused by microdeletion of chromosome 15q12 that includes the OCA₂ gene have mild pigmentary deficiency (see Chapter 98.8).

**OCA₃ (Rufous Albinism)**

This form has been identified predominantly in Africans, African-Americans, and natives of New Guinea. Patients with OCA₃ can make pheomelanin but not
eumelanin. Patients have reddish hair and reddish brown skin as adults. The skin color is peculiar to this form. In young persons the coloration may resemble that of OCA₂. The pathogenic variant is in the tyrosinase-related protein 1 (TYRP1) gene (located on chromosome 9p23), the function of which is not well-understood.

**OCA₄**

Similar manifestations to OCA₂ (both in the skin and the eyes) have been observed in OCA₄ patients (mostly from Japan) with pathogenic variants in the *SLC45A2* (previously called *MATP*) gene (located on chromosome 5p13.2).

**Ocular Albinism**

Patients with ocular albinism (OA) present in the 1st months of life with nystagmus, hypopigmentation of iris and fundus, foveal hypoplasia, and decreased visual acuity. Electron microscopy demonstrates characteristic macromelanosomes in skin biopsies or hair root specimens. Most patients affected by ocular albinism have ocular albinism type 1 (OA₁), an X-linked disorder caused by pathogenic variants in the *GPR143* gene. A rare form of OA with late-onset sensorineural deafness and apparent autosomal dominant inheritance has also been reported.

**Ocular Albinism Type 1 (Nettleship-Falls Ocular Albinism)**

OA₁ is an X-linked disorder characterized by congenital nystagmus, reduced pigmentation of ocular structures, and visual impairment in affected males. Heterozygous females may present with segments of abnormal retinal pigmention. Infrequently, depending on the pattern of X chromosome inactivation, heterozygous females may also present with severe manifestations, including nystagmus, iris and foveal hypopigmentation, foveal hypoplasia, and reduced visual acuity. In families with darker skin complexion, mild skin hypopigmentation can be seen. The diagnosis of OA₁ is suspected in males with features of albinism in the eye, normal to mildly reduced skin pigmentation, and a family history suggestive of an X-linked transmission. It is a nonprogressive disorder, and the eye findings often improve with age. In patients who are the first of their families to be affected, genetic analysis of the *GPR143* gene
Syndromic Forms of Generalized Albinism

Hermansky-Pudlak Syndrome

This group of autosomal recessive disorders is caused by pathogenic variants of 1 of 9 different genes located on different chromosomes, \( HPS1 \) to \( HPS9 \). Hermansky-Pudlak syndrome (HPS) is suspected in patients with albinism and a bleeding diathesis with inflammatory bowel disease (IBD) or pulmonary fibrosis. Disease subtype can be established with molecular studies (see Chapter 511).

The \( HPS \) genes are necessary for normal structure and function of lysosome-derived organelles, including melanosomes and platelet dense bodies. Patients have a tyrosinase-positive OCA of variable severity associated with platelet dysfunction (caused by the absence of platelet dense bodies). A ceroid-like material accumulates in tissues. HPS is panethnic. However, taking into account patients' ancestry can help develop a cost-effective testing strategy. HPS is prevalent in two regions of Puerto Rico (type 1 in the northwest and type 3 in the central regions as a result of different founder effects). The cutaneous and ocular symptoms of albinism are present. Patients can develop epistaxis, postsurgical bleeding, or abundant menses. Bleeding time is prolonged, but platelet count is normal. Major complications include progressive pulmonary fibrosis in young adults and Crohn-like IBD in adolescents and young adults. Kidney failure and cardiomyopathy have been reported. Neutropenia has been described in HPS type 2. Treatment is symptomatic.

Chédiak-Higashi Syndrome

Patients with this rare autosomal recessive condition have OCA of variable severity and susceptibility to infection (see Chapter 156). Bacterial infections of skin and upper respiratory tract are common. Giant peroxidase-positive lysosomal granules can be seen in granulocytes in a blood smear. Patients have a reduced number of melanosomes, which are abnormally large (macromelanosomes). The bleeding tendency is typically mild. If treatment is not successful, children can reach a stage of the disease known as the accelerated phase, which is a major, life-threatening complication of Chédiak-Higashi syndrome. It is caused by macrophage activation resulting in
hemophagocytic lymphohistiocytosis, and systemic manifestations include fever, lymphadenopathy, hepatosplenomegaly, cytopenia, and elevated plasma ferritin level. Patients surviving childhood may develop cerebellar atrophy, peripheral neuropathy, and cognitive delay. Pathogenic variants in the LYST gene on chromosome 1q42.3 are the only known cause of this syndrome. Hematopoietic stem cell transplantation offers an effective approach to control immunodeficiency and hematologic abnormalities as well as prevent development of the accelerated phase.

**Other Disorders Featuring Generalized Albinism**

Hypopigmentation is a feature of other syndromes, some with abnormalities of lysosomal biogenesis or melanosome biology. **Griscelli syndrome** patients have silver-gray hair, pigmentary dilution of skin, and melanosomal clumping in hair shafts and the center of melanocytes, with intellectual disability or macrophage activation with hemophagocytosis in different subtypes. **Vici syndrome** patients have combined immunodeficiency, intellectual disability, agenesis of the corpus callosum, cataracts, and cleft lip/palate. Patients with **MAPBP-interacting protein deficiency** have short stature, recurrent infections, neutropenia.

**Localized Albinism**

Localized albinism refers to localized patches of hypopigmentation of skin and hair, which may be evident at birth or develop with time. These conditions are caused by abnormal migration of melanocytes during embryonic development.

**Piebaldism**

Piebaldism is an autosomal dominant inherited condition in which the individual is usually born with a white forelock. The underlying skin is depigmented and devoid of melanocytes. In addition, there are usually white macules on the face, trunk, and extremities. Pathogenic variants in the **KIT** and **SNAI2** genes have been shown in affected patients.

**Waardenburg Syndrome**

In Waardenburg syndrome, a white forelock is often associated with lateral displacement of inner canthi of the eyes, broad nasal bridge, heterochromia of irides, and sensorineural deafness. This condition is inherited as an autosomal
dominant trait; 4 major types have been identified. Patients with Waardenburg syndrome type 1 (WS1, the most common form) have all the previous clinical findings, including lateral displacement of inner canthi. The condition is caused by pathogenic variants (>90%) in the PAX3 gene. Patients with Waardenburg syndrome type 2 (WS2) have the clinical findings of WS1 except for the lateral displacement of inner canthi. Genetically, this is a heterogeneous condition caused by pathogenic variants in several genes, including MITF, SOX10, and SNAI2. Patients with Waardenburg syndrome type 3 (WS3) have all the findings seen in individuals with WS1 plus hypoplasia and contractures of the upper limbs. It is caused by heterozygous or homozygous pathogenic variants of PAX3 gene. Waardenburg syndrome type 4 (WS4), associated with Hirschsprung disease, is genetically heterogeneous; pathogenic variants in different genes (EDN3, EDNRB, or SOX10) have been identified in different patients.

Other causes of localized hypopigmentation include vitiligo and hypomelanosis of Ito (see Chapter 672).

The usual pathway for catabolism of methionine, an essential amino acid, produces S-adenosylmethionine, which serves as a methyl group donor for methylation of a variety of compounds in the body, and cysteine, which is formed through a series of reactions collectively called trans-sulfuration (Fig. 103.3).
Homocystinuria (Homocystinemia)

Normally, most homocysteine, an intermediate compound of methionine degradation, is remethylated to methionine. This methionine-sparing reaction is
catalyzed by the enzyme methionine synthase, which requires a metabolite of folic acid (5-methyltetrahydrofolate) as a methyl donor and a metabolite of vitamin B$_{12}$ (methylcobalamin) as a cofactor (see Fig. 103.3). In healthy individuals, most plasma homocysteine is either protein-bound or exists as disulfides. Three major forms of homocystinemia and homocystinuria have been identified.

**Homocystinuria Caused by Cystathionine β-Synthase Deficiency (Classic Homocystinuria)**

This is the most common inborn error of methionine metabolism. Approximately 40% of affected patients respond to high doses of vitamin B$_6$ and usually have milder clinical manifestations than those who are unresponsive to vitamin B$_6$ therapy. These patients possess some residual enzyme activity.

Infants with classic homocystinuria appear normal at birth. **Clinical manifestations** during infancy are nonspecific and may include failure to thrive and developmental delay. Without newborn screening, the diagnosis can be delayed and is usually made after 3 yr of age, when subluxation of the ocular lens (*ectopia lentis*) occurs. This causes severe myopia and iridodonesis (quivering of the iris). Astigmatism, glaucoma, staphyloma, cataracts, retinal detachment, and optic atrophy may develop later in life. Progressive intellectual disability is common. Normal intelligence has been reported. In an international survey of >600 patients, IQ scores ranged from 10-135. Higher IQ scores are seen in vitamin B$_6$–responsive patients. Psychiatric and behavioral disorders have been observed in more than 50% of affected patients. Seizures are seen in approximately 20% of untreated patients. Affected individuals with homocystinuria manifest skeletal abnormalities resembling those of Marfan syndrome (see Chapter 722): tall with elongated limbs and arachnodactyly. Scoliosis, pectus excavatum or pectus carinatum, genu valgum, pes cavus, high-arched palate, and crowding of the teeth are typically seen. These children usually have fair complexions, blue eyes, and a peculiar malar flush. Generalized osteoporosis, especially of the spine, is the main x-ray finding. Thromboembolic episodes involving both large and small vessels, especially those of the brain, are common and may occur at any age. Optic atrophy, paralysis, cor pulmonale, and severe hypertension (from renal infarcts) are among the serious consequences of thromboembolism, which is likely caused by elevated homocysteine levels.
leading to abnormal angiogenesis and inhibition of fibrinolytic activity. The risk of thromboembolism increases after surgical procedures. Spontaneous pneumothorax and acute pancreatitis are rare complications.

Elevations of both methionine and homocysteine (or homocysteine) in body fluids are the diagnostic laboratory findings. Freshly voided urine should be tested for homocystine because this compound is unstable and may disappear after prolonged storage. Cysteine is low or absent in plasma. Total plasma homocysteine is the preferred analyte for management of classic homocystinuria. Free plasma homocysteine may normalize or remain normal when total plasma homocysteine is lowered. The diagnosis may be established by molecular analysis of cystathionine β-synthase (CBS) or by assay of the enzyme in cultured fibroblasts, phytohemagglutinin-stimulated lymphocytes, or liver biopsy specimens.

TREATMENT with high doses of vitamin B₆ (100-500 mg/24 hr) causes dramatic improvement in patients who are responsive to this therapy. The degree of response to vitamin B₆ treatment may vary across families. Some patients may not respond because of folate depletion; a patient should not be considered unresponsive to vitamin B₆ until folic acid (1-5 mg/24 hr) has been added to the treatment regimen. For patients who are unresponsive to vitamin B₆, restriction of methionine intake in conjunction with cysteine supplementation is also recommended. The need for dietary restriction and its extent remains controversial in patients with vitamin B₆ –responsive form. In some patients with this form, addition of betaine may obviate the need for any dietary restriction. Betaine (trimethylglycine, 6 g/24 hr for adults or 200-250 mg/kg/day for children) lowers homocysteine levels in body fluids by remethylating homocysteine to methionine (see Fig. 103.3 ), which may result in elevation of plasma methionine levels. This treatment has produced clinical improvement (preventing vascular events) in patients who are unresponsive to vitamin B₆ therapy. Cerebral edema has occurred in a patient with vitamin B₆ – nonresponsive homocystinuria and dietary noncompliance during betaine therapy.

More than 100 pregnancies in women with classic homocystinuria have been reported with favorable outcomes for both mothers and infants. The majority of infants were full-term and normal. Postpartum thromboembolic events occurred in a few mothers.

The screening of newborn infants for classic homocystinuria has been
performed worldwide, with an estimated prevalence of 1 in 200,000 to 1 in 350,000 live births, although it can be more common in some parts of the world (e.g., 1 : 1,800 in Qatar). Early treatment of patients identified by screening has produced favorable results. The mean IQ of patients with vitamin B₆ – unresponsive form treated in early infancy was in the normal range. Dislocation of the lens seemed to be prevented in some patients.

Classic homocystinuria is inherited as an autosomal recessive trait. The gene for cystathionine β-synthase (CBS) is located on chromosome 21q22.3. Prenatal diagnosis is feasible by DNA analysis or by performing an enzyme assay of cultured amniotic cells. Most affected patients are compound heterozygotes for 2 different alleles. Heterozygous carriers are asymptomatic.

**Homocystinuria Caused by Defects in Methylcobalamin Formation**

Methylcobalamin is the cofactor for the enzyme methionine synthase, which catalyzes remethylation of homocysteine to methionine. At least 7 distinct defects in the intracellular metabolism of cobalamin may interfere with the formation of methylcobalamin. (To better understand the metabolism of cobalamin, see Methylmalonic Acidemia in Chapter 103.6 and Figs. 103.3 and 103.4 .) The 7 defects are designated as cbl C, cbl D (including cbl D variant 1), cbl E (methionine synthase reductase), cbl G (methionine synthase), cbl F, cbl J, and cbl X. Patients with cbl C, cbl D, cbl F, cbl J, and cbl X defects have **methylmalonic acidemia** in addition to homocystinuria, because the formation of both adenosylcobalamin and methylcobalamin is impaired.
Patients with *cbl* E, *cbl* G, and *cbl* D variant 1 defects are unable to form methylcobalamin and develop homocystinuria without methylmalonic acidemia (Fig. 103.4). The clinical manifestations are similar in patients with these 3 defects. Nonspecific symptoms such as vomiting, poor feeding, failure to thrive,
lethargy, hypotonia, seizures, and developmental delay may occur in the 1st few months of life. Late-onset forms of these disorders may present with neurocognitive defects, psychosis, and peripheral neuropathy. **Laboratory findings** include megaloblastic anemia, hyperhomocysteinemia, homocystinuria, and hypomethioninemia. The absence of hypermethioninemia differentiates these conditions from cystathionine β-synthase deficiency (see earlier). Renal artery thrombosis, hemolytic uremic syndrome, pulmonary hypertension, and optic nerve atrophy have been reported in some patients with these defects.

**Diagnosis** is established by DNA testing or by complementation studies performed in cultured fibroblasts. Prenatal diagnosis has been accomplished by studies in amniotic cell cultures. *cbl* E, *cbl* G, and *cbl* D variant 1 deficiencies are inherited as autosomal recessive traits. The gene for *cbl* E is *MTRR*, encoding methionine synthase reductase (located on chromosome 5p15.31). The gene for *cbl* G is *MTR*, encoding methionine synthase (located on chromosome 1q43). The *cbl* D variant 1 deficiency is caused by pathogenic variants affecting the C-terminal of the *MMADHC* gene (located on chromosome 2q23.2).

**Treatment** with vitamin B₁₂ in the form of high-dose hydroxycobalamin helps improve the clinical and biochemical findings. Results vary among both diseases and sibships.

**Homocystinuria Caused by Deficiency of Methylenetetrahydrofolate Reductase (MTHFR Deficiency)**

This enzyme reduces 5,10-methylenetetrahydrofolate to form 5-methyltetrahydrofolate, which provides the methyl group needed for remethylation of homocysteine to methionine (see Fig. 103.3). The severity of the enzyme defect and the clinical manifestations vary considerably in different families. **Clinical findings** vary from apnea, seizure, microcephaly, coma, and death to developmental delay, ataxia, motor abnormalities, peripheral neuropathy, and psychiatric manifestations. Thromboembolism has also been observed. Exposure to the anesthetic nitrous oxide (which inhibits methionine synthase) in patients with MTHFR deficiency may result in neurologic deterioration and death.

**Laboratory findings** include moderate homocystinemia and homocystinuria. The methionine concentration is low or low-normal. This finding helps
differentiate this condition from classic homocystinuria caused by cystathionine β-synthase deficiency. The diagnosis may be confirmed by molecular analysis of \textit{MTHFR} or by the enzyme assay in cultured fibroblasts or leukocytes.

\textit{MTHFR} deficiency should be differentiated from \textbf{mild hyperhomocysteinemia} due to two common polymorphisms in the \textit{MTHFR} gene. Two “thermolabile” polymorphisms have been extensively studied, c.665C>T (p.Ala222Val, previously referred to as c.677C>T) and c.1286A>C (p.Glu429Ala, formerly referred to as c.1298A>C). These polymorphisms may minimally affect levels of plasma total homocysteine in some patients and are often confounded by dietary folate deficiency. Both polymorphisms have been studied as possible risk factors for a wide variety of medical conditions, including birth defects, autism, vascular disease, stroke, pregnancy loss, cancer, and response to chemotherapy. Population-based studies revealed a surprisingly high prevalence of homozygosity for these polymorphisms in the general population: up to 10–15% of the North American Caucasians and >25% in some Hispanics. It is hypothesized that fortification of flour with folate may have decreased the strength of associations observed in the past. To date, the best data support a role for the c.665C>T polymorphism (formerly c.677C>T) as a risk factor for neural tube defects. Although a clinical test for this polymorphism is widely available, recent meta-analyses have not supported the association between the \textit{MTHFR} polymorphism and risk for venous thromboembolism or between mild hyperhomocysteinemia and an increased risk for coronary heart disease.

The condition is inherited as an autosomal recessive trait. The \textbf{diagnosis} can be confirmed by \textit{MTHFR} gene analysis. Prenatal diagnosis can be achieved by molecular analysis of \textit{MTHFR} of the known familial pathogenic variants or by measuring \textit{MTHFR} enzyme activity in cultured chorionic villus cells or amniocytes.

\textbf{Treatment} of \textit{MTHFR} deficiency with a combination of folic acid, vitamin B\textsubscript{6}, vitamin B\textsubscript{12}, methionine supplementation, and betaine has been tried. Of these, early treatment with betaine appears to have the most beneficial effect.

\textbf{Hypermethioninemia}

\textbf{Primary (Genetic) Hypermethioninemia}

Elevation of plasma level of methionine occurs in several genetic conditions.
Classic Homocystinuria.

See earlier discussion.

**Hepatic Methionine Adenosyltransferase (MAT I/MAT III) Deficiency (Mudd Disease).**

This enzyme, which has 2 isoforms, MAT I (tetrameric) and MAT III (dimeric), is encoded by a single gene (MAT1A on chromosome 10q22.3) and is involved in the 1st step of methionine catabolism (see Fig. 103.3). Another structurally similar enzyme, MAT II, is encoded by a different gene (MAT2A on chromosome 2p11.2) and is expressed predominantly in nonhepatic tissues (kidney, brain, lymphocytes). Deficiency of MAT I/MAT III causes hypermethioninemia. In severe deficiency, total plasma homocysteine can also be elevated. The majority of these patients have been diagnosed in the neonatal period through screening for homocystinuria. Most affected individuals have residual enzyme activity and remain asymptomatic throughout life despite persistent hypermethioninemia. Some complain of an unusual odor to their breath, likely caused by accumulation of dimethylsulfide. A few patients with complete enzyme deficiency have had neurologic abnormalities related to demyelination (intellectual disability, dystonia, dyspraxia).

Laboratory studies reveal markedly elevated levels of plasma methionine with a normal or low level of S-adenosylmethionine and normal concentrations of S-adenosylhomocysteine and homocysteine. These findings help differentiate MAT I/MAT III deficiency from other causes of hypermethioninemia.

No uniformly accepted therapeutic regimen has yet emerged. Although no specific treatment is used in most patients, long-term follow-up to monitor for neurologic and liver abnormalities should be considered. Diets low in methionine result in lowering of plasma methionine, but the advisability of such diets has been questioned since lowering the plasma methionine level causes further lowering of S-adenosylmethionine in the body. Supplementation with S-adenosylmethionine in conjunction with a low-methionine diet seems prudent, but no large clinical experience is yet available. Normal pregnancies producing normal offspring have been reported in mothers with MAT I/MAT III (MAT1A) deficiency. The condition is inherited as an autosomal recessive trait, although pathogenic variant p.R264H in MAT1A appears to disrupt protein dimerization and may result in mild hypermethioninemia even in heterozygous patients.
Glycine N -Methyltransferase Deficiency.

Glycine N -methyltransferase mediates catabolism of S -adenosylmethionine to S -adenosylhomocysteine (see Fig. 103.3 ). A few patients with deficiency of this enzyme have been reported to date. Clinically, patients were asymptomatic except for mild hepatomegaly and elevated serum levels of transaminases. Other laboratory findings included hypermethioninemia and very high levels of serum S -adenosylmethionine. No specific treatment has yet been identified. The condition is inherited as an autosomal recessive trait; the gene GNMT is on chromosome 6p21.1.

S -Adenosylhomocysteine Hydrolase (SAHH) Deficiency.

Deficiency of SAHH (see Fig. 103.3 ) has been described infrequently. Intellectual disability, severe hypotonia, and progressive liver dysfunction were common clinical findings. Laboratory studies included elevated levels of serum creatine kinase, hypoalbuminemia (associated with fetal hydrops in one family), hypoprothrombinemia and greatly elevated levels of serum S -adenosylhomocysteine with moderate elevations of plasma methionine and S -adenosylmethionine. Marked elevation in S -adenosylhomocysteine has been thought to cause inhibition of methyltransferases, including those involved in the synthesis of creatine (see Fig. 103.10 ) and choline, resulting in their deficiencies. MRI of the brain can reveal delayed myelination of the white matter. The diagnosis can be achieved by the AHCY gene analysis (chromosome 20q11.22) or by biochemical assay of red blood cells, cultured skin fibroblasts, or liver biopsy. Treatment with a low-methionine diet has been used, but its long-term effectiveness has not been established.

Tyrosinemia Type I.

See Chapter 103.2 .

Citrin Deficiency.

See Chapter 103.12 .

Acquired (Nongenetic) Hypermethioninemia

Hypermethioninemia occurs in premature and some full-term infants receiving high-protein diets, in whom it may represent delayed maturation of the enzyme
MAT. Lowering the protein intake usually resolves the abnormality. It is also commonly found in patients with various forms of liver disease.

### Primary Cystathioninemia (Cystathioninuria)

Cystathionase (cystathionine γ-lyase) deficiency results in massive cystathioninuria and mild to moderate cystathioninemia. Deficiency of this enzyme is inherited as an autosomal recessive trait, with an estimated prevalence of 1 in 14,000 live births. A wide variety of clinical manifestations have been reported. Lack of a consistent clinical picture and the presence of cystathioninuria in a number of individuals free of clinical findings suggest that cystathionase deficiency may be of no clinical significance. Many reported cases are responsive to oral administration of large doses of vitamin B₆ (≥100 mg/24 hr). When cystathioninuria is discovered in a patient, vitamin B₆ treatment can be tried, but its beneficial effect has not been established. The gene encoding for cystathionase (CTH) is located on chromosome 1p31.1. The disorder is inherited as an autosomal recessive trait.

Primary cystathioninuria needs to be differentiated from secondary cystathioninuria, which can occur in patients with vitamin B₆ or B₁₂ deficiency, liver disease (particularly damage caused by galactosemia), thyrotoxicosis, hepatoblastoma, neuroblastoma, ganglioblastoma, or defects in remethylation of homocysteine.

**Cysteine** is a sulfur-containing amino acid that is synthesized from methionine (see [Fig. 103.3](#) ). Oxidation of cysteine forms **cystine**, a poorly soluble dimer. The most common genetic disorders of cysteine and cystine metabolism are cystinuria (see Chapter 562 ) and cystinosis (see Chapter 547.3 ).

## Sulfite Oxidase Deficiency and Molybdenum Cofactor Deficiency

In the last step in cysteine metabolism, sulfite is oxidized to sulfate by sulfite oxidase, and the sulfate is excreted in the urine (see [Fig. 103.3](#) ). Sulfite oxidase is encoded by **SUOX** (located on chromosome 12q13.2). This enzyme requires a molybdenum-pterin complex termed **molybdenum cofactor**. This cofactor is also necessary for the function of 2 other enzymes in humans: xanthine dehydrogenase (which oxidizes xanthine and hypoxanthine to uric acid) and aldehyde oxidase (involved in oxidizing a number of natural compounds and drugs). Three enzymes, encoded by 3 different genes (**MOCS1**, **MOCS2**, and
*GPHN*, mapped to chromosomes 6p21.2, 5q11.2, and 14q23.3, respectively), are involved in the synthesis of the cofactor. Deficiency of any of the 3 enzymes causes cofactor deficiency with similar phenotypes. Most patients, who were originally diagnosed as having sulfite oxidase deficiency, have been shown to have molybdenum cofactor deficiency. Sulfite oxidase deficiency and molybdenum cofactor deficiency are inherited as autosomal recessive traits.

The enzyme and cofactor deficiencies produce overlapping **clinical manifestations**. Refusal to feed, vomiting, an exaggerated startle reaction, severe intractable seizures (tonic, clonic, myoclonic), cortical atrophy with subcortical multicystic lesions, and severe developmental delay may develop within a few weeks after birth. The biochemical diagnosis should be considered in infants presenting with neonatal seizures and neonates with symptoms reminiscent of hypoxic-ischemic encephalopathy. Bilateral dislocation of ocular lenses is a common finding in patients who survive the neonatal period. The intractable seizures seen in this condition are in part a consequence of secondary vitamin B<sub>6</sub> dependency. The accumulation of sulfites in body fluids in this condition causes the inhibition of *antiquitin* enzyme, which is necessary for conversion of α-amino adipic semialdehyde to α-amino adipic acid; the resultant accumulation of α-amino adipic semialdehyde and its cyclic form, P6C, causes the inactivation of pyridoxal-5-phosphate (active form of vitamin B<sub>6</sub>) and thus the vitamin B<sub>6</sub>–dependent epilepsy (see also Chapter 103.14).

Affected children excrete large amounts of sulfite, thiosulfate, S-sulfocysteine, xanthine, and hypoxanthine in the urine. Urinary and serum levels of uric acid and urinary concentration of sulfate are diminished. Fresh urine should be used for screening purposes and for quantitative measurements of sulfite, because oxidation of sulfite to sulfate at room temperature may produce false-negative results. Increased concentrations of α-amino adipic semialdehyde and P6C are present in the cerebrospinal fluid, plasma, and urine.

**Diagnosis** is confirmed by measurement of sulfite oxidase and molybdenum cofactor in fibroblasts and liver biopsies, respectively or by DNA studies. Prenatal diagnosis is possible by performing an assay of sulfite oxidase activity in cultured amniotic cells, in samples of chorionic villi or by DNA studies. The prevalence of these deficiencies in the general population is not known, but likely is very low.

*No effective treatment is available.* Large doses of vitamin B<sub>6</sub> (5-100 mg/kg) result in alleviation of seizures but do not seem to alter the devastating
neurologic outcome. Most children die in the 1st 2 yr of life. Patients with molybdenum cofactor deficiency caused by pathogenic variants in MOCS1 have benefited from supplementation using intravenous cyclic pyranopterin monophosphate (cPMP), which is undergoing a multicenter clinical trial.

Tryptophan

Oleg A. Shchelochkov, Charles P. Venditti

Keywords

tryptophan
niacin
nicotinamide
serotonin
B0AT1
SLC6A19

Tryptophan is an essential amino acid and a precursor for nicotinic acid (niacin) and serotonin (Fig. 103.5). The genetic disorders of metabolism of serotonin, one of the major neurotransmitters, are discussed in Chapter 103.11.
**Hartnup Disorder**

In the autosomal recessive Hartnup disorder, named after the 1st affected family, a defect occurs in the transport of monoamino-monocarboxylic amino acids (neutral amino acids), including tryptophan, by the intestinal mucosa and renal tubules. The transporter protein for these amino acids (B⁰ AT₁) is encoded by the SLC6A19 gene (located on chromosome 5p15.33). Most children with Hartnup defect remain asymptomatic. Patients show significant variability in presentation, likely related to the nutritional factors, environment, and genetic heterogeneity (e.g., 2 proteins, TMEM27 and ACE2, that interact with B⁰ AT1). Decreased intestinal absorption of tryptophan in conjunction with its increased renal loss can lead to reduced availability of tryptophan for niacin synthesis. **Tryptophan deficiency** can be accentuated by malabsorption such as celiac disease. The major clinical manifestation in the rare symptomatic patient is **cutaneous photosensitivity**. The skin becomes rough and red after moderate exposure to the sun, and with greater exposure, a *pellagra-like rash* may develop. The rash may be pruritic, and a chronic eczema may develop. The skin changes have been reported in affected infants as young as 10 days of age. Some patients may have intermittent ataxia manifested as an unsteady, wide-based gait. The ataxia may last a few days and can respond to niacin supplementation.
Cognitive development is usually normal. Episodic psychiatric manifestations such as irritability, emotional instability, depression, and suicidal tendencies, have been observed; these changes are usually associated with bouts of ataxia. Short stature and atrophic glossitis are seen in some patients.

Most children diagnosed with Hartnup disorder by neonatal screening have remained asymptomatic. This indicates that other factors are also involved in pathogenesis of the clinical condition.

The main laboratory finding is **aminoaciduria**, which is restricted to neutral amino acids (alanine, serine, threonine, valine, leucine, isoleucine, phenylalanine, tyrosine, tryptophan, histidine). Urinary excretion of proline, hydroxyproline, and arginine remains normal. This finding helps differentiate Hartnup disorder from other causes of generalized aminoaciduria, such as Fanconi syndrome. Plasma concentrations of neutral amino acids are normal or mildly decreased. This seemingly unexpected finding reflects compensatory mechanisms required to maintain normal transport and utilization of amino acids. The indole derivatives (especially indican) may be found in large amounts in some patients, resulting from bacterial breakdown of unabsorbed tryptophan in the intestines.

**Diagnosis** of Hartnup disorder is established by the intermittent nature of symptoms and characteristic findings on the urine amino acid analysis. If necessary, the diagnosis can be confirmed molecularly by **SLC6A19** gene analysis.

**Treatment** with nicotinic acid or nicotinamide (50-300 mg/24 hr) and a high-protein diet results in a favorable response in symptomatic patients with Hartnup disorder. Because of the intermittent nature of the clinical manifestations, the efficacy of these treatments is difficult to evaluate. The prevalence of Hartnup disorder is estimated to be 1 in 20,000 to 1 in 55,000 live births. Normal outcome for both mother and fetus has been reported in several affected women.

The early steps in the degradation of the branched-chain amino acids (BCAAs)—isoleucine, leucine, and valine—are similar (see Fig. 103.4). Under catabolic conditions, BCAAs in the muscle tissue undergo a reversible reaction of transamination catalyzed by BCAA transaminase. α-Ketoacids formed by this reaction then undergo an oxidative decarboxylation step mediated by branched-chain α-ketoacid dehydrogenase (BCKDH) complex. The deficiency of BCKDH results in maple syrup urine disease, whereas the deficiency of enzymes mediating more distal steps results in accumulation of enzyme-specific organic acids excreted in the urine, thus giving those inborn errors of metabolism the eponyms organic acidemias and organic acidurias. These disorders typically cause metabolic acidosis, which usually occurs in the 1st few days of life. Although most of the clinical findings are nonspecific, some manifestations may provide important clues to the nature of the enzyme deficiency. Fig. 103.6 presents an approach to infants suspected of having an organic acidemia. The diagnosis is usually established by identifying and measuring specific organic acids in body fluids (blood, urine), identifying pathogenic variants in a respective gene, and enzyme assay.
Organic acidemias are not limited to defects in the catabolic pathways of BCAAs. Disorders causing accumulation of other organic acids include those derived from lysine (see Chapter 103.14), disorders of γ-glutamyl cycle (see Chapter 103.11), those associated with lactic acid (see Chapter 105), and dicarboxylic acidemias associated with defective fatty acid degradation (see Chapter 104.1).

Maple Syrup Urine Disease

Decarboxylation of leucine, isoleucine, and valine is accomplished by a complex enzyme system (BCKDH) using thiamine (vitamin B_1) pyrophosphate as a coenzyme. This mitochondrial enzyme consists of 4 subunits: E_{1α}, E_{1β}, E_2, and E_3. The E_3 subunit is shared with 2 other dehydrogenases, pyruvate dehydrogenase and α-ketoglutarate dehydrogenase. Deficiency of any of these subunits causes maple syrup urine disease (MSUD) (see Fig. 103.4), a disorder named after the sweet odor of maple syrup found in body fluids, especially urine. Clinical conditions caused by defects in E_{1α}, E_{1β}, E_2 and E_3 are
designated as MSUD type IA, type IB, type 2, and type 3, respectively. This
classification, however, is not very helpful clinically because the severity of
clinical manifestations does not correlate with, or correspond specifically to, any
single enzyme subunit. An affected infant with type 1A defect can have clinical
manifestations ranging from relatively mild to very severe. A more useful
classification, based on clinical findings and response to thiamine
administration, delineates 5 phenotypes of MSUD.

**Classic Maple Syrup Urine Disease**

Classic MSUD has the **most severe** clinical manifestations. The BCKDH
complex activity in this group varies between 0% and 2% of controls. Patients
with uncontrolled or poorly controlled disease develop signs of acute
encephalopathy. The mechanisms underlying this life-threatening complication
are complex, but leucine and its derivative, α-ketoisocaproic acid, appear to be
the key factors underlying acute encephalopathy. Elevated leucine competitively
inhibits the uptake of other amino acids by the large neutral amino acid (LNAA)
transporter. Once taken up by the brain tissue, leucine is metabolized by BCAA
aminotransferase to α-ketoisocaproic acid, which leads to the disrupted
metabolism of neurotransmitters and amino acids (glutamate, GABA, glutamine,
alanine, and aspartate). α-Ketoisocaproic acid can reversibly inhibit oxidative
phosphorylation and result in cerebral lactic acidosis. Collectively, these
processes are detrimental to the normal function of neurons and glia, clinically
manifesting as encephalopathy and brain edema and referred to as **leucinosis**.
Affected infants who appear healthy at birth develop poor feeding and vomiting
in the 1st days of life. Lethargy and coma may ensue within a few days. Physical
examination reveals hypertonicity and muscular rigidity with severe
opisthotonos. Periods of hypertonicity may alternate with bouts of flaccidity
manifested as repetitive movements of the extremities (“boxing” and
“bicycling”). Neurologic findings are often mistakenly thought to be caused by
generalized sepsis and meningitis. Cerebral edema may be present; convulsions
occur in most infants, and hypoglycemia is common. In contrast to most
hypoglycemic states, correction of the blood glucose concentration does not
improve the clinical condition. Aside from the blood glucose, routine laboratory
findings are usually unremarkable, except for varying degrees of ketoacidosis. If
left untreated, death can occur in the 1st few weeks or months of life.

**Diagnosis** is often suspected because of the peculiar odor of maple syrup in
urine, sweat, and cerumen. It is usually confirmed by amino acid analysis showing marked elevations in plasma levels of leucine, isoleucine, valine, and alloisoleucine (a stereoisomer of isoleucine not normally found in blood) and depressed level of alanine. Leucine levels are usually higher than those of the other 3 amino acids. Urine contains high levels of leucine, isoleucine, and valine and their respective ketoacids. These ketoacids may be detected qualitatively by adding a few drops of 2,4-dinitrophenylhydrazine reagent (0.1% in 0.1N HCl) to the urine; a yellow precipitate of 2,4-dinitrophenylhydrazone is formed in a positive test. Neuroimaging during the acute state may show cerebral edema, which is most prominent in the cerebellum, dorsal brainstem, cerebral peduncle, and internal capsule. After recovery from the acute state and with advancing age, hypomyelination and cerebral atrophy may be seen in neuroimaging of the brain.

**Treatment** of the acute state is aimed at hydration and rapid removal of the BCAAs and their metabolites from the tissues and body fluids. Uptake of leucine by the brain and accumulation of the downstream metabolite, α-ketoisocaproic acid, appear to be the key metabolic events underlying MSUD encephalopathy. Therefore, strategies of MSUD management focus on decreasing plasma leucine to control acute and chronic manifestations of the disease.

Because renal clearance of leucine is poor, hydration alone may not produce a rapid improvement. *Hemodialysis* is the most effective mode of therapy in critically ill infants and should be instituted promptly; significant decreases in plasma levels of leucine, isoleucine, and valine are usually seen within 24 hr. Sufficient calories and nutrients should be provided intravenously or orally as soon as possible to reverse patient's catabolic state. Cerebral edema, if present, may require treatment with mannitol, diuretics (e.g., furosemide), or hypertonic saline. Counterintuitively, supplementation with isoleucine and valine is also needed to control plasma leucine level in MSUD patients. Judiciously administered isoleucine and valine will compete with leucine for the LNAA transporter at the blood-brain barrier and thus decrease leucine entry into the central nervous system (CNS) and help in the prevention and treatment of leucine encephalopathy.

Treatment after recovery from the acute state requires a diet low in BCAAs. Synthetic formulas devoid of leucine, isoleucine, and valine are available commercially. Because these amino acids cannot be synthesized endogenously, age-appropriate amounts of BCAAs should be provided in the diet in the form of complete protein. To avoid essential amino acid deficiencies, the amount should be titrated carefully by performing frequent analyses of the plasma amino acids,
with close attention to plasma isoleucine, leucine, and valine levels. A clinical condition resembling acrodermatitis enteropathica (see Chapter 691) occurs in affected infants whose plasma isoleucine or valine become very low; addition of isoleucine or valine, respectively, to the diet will hasten the recovery of skin rash. Patients with MSUD need to remain on the diet for the rest of their lives. Liver transplantation has been performed in patients with classic MSUD, with promising results.

The long-term prognosis of affected children remains guarded. Severe ketoacidosis, cerebral edema, and death may occur during any stressful situation such as infection or surgery, especially in mid-childhood. Cognitive and other neurologic deficits are common sequelae.

**Intermediate (Mild) Maple Syrup Urine Disease**

Children with intermediate MSUD develop milder disease after the neonatal period. Clinical manifestations are insidious and limited to the CNS. Patients have mild to moderate intellectual disability with or without seizures. They have the odor of maple syrup and excrete moderate amounts of the BCAAs and their ketoacid derivatives in the urine. Plasma concentrations of leucine, isoleucine, and valine are moderately increased whereas those of lactate and pyruvate tend to be normal. These children are commonly diagnosed during an intercurrent illness, when signs and symptoms of classic MSUD may occur. The dehydrogenase activity is 3–40% of controls. Because patients with thiamine-responsive MSUD usually have manifestations similar to the mild form, a trial of thiamine therapy is recommended. Diet therapy, similar to that of classic MSUD, is needed.

**Intermittent Maple Syrup Urine Disease**

In intermittent MSUD, seemingly normal children develop vomiting, odor of maple syrup, ataxia, lethargy, and coma during any stress or catabolic state such as infection or surgery. During these attacks, laboratory findings are indistinguishable from those of the classic form, and death may occur. Treatment of the acute attack of intermittent MSUD is similar to that of the classic form. After recovery, although a normal diet can be tolerated, a low-BCAA diet is recommended. The BCKDH activity in patients with the intermittent form is higher than in the classic form and may reach 40% of the control activity.
Thiamine-Responsive Maple Syrup Urine Disease

Some children with mild or intermediate forms of MSUD who are treated with high doses of thiamine have dramatic clinical and biochemical improvement. Although some respond to treatment with thiamine at 10 mg/24 hr, others may require as much as 100 mg/24 hr for at least 3 wk before a favorable response is observed. These patients also require BCAA-restricted diets. The enzymatic activity in these patients can be up to 40% of normal.

Maple Syrup Urine Disease Caused by Deficiency of E₃ Subunit (MSUD Type 3)

Although sometimes referred to as “maple syrup urine disease type 3,” this very rare disorder leads to clinical and biochemical abnormalities that encompass a wide range of mitochondrial reactions. E₃ subunit, dihydrolipoamide dehydrogenase, is a component of the BCKDH complex, pyruvate dehydrogenase complex, and α-ketoglutarate dehydrogenase complex. Pathogenic variants in dihydrolipoamide dehydrogenase cause lactic acidosis, elevated pyruvate, as well as signs and symptoms similar to intermediate MSUD. Progressive neurologic impairment manifested by hypotonia and developmental delay occurs after 2 mo of age. Abnormal movements progress to ataxia or Leigh syndrome. Death may occur in early childhood.

Laboratory findings include persistent lactic acidosis with high levels of plasma pyruvate and alanine. Plasma BCAA concentrations are moderately increased. Patients excrete large amounts of lactate, pyruvate, α-ketoglutarate, and the 3 branched-chain ketoacids in their urine.

No effective treatment is available. BCAA-restricted diets and treatment with high doses of thiamine, biotin, and lipoic acid have been ineffective.

Genetics and Prevalence of Maple Syrup Urine Disease

All forms of MSUD are inherited as an autosomal recessive trait. The gene for each subunit resides on different chromosomes. The gene for E₁α (BCKDHA) is on chromosome 19q13.2; that for E₁β (BCKDHB) is on chromosome 6q14.1; the
gene for E₂ (DBT) is on chromosome 1p21.2; and that for E₃ (DLD) is on chromosome 7q31.1. Genotype-phenotype correlations are difficult to establish and are usually imprecise. The exception is thiamine-responsive MSUD, shown to be caused by pathogenic variants in DBT. Most patients are compound heterozygotes inheriting 2 different pathogenic alleles. Pathogenic variants in BCKDHA (45%) and BCKDHB (35%) account for approximately 80% of cases. Pathogenic variants in DBT are responsible for 20% of MSUD cases.

The prevalence is estimated at 1 in 185,000 live births. Classic MSUD is more prevalent in the Old Order Mennonites in the United States, at an estimated 1 in 380 live births. Affected patients in this population are homozygous for a specific pathogenic variant (c.1312T>A) in BCKDHA -encoding E₁α subunit.

Early detection of MSUD is feasible by universal newborn screening. In most cases, however, especially those with classic MSUD, the infant may be quite sick by the time screening results become available (see Chapter 102). Prenatal diagnosis has been accomplished by enzyme assay of the cultured amniocytes, cultured chorionic villus tissue, or direct assay of samples of the chorionic villi and by identification of the known pathogenic variants in the affected gene.

Several successful pregnancies have occurred in women with different forms of MSUD. The teratogenic potential of leucine during pregnancy is unknown. Tight control of isoleucine, leucine, and valine before and during the pregnancy is important to minimize the risk of metabolic decompensation and to optimize fetal nutrition. Mothers affected by MSUD require close monitoring and meticulous management of nutrition, electrolytes, and fluids in the postpartum period.

**Branched-Chain α-Ketoacid Dehydrogenase Kinase Deficiency**

A defect in the regulation of branched-chain α-ketoacid dehydrogenase (BCKDH) by BCKDH kinase (BCKDK), the enzyme responsible for the phosphorylation-mediated inactivation of the BCKDH complex, causes the reverse biochemical phenotype of MSUD. Pathogenic variants in BCKDK decrease the negative regulation by the kinase, resulting in uncontrolled degradation and depletion of isoleucine, leucine, and valine in plasma and brain. Patients with BCKDK deficiency present with low plasma concentrations of isoleucine, leucine, and valine associated with autism, intellectual impairment,
fine motor coordination problems, and seizures.

**Branched-Chain Amino Acid Transporter Deficiency**

Isoleucine, leucine, and valine are transported across the BBB mainly by the heterodimeric LNAA transporter LAT1 encoded by *SLC7A5*. A defect in LAT1 caused by pathogenic variants in *SLC7A5* results in low brain concentrations of isoleucine, leucine, and valine. Patients with this defect may present clinically similar to BCKDK-deficient patients, with autism, microcephaly, gross motor delays, and in some cases, seizures.

**Isovaleric Acidemia**

Isovaleric acidemia (*IVA*) is caused by deficiency of isovaleryl–coenzyme A (CoA) dehydrogenase (see *Fig. 103.4*). Decreased or lost activity of isovaleryl-CoA dehydrogenase results in impaired leucine degradation. Accumulating derivatives of isovaleric acid, isovaleryl-carnitine, isovaleryl-glycine, and 3-hydroxyisovaleric acid can be detected in body fluids and thus enable the biochemical diagnosis and screening. Clinically, the course of IVA is highly variable, ranging from essentially asymptomatic to severe. Introduction of newborn screening and proactive management of IVA changed its outlook and the clinical course. Older siblings of symptomatic newborn infants have been reported with identical genotype and biochemical abnormalities but without clinical manifestations, suggesting that presymptomatic detection of affected patients on the newborn screen can improve clinical outcomes.

Patients with severe IVA can present with vomiting, severe acidosis, hyperammonemia, hypoglycemia, hypocalcemia, and bone marrow suppression in the infantile period. Lethargy, convulsions, and coma may ensue, and death may occur if proper therapy is not initiated. Vomiting may be severe enough to suggest pyloric stenosis. The characteristic odor of *sweaty feet* or *rancid-cheese* may be present. Infants who survive this acute episode are at risk to develop episodes of metabolic decompensation later in life. In the mild form without treatment, typical clinical manifestations of severe IVA (vomiting, lethargy, acidosis or coma) may not appear until the child is a few months or a few years old. Acute episodes of metabolic decompensation may occur during a catabolic
state, such as infection, dehydration, surgery, or high-protein intake. Acute episodes may be mistaken for diabetic ketoacidosis. Some patients may experience acute and recurrent episodes of pancreatitis.

**Laboratory findings** during the acute attacks include ketoacidosis, neutropenia, thrombocytopenia, and occasionally pancytopenia. Hypocalcemia, hypoglycemia, and moderate to severe hyperammonemia may be present in some patients. Increases in plasma ammonia may suggest a defect in the urea cycle (see Chapter 103.12). In urea cycle defects, however, the infant usually shows no significant ketoacidosis (see Fig. 103.6).

**Diagnosis** is established by demonstrating marked elevations of isovaleric acid metabolites (isovalerylglucose, 3-hydroxyisovaleric acid) in body fluids, especially urine. The main compound in plasma is isovalerylcarnitine (C5-carnitine). C5-carnitine can be measured in dried blood spots, thus enabling universal newborn screen using tandem mass spectrometry. The diagnosis can be confirmed by molecular analysis of the IVD gene. In some patients with equivocal results, measurement of the enzyme activity in cultured skin fibroblasts may be necessary.

**Treatment** of the acute attack is aimed at hydration, reversal of the catabolic state (by providing adequate calories orally or intravenously), correction of metabolic acidosis, and facilitation of the isovaleric acid excretion. L-Carnitine (100 mg/kg/24 hr orally) also increases removal of isovaleric acid by forming isovalerylcarnitine, which is excreted in the urine. Because isovalerylglycine has a high urinary clearance, some centers recommend glycine supplementation (250 mg/kg/24 hr) to enhance the formation of isovalerylglycine. Temporary restriction of protein intake (<24 hr) may be beneficial in some cases. In patients with significant hyperammonemia (blood ammonia >200 µmol/L), measures that reduce blood ammonia should be employed (see Chapter 103.12). Renal replacement therapy may be needed if the previously described measures fail to produce significant clinical and biochemical improvement. Long-term management of IVA patients requires restriction of protein according to age-appropriate intake (recommended dietary allowance of protein). Patients benefit from carnitine supplementation with or without glycine. Normal development can be achieved with early and proper treatment.

**Prenatal diagnosis** can be accomplished by enzyme assay in cultured amniocytes, or if causative mutations are known, by the IVD gene analysis. Successful pregnancies with favorable outcomes have been reported. Universal newborn screening of IVA is used in the United States and other countries (see
Chapter 102. IVA is caused by autosomal recessive pathogenic variants in *IVD*. The prevalence of IVA is estimated from 1 in 62,500 (in parts of Germany) to 1 in 250,000 live births (in the United States).

**Multiple Carboxylase Deficiencies (Defects of Biotin Cycle)**

*Biotin* is a water-soluble vitamin that is a cofactor for all 4 carboxylase enzymes in humans: pyruvate carboxylase, acetyl-CoA carboxylase, propionyl-CoA carboxylase, and 3-methylcrotonyl-CoA carboxylase. The latter 2 are involved in the catabolic pathways of leucine, isoleucine, and valine (see Fig. 103.4). Most of the dietary biotin is bound to proteins. Free biotin is generated in the intestine by the action of digestive enzymes, by intestinal bacteria, and perhaps by biotinidase. *Biotinidase*, which is found in serum and most tissues, is also essential for the recycling of biotin in the body by releasing it from the apoenzymes (carboxylases; see Fig. 103.4). Free biotin must form a covalent bond with the apocarboxylases to produce the activated enzyme (holocarboxylase). This binding is catalyzed by holocarboxylase synthetase. Deficiencies in this enzyme activity or in biotinidase result in malfunction of all the carboxylases and in organic acidemias.

**Holocarboxylase Synthetase Deficiency**

Infants with this rare autosomal recessive disorder become symptomatic in the 1st few weeks of life. Symptoms may appear as early as a few hours after birth to as late as 8 yr of age. Clinically, shortly after birth, the affected infant develops breathing difficulties (tachypnea and apnea). Feeding problems, vomiting, and hypotonia are also usually present. If the condition remains untreated, *generalized erythematous rash with exfoliation and alopecia*, failure to thrive, irritability, seizures, lethargy, and even coma may occur. Developmental delay is common. Immune deficiency manifests with susceptibility to infection. Urine may have a peculiar odor, which has been described “tomcat urine.” The rash, when present, helps differentiate this condition from other organic acidemias (see Fig. 103.6).

**Laboratory findings** include metabolic acidosis, ketosis, hyperammonemia, and the presence of a variety of organic acids (lactic acid, 3-methylcrotonic acid,
3-methylcrotonylglycine, tiglylglycine, 3-OH-propionic acid, methylcitric acid, and 3-hydroxyisovaleric acid) in body fluids. **Diagnosis** is confirmed by identification of pathogenic variants in **HLCS** or by the enzyme assay in lymphocytes or cultured fibroblasts. Most pathogenic variants cause the enzyme to have an increased $K_m$ (Michaelis-Menten dissociation constant) for biotin; the enzyme activity in such patients can be restored by the administration of large doses of biotin. Newborn screening can identify holocarboxylase synthetase–deficient infants by detecting elevated C5-OH-carnitine on tandem mass spectrometry. In these infants, biotinidase enzymatic assay would be normal.

**Treatment** with biotin (10-20 mg/day orally) usually results in an improvement in clinical manifestations and biochemical abnormalities. Early diagnosis and treatment are critical to prevent irreversible neurologic damage. In some patients, however, complete resolution may not be achieved even with large doses (up to 60 mg/day) of biotin.

The gene for holocarboxylase synthetase (**HLCS**) is located on chromosome 21q22.13. **Prenatal diagnosis** can be accomplished by prenatal molecular analysis of the known pathogenic variants in **HLCS** or by assaying enzyme activity in cultured amniotic cells. Pregnant mothers who had previous offspring with holocarboxylase synthetase deficiency have been treated with biotin late in pregnancy. Affected infants were normal at birth, but the efficacy of prenatal treatment remains unclear.

**Biotinidase Deficiency**

Impaired biotinidase activity results in biotin deficiency. Affected infants may develop clinical manifestations similar to those seen in infants with holocarboxylase synthetase deficiency. Unlike the latter, however, symptoms tend to appear later, when the child is several months or years old. The delay in onset of symptoms presumably results from the presence of free biotin derived from the mother or the diet. Clinical manifestations are mostly confined to skin and the nervous system. Atopic or seborrheic dermatitis, candidiasis, alopecia, ataxia, seizures (usually myoclonic), hypotonia, developmental delay, optic nerve atrophy, sensorineural hearing loss, and immunodeficiency resulting from impaired T-cell function may occur. A small number of children with **intractable seborrheic dermatitis** and **partial** (15–30% activity) biotinidase deficiency, in whom the dermatitis resolved with biotin therapy, have been reported; these children were otherwise asymptomatic. Asymptomatic children and adults with
this enzyme deficiency have been identified in screening programs. Most of these individuals have been shown to have partial biotinidase deficiency. With universal newborn screening leading to early identification and treatment of the affected patients, the clinical disease is predicted to become extinct.

**Laboratory findings** and the pattern of organic acids in body fluids resemble those associated with holocarboxylase synthetase deficiency (see above). **Diagnosis** can be established by measurement of the enzyme activity in the serum or by the identification of the mutant gene. **Treatment** with free biotin (5-20 mg/day) results in a dramatic clinical and biochemical improvement. Treatment with biotin is also suggested for individuals with partial biotinidase deficiency. The prevalence of this autosomal recessive trait is estimated at 1 in 60,000 live births. The gene for biotinidase (BTD) is located on chromosome 3p25.1. **Prenatal diagnosis** is possible by identification of the known pathogenic variants in BTD, or less frequently by the measurement of the enzyme activity in the amniotic cells, although in practice, a prenatal approach is rarely used.

### Multiple Carboxylase Deficiency Caused by Acquired Biotin Deficiency

Acquired deficiency of biotin may occur in infants receiving total parenteral nutrition without added biotin, in patients with prolonged use of antiepileptic drugs (phenobarbital, phenytoin, primidone, carbamazepine), and in children with short bowel syndrome or chronic diarrhea who are receiving formulas low in biotin. Excessive ingestion of raw eggs may also cause biotin deficiency because the protein avidin in egg white binds biotin, decreasing its absorption. Infants with biotin deficiency may develop dermatitis, alopecia, and candidal skin infections. This condition readily responds to treatment with oral biotin.

### 3-Methylcrotonyl-CoA Carboxylase Deficiency

This enzyme is 1 of the 4 carboxylases requiring biotin as a cofactor (see Fig. 103.4). An isolated deficiency of this enzyme must be differentiated from disorders of biotin metabolism (multiple carboxylase deficiency), which causes diminished activity of all 4 carboxylases (see earlier). 3-Methylcrotonyl-CoA
carboxylase (3-MCC) is a heteromeric enzyme consisting of α (biotin containing) and β subunits, encoded by genes *MCCC1* and *MCCC2*, respectively. 3-MCC deficiency can be detected in the newborn period by identifying elevated 3-hydroxyisovalerylcarnitine (C5-OH) in dried blood spots. Universal newborn screening using tandem mass spectrometry has identified an unexpectedly high number of infants with 3-MCC deficiency, with prevalence ranging from 1 : 2,400 to 1 : 68,000.

**Clinical manifestations** are highly variable, ranging from completely asymptomatic adults (including mothers of affected newborn infants), to children presenting with developmental delay without episodes of metabolic decompensation, to patients with seizures, hyperammonemia, and metabolic acidosis. In severe 3-MCC deficiency the affected infant who has been seemingly normal develops an acute episode of vomiting, hypotonia, lethargy, and convulsions after a minor infection, in some cases progressing to life-threatening complications (e.g., Reye syndrome, coma). In patients prone to developing these symptoms, the onset is usually between 3 wk and 3 yr of age. Among infants identified through newborn screening, 85–90% of children remain apparently asymptomatic. The reason for differences in outcomes is unknown. None of the symptoms reported so far could be clearly attributed to the degree of enzyme deficiency.

**Laboratory findings** during acute episodes include mild to moderate metabolic acidosis, ketosis, hypoglycemia, hyperammonemia, and elevated serum transaminase levels. Large amounts of 3-hydroxyisovaleric acid and 3-methylcrotonylglycine are found in the urine. Urinary excretion of 3-methylcrotonic acid is not usually increased in this condition because the accumulated 3-methylcrotonyl-CoA is converted to 3-hydroxyisovaleric acid. Plasma acylcarnitine profile shows elevated 3-hydroxyisovaleryl carnitine (C5-OH). Severe secondary carnitine deficiency is common. 3-MCC deficiency should be differentiated biochemically from multiple carboxylase deficiency (see earlier), in which, in addition to 3-hydroxyisovaleric acid, lactic acid and metabolites of propionic acid are also present. **Diagnosis** may be confirmed by molecular analysis or by measurement of the enzyme activity in cultured fibroblasts. Documentation of normal activities of other carboxylases is necessary to rule out multiple carboxylase deficiency.

**Treatment** of acute episodes is similar to that of isovaleric acidemia (see earlier). Hydration and measures to correct hypoglycemia and severe metabolic acidosis by infusing glucose and sodium bicarbonate should be instituted.
promptly. Secondary carnitine deficiency, seen in up to 50% of patients, can be corrected with L-carnitine supplementation. For symptomatic patients, some centers recommend keeping protein intake at the recommended dietary allowance in conjunction with the oral administration of L-carnitine and the proactive management of catabolic states. Normal growth and development are expected in most patients.

3-MCC deficiency is an autosomal recessive condition. The gene for α-subunit (MCCC1) is located on chromosome 3q27.1, and that for the β-subunit (MCCC2) is mapped to chromosome 5q13.2. Pathogenic variants in either of these genes result in the enzyme deficiency with overlapping clinical features.

3-Methylglutaconic Acidurias

The 3-methylglutaconic acidurias are a heterogeneous group of metabolic disorders characterized by excessive excretion of 3-methylglutaconic acid in the urine (Table 103.2). Other metabolites found in 3-methylglutaconic aciduria patients may include 3-methylglutaric acid and 3-hydroxyisovaleric acid. Current classification distinguishes primary and secondary forms. Primary 3-methylglutaconic aciduria is caused by the deficiency of mitochondrial 3-methylglutaconyl-CoA hydratase (see Fig. 103.4), formerly 3-methylglutaconic aciduria type I. Secondary 3-methylglutaconic aciduria can be further classified based on the underlying mechanism (e.g., defective phospholipid remodeling vs dysfunction of mitochondrial membrane) or the known molecular cause. Known secondary 3-methylglutaconic aciduria includes TAZ-related syndrome (Barth syndrome), OPA3-related 3-methylglutaconic aciduria (Costeff syndrome), SERAC1-related syndrome (MEGDEL syndrome), TMEM70-related syndrome, and DNAJC19-related syndrome (DCMA syndrome).

Significant and persistent 3-methylglutaconic aciduria with negative molecular evaluation for known genetic causes represents a heterogeneous group called 3-methylglutaconic aciduria not otherwise specified awaiting further molecular characterization. Primary and secondary 3-methylglutaconic aciduria should be distinguished from mild and transient urinary elevations of 3-methylglutaconic acid seen in patients affected by other metabolic disorders, such as mitochondrial disorders of diverse etiology.

### 3-Methylglutaconyl-CoA Hydratase Deficiency

Two main clinical forms of 3-methylglutaconyl-CoA hydratase deficiency have been described (see Fig. 103.4 ). In the childhood form, nonspecific
neurodevelopmental findings such as speech delay or regression, choreoathetoid movements, optic nerve atrophy, and mild psychomotor delay may be present. Metabolic acidosis may occur during a catabolic state. In the **adulthood** form, affected individuals may remain asymptomatic until the 2nd or 3rd decade of life, when a clinical picture of *slowly progressing leukoencephalopathy* with optic nerve atrophy, dysarthria, ataxia, spasticity, and dementia occurs. Brain MRI typically shows white matter abnormalities, which may precede the appearance of clinical symptoms by years. Asymptomatic pediatric and adult patients have also been reported. Patients excrete large amounts of 3-methylglutaconic acid and moderate amounts of 3-hydroxyisovaleric and 3-methylglutaric acids in urine. **Treatment** with $L$-carnitine may help some patients. The effectiveness of a low-leucine diet has not been established. The condition is inherited as an autosomal recessive trait. The gene for the hydratase enzyme (*AUH*) is mapped to chromosome 9q22.31.

### Barth Syndrome (*TAZ*-Related Disorder)

This X-linked condition is caused by deficiency of *tafazzin*, a mitochondrial protein, encoded by *TAZ* gene. This enzyme is necessary for remodeling of immature cardiolipin into its mature form. *Cardiolipin*, a mitochondrial phospholipid, is critical for the integrity of inner mitochondrial membrane. **Clinical manifestations** of Barth syndrome, which usually occur in the 1st yr of life in a male infant, include cardiomyopathy, hypotonia, growth retardation, hypoglycemia, and mild to severe neutropenia. The onset of clinical manifestations may be as late as adulthood, but most affected individuals become symptomatic by adolescence. If patients survive infancy, relative improvement may occur with advancing age. Cognitive development is usually normal, although delayed motor function and learning disabilities are possible.

**Laboratory findings** include mild to moderate increases in urinary excretion of 3-methylglutaconic, 3-methylglutaric, and 2-ethylhydracrylic acids. Unlike primary 3-methylglutaconic aciduria (type I), urinary excretion of 3-hydroxyisovaleric acid is not elevated. The activity of the enzyme 3-methylglutaconyl-CoA hydratase is normal. *Neutropenia is a common finding*. Lactic acidosis, hypoglycemia, low serum cholesterol concentration, low prealbumin, and abnormal mitochondrial ultrastructure have been shown in some patients. Total cardiolipin and subclasses of cardiolipin are very low in skin fibroblast cultures from these patients. The monolysocardiolipin/cardiolipin ratio
in cultured fibroblast may be useful for establishing the diagnosis in patients with negative or equivocal molecular results. Because of its nonspecific presentation, the condition could be underdiagnosed and underreported.

The condition is inherited as an \textit{X-linked} recessive trait. The gene (\textit{TAZ}) has been mapped to chromosome Xq28. The modest 3-methylglutaconic aciduria seen in Barth syndrome is thought to be related to the defect in mitochondrial membrane, causing the leakage of this organic acid. \textit{Specific treatment is not available}. Patients with an unsatisfactory response to medical management of cardiomyopathy may benefit from cardiac transplantation. Daily aspirin to reduce the risk of strokes has been described.

\textbf{OPA3 - Related 3-Methylglutaconic Aciduria (Costeff Syndrome)}

Clinical manifestations in patients with Costeff syndrome include early-onset optic nerve atrophy and later development of choreoathetoid movements, spasticity, ataxia, dysarthria, and cognitive impairment. Patients excrete moderate amounts of 3-methylglutaconic and 3-methylglutaric acids. Activity of the enzyme 3-methylglutaconyl-CoA hydratase is normal. The condition is inherited as an autosomal recessive trait. The gene for this condition (\textit{OPA3}) is mapped to chromosome 19q13.32. Pathogenic variants in \textit{OPA3} are thought to cause electron transport chain dysfunction. Treatment is supportive.

\textbf{Disorders Formerly Described as 3-Methylglutaconic Aciduria Type IV}

3-Methylglutaconic aciduria type IV represents a group of disorders with diverse genetic etiology. Two disorders in this group have been linked to specific molecular etiology, while other conditions are still awaiting the discovery of their underlying molecular defect.

\textbf{MEGDEL syndrome} (3-methylglutaconic aciduria with deafness, encephalopathy and Leigh-like) is an autosomal recessive disorder caused by deleterious mutations in \textit{SERAC1} on chromosome 6q25.3. Affected patients experience progressive deafness, dystonia, spasticity and basal ganglia injury similar to patients with Leigh syndrome. Treatment is symptomatic.

\textbf{TMEM70 - related disorder} is also inherited in an autosomal recessive fashion. Pathogenic variants in \textit{TMEM70} result in the mitochondrial complex V
deficiency, although the exact mechanism of disease is unknown. Clinical manifestations include developmental delay, developmental regression, Reye syndrome–like episodes, intellectual disability, failure to thrive, microcephaly, cardiomyopathy, and dysmorphic findings. Patients are prone to metabolic decompensation, characterized by hyperammonemia (up to 900 µmol/L) and lactic acidosis, which are more common in the 1st yr of life. Acute hyperammonemic episodes are treated with intravenous glucose, lipid emulsion, ammonia-scavenging drugs, and occasionally require hemodialysis. Long-term therapy that has been described includes L-carnitine, coenzyme Q₁₀, and bicarbonate substitution (e.g., citric acid/sodium citrate). Patients require interval echocardiographic and electrocardiographic (ECG) monitoring to enable early diagnosis and management of cardiomyopathy.

**DCMA Syndrome (DNAJC19-Related Syndrome, 3-Methylglutaconic Aciduria Type V)**

DCMA syndrome (dilated cardiomyopathy with a taxia) is a novel autosomal recessive disorder identified in patients of the Canadian Dariusleut Hutterite ancestry living in The Great Plains of North America. As the disorder's abbreviated name suggests, affected individuals present with dilated cardiomyopathy, long QTc interval, and CNS involvement. Neurologic symptoms include intellectual disability, cerebellar involvement, and optic atrophy. Growth is affected in all patients. Intrauterine growth restriction is seen in up to 50% of patients. Cryptorchidism and hypospadias are frequent findings in affected boys. Urine organic acid assay reveals increased 3-methylglutaconic acid and 3-methylglutaric acid. Pathogenic variants in DNAJC19 (3q26.33) are the underlying cause of DCMA syndrome. Treatment is symptomatic. Interval echocardiography and ECG can prospectively identify patients requiring treatment of cardiomyopathy and long QTc interval.

**β-Ketothiolase (3-Oxothiolase) Deficiency (Mitochondrial Acetoacetyl-CoA Thiolase [T₂] Deficiency)**

This reversible mitochondrial enzyme is involved in the final steps of isoleucine
catabolism and in ketolysis. In the isoleucine catabolic pathway, the enzyme cleaves 2-methylacetoacetyl-CoA into propionyl-CoA and acetyl-CoA (see Fig. 103.4). In the fatty acid oxidation pathway, the enzyme generates 2 moles of acetyl-CoA from 1 mole of acetoacetyl-CoA (Fig. 103.7). The same enzyme synthesizes 2-methyloacetoacetate-CoA and acetoacetyl-CoA in the reverse direction. The hallmark of this disorder is ketoacidosis, often triggered by infections, prolonged fasting, and large protein load. The mechanism of ketosis in this condition is incompletely understood, because in this enzyme deficiency one expects impaired ketone formation (Fig. 103.7). It is postulated that excess acetoacetyl-CoA produced from other sources can be used as a substrate for 3-hydroxy-3-methylglutaryl-CoA synthesis in the liver.

**Clinical manifestations** are quite variable, ranging from mild cases showing normal development to severe episodes of acidosis starting in the 1st yr of life.
causing severe cognitive impairment. Unless identified on the newborn screening, affected children present with intermittent episodes of unexplained ketoacidosis. These episodes usually occur after an intercurrent infection and typically respond promptly to intravenous fluids and bicarbonate therapy. Mild to moderate hyperammonemia may also be present during attacks. Both hypoglycemia and hyperglycemia have been reported in isolated cases. The child may be completely asymptomatic between episodes and may tolerate a normal protein diet. Cognitive development is normal in most children. The episodes may be misdiagnosed as salicylate poisoning because of the similarity of the clinical findings and the interference of elevated blood levels of acetoacetate with the colorimetric assay for salicylate.

**Laboratory findings** during the acute attack include ketoacidosis, and hyperammonemia. Findings of ketones in the urine and hyperglycemia may be interpreted as diabetic ketoacidosis, and the high index of suspicion is needed to identify this metabolic disorder. Urine organic acid assay can provide clues leading to correct diagnosis. Urine contains large amounts of 2-methylacetoacetate and its decarboxylated products butanone, 2-methyl-3-hydroxybutyrate, and tiglylglycine. Lower concentrations of urinary metabolites can be seen when patients are stable. Mild hyperglycinemia may also be present. Plasma acylcarnitine profile show elevations of C5 : 1 and C5-OH carnitines, although these metabolites can normalize in between catabolic episodes. Minimal elevations of C5 : 1 and C5-OH carnitines can result in false-negative results on the newborn screening of affected infants who were clinically well at the time of blood collection. The clinical and biochemical findings should be differentiated from those seen with propionic and methylmalonic acidemias (see later).

**Treatment** of acute episodes includes hydration. Recalcitrant metabolic acidosis can be severe enough to require infusion of bicarbonate. A 10% glucose solution with the appropriate electrolytes is used to suppress protein catabolism, lipolysis, and ketogenesis. Restriction of protein intake to age-appropriate physiologic requirements is recommended for long-term therapy. Oral L-carnitine (50-100 mg/kg/24 hr) is also recommended to prevent possible secondary carnitine deficiency. Long-term prognosis for achieving normal quality of life seems very favorable. Successful pregnancy with a normal outcome has been reported.

β-Ketothiolase deficiency is inherited as an autosomal recessive trait and may be more prevalent than previously appreciated. The gene *(ACAT1)* for this
enzyme is located on chromosome 11q22.3. **Diagnosis** may be confirmed by molecular analysis of the *ACAT1* gene or using enzyme assay of leukocytes or cultured fibroblasts.

**Cytosolic Acetoacetyl-CoA Thiolase Deficiency**

This enzyme catalyzes the cytosolic production of acetoacetyl-CoA from two moles of acetyl-CoA (see Fig. 103.7). Cytosolic acetoacetyl-CoA is the precursor of hepatic cholesterol synthesis. Cytosolic acetoacetyl-CoA thiolase should be differentiated from the mitochondrial thiolase (see earlier and Fig. 103.4). Clinical manifestations in patients with this very rare enzyme deficiency have been incompletely characterized. Patients may present with severe progressive developmental delay, hypotonia, and choreoathetoid movements in the 1st few months of life. Laboratory findings are nonspecific; elevated levels of lactate, pyruvate, acetoacetate, and 3-hydroxybutyrate may be found in blood and urine. One patient had normal levels of acetoacetate and 3-hydroxybutyrate. Diagnosis can be aided by demonstrating a deficiency in cytosolic thiolase activity in liver biopsy or in cultured fibroblasts or by DNA analysis. No effective treatment has been described, although a low-fat diet helped to diminish ketosis in one patient.

**Mitochondrial 3-Hydroxy-3-Methylglutaryl-CoA Synthase Deficiency**

This enzyme catalyzes synthesis of 3-hydroxy-3-methylglutaryl (HMG)-CoA from acetoacetyl-CoA and acetyl-CoA in the mitochondria. This is a critical step in ketone body synthesis in the liver (see Fig. 103.7). A few patients with deficiency of this enzyme have been reported. The principal clinical syndrome is hypoketotic hypoglycemia triggered by physiologic stress, such as infections or fasting. Age at presentation has ranged from infancy to 6 yr. Children tend to be asymptomatic before these episodes and with appropriate management can remain stable after the recovery (except for mild hepatomegaly with fatty infiltration). Future episodes can be prevented by avoiding prolonged fasting during ensuing intercurrent illnesses. Hepatomegaly is a consistent physical
finding in these patients. **Laboratory findings** include hypoglycemia, acidosis with mild or no ketosis, elevated levels in liver function tests, and massive dicarboxylic aciduria. The clinical and laboratory findings may be confused with fatty acid metabolism defects (see Chapter 104.1). In contrast to the latter, in patients with HMG-CoA synthase deficiency the blood concentrations of acylcarnitine conjugates are negative for acylcarnitine findings characteristic of fatty acid oxidation disorders. Treatment of the secondary carnitine deficiency with L-carnitine supplementation can result in elevated plasma acetyl carnitine (C2-carnitine), likely reflecting intracellular accumulation of acetyl-CoA. A controlled fasting study can produce the clinical and biochemical abnormalities.

**Treatment** consists of provision of adequate calories and avoidance of prolonged periods of fasting. No dietary protein restriction was needed.

The condition is inherited as an autosomal recessive trait. The gene (HMGCS2) for this enzyme is located on chromosome 1p12. The condition should be considered in any child with fasting hypoketotic hypoglycemia and may be more common than appreciated.

### 3-Hydroxy-3-Methylglutaryl-CoA Lyase Deficiency (3-Hydroxy-3-Methylglutaric Aciduria)

3-HMG-CoA lyase (see Fig. 103.4) catalyzes the conversion of 3-HMG-CoA to acetoacetate and is a rate-limiting enzyme for ketogenesis (see Fig. 103.7). The deficiency of this enzyme is a rare disorder seen with increased frequency in Saudi Arabia, the Iberian Peninsula, and in Brazil in patients of Portuguese ancestry. Clinically, approximately 30% develop symptoms in the first few days of life, and >60% of patients become symptomatic between 3 and 11 mo of age. Infrequently, patients may remain asymptomatic until adolescence. With the addition of 3-HMG-CoA lyase deficiency to the newborn screening using C5-OH-carnitine, many infants are identified presymptomatically in the newborn period. Similar to 3-HMG-CoA synthase deficiency, patients affected by 3-HMG-CoA lyase deficiency may present with acute hypoketotic hypoglycemia. Episodes of vomiting, severe hypoglycemia, hypotonia, acidosis with mild or no ketosis, and dehydration may rapidly lead to lethargy, ataxia, and coma. These episodes often occur during a catabolic state such as prolonged fasting or an
intercurrent infection. Hepatomegaly is common. These manifestations may be mistaken for Reye syndrome or fatty acid oxidation defects such as medium-chain acyl-CoA dehydrogenase deficiency. Long-term complications can include dilated cardiomyopathy, hepatic steatosis, and pancreatitis. Development can be normal, but intellectual disability and seizures with abnormalities in the white matter seen on MRI have been observed in patients after prolonged episodes of hypoglycemia.

**Laboratory findings** include hypoglycemia, moderate to severe hyperammonemia, and acidosis. There is mild or no ketosis (see Fig. 103.7). Urinary excretion of 3-hydroxy-3-methylglutaric acid and other proximal intermediate metabolites of leucine catabolism (3-methylglutaric acid, 3-methylglutaconic acid, and 3-hydroxyisovaleric acid) is markedly increased, causing the urine to smell like cat urine. Glutaric and dicarboxylic acids may also be increased in urine during acute attacks. Secondary carnitine deficiency is common. The condition is inherited as an autosomal recessive trait. 3-HMG-CoA lyase is encoded by gene *HMGCL*. **Diagnosis** may be confirmed by molecular analysis of *HMGCL* or by enzyme assay in cultured fibroblasts, leukocytes, or liver specimens. Prenatal diagnosis is possible by molecular DNA analysis if the familial pathogenic variants are known or by enzymatic assay of the cultured amniocytes or a chorionic villi biopsy.

**Treatment** of acute episodes includes hydration, infusion of glucose to control hypoglycemia, provision of adequate calories, and administration of bicarbonate to correct acidosis. Hyperammonemia should be treated promptly (see Chapter 103.12). Renal replacement therapy may be required in patients with severe recalcitrant hyperammonemia. Restriction of protein and fat intake is recommended for long-term management. Oral administration of L-carnitine (50-100 mg/kg/24 hr) prevents secondary carnitine deficiency. Prolonged fasting should be avoided.

**Succinyl-CoA:3-Oxoacid-CoA Transferase Deficiency**

Succinyl-CoA:3-oxoacid-CoA transferase (SCOT) deficiency and β-ketothiolase deficiency collectively are referred to as ketone utilization disorders. SCOT participates in the conversion of ketone bodies (acetoacetate and 3-hydroxybutyrate) generated in liver mitochondria into acetoacetyl-CoA in
the nonhepatic tissues (see Fig. 103.7). A deficiency of this enzyme results in the accumulation of ketone bodies, ketoacidosis, increased utilization of glucose, and hypoglycemia. During fasting, patients tend to have a proportional elevation of plasma free fatty acids. More than 30 patients with SCOT deficiency have been reported to date. The condition may not be rare because many cases may be mild and may remain undiagnosed. SCOT deficiency can be distinguished from β-ketothiolase deficiency by the absence of 2-methylacetoacetate, 2-methyl-3-hydroxybutyrate, and tiglylglycine, characteristic of the latter disorder. Plasma acylcarnitine profile tends to show no specific abnormalities.

A common clinical presentation is an acute episode of severe ketoacidosis in an infant who had been growing and developing normally. About half the patients become symptomatic in the 1st wk of life, and practically all become symptomatic before 2 yr of age. The acute episode is often precipitated by a catabolic state triggered by an infection or prolonged fasting. Without treatment, the ketoacidotic episode can result in death. A chronic subclinical ketosis may persist between the attacks. Development is usually normal, although severe and recurrent episodes of ketoacidosis and hypoglycemia can predispose patients to neurocognitive impairment.

**Laboratory findings** during the acute episode are nonspecific and include metabolic acidosis and ketonuria with high levels of acetoacetate and 3-hydroxybutyrate in blood and urine. No other organic acids are found in the blood or in the urine. Blood glucose levels are usually normal, but hypoglycemia has been reported in some affected newborn infants with severe ketoacidosis. Plasma amino acids and plasma acylcarnitine profile are usually normal. Severe SCOT deficiency can be accompanied by ketosis even when patients are clinically stable. This condition should be considered in any infant with unexplained bouts of ketoacidosis. **Diagnosis** can be established by molecular analysis of OXCT1 or by demonstrating a deficiency of enzyme activity in cultured fibroblasts. The condition is inherited as an autosomal recessive trait.

**Treatment** of acute episodes consists of rehydration with solutions containing dextrose, correction of acidosis, and the provision of a diet adequate in calories. Long-term treatment should include high-carbohydrate diet and avoidance of prolonged fasting and administration of dextrose before anticipated or during established catabolic states.

**Mevalonate Kinase Deficiency**
Mevalonic acid, an intermediate metabolite of cholesterol synthesis, is converted to 5-phosphomevalonic acid by the action of the enzyme mevalonate kinase (MVK) (see Fig. 103.7). Based on clinical manifestations and degree of enzyme deficiency, 2 conditions have been recognized: mevalonic aciduria and hyperimmunoglobulinemia D syndrome. Both disorders are accompanied by recurrent fever, gastrointestinal symptoms, mucocutaneous manifestations, and lymphadenopathy. Patients with mevalonic aciduria also show growth retardation and nervous system involvement. In practice, the 2 disorders represent the 2 ends of the spectrum.

**Mevalonic Aciduria**

Clinical manifestations include failure to thrive, growth retardation, intellectual disability, hypotonia, ataxia, myopathy, hepatosplenomegaly, cataracts, and facial dysmorphisms (dolichocephaly, frontal bossing, low-set ears, downward slanting of eyes, long eyelashes). Most patients experience recurrent crises characterized by fever, vomiting, diarrhea, hepatosplenomegaly, arthralgia, lymphadenopathy, edema, and morbilliform rash. These episodes typically last 2-7 days and recur up to 25 times a year. Death may occur during these crises.

**Laboratory findings** include marked elevation of mevalonic acid in urine; the concentration of urinary mevalonic acid ranges between 500 and 56,000 mmol/mol of creatinine (normal: <0.3 mmol/mol of creatinine). Plasma levels of mevalonic acid are also greatly increased (as high as 540 µmol/L; normal: <0.04 µmol/L). Mevalonic acid levels tend to correlate with the severity of the condition and increase during crises. Serum cholesterol concentration is normal or mildly decreased. Serum concentration of creatine kinase can be greatly increased. Inflammatory markers are elevated during the crises. Brain MRI may reveal progressive atrophy of the cerebellum.

**Diagnosis** may be confirmed by DNA analysis or by assaying the MVK activity in lymphocytes or cultured fibroblasts. The enzyme activity in this form of the condition is below the detection level. **Treatment** with high doses of prednisone helps in the acute crises, but due to side effects, it is not routinely used long term. *Etanercept* (tumor necrosis factor inhibitor) and *anakinra* (interleukin-1 receptor antagonist) have shown to be effective in bringing significant clinical improvement. The condition is inherited as an autosomal recessive trait. **Prenatal diagnosis** is possible by identifying known familiar pathogenic variants in *MVK*, by measurement of mevalonic acid in the amniotic
fluid, or by assaying the enzyme activity in cultured amniocytes or chorionic villi samples. The gene \((MVK)\) for the enzyme is on chromosome 12q24.11.

**Hyperimmunoglobulinemia D Syndrome (Hyperimmunoglobulinemia D and Periodic Fever Syndrome)**

Some pathogenic variants of mevalonic kinase gene \((MVK)\) cause milder enzyme deficiency and produce the clinical picture of periodic fever with hyperimmunoglobulinemia D. These patients have periodic bouts of fever associated with abdominal pain, vomiting, diarrhea, arthralgia, arthritis, hepatosplenomegaly, lymphadenopathy, and morbilliform rash (even petechiae and purpura), which usually start before 1 yr of age. The attacks can be triggered by vaccination, minor trauma, or stress and can occur every 1-2 mo, lasting 2-7 days. Patients are free of symptoms between acute attacks. The diagnostic laboratory finding is elevation of serum immunoglobulin D (IgD). IgA is also elevated in 80% of patients. During acute attacks, leukocytosis, increased C-reactive protein, and mild mevalonic aciduria may be present. High concentrations of serum IgD help differentiate this condition from familial Mediterranean fever. See Chapter 188 for treatment recommendations.

**Propionic Acidemia (Propionyl-CoA Carboxylase Deficiency)**

Propionic acid is an intermediate metabolite of isoleucine, valine, threonine, methionine, odd-chain fatty acids, and side chains of cholesterol. Normally, propionic acid in the form of propionyl-CoA undergoes carboxylation to \(\text{D}-\text{methylmalonyl-CoA}\), catalyzed by the mitochondrial enzyme propionyl-CoA carboxylase. This enzyme requires biotin as a cofactor; thus the disorders of biotin metabolism, among other findings, can also result in elevation of propionic acid metabolites (see Fig. 103.4). Propionyl-CoA carboxylase is a multimeric enzyme composed of 2 nonidentical subunits, \(\alpha\) and \(\beta\), encoded by 2 genes, \(PCCA\) and \(PCCB\), respectively. Pathogenic variants in propionyl-CoA carboxylase result in the disorder called propionic acidemia. **Clinical findings** of propionic acidemia are not specific to this disorder only.
In the severe form, patients develop symptoms in the 1st few days of life. Poor feeding, vomiting, hypotonia, lethargy, dehydration, a sepsis-like picture, and clinical signs of severe ketoacidosis progress rapidly to coma and death. Seizures occur in approximately 30% of affected infants. If an infant survives the first attack, similar episodes of metabolic decompensation may occur during an intercurrent infection, trauma, surgery, prolonged fasting, severe constipation, or after ingestion of a high-protein diet. Moderate to severe intellectual disability and neurologic manifestations reflective of extrapyramidal (dystonia, choreoathetosis, tremor) and pyramidal (paraplegia) dysfunction are common sequelae in the survivors. Neuroimaging shows that these abnormalities, which often occur after an episode of metabolic decompensation, are the result of damage to the basal ganglia, especially to the globus pallidus. This phenomenon has been referred to as metabolic stroke. This is the main cause of neurologic sequelae seen in the surviving affected children. Additional long-term complications include failure to thrive, optic nerve atrophy, pancreatitis, cardiomyopathy, and osteopenia.

In the milder form, episodes of metabolic decompensation are less frequent, but these children are still at risk to develop intellectual disability, seizures, long QTC interval, and severe cardiomyopathy. Universal newborn screening can identify propionic acidemia by detecting elevated propionylcarnitine (C3) in dried blood spots. However, in patients with the mild form of propionic acidemia, propionylcarnitine could remain below the cutoff value set by the screening laboratory, resulting in a false-negative result. Therefore, physicians should maintain a high index of suspicion for this disorder and follow up with a biochemical evaluation of infants and children presenting with unexplained ketosis or metabolic acidosis.

Laboratory findings during the acute attack include various degrees of metabolic acidosis, often with a large anion gap, ketosis, ketonuria, hypoglycemia, anemia, neutropenia, and thrombocytopenia. Moderate to severe hyperammonemia is common; plasma ammonia concentrations usually correlate with the severity of the disease. In contrast to other causes of hyperammonemia, plasma concentration of glutamine tends to be within normal limits or decreased. Presence of severe metabolic acidosis and normal to reduced plasma glutamine help differentiate propionic academia from hyperammonemia caused by urea cycle defects. Measurement of plasma ammonia is especially helpful in planning therapeutic strategy during episodes of exacerbation in a patient whose diagnosis has been established. Mechanisms of hyperammonemia in propionic acidemia
are not well understood but are likely related to the perturbed biochemical and pH environment of the mitochondrial matrix, where the proximal part of urea cycle resides. **Glycine** concentration can be elevated in all body fluids (blood, urine, CSF) and possibly are the result of the inhibited glycine cleavage system in the hepatic mitochondria (Fig. 103.8). Glycine elevation has also been observed in patients with methylmalonic acidemia. These disorders were collectively referred to as **ketotic hyperglycinemia** in the past before the specific enzyme deficiencies were elucidated. Mild to moderate increase in blood lactate and lysine may also be present in these patients. Concentrations of propionylcarnitine, 3-hydroxypropionic acid, and methylcitric acid (presumably formed through condensation of propionyl-CoA with oxaloacetic acid) are greatly elevated in the plasma and urine of infants with propionic acidemia. Propionylglycine and other intermediate metabolites of branched-chain amino acid catabolism, such as tiglylglycine, can also be found in urine. Moderate elevations in blood levels of glycine, and previously mentioned organic acids can persist between the acute attacks. Brain imaging may reveal cerebral atrophy, delayed myelination, and abnormalities in the globus pallidus and other parts of the basal ganglia.
The diagnosis of propionic acidemia should be differentiated from multiple carboxylase deficiencies (see earlier and Fig. 103.6). In addition to propionic acid metabolites, infants with the latter condition excrete large amounts of lactic acid, 3-methylcrotonylglycine, and 3-hydroxyisovaleric acid. The presence of hyperammonemia may suggest a genetic defect in the urea cycle enzymes. Infants with defects in the urea cycle are usually not acidic (see Fig. 103.1) and have elevated levels of plasma glutamine. The definitive diagnosis of propionic acidemia can be established through molecular analysis of PCCA and PCCB or by measuring the enzyme activity in leukocytes or cultured fibroblasts.

Treatment of acute episodes of metabolic decompensation includes hydration with solutions containing glucose, correction of acidosis, and amelioration of the catabolic state by provision of adequate calories through enteral or parenteral...
A brief restriction of protein intake, no more than 24 hr, is often necessary. Depending on the clinical status, gradual reintroduction of protein is recommended. If enteral feedings cannot be tolerated after 48 hours of protein restriction, parenteral nutrition should be instituted to achieve the age-specific recommended dietary protein intake. Patients unable to tolerate the recommended dietary allowance of protein can receive specialized medical foods free of isoleucine, valine, threonine, and methionine. The composition and the amount of protein vary among patients. The metabolic diet composition can be adjusted by monitoring growth and plasma amino acids drawn 3-4 hr after the typical feeding. Some patients may benefit from the suppression of propionogenic gut microflora. This can be achieved by oral antibiotics such as oral neomycin or metronidazole. Prolonged use of metronidazole should be avoided because it has been associated with reversible peripheral neuropathy and increased QTc interval. The risk of QTc prolongation can be problematic in propionic acidemia patients, who are at risk for cardiomyopathy and long QT interval. Baseline and interval electrocardiograms (ECGs) are recommended before and after initiation of the metronidazole therapy. Patients may benefit from management of constipation.

Patients with propionic acidemia often develop secondary carnitine deficiency, presumably as a result of the urinary loss of propionylcarnitine. Administration of L-carnitine (50-100 mg/kg/24 hr orally or intravenously) helps restore free carnitine in blood. In patients with concomitant hyperammonemia, measures to reduce blood ammonia should be employed (see Chapter 103.12). Very ill patients with severe acidosis and hyperammonemia require hemodialysis to remove ammonia and other toxic compounds rapidly and efficiently. N-carbamoylglutamate (carglumic acid) and nitrogen scavengers (sodium benzoate, sodium phenylacetate, sodium phenylbutyrate) can aid in the treatment of acute hyperammonemia. Although no infant with propionic acidemia has been found to be responsive to biotin, this compound should be administered (10 mg/24 hr orally) to all infants during the first attack and until the diagnosis is established and multiple carboxylase deficiency ruled out.

Long-term treatment consists of a low-protein diet meeting age-specific recommended dietary allowance and administration of L-carnitine (50-100 mg/kg/24 hr orally). Some centers manage mild cases of propionic acidemia without medical foods, opting for only restricting the protein intake to recommended dietary allowance. Patients unable to tolerate the recommended dietary intake of protein may require medical foods free of propionate precursors.
(isoleucine, valine, methionine, and threonine). Excessive use of medical foods while restricting natural-source protein may cause a deficiency of the essential amino acids, especially isoleucine and valine, which may cause a condition resembling acrodermatitis enteropathica (see Chapter 691). Overrestriction of methionine, especially in the 1st years of life, may contribute to the reduced brain growth and microcephaly. To avoid this problem, natural proteins should comprise most of the dietary protein. Some patients may require bicarbonate substitution (e.g., citric acid/sodium citrate) to correct chronic acidosis. The concentration of plasma ammonia usually normalizes between attacks, although some patients may experience mild chronic hyperammonemia. Acute attacks triggered by infections, fasting, trauma, stress, constipation, or dietary indiscretions should be treated promptly and aggressively. Close monitoring of plasma ammonia, plasma amino acids obtained 3-4 hr after the last typical meal (especially isoleucine, leucine, valine, threonine, and methionine), and growth parameters is necessary to ensure the diet is appropriate. Orthotopic liver transplantation is used in clinically unstable patients experiencing recurrent hyperammonemia, frequent metabolic decompensations, and poor growth. Liver transplantation does not cure propionic acidemia, and lifelong dietary management and proactive management during periods of significant metabolic stress are recommended.

Long-term prognosis is guarded. Death may occur during an acute attack. Normal psychomotor development is possible in the mild form identified through newborn screening. Children identified clinically may manifest some degree of permanent neurodevelopmental deficit, such as tremor, dystonia, chorea, and spasticity despite adequate therapy. These neurologic findings may be the sequelae of a metabolic stroke occurring during an acute decompensation. Long QTc interval as well as cardiomyopathy with potential progression to heart failure, fatal arrhythmias, and death may develop in older affected children despite adequate metabolic control. Acute pancreatitis is a common and severe complication in propionic acidemia. Osteoporosis can predispose to fractures, which can occur even after minimal mechanical stress.

Prenatal diagnosis can be achieved by identification of the known familial pathogenic variants in PCCA or PCCB or by measuring the enzyme activity in cultured amniotic cells or in samples of uncultured chorionic villi.

Propionic acidemia is inherited as an autosomal recessive trait and has a worldwide prevalence of 1 : 105,000 to 1 : 250,000 live births. It is more prevalent in Greenlandic Inuits (1 : 1,000) and in some Saudi Arabian tribes (1 :
2,000 to 1 : 5,000 live births). The gene for the α-subunit (PCCA) is located on chromosome 13q32.3 and that of the β-subunit (PCCB) is mapped to chromosome 3q22.3. Pathogenic variants in either gene result in similar clinical and biochemical manifestations. Although pregnancies with normal outcomes have been reported, the perinatal period poses special risks to females with propionic acidemia because of hyperemesis gravidarum, worsening cardiomyopathy, changing protein requirements, and risk of metabolic decompensation.

Isolated Methylmalonic Acidemias

Methylmalonic acidemias are a group of metabolic disorders of diverse etiology characterized by impaired conversion of methylmalonyl-CoA into succinyl-CoA. Propionyl-CoA derived from catabolism of isoleucine, valine, threonine, methionine, side chain of cholesterol, and odd-chain fatty acids is catalyzed by propionyl-CoA carboxylase to form D-methylmalonyl-CoA. Methylmalonyl-CoA epimerase then converts D-methylmalonyl-CoA to its enantiomer L-methylmalonyl-CoA. Methylmalonyl-CoA epimerase deficiency is a rare disorder associated with persistent elevations of propionate-related metabolites and methylmalonic acid. It may present with metabolic acidosis, ketosis, but known patients appear more clinically stable than those with severe forms of methylmalonic acidemia.

In the next biochemical step, L-methylmalonyl-CoA is converted to succinyl-CoA by methylmalonyl-CoA mutase (see Fig. 103.4). The latter enzyme requires adenosylcobalamin, a metabolite of vitamin B<sub>12</sub>, as a coenzyme. Deficiency of either the mutase or its coenzyme results in the accumulation of methylmalonic acid and its precursors in body fluids. Two biochemical forms of methylmalonyl-CoA mutase deficiencies have been identified. These are designated mut<sup>0</sup>, referring to no detectable enzyme activity, and mut<sup>−</sup>, indicating residual, although insufficient, mutase activity. Patients with methylmalonic acidemia due to deficiency of the mutase apoenzyme (mut<sup>0</sup>) are not responsive to hydroxocobalamin therapy.

In the remaining methylmalonic acidemia patients, the defect resides in the formation of adenosylcobalamin from dietary vitamin B<sub>12</sub>. The absorption of dietary vitamin B<sub>12</sub> in the terminal ileum requires intrinsic factor, a glycoprotein secreted by the gastric parietal cells. It is transported in the blood by haptocorrin
and transcobalamin II. The transcobalamin II–cobalamin complex (TCII-Cbl) is recognized by a specific receptor on the cell membrane (transcobalamin receptor encoded by CD320) and enters the cell by endocytosis. In the lysosome, TCII-Cbl is hydrolyzed, and, with the participation of LMBRD1 (cbl F) and ABCD4 (cbl J), free cobalamin is released into the cytosol (see Fig. 103.4). Pathogenic variants in either LMBRD1 or ABCD4 genes result in impaired release of cobalamin from lysosomes. In the cytoplasm, cobalamin binds to the MMACHC protein (see cbl C later), which removes a moiety attached to cobalt in the cobalamin molecule and reduces the cobalt from oxidation state +3 (cob[III]alamin) to +2 (cob[II]alamin). It then enters the mitochondria, where it is catalyzed by MMAB (cbl B) and MMAA (cbl A) to form adenosylcobalamin, a coenzyme for methylmalonyl-CoA mutase. The other arm of the pathway directs cytosolic cobalamin toward methionine synthase reductase (cbl E), which forms methylcobalamin, acting as a coenzyme for methionine synthase (cbl G, see Fig. 103.3). The MMADHC protein (see cbl D) appears to play a role in determining whether cobalamin enters the mitochondria or remains in the cytoplasm.

The uptake of TCII-Cbl by cells is impaired in individuals with pathogenic variants affecting transcobalamin receptor (CD320), which is located on the cell surface. Individuals homozygous for pathogenic variants in the CD320 gene encoding the transcobalamin receptor may have mild elevations of methylmalonic acid in blood and urine. These patients can be identified by the newborn screen based on the elevated propionylcarnitine (C3). In transcobalamin receptor deficiency, methylmalonic acid levels and plasma propionylcarnitine tend to normalize in the 1st yr of life. It is not clear whether there is a long-term clinical phenotype associated with this defect.

Nine different defects in the intracellular metabolism of cobalamin have been identified. These are designated cbl A through cbl G, cbl J, and cbl X, where cbl stands for a defect in any step of cobalamin metabolism. The cbl A, cbl B, and cbl D variant 2 defects cause methylmalonic acidemia alone. In patients with cbl C, classic cbl D, cbl F, cbl J, and cbl X defects, synthesis of both adenosylcobalamin and methylcobalamin is impaired, resulting in combined methylmalonic acidemia and homocystinuria. The cbl D variant 1, cbl E, and the cbl G defects affect only the synthesis of methylcobalamin, resulting in homocystinuria without methylmalonic aciduria (see Chapter 103.3).

Biochemical manifestations of patients with isolated methylmalonic acidemia caused by mut⁰, mut⁻, cbl A, cbl B, and cblD variant 2 overlap. The wide
variations in severity of clinical course range from very sick newborn infants to apparently asymptomatic adults. In severe forms, lethargy, feeding problems, vomiting, a sepsis-like picture, tachypnea (from metabolic ketoacidosis), and hypotonia may develop in the first few days of life and may progress to hyperammonemic encephalopathy, coma, and death if left untreated. Infants who survive the first attack may go on to develop similar acute metabolic episodes during a catabolic state such as infection or prolonged fasting or after ingestion of a high-protein diet. In certain situations, such acute events can cause a sudden injury of the basal ganglia (movement centers in CNS), a metabolic stroke, resulting in a debilitating movement disorder. Between the acute attacks, the patient usually continues to exhibit hypotonia and feeding problems with failure to thrive, while other complications of the disease occur with age, including recurrent episodes of pancreatitis, bone marrow suppression, osteopenia, and optic nerve atrophy. Chronic renal failure and tubulointerstitial nephritis necessitating renal transplant have been reported in older patients. Renal complications are more severe in patients with the mut° and severe cbl B forms of methylmalonic acidemia. In milder forms, patients may present later in life with hypotonia, failure to thrive, and developmental delay. Neurocognitive development of patients with mild methylmalonic acidemia may remain within the normal range.

The episodic nature of the condition and its biochemical abnormalities in some patients may be confused with those of ethylene glycol (antifreeze) ingestion. The peak of propionate in a blood sample from an infant with methylmalonic acidemia has been mistaken for ethylene glycol when the sample was assayed by gas chromatography without mass spectrometry.

**Laboratory findings** include ketosis, metabolic acidosis, hyperglycinemia, hyperammonemia, hypoglycemia, anemia, neutropenia, thrombocytopenia, and the presence of large quantities of methylmalonic acid in body fluids (see Fig. 103.6). Metabolites of propionic acid (3-hydroxypropionate and methylcitrate) are also found in the urine. Plasma acylcarnitine profile reveals elevated propionylcarnitine (C3) and methylmalonylcarnitine (C4DC). Hyperammonemia in methylmalonic acidemia may be confused with a urea cycle disorder. However, patients with defects in urea cycle enzymes are typically not acidic and tend to have high plasma glutamine (see Fig. 103.12). The reason for hyperammonemia is not well understood, but it is likely related to the inhibition of proximal urea cycle in the mitochondrial matrix.

Diagnosis can be confirmed by identifying pathogenic variants in the causal
gene, by measuring propionate incorporation with complementation analysis in cultured fibroblasts, and by measuring the specific activity of the mutase enzyme in biopsies or cell extracts.

**Treatment** of acute attacks is similar to propionic acidemia. Long-term treatment consists of administration of a low-protein diet limited to the recommended dietary allowance, L-carnitine (50-100 mg/kg/24 hr orally). Patients with severe forms of methylmalonic acidemia may require protein diet modifications similar to those prescribed for patients with propionic acidemia. Patients with isolated methylmalonic acidemia caused by defects in the intracellular metabolism of cobalamin (cbl A, cblD variant 2, and some patients with cbl B) respond to parenteral hydroxocobalamin. Chronic bicarbonate replacement therapy is usually required to correct chronic acidosis. Plasma ammonia tends to normalize between the attacks, and chronic treatment of hyperammonemia is rarely needed. Stressful situations that may trigger acute attacks (infection, prolonged fasting, trauma, surgeries, high-protein meals) should be treated promptly.

Inadequate oral intake secondary to poor appetite, protein overrestriction, or essential amino acid deficiencies are common complications in long-term management of these patients. Consequently, enteral feeding through gastrostomy is often recommended early in the course of treatment. Close monitoring of blood pH, essential amino acid levels, blood and urinary concentrations of methylmalonate, and growth parameters is required to ensure the nutritional prescription meets patient's metabolic demands. In addition, frequent monitoring of kidney function, vision, hearing, and bone mineral density are necessary for early recognition and management of chronic complications. Glutathione deficiency responsive to treatment with ascorbate has been described.

Liver, kidney, and combined liver-kidney transplantations have been attempted in an increasing number of affected patients. Liver and liver-kidney transplantation can alleviate but not eliminate the metabolic abnormalities. Liver and liver-kidney transplants do not provide complete protection against the occurrence of metabolic stroke. Kidney transplantation alone can restore the renal function but results in only minor improvement of the clinical stability of patients.

**Prognosis** depends on the severity of symptoms and the occurrence of complications. In general, patients with complete deficiency of mutase apoenzyme (mut$^0$) and severe forms of cbl B deficiency have the least favorable
prognosis, and those with $mut^-$ and $cbl$ A defects have a better outcome.

Methylmalonic acidemia can be identified on the universal newborn screening by measuring propionylcarnitine (C3) using tandem mass spectrometry. The prevalence of all forms of methylmalonic aciduria is estimated at 1 : 50,000 to 1 : 100,000 live births. All defects causing isolated methylmalonic acidemia are inherited as autosomal recessive traits. The gene for the mutase ($MUT$) is on the short arm of chromosome 6p12.3. Neonates with methylmalonic acidemia and severe diabetes caused by $\beta$-cell agenesis, who have paternal uniparental isodisomy of chromosome 6, have been reported. Pathogenic variants in the genes for $cbl$ A ($MMAA$, on chromosome 4q31.21), $cbl$ B ($MMAB$, on chromosome 12q24.11), and all forms of $cbl$ D ($MMADHC$, on chromosome 2q23.2) have been identified in affected patients. The previously described $cbl$ H group is identical to $cbl$ D variant 2.

**Combined Methylmalonic Aciduria and Homocystinuria ($cbl$ C, $cbl$ D, $cbl$ F, $cbl$ J, and $cbl$ X Defects)**

Combined methylmalonic acidemia and homocystinuria caused by $cbl$ C deficiency is the most common type of intracellular cobalamin (vitamin $B_{12}$) biosynthesis defects. Deficiency of $cbl$ C is as common as methylmalonyl-CoA mutase deficiency. The other disorders ($cbl$ D, $cbl$ F, $cbl$ J, $cbl$ X) are much rarer (see Figs. 103.3 and 103.4). Neurologic findings are prominent in patients with $cbl$ C, $cbl$ D and $cbl$ X defects. Most patients with the $cbl$ C defect present in the 1st mo of life because of failure to thrive, lethargy, poor feeding, developmental delay, nystagmus and seizures. Hyperammonemia may be seen infrequently, while hyperglycinemia is not present, unlike in isolated $mut$ -type methylmalonic acidemia. Intrauterine growth restriction and microcephaly suggest that $cbl$ C can manifest prenatally in some affected infants. Late-onset patients with sudden development of dementia and myelopathy have been reported, even with presentation in adulthood. Megaloblastic anemia is a common finding in patients with $cbl$ C defect. Mild to moderate increases in concentrations of methylmalonic acid and significant elevations in total plasma homocysteine are found in blood. Unlike classic homocystinuria, in untreated $cbl$ C patients plasma methionine is low to normal. Retinal abnormalities (e.g., bull's eye
maculopathy) resulting in severe progressive vision loss are common and can be seen as early as 3 mo of age, even in prospectively identified and well-treated patients. Thrombotic microangiopathy can present as hemolytic uremic syndrome, pulmonary hypertension, and cor pulmonale. Hydrocephalus, and non-compaction cardiomyopathy have been reported as complications in patients with cbl C defect.

Similar to cblC patients, males with cbl X have elevations of both total plasma homocysteine and methylmalonic acid, but they tend to have milder elevations of these metabolites. Unlike cbl C-deficient patients, who tend to respond to treatment, cbl X-deficient patients experience failure to thrive, severe developmental delay, and intractable epilepsy despite aggressive treatment.

Clinical findings in cbl F deficiency are quite variable. Patients may present with poor feeding, growth and developmental delay, and persistent stomatitis manifesting in the 1st mo of life. Delay in diagnosis and treatment can be accompanied by hyperpigmentation of skin, developmental delay, intellectual disability, and short stature. Vitamin B₁₂ malabsorption and low plasma vitamin B₁₂ has been noted in patients with cbl F defect. Clinical manifestations of cbl J defect show significant overlap with those of the cbl F deficiency. Dysmorphic features and congenital heart disease have been reported in some patients with cbl F and cbl J defects.

Experience with treatment of patients with cbl C, cbl D, cbl F, cbl J, and cbl X defects is limited. Large doses of hydroxocobalamin (up to 0.3 mg/kg/day) in conjunction with betaine (up to 250 mg/kg/day) produce biochemical improvement with variable clinical effect. Patients with cbl F and cbl J deficiency typically show favorable biochemical and clinical response to smaller hydroxocobalamin doses (1 mg once weekly to 1 mg daily parenterally). Folic or folinic acid supplementation is recommended. Dietary methionine deficiency should be avoided.

The cbl C disorder is caused by pathogenic variants in the MMACHC gene (on chromosome 1p34.1). A frameshift variant (c.271dupA) is seen in up to 40% of MMACHC alleles and is associated with a less favorable clinical outcome. The cbl D disorder is caused by pathogenic variants in the MMADHC gene (on chromosome 2q23.2). Pathogenic variants resulting in cbl D variant 1 (causing only homocystinuria) affect the C-terminal domain of the gene product; those resulting in cbl D variant 2 (causing only methylmalonic aciduria) affect the N-terminus. Patients with classic cbl D, with both homocystinuria and methylmalonic acidemia, have pathogenic variants resulting in decreased protein
expression. The cbl F disorder is caused by pathogenic variants in the \textit{LMBRD1} gene (on chromosome 6q13) encoding a lysosomal membrane protein. The cbl J disorder is associated with pathogenic variants in the \textit{ABCD4} gene (on chromosome 14q24.3), encoding an adenosine triphosphate–binding cassette protein localized to the lysosomal membrane. The cbl X disorder is caused by pathogenic variants in the \textit{HCFC1} gene on the X chromosome (Xq28), which encodes a transcription factor that appears to be essential for expression of the \textit{MMACHC} gene. This is the only X-linked disorder in the B\textsubscript{12} intracellular metabolism pathway.

**Isolated Homocystinuria**

Patients with cbl D variant 1, cbl E, and cbl G deficiency present with isolated homocystinuria without methylmalonic acidemia (see Chapter 103.3, Homocystinuria Caused by Defects in Methylcobalamin Formation).

**Combined Malonic and Methylmalonic Aciduria (ACSF3 -Related Disorder)**

Combined malonic and methylmalonic aciduria (CMAMMA) is a rare autosomal recessive disorder resulting from pathogenic variants in ACSF3. ACSF3 is a putative acyl-CoA synthetase required for the conversion of malonic and methylmalonic acids to their CoA derivatives in the mitochondrial matrix. The disorder can be suspected based on the presence of elevated malonic and methylmalonic acids in urine and plasma. It is distinguished from malonyl-CoA decarboxylase, because methylmalonic acid is about 5-fold greater than malonic acid in the urine. Plasma propionylcarnitine (C3-carnitine) in CMAMMA patients is normal, so universal newborn screening programs using C3-carnitine in blood spots to screen for methylmalonic acidemia would not detect this condition. The clinical phenotype is incompletely understood. Young patients identified prospectively in infancy through urine-based newborn screening were reported to be asymptomatic, but the long-term outcome in this cohort awaits further characterization. Older patients ascertained clinically have highly variable presentations, including metabolic crises, failure to thrive, seizures, memory problems, optic nerve or spinal cord atrophy, and progressive
neurodegeneration. Treatment of CMAMMA is supportive and includes avoidance of an excessively high-protein diet. Vitamin B_{12} supplementation does not appear to lower malonic and methylmalonic metabolites in body fluids.

Glycine

Oleg A. Shchelochkov, Charles P. Venditti

Glycine is a nonessential amino acid synthesized mainly from serine and threonine. Structurally, it is the simplest amino acid. Glycine is involved in many reactions in the body, especially in the nervous system, where it functions as a neurotransmitter (excitatory in the cortex, inhibitory in the brainstem and the spinal cord; see Chapter 103.11 ). Its main catabolic pathway requires the glycine cleavage system, a pyridoxal phosphate–dependent, mitochondrial enzyme complex that converts glycine to carbon dioxide and ammonia and transfers α-carbon to tetrahydrofolate (see Fig. 103.8 ). The glycine cleavage system is composed of 4 proteins: P protein (glycine decarboxylase), H protein, T protein,
and L protein, which are encoded by 4 different genes.

**Hypoglycinemia**

Defects in the biosynthetic pathway of serine (see Chapter 103.8) cause deficiency of glycine in addition to that of serine in body fluids, especially in the cerebrospinal fluid (CSF). Isolated primary deficiency of glycine has not been reported.

**Hyperglycinemia**

Elevated levels of glycine in body fluids occur in propionic acidemia, methylmalonic acidemia, isovaleric acidemia, and β-ketothiolase deficiency, which are collectively referred to as ketotic hyperglycinemia because of the coexistence of acidosis and ketosis. The pathogenesis of hyperglycinemia in these disorders is not fully understood, but inhibition of the glycine cleavage enzyme system by the various organic acids has been shown to occur in some of these patients. The term **nonketotic hyperglycinemia (NKH)** is reserved for the clinical condition caused by the genetic deficiency of the glycine cleavage enzyme system (see Fig. 103.8). In this condition, hyperglycinemia is present without ketosis.

**Nonketotic Hyperglycinemia (Glycine Encephalopathy)**

Four forms of NKH have been identified: neonatal, infantile, late onset, and transient.

**Neonatal Nonketotic Hyperglycinemia**

This is the most common form of NKH. Clinical manifestations develop in the 1st few days of life (between 6 hr and 8 days after birth). Poor feeding, failure to suck, lethargy, and profound hypotonia may progress rapidly to a deep coma, apnea, and death. Convulsions, especially myoclonic seizures and hiccups, are common.
Laboratory findings reveal moderate to severe hyperglycinemia (as high as 8 times normal) and hyperglycinuria. The unequivocal elevation of glycine concentration in CSF (15-30 times normal) and the high ratio of glycine concentration in CSF to that in plasma (a value >0.08, normal <0.02) are diagnostic of NKH. Affected patients' blood pH is usually normal, and urine assay is negative for organic acids. CSF serine levels can be low.

Approximately 30% of NKH infants die despite supportive therapy. Those who survive develop profound psychomotor retardation and intractable seizure disorders (myoclonic and/or grand mal seizures). Hydrocephalus, requiring shunting, and pulmonary hypertension have been noted in some survivors. In some patients the hyperglycemia is transient.

**Infantile Nonketotic Hyperglycinemia**

These previously normal infants develop signs and symptoms of neonatal NKH after 6 mo of age. Seizures and hypotonia are the common presenting signs. Infantile NKH appears to be a milder form of neonatal NKH; infants usually survive, and intellectual disability is not as profound as in the neonatal form.

Laboratory findings in patients with infantile NKH are identical to those seen in neonatal NKH.

**Late-Onset Nonketotic Hyperglycinemia**

Clinical manifestations of this atypical form of NKH include progressive spastic diplegia, optic nerve atrophy, and choreoathetotic movements. Age of onset has been between 2 and 33 yr. Symptoms of delirium, chorea, and vertical gaze palsy may occur episodically in some patients during an intercurrent infection. Mental development is usually normal, but mild cognitive impairment and infrequent seizures have been reported in some patients.

Laboratory findings in late-onset NKH are similar but not as pronounced as in neonatal NKH.

All forms of NKH should be differentiated from *ketotic* hyperglycinemia, pyridox(am)ine phosphate oxidase (PNPO) deficiency, ingestion of valproic acid, and transient glycine encephalopathy. Valproic acid can moderately increase blood, CSF, and urinary concentrations of glycine. Repeat assays after discontinuation of the drug will help establish the diagnosis.
Transient Nonketotic Hyperglycinemia

Most clinical and laboratory manifestations of transient NKH are indistinguishable from those of the neonatal form. By 2-8 wk of age, however, a complete clinical recovery may occur, and the elevated glycine levels in plasma and CSF normalize after the patient stops a glycine-lowering medication. Some of these patients develop normally with no neurologic sequelae, but intellectual disability has been noted in others. The etiology of this condition is not known, but it is thought to be a consequence of immaturity of the enzyme system.

Diagnosis and Treatment

Diagnosis of NKH can be suspected based on the findings of elevated glycine in plasma or CSF and the abnormal CSF/plasma ratio of glycine. The diagnosis is confirmed using molecular analysis of the NKH-related genes. Rarely, assay of the enzyme in liver or brain specimens is necessary to establish the diagnosis. Enzyme activity in the neonatal form is close to zero, whereas in the other forms, some residual activity is present. In most patients with neonatal NKH, the enzyme defect resides in the P protein (75%); defects in the T protein account for approximately 20% of cases, whereas <1% are caused by pathogenic variants in the H protein.

No effective treatment is known. Exchange transfusion, dietary restriction of glycine, and administration of sodium benzoate or folate have not altered the neurologic outcome in severe forms of NKH. Patients with attenuated NKH may experience clinical improvement from enteral sodium benzoate. Drugs that counteract the effect of glycine on neuronal cells, such as dextromethorphan and felbamate, have shown some beneficial effects in patients with the mild forms of the condition.

NKH is inherited as an autosomal recessive trait. The prevalence is not known, but high frequency of the disorder has been noted in northern Finland (1 in 12,000 live births) suggesting that this disorder is likely underdiagnosed. The gene for P protein (GLDC) is on chromosome 9p24.1. The gene encoding T protein (AMT) is on chromosome 3p21.31 and that for H protein (GCSH) is mapped to chromosome 16q23.2. The L protein gene (DLD) on chromosome 7q31.7 encodes dihydrolipoamide dehydrogenase, the E3 component of α-ketoacid dehydrogenase complexes and is discussed in Chapter 103.6 (Valine, Leucine, Isoleucine, and Related Organic Acidemias). Prenatal diagnosis has
been accomplished by identification of the known familial pathogenic variants in the affected gene or by performing an assay of the enzyme activity in chorionic villus biopsy specimens.

Sarcosinemia

Increased concentrations of sarcosine (N-methylglycine) are observed in both blood and urine, but no consistent clinical picture has been attributed to sarcosinemia. This autosomal recessive metabolic condition is caused by a defect in sarcosine dehydrogenase, the enzyme that converts sarcosine to glycine (see Fig. 103.8). The gene for this enzyme (SARDH) is on chromosome 9q34.2.

Primary Trimethylaminuria

Trimethylamine is normally produced in the intestine from the breakdown of dietary choline and trimethylamine oxide by bacteria. Egg yolk and liver are the main sources of choline, and fish is the major source of trimethylamine oxide. Trimethylamine is absorbed and oxidized in the liver by trimethylamine oxidase (flavin-containing monooxygenases) to trimethylamine oxide, which is odorless and excreted in the urine (see Fig. 103.8). Deficiency of this enzyme results in massive excretion of trimethylamine in urine. There is a body odor that resembles that of a fish, which may have significant social and psychosocial ramifications. Transient symptomatic trimethylaminuria can occur in normal individuals following ingestion of large quantities of the above mentioned foods. Treatment with oral activated charcoal, short courses of oral metronidazole, neomycin, or lactulose cause temporary reduction in the body odor. Restriction of fish, eggs, liver, and other sources of choline (e.g., nuts, grains) in the diet significantly reduces the odor. Topical use of acidic soaps (pH 5.5) can also help control the odor. The gene for trimethylamine oxidase (FMO3) has been mapped to chromosome 1q24.3.

Hyperoxalururia and Oxalosis

Normally, oxalic acid is derived mostly from oxidation of glyoxylic acid and, to a lesser degree, from oxidation of ascorbic acid (see Fig. 103.8). Glyoxylic acid is formed from oxidation of glycolic acid and glycine in the peroxisomes, and
catabolism of **hydroxyproline** in the mitochondria (Fig. 103.9). Vegetables and foods containing oxalic acid, such as spinach, rhubarb, and almond milk, are the main *exogenous* sources of glycolic and oxalic acids; most of glyoxylic and oxalic acids are produced endogenously. Normally, a major portion of glyoxylate produced in the body is shuttled to peroxisomes, where it is converted to glycine by the action of the enzyme alanine:glyoxylate transaminase. Deficiency of this enzyme causes hyperoxaluria type 1. Most of the remaining glyoxylate in the cytosol is reduced to glycolate by the action of the enzyme glyoxylate reductase/hydroxypyruvate reductase. Deficiency of this enzyme causes hyperoxaluria type 2. These 2 pathways protect the body from excessive production of oxalic acid (see Fig. 103.8). Any glyoxylate that cannot be disposed of through these pathways is readily converted to oxalic acid by the action of the enzyme lactate dehydrogenase (LDH). Oxalic acid cannot be further metabolized in humans and is excreted in the urine as oxalates. Calcium oxalate is relatively insoluble in water and precipitates in tissues (kidneys and joints) if its concentration increases in the body.

**Secondary hyperoxaluria** has been observed in pyridoxine deficiency (cofactor for alanine:glyoxylate transaminase), in patients with inflammatory bowel disease, extensive resection of small bowel, or jejunoileal bypass (*enteric*
hyperoxaluria), after ingestion of ethylene glycol or high doses of vitamin C, and after administration of the anesthetic agent methoxyflurane (which oxidizes directly to oxalic acid). Acute, fatal hyperoxaluria may develop after ingestion of plants with high oxalic acid content (e.g., sorrel) or intentional ingestion of oxalic acid. Precipitation of calcium oxalate in tissues causes hypocalcemia, liver necrosis, renal failure, cardiac arrhythmia, and death. The lethal dose of oxalic acid is estimated at 5-30 g.

**Primary hyperoxaluria** is a group of disorders in which large amounts of oxalates accumulate in the body. Three types of primary hyperoxaluria have been identified to date. The term **oxalosis** refers to deposition of calcium oxalate in parenchymal tissues.

**Primary Hyperoxaluria Type 1**

This rare condition (prevalence of 1 : 120,000 live births in Europe) is the most common form of primary hyperoxaluria. It is caused by deficiency of the peroxisomal enzyme alanine:glyoxylate transaminase, which is expressed only in the liver peroxisomes and requires pyridoxine (vitamin B₆) as a cofactor. In the absence of this enzyme, glyoxylic acid, which cannot be converted to glycine, is transferred to the cytosol, where it is oxidized to oxalic acid (see earlier and Fig. 103.8).

The age of presentation varies widely, from neonatal period to late adulthood. The majority of patients become symptomatic in late childhood or early adolescence. In about 20% of cases, symptoms develop before 1 yr of age. The initial clinical manifestations are related to renal stones and nephrocalcinosis. Renal colic and asymptomatic hematuria lead to a gradual deterioration of renal function, manifested by growth retardation and uremia. If the disorder is left untreated, most patients die before 20 yr of age from renal failure. Other frequent manifestations of the disease include failure to thrive, short stature, arterial calcifications, arrhythmia, heart failure, hypothyroidism, and skin nodules. Acute arthritis is a rare manifestation and may be misdiagnosed as gout because uric acid is usually elevated in patients with type 1 hyperoxaluria. Crystalline retinopathy and optic neuropathy causing visual loss have occurred in a few patients.

A marked increase in urinary excretion of oxalate (normal excretion: 10-50 mg/24 hr) is the most important laboratory finding. The presence of oxalate crystals in urinary sediment is rarely helpful for diagnosis because such crystals
can also be seen in normal individuals. Urinary excretion of glycolic acid and glyoxylic acid is increased in most but not all patients. Diagnosis can be confirmed by identification of pathogenic variants in the AGXT gene or by performing an enzymatic assay in liver specimens.

**Treatment** focuses on the reduction of oxalic acid production and on increasing calcium oxalate disposal. Patients with primary hyperoxaluria type 1 should receive a 3-mo trial of pyridoxine treatment to establish pyridoxine responsiveness. In up to 30% of patients (e.g., homozygous for pathogenic variant c.508G>A in AGXT), administration of large doses of pyridoxine reduces plasma level and urinary excretion of oxalate. To increase calcium oxalate disposal and prevent nephrolithiasis, high oral fluid intake (2-3 L/m²/24 hr while controlling for fluid balance), urine alkalinization, phosphate supplementation, monitoring of vitamin C and vitamin D intake, and avoidance of drugs that increase urinary calcium excretion (e.g., loop diuretics) are recommended. Urinary stones should be managed by experienced urologists because excessive surgical trauma may contribute to renal dysfunction. Renal function replacement strategies (e.g., hemodialysis) are used in some patients (e.g., to bridge patients to transplant or when transplant is not a viable option).

Organ **transplantation** has emerged as the most definitive treatment. The decision to undergo kidney, liver, or liver-kidney transplant is complex and may vary from one medical center to another. Except for older patients with pyridoxine-responsive form of disease, renal transplantation for patients in renal failure may not improve the outcome, because oxalosis will recur in the transplanted kidney. Combined liver-kidney transplants have resulted in a significant decrease in plasma and urinary oxalate and thus may be the most effective treatment strategy in this disorder, particularly in children.

The condition is inherited as an autosomal recessive trait. The gene for this enzyme (AGXT) is mapped to chromosome 2q37.3. The most common pathogenic variant in patients with high residual enzyme activity (c.508G>A, p.Gly170Arg) results in mistargeting of the enzyme to the mitochondria instead of the peroxisomes and loss of in vivo function. **Prenatal diagnosis** has been achieved by DNA analysis of chorionic villus samples or by the measurement of fetal hepatic enzyme activity obtained by needle biopsy.

**Primary Hyperoxaluria Type 2 (L-Glyceric Aciduria)**
This rare condition is caused by a deficiency of the glyoxylate reductase–hydroxypyruvate reductase enzyme complex (see Fig. 103.8). A deficiency in the activity of this complex results in an accumulation of two intermediate metabolites, hydroxypyruvate (the ketoacid derivative of serine) and glyoxylic acid. Both these compounds are further metabolized by LDH to L-glyceric acid and oxalic acid, respectively. A high prevalence of this disorder is reported in the Saulteaux-Ojibway Indians of Manitoba.

Primary hyperoxaluria type 2 results in the deposition of calcium oxalate in the renal parenchyma and urinary tract. Renal stones presenting with renal colic and hematuria may develop before age 2 yr. Renal failure is less common in this condition than in primary hyperoxaluria type 1.

Urinary testing reveals large amounts of L-glyceric acid in addition to high levels of oxalate. Urinary L-glyceric acid is considered a pathognomonic finding in primary hyperoxaluria type 2. Urinary excretion of glycolic acid and glyoxylic acid is not increased. The presence of L-glyceric acid without increased levels of glycolic and glyoxylic acids in urine differentiates this type from type 1 hyperoxaluria. Diagnosis can be confirmed by molecular analysis of GRHPR (9p13.2) or by the enzyme assay in liver biopsy.

Principles of therapy are similar to those in primary hyperoxaluria type 1. Renal transplant is used in some patients; no experience with kidney-liver transplantation is available at this time.

**Primary Hyperoxaluria Type 3**

Approximately 10% of patients with primary hyperoxaluria have deficiency of 4-hydroxy-2-oxoglutarate aldolase 1 (HOGA1), the underlying cause of hyperoxaluria type 3. The enzyme is encoded by HOGA1 mapped to chromosome 10q24.2. This mitochondrial enzyme catalyzes the final step in the metabolic pathway of hydroxyproline generating pyruvate and glyoxylate from 4-hydroxy-2-oxoglutarate (HOG; see Figs. 103.8 and 103.9). In vitro studies show inhibition of glyoxylate reductase–hydroxypyruvate reductase enzyme activity by high concentration of HOG that accumulates in patients with hyperoxaluria type 3. This inhibition results in a biochemical phenotype similar to hyperoxaluria type 2 (see Fig. 103.8).

Patients with primary hyperoxaluria type 3 usually presented with calcium oxalate kidney stones in early childhood, but asymptomatic older siblings were also identified. Gradually, renal function may decline, infrequently resulting in
end-stage renal disease. Increased levels of HOG in urine, serum, and liver biopsy samples of these patients is the distinguishing feature of this disorder. **Treatment** involves high oral fluid intake, management of oral citrate or phosphate intake to prevent calcium oxalate renal stone formation, and avoidance of dehydration to prevent acute kidney injury. In severe forms of this disorder, dialysis and transplantation may be required to address the end-stage renal disease.

**Creatine Deficiency Disorders**

Creatine is synthesized mainly in the liver, pancreas, and kidneys and to a lesser degree in the brain from arginine and glycine and is transported to muscles and the brain, where there is high activity of the enzyme creatine kinase (Fig. 103.10). Phosphorylation and dephosphorylation of creatine in conjunction with adenosine triphosphate and diphosphate provide high-energy phosphate transfer reactions in these organs. Creatine is nonenzymatically metabolized to creatinine at a constant daily rate and is excreted in the urine. Three genetic conditions are known to cause creatine deficiency in the brain and other tissues. Two enzymes, arginine:glycine amidinotransferase (AGAT) and guanidinoacetate methyltransferase (GAMT; Fig. 103.10), are involved in the biosynthesis of creatine. Both conditions may respond to creatine supplementation, especially when the treatment is started in early age. The 3rd condition, an X-linked inherited defect, is caused by deficiency of the creatinine transporter (CRTR) protein mediating uptake of creatine by brain and muscle.
Clinical manifestations of the 3 defects overlap, relate to the brain and muscle, and may appear in the 1st few wk or mo of life. Developmental delay, intellectual disability, speech delay, psychiatric symptoms (autism and psychosis), hypotonia, ataxia, and seizures are common findings. Dystonic movements have been documented in GAMT and CRTR deficiency.

Laboratory findings include decreased creatine in plasma in patients with AGAT and GAMT defects. Plasma creatinine level alone is insufficient to diagnose these disorders. Secondary to impaired reabsorption of creatine in kidneys, the urinary ratio of creatine to creatinine is increased in male patients with a CRTR defect but can also be mildly elevated in female carriers. Marked elevations of guanidinoacetate in blood, urine, and especially in CSF, are diagnostic of GAMT defects. In contrast, low levels of guanidinoacetate can be found in body fluids in the AGAT defect. Absence of creatine and creatine phosphate (in all 3 defects) and high levels of guanidinoacetate (in GAMT defect) can be demonstrated in the brain by magnetic resonance spectroscopy (MRS). Brain MRI may show signal hyperintensity in the globus pallidus.

Diagnosis of AGAT deficiency or GAMT deficiency may be confirmed by DNA analysis or by measuring of enzymatic activity in cultured fibroblasts (GAMT) or lymphoblasts (AGAT). Diagnosis of CRTR deficiency can be confirmed by DNA analysis or a creatine uptake assay in fibroblasts.
The outcomes of treatment are age-dependent and best with treatment started in the neonatal period or presymptomatically. In AGAT-deficient patients, oral creatine monohydrate (up to 400-800 mg/kg/24 hr) may improve muscle weakness in most and neurocognitive outcomes in some patients. In GAMT-deficient patients, supplementation with oral creatine monohydrate (up to 400-800 mg/kg/24 hr), ornithine (up to 400-800 mg/kg/24 hr), and dietary arginine restriction may result in improved muscle tone and neurocognitive development and may alleviate seizures. In CRTR-deficient patients, administration of creatine and its precursors (arginine and glycine) does not restore creatine in the brain, but some patients may experience improvements of seizures and neurocognitive outcomes.

AGAT and GAMT defects are inherited as autosomal recessive traits. The gene for AGAT (GATM) is on chromosome 15q21.1 and that for GAMT (GAMT) is on chromosome 19p13.3. CRTR is an X-linked disorder and the gene (SLC6A8) is on Xq28. CRTR defect is the most common cause of creatine deficiency, accounting for up to 1–2% of males with intellectual disability of unknown cause.

Serine is a nonessential amino acid supplied through dietary sources and through its endogenous synthesis, mainly from glucose and glycine. The endogenous production of serine comprises an important portion of the daily requirement of this amino acid, especially in the synaptic junctions where it contributes to the metabolism of phospholipids as well as $\alpha$ -serine and glycine, both involved in neurotransmission (see Chapter 103.11). Consequently, deficiency of any of the enzymes involved in the biosynthesis of serine or its transport causes neurologic manifestations. The clinical spectrum of serine deficiency disorders is wide and varies from Neu-Laxova syndrome on the severe end of spectrum to epilepsy and developmental delay on the milder end. Affected patients respond favorably to oral supplementation with serine and glycine provided that the treatment is initiated very early in life. Figs. 103.8 and 103.10 show the metabolic pathway for synthesis and catabolism of serine.

3-Phosphoglycerate Dehydrogenase Deficiency

3-Phosphoglycerate dehydrogenase (PHGDH) deficiency has a broad range of symptoms and ages of presentation. Neu-Laxova syndrome type 1 is the most severe manifestation and presents prenatally with intrauterine growth restriction and congenital anomalies, including dysmorphic facial features, microcephaly, CNS malformations, limb deformities, and ichthyosis. Most patients with this form are stillborn or have early neonatal mortality. Infantile-onset PHGDH deficiency presents with feeding problems, failure to thrive, vomiting, irritability, intractable seizures, severe developmental delay, and hypertonia progressing to spastic quadriplegia. Nystagmus, cataracts, hypogonadism, and megaloblastic anemia have been observed in some affected infants. Patients with a milder form of this disorder experience cognitive impairment, behavioral problems, sensorineural polyneuropathy, and childhood-onset seizures.

Laboratory findings include low fasting levels of serine and glycine in plasma and very low levels of serine and glycine in CSF. No abnormal organic acid metabolite is found in the urine. MRI of the brain shows cerebral atrophy with enlarged ventricles, significant attenuation of white matter, and impaired myelination. Diagnosis can be confirmed by DNA analysis or by measurement of the enzyme activity in cultured fibroblasts. Treatment with high doses of serine (200-700 mg/kg/24 hr orally) and glycine (200-300 mg/kg/24 hr)
normalizes the serine levels in the blood and CSF. When started postnatally, this treatment may improve seizures, spasticity, and brain myelination. One case report suggests that developmental delay may be prevented if the treatment commences in the 1st days of life or prenatally.

The condition is inherited as an autosomal recessive trait. The gene for 3-phosphoglycerate dehydrogenase enzyme (PHGDH) has been mapped to chromosome 1p12. If familial pathogenic variants are known, molecular prenatal diagnosis is possible. Administration of serine to the mother carrying an affected fetus was associated with stabilization of the fetal head circumference, as evidenced by ultrasound. Treatment with supplemental serine has continued postnatally; the patient remained normal neurologically at 4 yr of age. The favorable response of this condition to a relatively straightforward treatment makes this diagnosis an important consideration in any child with microcephaly and neurologic defects such as psychomotor delay or a seizure disorder. Measurements of serine and glycine in the CSF are critical for diagnosis because mild decreases of these amino acids in the plasma can be easily overlooked.

**Phosphoserine Aminotransferase Deficiency**

Phosphoserine aminotransferase 1 (PSAT1) catalyzes conversion of 3-phosphohydroxypyruvate to 3-phosphoserine (see Fig. 103.10). Deficiency of this enzyme may present in the neonatal period with poor feeding, cyanotic episodes, and irritability and may progress to intractable, multifocal seizures and microcephaly. Brain imaging may reveal generalized cerebral and cerebellar atrophy. Laboratory studies done on postprandial plasma samples may reveal normal or mildly decreased levels of serine and glycine. Serine and glycine levels are usually more depressed on the CSF amino acid analysis. Treatment with serine and glycine as outlined earlier may result in clinical improvement. The condition is inherited as an autosomal recessive trait, and the gene (PSAT1) is mapped to chromosome 9q21.2.

**3-Phosphoserine Phosphatase**
Deficiency

3-Phosphoserine phosphatase catalyzes the final step in the L-serine synthesis converting 3-phosphoserine to L-serine. Deficiency of this enzyme results in a rare disorder with clinical and biochemical findings indistinguishable from the PHGDH and PSAT1 deficiencies. The disorder is caused by autosomal recessive pathogenic variants in PSPH mapped to chromosome 7p11.2.

Proline is a nonessential amino acid synthesized endogenously from glutamic
acid, ornithine, and arginine (see Fig. 103.9). Proline and hydroxyproline are found in high concentrations in collagen. Normally, neither of these amino acids is found in large quantities in urine. Excretion of proline and hydroxyproline as iminopeptides (dipeptides and tripeptides containing proline or hydroxyproline) is increased in disorders of accelerated collagen turnover, such as rickets or hyperparathyroidism. Proline is also found in synapses, where it can interact with glycine and glutamate receptors (see Chapter 103.11). The catabolic pathway of proline and hydroxyproline produces glyoxylic acid, which can be further metabolized to glycine or oxalic acid (see Fig. 103.8).

Accumulation of proline in tissues is associated with disorders of hyperprolinemia type 1 and hyperprolinemia type 2. Reduced de novo synthesis of proline causes syndromes manifesting with cutis laxa (see Fig. 678.8) with progeroid features or spastic paraplegia. Two types of primary hyperprolinemia have been described.

**Hyperprolinemia Type I**

This rare autosomal recessive condition is caused by deficiency of proline oxidase (proline dehydrogenase; see Fig. 103.9). Most patients with hyperprolinemia type 1 appear asymptomatic, although some may present with intellectual disability, seizures, and behavioral problems. Hyperprolinemia may also be a risk factor for autism spectrum disorders and schizophrenia. The nature of such wide phenotypic range in this biochemical condition has not been elucidated. The gene encoding proline oxidase (PRODH) is mapped to 22q11.2 and is located within the critical region for the velocardiofacial syndrome. Laboratory studies reveal high concentrations of proline in plasma, urine, and CSF. Increased urinary excretion of hydroxyproline and glycine is also present, which could be related to saturation of the shared tubular reabsorption mechanism due to massive prolinuria.

*No effective treatment has yet emerged.* Restriction of dietary proline causes modest improvement in plasma proline with no proven clinical benefit.

**Hyperprolinemia Type II**

This is a rare autosomal recessive condition caused by the deficiency of Δ¹-pyrroline-5-carboxylate dehydrogenase (aldehyde dehydrogenase 4; see Fig.
103.9). Intellectual disability and seizures (usually precipitated by an intercurrent infection) have been reported in affected children, but asymptomatic patients have also been described. The cause for such disparate clinical outcomes is incompletely understood. The gene encoding P5C dehydrogenase (ALDH4A1) is mapped to chromosome 1p36.13.

Laboratory studies reveal increased concentrations of proline and Δ¹-pyrroline-5-carboxylic acid (P5C) in blood, urine, and CSF. The presence of P5C differentiates this condition from hyperprolinemia type I. Increased level of P5C in body fluids, especially in the CNS, appears to antagonize vitamin B₆ and lead to vitamin B₆ dependency (see Chapter 103.14). Vitamin B₆ dependency may be the main cause of seizures and neurologic findings in this condition and may explain the variability in clinical manifestations in different patients. Treatment with high doses of vitamin B₆ is recommended.

**Prolidase Deficiency**

During collagen degradation, imidodipeptides are formed and are normally cleaved by tissue prolidase. Deficiency of prolidase, which is inherited as an autosomal recessive trait, results in the accumulation of imidodipeptides in body fluids. Age at onset varies from 6 mo to the 3rd decade of life.

The clinical manifestations of this rare condition also vary and include recurrent, severe, and painful skin ulcers, which are typically on hands and legs. Other skin lesions that may precede ulcers by several years may include a scaly erythematous maculopapular rash, purpura, and telangiectasia. Most ulcers become infected. Healing of the ulcers may take months. Other findings include developmental delays, intellectual disability, organomegaly, anemia, thrombocytopenia, and immune dysfunction resulting in increased susceptibility to infections (recurrent otitis media, sinusitis, respiratory infection, splenomegaly). Some patients may have craniofacial abnormalities such as ptosis, ocular proptosis, hypertelorism, small beaked nose, and prominent cranial sutures. Asymptomatic cases have also been reported. Increased incidence of systemic lupus erythematosus has been noted in children. High levels of urinary excretion of imidodipeptides are diagnostic. The gene for prolidase (PEPD) has been mapped to chromosome 19q13.11. The diagnosis can be confirmed using DNA analysis. Enzyme assay may be performed in erythrocytes or cultured skin fibroblasts.
Treatment of prolidase deficiency is supportive. Infectious complications can be fatal and warrant close and proactive antibiotic management. Oral supplementation with proline, ascorbic acid, and manganese and topical proline and glycine have not been found to be consistently effective in all patients.

**Disorders of De Novo Proline Synthesis**

De novo synthesis of proline and ornithine from glutamate appears to be critical in the normal biology of connective tissue and to maintain urea cycle in a repleted state. Correspondingly, clinical manifestations of these disorders encompass connective tissue abnormalities, nervous system abnormalities, and variable biochemical abnormalities reflecting urea cycle dysfunction. This section summarizes clinical and laboratory findings associated with the deficient function of Δ¹-pyrroline-5-carboxylate (P5C) synthase (see Fig. 103.9) encoded by *ALDH18A1* (mapped to 10q24.1) and PSC reductase encoded by *PYCR1* (mapped to 17q25.3).

Deficient activity of P5C synthase has been associated with several phenotypes, including de Barsy syndrome, characterized by cataracts, growth retardation, intellectual disability, a prematurely aged appearance (progeroid features), and cutis laxa. Some patients may show pyramidal signs. Skin biopsy may reveal decreased size of elastic fibers and collagen abnormalities. Brain imaging studies show cortical atrophy, ventriculomegaly, and reduced creatine. Laboratory findings include reduced levels of proline, ornithine, citrulline, and arginine as well as mild fasting hyperammonemia. Patients may show only intermittent abnormalities of plasma amino acids, likely related to the time of blood sampling in relation to the last meal. Interestingly, both autosomal recessive and autosomal dominant forms of inheritance have been described. The diagnosis can be suspected in a patient presenting with cutis laxa, developmental delay, mild hyperammonemia, and amino acid abnormalities. The diagnosis can be confirmed using molecular DNA analysis or using the glutamine loading test on skin fibroblasts. Treatment is supportive, although supplementation with citrulline or arginine to address hyperammonemia and cerebral creatine depletion have been proposed.

Deleterious mutations in *PYCR1* result in the abnormal function of the mitochondrial Δ¹-pyrroline-5-carboxylate reductase, which catalyzes the last step in the synthesis of proline from P5C. The most consistent finding in patients
carrying proven pathogenic variants in PYCR1 include triangular facies, cutis laxa (de Barsy–like syndrome), joint hypermobility, wrinkled skin, gerodermia osteodysplastica, and progeroid features. Skin biopsy reveals reduction of the elastic fibers and infiltration with inflammatory cells. Some patients may have epilepsy, developmental delays, intellectual disability, cataracts, osteopenia, and failure to thrive. However, many of the affected families are consanguineous, thus confounding the phenotype. Of note, plasma amino acid analysis typically reveals no specific abnormalities. The diagnosis depends on the recognition of the skin findings and can be confirmed using molecular DNA analysis. Available pedigrees of families affected by PYCR1-related disorder supports the autosomal recessive mode of inheritance.

- 5-oxoprolinemia
Glutamic acid and its amide derivative glutamine have a wide range of functions in the body. *Glutamate* plays numerous biologic roles, functioning as a neurotransmitter, an intermediate compound in many fundamental biochemical reactions, and a precursor of an inhibitory neurotransmitter γ-amino butyric acid (GABA) (see Chapter 103.11). Another major product of glutamate is *glutathione* (γ-glutamylcysteinylglycine). This ubiquitous tripeptide, with its function as the major antioxidant in the body, is synthesized and degraded through a complex cycle called the γ-glutamyl cycle (Fig. 103.11). Because of its free sulfhydryl (−SH) group and its abundance in the cell, glutathione protects other sulfhydryl-containing compounds (e.g., enzymes, coenzyme A) from oxidation. It is also involved in the detoxification of peroxides, including hydrogen peroxide, and in keeping the intracellular milieu in a reduced state. In addition, glutathione participates in amino acid transport across the cell membrane through the γ-glutamyl cycle.
The γ-glutamyl cycle and related pathways. Defects of the glutathione (GSH) synthesis and degradation are noted. Enzymes: (1) γ-Glutamyl transpeptidase (GGT), (2) γ-glutamyl cyclotransferase, (3) 5-oxoprolinase, (4) γ-glutamyl-cysteine synthetase, (5) glutathione synthetase, (6) glutamate decarboxylase, (7) γ-aminobutyric acid (GABA) transaminase, (8) succinate-semialdehyde dehydrogenase, (9) glutamine synthetase, (10) dipeptidase.

One of the biochemical manifestations of γ-glutamyl cycle deficiency is increased urinary excretion of 5-oxoproline, which could be the result of both genetic and non-genetic causes. 5-Oxoprolinemia should be routinely considered in the differential diagnosis of high–anion gap metabolic acidosis (HAGMA). Two metabolic disorders can present with massive 5-oxoprolinuria: glutathione synthetase deficiency and 5-oxoprolinase deficiency (Fig. 103.11). However, a more common clinical scenario is a transient and mild urinary elevation of 5-oxoproline in urine that can be seen in a variety of metabolic and acquired conditions, such as exposure to acetaminophen and some hydrolyzed-protein
formulas, severe burns, Stevens-Johnson syndrome, homocystinuria, urea cycle defects, and tyrosinemia type I.

**Glutathione Synthetase Deficiency**

Three forms of this rare condition have been reported. In the **mild form**, enzyme deficiency causes glutathione deficiency only in erythrocytes. These patients present with hemolytic anemia without chronic metabolic acidosis and demonstrate high residual activity of glutathione synthetase on enzymatic testing. A **moderate form** has also been observed in which the hemolytic anemia is associated with variable degrees of metabolic acidosis and 5-oxoprolinuria. Its **severe form** is distinguished by presence of hemolytic anemia accompanied by severe acidosis, massive 5-oxoprolinuria, and neurologic manifestations.

**Glutathione Synthetase Deficiency, Severe and Moderate Forms**

Affected newborn infants with this rare condition usually develop acute symptoms of metabolic acidosis, jaundice, and mild to moderate hemolytic anemia in the 1st few days of life. Chronic acidosis continues after recovery. Similar episodes of life-threatening acidosis may occur during an infection (e.g., gastroenteritis) or after a surgical procedure. Progressive neurologic damage develops with age, manifested by intellectual disability, spastic tetraparesis, ataxia, tremor, dysarthria, and seizures. Susceptibility to infections, presumably because of granulocyte dysfunction, is observed in some patients. Patients with the moderate form of glutathione synthetase deficiency have milder acidosis and less 5-oxoprolinuria than is seen in the severe form, with no neurologic manifestations.

**Laboratory findings** include metabolic acidosis, mild to moderate degrees of hemolytic anemia, and 5-oxoprolinuria. High concentrations of 5-oxoproline are also found in blood. The urinary and blood levels of 5-oxoproline is less pronounced in patients with moderate form of the condition. The glutathione content of erythrocytes is markedly decreased. Increased synthesis of 5-oxoproline in this disorder is thought to be the result of the conversion of γ-glutamylcysteine to 5-oxoproline by the enzyme γ-glutamyl cyclotransferase.
(see Fig. 103.11). γ-Glutamylcysteine production increases greatly because the normal inhibitory effect of glutathione on the γ-glutamylcysteine synthetase enzyme is removed.

**Treatment** of acute attack includes hydration, correction of acidosis (by infusion of sodium bicarbonate), and measures to correct anemia and hyperbilirubinemia. Chronic administration of alkali is usually needed indefinitely. Supplementation with vitamin C, vitamin E, and selenium is recommended. Drugs and oxidants known to cause hemolysis and stressful catabolic states should be avoided. Oral administration of glutathione analogs has been tried with variable success.

**Prenatal diagnosis** can be achieved by the measurement of 5-oxoproline in amniotic fluid, by enzyme analysis in cultured amniocytes or chronic villus samples, or by DNA analysis. Successful pregnancy in an affected female (moderate form) has been reported, with favorable outcomes for both mother and infant.

**Glutathione Synthetase Deficiency, Mild Form**

The mild form has been reported in only a few patients. Mild to moderate hemolytic anemia has been the only clinical finding. Splenomegaly has been reported in some patients. Cognitive development is normal. Chronic metabolic acidosis typically is not seen. Some patients can have increased concentrations of 5-oxoproline in the urine. Pathogenic variants in the gene for this enzyme (GSSD) appear to decrease the half-life of the enzyme, which causes an increased rate of protein turnover without affecting its catalytic function. The expedited rate of enzyme turnover caused by these pathogenic variants is of little or no consequence for tissues with protein synthetic capability. However, inability of mature erythrocytes to synthesize protein results in glutathione deficiency in the erythrocytes. **Treatment** is that of hemolytic anemia and avoidance of drugs and oxidants that can trigger the hemolytic process.

All forms of glutathione synthetase deficiency are inherited as an autosomal recessive trait. **GSSD** is located on chromosome 20q11.22. **Diagnosis** can be confirmed by DNA analysis or enzyme activity in erythrocytes or skin fibroblasts.

**5-Oxoprolinase Deficiency**
More than 20 patients with 5-oxoprolinuria (4-10 g/day) caused by 5-oxoprolinase (see Fig. 103.11) deficiency have been described. No specific clinical picture has yet emerged; completely asymptomatic affected individuals have also been identified. It is therefore not clear whether 5-oxoprolinase deficiency is of any clinical consequence. No treatment is currently recommended. The gene for the enzyme (OPLAH) is on chromosome 8q24.3.

**γ-Glutamylcysteine Synthetase Deficiency (Glutamate-Cysteine Ligase Deficiency)**

Only a few patients with this enzyme deficiency have been reported. The most consistent clinical manifestation has been mild chronic hemolytic anemia. Acute attacks of hemolysis have occurred after exposure to sulfonamides. Peripheral neuropathy and progressive spinocerebellar degeneration have been noted in 2 siblings in adulthood. Laboratory findings of chronic hemolytic anemia were present in all patients. Generalized aminoaciduria is also present because the γ-glutamyl cycle is involved in amino acid transport in cells (see Fig. 103.11).

**Treatment** should focus on the management of hemolytic anemia and avoidance of drugs and oxidants that may trigger the hemolytic process. The condition is inherited as an autosomal recessive trait; the gene (GCLC) is mapped to chromosome 6p12.1.

**γ-Glutamyl Transpeptidase Deficiency (Glutathionemia)**

γ-Glutamyl transpeptidase (GGT) is present in any cell that has secretory or absorptive functions. It is especially abundant in the kidneys, pancreas, intestines, and liver. The enzyme is also present in the bile. Measurement of GGT in the blood is frequently performed to evaluate liver and bile duct diseases.

GGT deficiency causes elevation in glutathione concentrations in body fluids, but the cellular levels remain normal (see Fig. 103.11). Because only a few patients with GGT deficiency have been reported, the scope of clinical manifestations has not yet been defined. Mild to moderate intellectual disability and severe behavioral problems were observed in 3 patients. However, 1 of 2 sisters with this condition had normal intelligence as an adult, and the other had
Laboratory findings include marked elevations in urinary concentrations of glutathione (up to 1 g/day), γ-glutamylcysteine, and cysteine. None of the reported patients has had generalized aminoaciduria, a finding that would have been expected to occur in this enzyme deficiency (see Fig. 103.11).

Diagnosis can be confirmed by measurement of the enzyme activity in leukocytes or cultured skin fibroblasts. No effective treatment has been proposed. The condition is inherited as an apparent autosomal recessive trait. γ-Glutamyl transpeptidases represent a large family of enzymes encoded by at least 7 genes.

Neurotransmitters are chemical substances released from the axonal end of excited neurons at the synaptic junctions; they mediate initiation and amplification or inhibition of neural impulses. A number of amino acids and their metabolites comprise the bulk of neurotransmitters. Pathogenic variants in genes responsible for the synthesis, transport, or degradation of these substances may cause conditions that manifest neurologic and/or psychiatric abnormalities (Table 103.3). Previously, children affected by disorders of neurotransmitters have been given syndromic diagnoses such as cerebral palsy, epilepsy, parkinsonism, dystonia, or autism. Diagnosis, in most cases, requires specialized laboratory studies of the cerebrospinal fluid (CSF), because some of the neurotransmitters generated in the central nervous system (CNS), dopamine and serotonin, do not cross the blood-brain barrier, and their abnormal concentrations are not detected in the serum or urine. A growing number of these conditions are being identified; diseases once thought to be rare are now diagnosed with increasing frequency.

Table 103.3
Genetic Disorders of Neurotransmitters in Children
Tyrosine Hydroxylase Deficiency  
(Infantile Parkinsonism, Autosomal Recessive Dopa-Responsive Dystonia, Autosomal Recessive Segawa Syndrome)

Tyrosine hydroxylase catalyzes the formation of L-dopa from tyrosine. Deficiency of this enzyme results in deficiencies of dopamine and norepinephrine (see Fig. 103.2 ). The differential diagnosis includes a wide range of inherited dystonias, including autosomal dominant dystonia caused by GTP cyclohydrolase 1 deficiency.

**Clinical manifestations** range from mild to very severe. In general, 2 phenotypes have been recognized. In the **mild** form (dopa-responsive dystonia, or **type A**), symptoms of unilateral limb dystonia causing gait incoordination and postural tremor occur in childhood and worsen with age if the condition remains untreated. Diurnal variation of symptoms (worse at the end of the day) may be present. Cognitive development is usually normal.

In the **severe** form of tyrosine hydroxylase deficiency (infantile parkinsonism, infantile encephalopathy, or **type B**), the clinical manifestations occur at birth or shortly thereafter and include microcephaly, developmental delay, involuntary movements of the limbs with spasticity, dystonia, ptosis, expressionless face, oculogyric crises (upward eye-rolling movements), and autonomic dysfunction (temperature instability, excessive sweating, hypoglycemia, salivation, tremor,
gastrointestinal reflux, constipation). Brisk reflexes, myoclonus, athetosis, and distal chorea may be present. The patient with the severe form usually shows incomplete response to treatment with L-dopa and is prone to developing L-dopa–induced dyskinesia as a side effect.

**Laboratory findings** include reduced levels of dopamine and its metabolite homovanillic acid (HVA) and normal concentrations of tetrahydrobiopterin (BH₄), neopterin, and 5-hydroxyindoleacetic acid (5-HIAA, a metabolite of serotonin) in the CSF. Serum prolactin levels are usually elevated. These findings are not diagnostic of the condition; diagnosis should be established by molecular gene analysis.

**Treatment** with L-dopa/carbidopa results in significant clinical improvement in most patients, but the severe forms are invariably associated with L-dopa–induced dyskinesias. To minimize the side effects of therapy, the treatment should be started with a low dose and increased very slowly, if needed. Other therapeutic interventions include anticholinergics, serotonergic agents, and monoamine oxidase (MAO) B inhibitors, including amantadine, biperiden, and selegiline. Bilateral subthalamic nucleus deep brain stimulation has shown clinical efficacy in one case. Tyrosine hydroxylase deficiency is inherited as an autosomal-recessive trait. Molecular testing for pathogenic variants in the *TH* gene is available clinically.

**Aromatic L-Amino Acid Decarboxylase Deficiency**

Aromatic L-amino acid decarboxylase (AADC) is a vitamin B₆–dependent enzyme that catalyzes the decarboxylation of both 5-hydroxytryptophan to form serotonin (see Fig. 103.5) and L-dopa to generate dopamine, (see Fig. 103.2). **Clinical manifestations** are related to reduced availability of dopamine and serotonin. Poor feeding, lethargy, hypotension, hypothermia, oculogyric crises, and ptosis have been observed in affected neonates. Clinical findings in infants and older children include developmental delay, truncal hypotonia with hypertonia of limbs, oculogyric crises, extrapyramidal movements (choreoathetosis, dystonia, myoclonus), and autonomic abnormalities (sweating, salivation, irritability, temperature instability, hypotension). Symptoms may have a diurnal variation, becoming worse by the end of the day. **Laboratory findings** include decreased concentrations of dopamine and
serotonin and their metabolites (HVA, 5-HIAA, norepinephrine, vanillylmandelic acid [VMA]) and increased levels of 5-hydroxytryptophan, L-dopa, and its metabolite (3-O-methyldopa) in body fluids, especially in CSF. Elevated serum concentrations of prolactin (a result of dopamine deficiency) have also been observed. MRI of the brain reveals cerebral atrophy with degenerative changes in the white matter. A urine screening program, focused on 3-O-methyl-dopa and VMA, has demonstrated diagnostic promise in high-disease prevalence populations.

Treatment with neurotransmitter precursors has produced limited clinical improvement. Dopamine and serotonin have no therapeutic value because of their inability to cross the blood-brain barrier. Dopamine agonists (L-dopa/carbidopa, bromocriptine), MAO inhibitors (tranylcypromine), serotonergic agents and high doses of pyridoxine, a cofactor for AADC enzyme, have been tried. Pyridoxine supplementation in patients harboring the p.S250F variant in AADC may be beneficial. The recent demonstration of CNS-directed gene therapy with an adeno-associated viral vector has shown benefit in some patients. Preimplantation genetic diagnosis after in vitro fertilization has been achieved in the high-prevalence Taiwanese population. The gene encoding AADC (DDC) is on chromosome 7p12.1. The condition is inherited as an autosomal recessive trait.

**Tetrahydrobiopterin Deficiency**

See Chapter 103.1.

BH$_4$ is the cofactor for phenylalanine hydroxylase (see Fig. 103.1), tyrosine hydroxylase (see Fig. 103.2), tryptophan hydroxylase (see Fig. 103.5), and nitric oxide synthase. It is synthesized from GTP in many tissues (see Fig. 103.1). Deficiencies of enzymes involved in the biosynthesis of BH$_4$ result in inadequate production of this cofactor, which causes deficiencies of monoamine neurotransmitters with or without concomitant hyperphenylalaninemia.

**Tetrahydrobiopterin Deficiency With Hyperphenylalaninemia**

See Chapter 103.1.
Tetrahydrobiopterin Deficiency Without Hyperphenylalaninemia

GTP Cyclohydrolase 1 Deficiency (Hereditary Progressive Dystonia, Autosomal Dominant Dopa-Responsive Dystonia, Autosomal Dominant Segawa Syndrome)

This form of dystonia, caused by guanosine triphosphate (GTP) cyclohydrolase 1 deficiency, is inherited as an autosomal dominant trait and is more common in females than males (4 : 1 ratio) (see Chapter 615.4). Clinical manifestations usually start in early childhood with tremor and dystonia of the lower limbs (toe gait), which may spread to all extremities within a few years. Torticollis, dystonia of the arms, and poor coordination may precede dystonia of the lower limbs. Early development is generally normal. Symptoms have an impressive diurnal variation, becoming worse by the end of the day and improving with sleep. Autonomic instability is not uncommon. Parkinsonism may also be present or develop with advancing age. Late presentation in adult life has also been reported, associated with action dystonia (“writer's cramp”), torticollis, or generalized rigid hypertonia with tremor but without postural dystonia. Additionally, limited data on adults suggest symptoms related to serotonin deficiency (sleep disturbance, cognitive impairment, impulsivity).

Laboratory findings show reduced levels of BH$_4$ and neopterin in the CSF without hyperphenylalaninemia (see Chapter 103.1). Dopamine and its metabolite (HVA) may also be reduced in CSF. The serotonergic pathway is less affected by this enzyme deficiency; thus concentrations of serotonin and its metabolites are usually normal. Plasma phenylalanine is normal, but an oral phenylalanine loading test (100 mg/kg) produces an abnormally high plasma phenylalanine level with an elevated phenylalanine/tyrosine ratio. The ratio, obtained at the 2-3 hr after the load, in combination with urine neopterin level, has optimal diagnostic specificity and sensitivity. The existence of asymptomatic carriers indicates that other factors or genes may play a role in pathogenesis. The asymptomatic carrier may be identified by the phenylalanine loading test. Diagnosis may be confirmed by reduced levels of BH$_4$ and neopterin in CSF, measurement of the enzyme activity, and molecular genetic analysis (see Chapter 103.1). Clinically, the condition should be differentiated from other causes of dystonias and childhood parkinsonism, especially tyrosine hydroxylase, sepiapterin reductase, and aromatic amino acid decarboxylase deficiencies.
**Treatment** with L-dopa/carbidopa usually produces dramatic clinical improvement. Oral administration of BH₄ is also effective but is rarely used. The gene for GTP cyclohydrolase 1 (GCH1) is located on chromosome 14q22.2.

### Sepiapterin Reductase Deficiency

Sepiapterin reductase is involved in conversion of 6-pyruvoyl-tetrahydropterin to BH₄. It also participates in the salvage pathway of BH₄ synthesis (see Fig. 103.1). Sepiapterin reductase deficiency results in accumulation of 6-lactoyl-tetrahydropterin, which can be converted to sepiapterin nonenzymatically. The majority of sepiapterin is metabolized to BH₄ through the salvage pathway in peripheral tissues (see Fig. 103.1), but because of the low activity of dihydrofolate reductase in brain, the amount of BH₄ remains insufficient for proper synthesis of dopamine and serotonin. This explains the absence of hyperphenylalaninemia and the often-delayed diagnosis. **Clinical manifestations** usually appear within a few months of life. Cardinal manifestations include paroxysmal stiffening, oculogyric crises, and hypotonia. Additional findings include motor and language delays, weakness, limb hypertonia, dystonia, hyperreflexia, and early-onset parkinsonism. The symptoms usually have a diurnal variation. Misdiagnosis as cerebral palsy is common and a wide variability of symptoms have been reported. **Diagnosis** is established by measurement of CSF neurotransmitters and pterin metabolites, which reveal decreased dopamine, HVA, norepinephrine, and 5-HIAA and marked elevations of sepiapterin and dihydrobiopterin. The serum concentration of prolactin may be elevated. The phenylalanine loading test may have diagnostic utility. Diagnosis may be confirmed by molecular genetic analysis or enzyme assay in fibroblasts. **Treatment** with slowly increasing doses of L-dopa/carbidopa and 5-hydroxytryptophan usually produces dramatic clinical improvement. The condition is inherited as an autosomal recessive trait; the gene SPR encoding sepiapterin reductase is located on chromosome 2p13.2.

### Dopamine β-Hydroxylase Deficiency

Dopamine β-hydroxylase catalyzes the conversion of dopamine to norepinephrine (see Fig. 103.2). The deficiency of this enzyme results in reduced or absent synthesis of norepinephrine, leading to dysregulation of the
sympathetic function. Infants and children may present with difficulty opening eyes, ptosis, hypotension, hypothermia, hypoglycemia, and nasal stuffiness. Adult patients may present with profound deficits of autonomic regulation, resulting in severe orthostatic hypotension, and sexual dysfunction in males. Presyncopal symptomatology includes dizziness, blurred vision, dyspnea, nuchal discomfort, and chest pain; olfactory function remains relatively intact. The diagnosis can be aided by performing autonomic function testing (measurement of the sinus arrhythmia ratio, blood pressure studies during controlled hyperventilation, Valsalva maneuver, cold pressor, handgrip exercise). 

**Laboratory findings** include decreased or absent norepinephrine and epinephrine and their metabolites, with elevated levels of dopamine and its metabolite (HVA), in plasma, CSF, and urine. Elevated plasma dopamine may be pathognomonic for this disease. MRI of the brain shows decreased brain volume, consistent with the neurotrophic role of norepinephrine. 

**Treatment** with L-dihydroxyphenylserine, which is converted to norepinephrine directly in vivo by the action of AADC, leads to significant improvement in orthostatic hypotension and normalizes noradrenaline and its metabolites. The condition is inherited as an autosomal recessive trait; the gene (DBH) encoding dopamine β-hydroxylase resides on chromosome 9q34.2.

**Monoamine Oxidase a Deficiency**

Human genome encodes 2 monoamine oxidase (MAO) isoenzymes: MAO A and MAO B. Both enzymes catalyze oxidative deamination of most biogenic amines in the body, including serotonin (see Fig. 103.5), norepinephrine, epinephrine, and dopamine (see Fig. 103.2). The genes for both isoenzymes are on the X chromosome (Xp11.3), residing in close proximity. A deletion of both genes can also encompass a neighboring gene, NDP, resulting in a contiguous deletion syndrome, which can present as an atypical Norrie disease (see Chapter 640). Male patients with MAO A deficiency manifest borderline intellectual deficiency and impaired impulse control. The consequences of the isolated MAO B deficiency are incompletely understood. Combined MAO A and B deficiency causes severe intellectual disability and behavioral problems and can be associated with pronounced laboratory abnormalities (e.g., 4-6–fold serotonin elevation in physiologic fluids, elevated O-methylated amine metabolites, and reduced deamination products [VMA, HVA]). Dietary intervention (low tyramine, phenylethylamine, and L-dopa/dopamine intake) did not improve
patients' blood serotonin levels. Inheritance of MAO deficiency is X-linked. 

**Treatment** of MAO A deficiency is supportive.

### Disorders of γ-Aminobutyric Acid (GABA) Metabolism

GABA is the main inhibitory neurotransmitter synthesized in the synapses through decarboxylation of glutamic acid by glutamate decarboxylase (GAD). The same pathway is responsible for production of GABA in other organs, especially the kidneys and the β-cells of the pancreas. GAD enzyme requires pyridoxine (vitamin B₆) as cofactor. Two GAD enzymes, GAD1 (GAD₆₇) and GAD2 (GAD₆₅) have been identified. **GAD1** is the main enzyme in the brain, and **GAD2** is the major enzyme in the β-cells. Antibodies against GAD₆₅ and GAD₆₇ have been implicated in the development of type 1 diabetes and **stiff-person syndrome**, respectively. GABA is catabolized to succinic acid by 2 enzymes, GABA transaminase and succinic semialdehyde dehydrogenase (SSADH) (see Fig. 103.11).

### γ-Aminobutyric Acid Transaminase Deficiency

Clinical manifestations in the 2 index infant siblings included severe psychomotor retardation, hypotonia, hyperreflexia, lethargy, refractory seizures, and increased linear growth likely related to GABA-mediated increased secretion of growth hormone. Increased concentrations of GABA and β-alanine were found in CSF (see Fig. 103.11). Evidence of leukodystrophy was noted in the postmortem examination of the brain. A 3rd patient showed severe psychomotor retardation, recurrent episodic lethargy, and intractable seizures with comparable CSF metabolite abnormalities to those of the index probands. GABA transaminase deficiency is demonstrated in brain and lymphocytes. **Treatment** is symptomatic. Intervention with vitamin B₆, the cofactor for the enzyme, was without therapeutic benefit. The gene (**ABAT**), maps to chromosome 16p13.2; the condition is inherited as an autosomal recessive trait.

### Succinic Semialdehyde Dehydrogenase
Deficiency (γ-Hydroxybutyric Aciduria)

Clinical manifestations of SSADH deficiency usually begin in infancy with developmental delays with a disproportionate deficit in expressive language, hypotonia, and ataxia; seizures occur in approximately 50% of patients (see Fig. 103.11). Many patients also carry the diagnosis of autism spectrum disorder. Neuropsychiatric comorbidity (especially oppositional defiance, obsession-compulsion, and hyperactivity) can be disabling, particularly in adolescents and adults. Abnormal EEG findings include background slowing and generalized spike-wave paroxysms, with variable lateralization in hemispheric onset and voltage predominance. Photosensitivity and electrographic status epilepticus of sleep have been reported in combination with difficulties in sleep maintenance and excessive daytime somnolence. MRI of the brain shows an increased T2-weighted hyperintensity involving the globus pallidi, cerebellar dentate nuclei, and subthalamic nuclei, usually in a bilaterally symmetric distribution.

The biochemical hallmark, γ-hydroxybutyric acid (GHB), is elevated in physiologic fluids (CSF, plasma, urine) in all patients. Increased concentrations of GABA are also found in CSF. Heightened diagnostic suspicion evolves through documentation of elevated urinary GHB, and confirmation is achieved by molecular genetic testing.

Treatment remains elusive; vigabatrin (GABA-transaminase inhibitor) has been employed empirically, with mixed outcomes, and there is concern with its use as it further elevates CNS GABA in an already hyper-GABAergic disorder. Additionally, vigabatrin can cause constriction of the visual field and long-term use is contraindicated.

The gene for SSADH (ALDH5A1) is located on chromosome 6p22, and inheritance follows an autosomal-recessive pattern. Prenatal diagnosis has been achieved by measurement of GHB in the amniotic fluid, assay of the enzyme activity in the amniocytes, chorionic villus sampling, or DNA analysis.

Defects in Neurotransmitter Transporter Proteins

More than 20 different proteins are involved in transporting different neurotransmitters across the neuronal membranes. The main function of most of these transporters is to remove the excess neurotransmitters from the synaptic
junction back into the presynaptic neurons (reuptake). This recycling process not only regulates the precise effect of neurotransmitters at the synaptic junction, but also resupplies the presynaptic neurons with neurotransmitters for future use. A few transporter proteins are involved in shuttling neurotransmitters from the neuronal cytoplasm across the membrane of synaptic vesicles for storage (vesicular transporters). On neuronal stimulation, these vesicles release a bolus of neurotransmitters through exocytosis. As expected, pathogenic variants in transporter proteins interfere with the proper reuptake and storage of neurotransmitters and may result in clinical manifestations similar to those seen in deficiencies of neurotransmitters metabolism. Several conditions caused by pathogenic variants of neurotransmitter protein transporters have been described, including dopamine transporter protein deficiency and dopamine-serotonin vesicular transporter disease.

**Dopamine Transporter Protein Deficiency**

This transporter protein is involved in reuptake of dopamine by the presynaptic neurons, and its deficiency causes depletion of dopamine and thus a dopamine deficiency state. Dopamine transporter protein (DAT) is encoded by SLC6A3 gene on chromosome 5p15.33. Pathogenic variants of this gene has been reported in 13 children. These children presented with symptoms of infantile parkinsonism-dystonia syndrome. Irritability and feeding difficulties started shortly after birth and progressed to hypotonia, lack of head control, parkinsonism, dystonia, and global developmental delay by early infancy. Brain MRI usually shows no abnormalities.

CSF examination revealed elevation of HVA and normal level of 5-HIAAs. The urinary level of HVA and serum concentration of prolactin were increased. Diagnosis was established by demonstrating the loss-of-function mutation in the SLC6A3 gene. *No effective treatment* has been identified; L-dopa/carbidopa did not result in improvements in clinical or biochemical parameters.

**Dopamine-Serotonin Vesicular Transporter Disease (Vesicular Monoamine Transporter Deficiency)**

This autosomal recessive condition, described in 8 children from a consanguineous Saudi Arabian family, is caused by a pathogenic variant in the
SLC18A2 gene. This gene encodes the vesicular monoamine transporter 2 (VMAT2), which is involved in transporting dopamine and serotonin from the cytoplasm into the synaptic storage vesicles located in the axonal terminals of the presynaptic neurons. Most affected children presented in the 1st yr of life with symptoms consistent with deficiencies of dopamine (hypotonia progressing into dystonia, parkinsonism, oculogyric crises), serotonin (sleep and psychiatric disturbances), and norepinephrine-epinephrine (excessive sweating, tremors, temperature instability, postural hypotension, ptosis). Neurocognitive delays become apparent in the 1st yr of life. No diurnal variation of the symptoms was noted. Brain imaging studies were within normal limits. Changes in the levels of CNS neurotransmitters and their metabolites have been inconsistent.

The phenotype resembles that seen in AADC and BH₄ deficiencies (see earlier). Diagnosis requires molecular analysis of SLC18A2 (located on chromosome 10q25.3). *Treatment* with L-dopa/carbidopa caused exacerbation of symptoms, whereas pramipexole, a dopamine receptor agonist, resulted in a promising clinical response.

**Histidine Decarboxylase Deficiency**

Decarboxylation of histidine by histidine decarboxylase produces histamine, which functions as a neurotransmitter in the brain. Deficiency of this enzyme (expressed mainly in the posterior hypothalamus) results in deficiency of histamine in the CNS and in one family caused an autosomal dominant form of Tourette syndrome (see Chapter 103.13).

**Hyperprolinemia**

Intellectual disability and seizures are common findings in most patients with hyperprolinemia types I and II. Patients with **type I** hyperprolinemia typically show a benign clinical course but could have an increased risk of developing schizophrenia. The contribution of increased concentration of proline to the mechanisms of schizophrenia, however, remains unclear. The neurologic abnormalities observed in hyperprolinemia **type II** are mainly caused by development of vitamin B₆ dependency in this condition (see Chapter 103.9). Dietary intervention in hyperprolinemias type I and II is neither feasible nor recommended.

Catabolism of amino acids results in the production of free ammonia, which in high concentration is toxic to the CNS. Mammals detoxify ammonia to urea through a series of reactions known as the **urea cycle** (Fig. 103.12), which is composed of 5 enzymes: carbamoyl phosphate synthetase 1 (**CPS1**), ornithine transcarbamylase (**OTC**), argininosuccinate synthetase (**ASS**), argininosuccinate lyase (**ASL**), and arginase 1. A 6th enzyme, N-acetylglutamate (**NAG**), catalyzes synthesis of **NAG**, which is an obligatory activator (effector) of the **CPS1** enzyme. Individual deficiencies of these enzymes have been observed and, with an overall estimated prevalence of 1 in 35,000 live births, they are the most common genetic causes of hyperammonemia in infants.
Genetic Causes of Hyperammonemia

Hyperammonemia, sometimes severe, occurs in inborn errors of metabolism other than the urea cycle defects (Table 103.4; see also Table 102.5). The mechanisms of hyperammonemia in some of these conditions are diverse and include accumulation of toxic metabolites (e.g., organic acids), impaired transport of urea cycle intermediates (e.g., HHH syndrome), or depletion of urea cycle intermediates (e.g., lysinuric protein intolerance), leading to compromised function of the urea cycle.

Table 103.4
Inborn Errors of Metabolism Causing Hyperammonemonia

- Deficiencies of the urea cycle enzymes
  - Carbamyl phosphate synthetase 1
  - Ornithine transcarbamylase
  - Argininosuccinate synthetase
  - Argininosuccinate lyase
  - Arginase 1
  - N-acetylglutamate synthetase

- Organic acidemias
  - Propionic acidemia
  - Methylmalonic acidemia
  - Isovaleric acidemia
  - β-Ketothiolase deficiency
  - Multiple carboxylase deficiencies
  - Medium-chain fatty acid acyl-CoA dehydrogenase deficiency
  - Glutaric acidemia type I
  - 3-Hydroxy-3-methylglutaric aciduria

- Lysinuric protein intolerance
- Hyperammonemia-hyperornithinemia-homocitrullinemia syndrome
- Transient hyperammonemia of the newborn
- Congenital hyperinsulinism with hyperammonemonia

Clinical Manifestations of Hyperammonemonia

In the neonatal period, symptoms and signs are mostly related to brain dysfunction and are similar regardless of the cause of the hyperammonemonia. The affected infant appears normal at birth but becomes symptomatic following the introduction of dietary protein. Refusal to eat, vomiting, tachypnea, and lethargy can quickly progress to a deep coma. Seizures are common. Physical examination may reveal hepatomegaly in addition to obtundation. Hyperammonemonia can trigger increased intracranial pressure that may be manifested by a bulging fontanelle and dilated pupils.
In **infants and older children**, acute hyperammonemia is manifested by vomiting and neurologic abnormalities such as ataxia, confusion, agitation, irritability, combativeness, and psychosis. These manifestations may alternate with periods of lethargy and somnolence that may progress to coma.

Routine laboratory studies show no specific findings when hyperammonemia is caused by defects of the urea cycle enzymes. Blood urea nitrogen is usually low in these patients. Some patients may initially present with unexplained elevated serum alanine transaminase (ALT) and aspartate transaminase (AST) and even meet the criteria for acute liver failure. In infants with organic acidemias, hyperammonemia is commonly associated with severe acidosis as well as ketonuria. Newborn infants with hyperammonemia are often misdiagnosed as having sepsis; they may succumb without a correct diagnosis. Neuroimaging may reveal cerebral edema. Autopsy may reveal microvesicular steatosis, mild cholestasis, and fibrosis of the liver. Thus, because of the nonspecific presentation or urea cycle disorders, it is imperative to measure plasma ammonia levels in any ill infant with severe sepsis, unexplained liver dysfunction, recurrent emesis, or progressive encephalopathy.

**Diagnosis**

The main criterion for diagnosis is hyperammonemia. Each clinical laboratory should establish its own normal values for blood ammonia. Normal newborn values are higher than those of the older child or adult. Levels as high as 100 µmol/L can occur in healthy term infants. An ill infant usually manifests a blood ammonia level >150 µmol/L. **Fig. 103.13** illustrates an approach to the differential diagnosis of hyperammonemia in the newborn infant. Careful inspection of individual plasma amino acids usually reveals abnormalities that may help the diagnosis. In patients with deficiencies of CPS1, OTC, or NAGS, frequent findings include elevations in plasma glutamine and alanine with concurrent decrements in citrulline and arginine. These disorders cannot be differentiated from one another by the plasma amino acid levels alone. A marked increase in urinary orotic acid in patients with OTC deficiency helps differentiate this defect from CPS1 deficiency. Differentiation between the CPS1 deficiency and the NAGS deficiency may require an assay of the respective enzymes or molecular analysis of the relevant genes. Clinical improvement occurring after oral administration of carbamylglutamate, however, may suggest NAGS deficiency. Patients with a deficiency of ASS, ASL, or arginase 1 have marked
increases in the plasma levels of citrulline, argininosuccinic acid, or arginine, respectively. The combination of hyperammonemia and marked hypercitrullinemia or argininosuccinic acidemia is virtually pathognomonic for these disorders. Children with urea cycle defects often self-select a low-protein, high-carbohydrate diet, especially those with late-onset disease or symptomatic females with partial OTC deficiency.

**FIG. 103.13** Clinical approach to a newborn infant with symptomatic hyperammonemia. CPS1, Carbamoyl phosphate synthetase 1; HHH syndrome, hyperornithinemia-hyperammonemia-homocitrullinemia; NAGS, N-acetylglutamate synthetase; OTC, ornithine carbamoyltransferase.

Mass screening of newborn infants identifies patients with ASS, ASL, and arginase 1 deficiencies.
Treatment of Acute Hyperammonemia

Clinical outcome depends mainly on the severity and the duration of hyperammonemia. Serious neurologic sequelae are likely in newborns with severe elevations in blood ammonia (>300 µmol/L) for more than 12 hr. Thus, acute hyperammonemia should be treated promptly and vigorously. The goal of therapy is to lower the concentration of ammonia. This is accomplished by (1) removal of ammonia from the body in a form other than urea and (2) minimizing endogenous protein breakdown and favoring endogenous protein synthesis by providing adequate calories and essential amino acids (Table 103.5). Fluid, electrolytes, glucose (10–15%), and lipids (1-2 g/kg/24 hr) should be infused intravenously, together with minimal amounts of protein (0.25 g/kg/24 hr), preferably including essential amino acids. Oral feeding with a low-protein formula (0.5-1.0 g/kg/24 hr) through a nasogastric tube should be started as soon as sufficient improvement is seen.

Table 103.5

<table>
<thead>
<tr>
<th>Treatment of Acute Hyperammonemia in an Infant</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Provide adequate calories, fluid, and electrolytes intravenously (10% glucose, NaCl* and intravenous lipids 1 g/kg/24 hr). Add minimal amounts of protein preferably as a mixture of essential amino acids (0.25 g/kg/24 hr) during the 1st 24 hr of therapy.</td>
</tr>
<tr>
<td>2. Give priming doses of the following compounds: (To be added to 20 mL/kg of 10% glucose and infused within 1-2 hr)</td>
</tr>
<tr>
<td>• Sodium benzoate 250 mg/kg †</td>
</tr>
<tr>
<td>• Sodium phenylacetate 250 mg/kg †</td>
</tr>
<tr>
<td>• Arginine hydrochloride 200-600 mg/kg as a 10% solution</td>
</tr>
<tr>
<td>3. Continue infusion of sodium benzoate † (250-500 mg/kg/24 hr), sodium phenylacetate † (250-500 mg/kg/24 hr), and arginine (200-600 mg/kg/24 hr ‡) following the above priming doses. These compounds should be added to the daily intravenous fluid.</td>
</tr>
<tr>
<td>4. Initiate peritoneal dialysis or hemodialysis if above treatment fails to produce an appreciable decrease in plasma ammonia.</td>
</tr>
</tbody>
</table>
The concentration of sodium chloride should be calculated to be 0.45–0.9%, including the amount of the sodium in the drugs.

† Sodium from these drugs should be included as part of the daily sodium requirement.

‡ The higher dose is recommended in the treatment of patients with citrullinemia and argininosuccinic aciduria. Arginine is not recommended in patients with arginase deficiency and in those whose hyperammonemia is secondary to organic acidemia. Sodium benzoate and sodium phenylacetate should be used with caution in patients with organic acidemias.

Because the kidneys clear ammonia poorly, its removal from the body must be expedited by formation of compounds with a high renal clearance. An important advance in the treatment of hyperammonemia has been the introduction of acylation therapy by using an exogenous organic acid that is acylated endogenously with nonessential amino acids to form a nontoxic compound with high renal clearance. The main organic acids used for this purpose are sodium salts of benzoic acid and phenylacetic acid. Benzoate forms hippurate with endogenous glycine in the liver (see Fig. 103.12). Each mole of benzoate removes 1 mole of ammonia as glycine. Phenylacetate conjugates with glutamine to form phenylacetylglutamine, which is readily excreted in the urine. One mole of phenylacetate removes 2 moles of ammonia as glutamine from the body (see Fig. 103.12). Sodium phenylbutyrate, metabolized to phenylacetate, is the primary oral formulation. For intravenous (IV) use, a combined formulation of benzoate and phenylacetate (Ammonul) is commercially available.

Another valuable therapeutic adjunct is IV infusion of arginine, which is effective in all patients (except those with arginase deficiency). Arginine administration supplies the urea cycle with ornithine (see Fig. 103.12). In patients with citrullinemia, 1 mole of arginine reacts with 1 mole of ammonia (as carbamoyl phosphate) to form citrulline. In patients with argininosuccinic acidemia, 2 moles of ammonia (as carbamoyl phosphate and aspartate) react with arginine to form argininosuccinic acid. Citrulline and argininosuccinate are less toxic than ammonia and more readily excreted by the kidneys. In patients with CPS1 or OTC deficiencies arginine administration is indicated because this amino acid is not produced in sufficient amounts to enable endogenous protein synthesis. For enteral therapy, patients with OTC deficiency benefit from
supplementation with *citrulline* (200 mg/kg/24 hr) because 1 mole of citrulline reacts with 1 mole of ammonia (through aspartic acid) to form arginine. Administration of arginine or citrulline is contraindicated in patients with arginase deficiency, a rare condition in which the usual presenting clinical picture is spastic diplegia rather than hyperammonemia. Arginine therapy is of no benefit if hyperammonemia is secondary to an organic acidemia. In a newborn infant with an initial episode of hyperammonemia, arginine should be used until the diagnosis is established (see Table 103.5).

Benzoate, phenylacetate, and arginine may be administered together for maximal therapeutic effect. A priming dose of these compounds is followed by continuous infusion until recovery from the acute state occurs. Both benzoate and phenylacetate are usually supplied as concentrated solutions and should be properly diluted (1–2% solution) for IV use. The recommended therapeutic doses of both compounds deliver a substantial amount of sodium to the patient; this amount should be included in calculation of the daily sodium requirement. Benzoate and phenylacetate (or the combined formulation, Ammonul) should be used with caution in newborn infants with hyperbilirubinemia because they may displace bilirubin from albumin; however, there are no documented cases of kernicterus (see Chapter 123.4) reported in neonates with hyperammonemia who have received such therapies. In infants at risk, it is advisable to reduce bilirubin to a safe level while considering IV administration of benzoate or phenylacetate.

If the initial ammonia level is <500 µmol/L, and if the foregoing therapies fail within 4-6 hr to produce any appreciable change in the blood ammonia level, hemodialysis should be used. For patients presenting with an ammonia level >500 µmol/L, extracorporeal detoxification is the initial method of ammonia removal. Exchange transfusion has little effect on reducing total body ammonia. It should be used only if dialysis cannot be employed promptly or when the patient is a newborn infant with hyperbilirubinemia (see earlier). Hemodialysis dramatically lowers blood ammonia within a few hours, but if it is unavailable or technically unfeasible, peritoneal dialysis may be used as an alternative. When hyperammonemia is caused by an organic acidemia and hemodialysis is not available, peritoneal dialysis can be used to remove both the offending organic acid and ammonia.

Oral administration of neomycin limits growth of intestinal bacteria that can produce ammonia. However, this modality is of limited use in patients (e.g., affected neonates) in whom reduction of hyperammonemia is an urgent priority.
Oral lactulose acidifies the intestinal lumen, thereby reducing the diffusion of ammonia across the intestinal epithelium. This agent is of limited applicability in newborns, who have a high risk of acidemia and dehydration.

There has been interest in the use of cooling as a therapeutic adjunct in newborn infants with metabolic encephalopathy such as that caused by hyperammonemia. Clinical studies are in progress to evaluate the efficacy of this approach. There may be considerable lag between the normalization of ammonia level and an improvement in the patient's neurologic status. Several days may be needed before the infant becomes fully alert.

Long-Term Therapy

Once the infant is alert, therapy should be tailored to the underlying cause of the hyperammonemia. In general, all patients, regardless of the enzymatic defect, require protein restriction limited to age-adjusted recommended dietary allowance (RDA). In pediatric patients with defects in the urea cycle, chronic administration of sodium benzoate (250 mg/kg/24 hr), sodium phenylbutyrate (250-500 mg/kg/24 hr), and arginine (200-400 mg/kg/24 hr) or citrulline (in patients with OTC deficiency, 200-400 mg/kg/24 hr) is effective in maintaining blood ammonia levels within the normal range (shown doses are for patients who weigh <20 kg). Arginine and citrulline are contraindicated in patients with argininemia. Patients who have difficulty taking sodium phenylbutyrate can receive a trial of glycerol phenylbutyrate. This compound conceals the offensive odor of sodium phenylbutyrate and may help with patient adherence. Glycerol phenylbutyrate is not yet approved for use in children <2 months of age. Benzoate and phenylacetate may lower carnitine levels, but clinical signs of carnitine deficiency or benefit from carnitine supplementation have not yet been demonstrated. These compounds have been used during pregnancy without obvious teratogenic effect. However, experience is still limited, and appropriate caution should be exercised.

Growth parameters, especially head circumference, and nutritional indices (blood albumin, prealbumin, pH, electrolytes, amino acids, zinc, selenium) should be followed closely. Long-term care of these patients is best achieved by a team of experienced professionals (pediatrician, nutritionist, child neurologist, metabolic geneticist). Skin lesions resembling acrodermatitis enteropathica (see Chapter 691) have been noted in a few patients with different types of urea cycle defects, presumably from deficiency of essential amino acids, caused by
overzealous dietary protein restriction. Catabolic states (infections, fasting) that may trigger hyperammonemia should be avoided. They must be treated vigorously if they occur. It is important that all children with urea cycle defects avoid valproic acid because this drug can elevate blood ammonia even in some healthy individuals. In patients with CPS1, OTC, or ASS deficiency, acute hyperammonemnic attacks may be precipitated by valproate administration.

**Carbamoyl Phosphate Synthetase 1 and N-Acetylglutamate Synthase Deficiencies**

Deficiencies of these 2 enzymes produce similar clinical and biochemical manifestations (see Figs. 103.12 and 103.13). There is a wide variation in severity of symptoms and in the age at presentation. In near-complete enzymatic deficiency, symptoms appear during the 1st few days or even hours of life with signs and symptoms of hyperammonemia (refusal to eat, vomiting, lethargy, convulsion, coma). Increased intracranial pressure is frequent. Late forms (as late as the 4th decade of life) may present as an acute bout of hyperammonemia (lethargy, headache, seizures, psychosis) in a seemingly normal individual. Coma and death may occur during these episodes (a previously asymptomatic 26-yr-old female died from hyperammonemia during childbirth). Diagnostic confusion with migraine is common. Intermediate forms with intellectual disability and chronic subclinical hyperammonemia interspersed with bouts of acute hyperammonemia have also been observed.

**Laboratory findings** include hyperammonemia. The plasma amino acid analysis typically shows a marked increase of glutamine and alanine with relatively low levels of citrulline and arginine. These are nondiagnostic changes that occur in hyperammonemia of diverse cause. Urinary orotic acid is usually low or may be absent (see Fig. 103.13).

**Treatment** of acute hyperammonemic attacks and the long-term therapy of the condition are previously outlined (see Table 103.5). Patients with NAGS deficiency benefit from oral administration of carbamylglutamate. It is therefore important to differentiate between CPS1 and NAGS deficiencies by gene sequencing. Deficiency of NAGS is rare in North America.

CPS1 and NAGS deficiencies are inherited as an autosomal recessive trait; the
CPS1 enzyme is normally present in liver and intestine. The gene \((CPS1)\) is mapped to chromosome 2q34. The prevalence of the condition is approximately \(1 : 1,300,000\). The gene for NAG synthetase \((NAGS)\) is located on chromosome 17q21.31. Neither of these conditions is identified by the mass screening of the newborn infants.

**Ornithine Transcarbamylase Deficiency**

In this X-linked disorder, the hemizygous males are more severely affected than heterozygous females (see Figs. 103.12 and 103.13). The heterozygous females may have a mild form of the disease, but the majority (approximately 75%) remain asymptomatic, although investigations indicate subtle neurologic defects even in women without a frank history of hyperammonemia. Ornithine transcarbamylase \((OTC)\) deficiency is the most common form of all the urea cycle disorders, comprising approximately 40% of cases of urea cycle disorders.

**Clinical manifestations** in a male newborn are usually those of severe hyperammonemia (see earlier) occurring in the 1st few days of life. **Mild forms**, such as in some heterozygous females, characteristically have episodic manifestations, which may occur at any age (usually after infancy). Episodes of hyperammonemia, manifested by vomiting and neurologic abnormalities (e.g., ataxia, mental confusion, agitation, combative ness, frank psychosis), are separated by periods of wellness. These episodes usually occur after ingestion of a high-protein diet or as a result of a catabolic state such as infection. Hyperammonemic coma, cerebral edema, and death may occur during one of these attacks. Cognitive development may proceed normally. Mild to moderate intellectual disability, however, is common. Gallstones have been seen in the survivors; the mechanism remains unclear.

The major **laboratory finding** during the acute attack is hyperammonemia accompanied by marked elevations of plasma concentrations of glutamine and alanine with low levels of citrulline and arginine. The blood level of urea is usually low. A marked increase in the urinary excretion of orotic acid differentiates this condition from CPS1 deficiency (see Fig. 103.13). Orotate may precipitate in urine as pink-colored gravel or stones. In the **mild form**, these laboratory abnormalities may revert to normal between attacks. This form should be differentiated from all the episodic conditions of childhood. In particular, patients with lysinuric protein intolerance (see Chapter 103.14) may demonstrate some features of OTC deficiency, but the former can be
differentiated by increased urinary excretion of lysine, ornithine, and arginine and elevated blood concentrations of citrulline.

The **diagnosis** is most conveniently confirmed by gene analysis. As many as 20% of affected patients demonstrate a normal sequence, perhaps because the pathogenic variant involves copy number variants and pathogenic variants involving introns or a promoter region. Copy number variants can be evaluated using a chromosomal microarray, and if positive, a contiguous gene deletion should be considered. If the molecular diagnostic approach is negative, a liver biopsy may be indicated. Prenatal diagnosis is feasible by analysis of DNA in amniocytes or chorionic villus samples. Increase in urinary excretion of orotidine after an allopurinol loading test can identify female carriers. Mild cerebral dysfunction may be present in asymptomatic female carriers. The importance of a detailed family history should be emphasized. A history of migraine or protein aversion is common in maternal female relatives of the proband. Indeed, careful scrutiny of the family history may reveal a pattern of unexplained deaths in male newborns in the maternal lineage.

**Treatment** of acute hyperammonemnic attacks and the long-term therapy of the condition are previously outlined. For enteral use, citrulline is used in place of arginine in patients with OTC deficiency. Liver transplantation is a successful treatment for patients with severe OTC deficiency.

The gene for OTC has been mapped to the X chromosome (Xp21.1). Many disease-causing pathogenic variants (>300) have been identified. The prevalence of OTC deficiency is 1 : 56,000-1 : 77,000 live births. Genotype and the resulting degree of enzyme deficiency determine severity of the phenotype in most cases. Mothers of affected infants are expected to be carriers of the mutant gene unless a de novo pathogenic variant has occurred. A mother who gave birth to 2 affected male offspring was found to have a normal genotype, suggesting that gonadal mosaicism can be seen in some families. This condition is not identified by the mass screening of newborn infants.

**Citrullinemia**

Two clinically and genetically distinct forms of citrullinemia have been identified. The classic form (type I) is caused by the deficiency of the ASS enzyme. Citrullinemia type II is caused by the deficiency of a mitochondrial transport protein named *citrin*. (See Figs. 103.12 and 103.13.)
Citrullinemia Type I (Argininosuccinate Synthetase Deficiency, Classic Citrullinemia)

This condition is caused by the deficiency of ASS (see Fig. 103.12) and has variable clinical manifestations depending on the degree of the enzyme deficiency. Two major forms of the condition have been identified. The severe or neonatal form, which is most common, appears in the 1st few days of life with signs and symptoms of hyperammonemia (see earlier). In the subacute or mild form, clinical findings such as failure to thrive, frequent vomiting, developmental delay, and dry, brittle hair appear gradually after 1 yr of age. Acute hyperammonemia, triggered by an intercurrent catabolic state, may bring the diagnosis to light.

Laboratory findings are similar to those found in patients with OTC deficiency, except that the plasma citrulline concentration is greatly elevated (50-100 times normal) (see Fig. 103.13). Urinary excretion of orotic acid is moderately increased; crystalluria may also occur as a result of precipitation of orotates. The diagnosis is confirmed by DNA analysis or less frequently by assay of enzyme activity in cultured fibroblasts. Prenatal diagnosis is feasible with enzyme assay in cultured amniotic cells or by DNA analysis of cells obtained from chorionic villus biopsy.

Treatment of acute hyperammonemic attacks and long-term therapy are outlined earlier (see Table 103.5). Plasma concentration of citrulline remains elevated at all times and may increase further after administration of arginine. Patients can do well on a protein-restricted diet in conjunction with sodium benzoate, phenylbutyrate, and arginine therapy. Mild to moderate cognitive impairment is a common sequela, even in a well-treated patient.

Citrullinemia is inherited as an autosomal recessive trait. The gene (ASS1) is located on chromosome 9q34.11. The majority of patients are compound heterozygotes for 2 different alleles. The prevalence of the condition is 1 : 250,000 live births. The recent introduction of neonatal screening for urea cycle defects has shown that some affected patients are ostensibly asymptomatic even with ingestion of a regular diet. Long-term follow-up is needed to be certain that these individuals do not sustain neurologic sequelae.

Citrin Deficiency (Citrullinemia Type II)

Citrin (aspartate-glutamate carrier protein) is a mitochondrial transporter
encoded by a gene (SLC25A13) located on chromosome 7q21.3. One of this protein's functions is to transport aspartate from mitochondria into cytoplasm and replenish the cytosolic aspartate pool required for converting citrulline to argininosuccinic acid (see Fig. 103.12). If aspartate is unavailable to the cytoplasmic component of the urea cycle, urea will not be formed at a normal rate, and citrulline will accumulate. ASS activity is diminished in the liver of these patients, but no pathogenic variant in the ASS1 gene has been found. It is postulated that citrin deficiency interferes with translation of messenger RNA for ASS enzyme in the liver. The condition initially was reported in Japan, but non-Japanese patients have also been identified. Two clinical forms of citrin deficiency have been described.

**Neonatal Intrahepatic Cholestasis (Citrullinemia Type II, Neonatal Form)**

Clinical and laboratory manifestations, which usually start before 1 yr of age, include cholestatic jaundice with mild to moderate direct (conjugated) hyperbilirubinemia, marked hypoproteinemia, clotting dysfunction (increased prothrombin time and partial thromboplastin time), and increased serum γ-glutamyltransferase and alkaline phosphatase activities; liver transaminases are usually normal. Plasma concentrations of ammonia and citrulline are usually normal, but moderate elevations have been reported. There may be increases in plasma concentrations of methionine, tyrosine, alanine, and threonine. Elevated levels of serum galactose have been found, even though the enzymes of galactose metabolism are normal. The reason for hypergalactosemia is not known. Marked elevation in the serum level of α-fetoprotein is also present. These findings resemble those of tyrosinemia type I, but unlike the latter condition, urinary excretion of succinylacetone is not elevated (see Chapter 103.2). Liver biopsy shows fatty infiltration, cholestasis with dilated canaliculi, and a moderate degree of fibrosis. The condition is usually self-limiting, and the majority of infants recover spontaneously by 1 yr of age with supportive and symptomatic treatment. Hepatic failure requiring liver transplantation has occurred in a few cases. Although the condition is commonly seen in Japan, the diagnosis should be considered in any case of unexplained neonatal hepatitis with cholestasis. Data on the long-term prognosis and the natural history of the condition are limited; development into the adult form of the condition after several years of seemingly asymptomatic hiatus has been observed.
**Citrullinemia Type II, Adult Form (Adult-Onset Citrullinemia; Citrullinemia Type II, Mild Form)**

This form of citrullinemia type II starts acutely in a previously apparently normal individual and manifests with neuropsychiatric symptoms such as disorientation, delirium, delusion, aberrant behavior, tremors, and frank psychosis. Moderate degrees of hyperammonemia and hypercitrullinemia are present. The age at onset is usually between 20 and 40 yr (range: 11 to >100 yr). Patients who recover from the 1st episode may have recurrent attacks. Pancreatitis, hyperlipidemia, and hepatoma are major complications among the survivors. Medical treatment has been mostly ineffective for prevention of future attacks. Diet enriched for protein and lipids helps restore cytosolic aspartate pool and stimulate ureagenesis. Indeed, some have speculated that the administration of large amounts of glucose might even prove deleterious, because the citrin transporter is important to the glycolytic pathway. Although liver transplantation appears to be effective in preventing future episodes of hyperammonemia, enteral supplementation with arginine, pyruvate, and medium-chain triglycerides can be tried first to improve hyperammonemic episodes and growth.

Several disease-causing mutations of the gene have been identified in affected Japanese and non-Japanese families. Although the frequency of homozygosity is relatively high in Japan (1 : 20,000 people), the clinical condition has a frequency of only 1 : 100,000 to 1 : 230,000. This indicates that a substantial number of homozygous individuals remain asymptomatic.

**Argininosuccinate Lyase Deficiency (Argininosuccinic Aciduria)**

The severity of the clinical and biochemical manifestations varies considerably (see Figs. 103.12 and 103.13 ). In severe form of ASL deficiency, signs and symptoms of severe hyperammonemia (see earlier) develop in the 1st few days of life, and without treatment, mortality can be high. Clinical course of ASL deficiency in patients who survive the initial acute episode can be characterized by intellectual disability, failure to thrive, hypertension, gallstones, liver fibrosis, and hepatomegaly. A common finding in untreated patients is dry and brittle hair (trichorrhexis nodosa ). Acute attacks of severe hyperammonemia may occur during a catabolic state.
Laboratory findings include hyperammonemia, moderate elevations in liver enzymes, nonspecific increases in plasma levels of glutamine and alanine, a moderate increase in plasma levels of citrulline (less than in citrullinemia), and marked increase in the concentration of argininosuccinic acid in plasma, urine, and CSF. The CSF levels are usually higher than those in plasma. The enzyme is normally present in erythrocytes, the liver, and cultured fibroblasts. **Prenatal diagnosis** is possible by measurement of the enzyme activity in cultured amniotic cells or by identification of pathogenic variants in the ASL gene. Argininosuccinic acid is also elevated in the amniotic fluid of affected fetuses.

**Treatment** of acute hyperammonemic attacks and the long-term therapy of the condition are outlined earlier in this chapter. Intellectual disability, persistent hepatomegaly with mild increases in liver enzymes, and bleeding tendencies as a result of abnormal clotting factors are common sequelae. This deficiency is inherited as an autosomal recessive trait with a prevalence of about 1 in 220,000 live births. The gene (ASL) is located on chromosome 7q11.21. Early detection is achieved through mass screening of newborn infants.

**Arginase 1 Deficiency (Hyperargininemia)**

This defect is inherited as an autosomal recessive trait (see Figs. 103.12 and 103.13). There are 2 genetically distinct arginases in humans. One is cytosolic (ARG1) and is expressed in the liver and erythrocytes, and the other (ARG2) is found in renal and brain mitochondria. The gene for ARG1, the enzyme that is deficient in patients with arginase 1 deficiency, is mapped to chromosome 6q23.2. The role of the mitochondrial enzyme is not well understood; its activity increases in patients with argininemia but has no protective effect.

**Clinical manifestations** of this rare distal urea cycle disorder are somewhat different from those of other urea cycle enzyme defects, although acute neonatal form with intractable seizures, cerebral edema, and death has also been reported. The onset arginase 1 deficiency often is insidious; the infant can remain asymptomatic in the 1st few mo or yr of life. A **progressive spastic diplegia** with scissoring of the lower extremities, choreoathetotic movements, loss of developmental milestones, and failure to thrive in a previously normal infant may suggest a degenerative disease of the CNS. Some children were treated for years as cases of cerebral palsy before their arginase 1 deficiency was confirmed.
Intellectual disability is progressive; seizures are common, but episodes of severe hyperammonemia are not as frequent as in the more proximal urea cycle defects. Hepatomegaly may be present.

**Laboratory findings** include marked elevations of arginine in plasma and CSF (see Fig. 103.13). Urinary orotic acid can be increased. Determination of amino acids in plasma is a critical step in the diagnosis of argininemia. The guanidino compounds (α-keto-guanidinovaleric acid and α-keto-argininic acid) are markedly increased in urine. The diagnosis is confirmed by assaying arginase activity in erythrocytes or by the identification of the mutant gene.

**Treatment** consists of a low-protein diet providing the RDA. The composition of the diet and the daily intake of protein should be monitored by frequent plasma amino acid determinations. Sodium benzoate or sodium phenylbutyrate are also effective in controlling hyperammonemia and lowering plasma arginine levels. Intellectual disability is a common sequela of the condition. One patient developed type 1 diabetes by 9 yr of age while his argininemia was under good control. Liver transplantation has produced promising results, but experience with long-term outcome is limited. Early detection is feasible through mass screening of newborn infants.

**Transient Hyperammonemia of the Newborn**

The blood concentration of ammonia in full-term infants may be as high as 100 µmol/L, or 2-3 times greater than that of the older child or adult. Blood levels approach the adult normal values after a few weeks of life (see Fig. 103.13).

**Severe** transient hyperammonemia is observed in some newborn infants. The majority of affected infants are premature and have mild respiratory distress syndrome. Hyperammonemic coma may develop within 2-3 days of life, and the infant may succumb to the disease if treatment is not started immediately. Laboratory studies reveal marked hyperammonemia (plasma ammonia as high as 4,000 µmol/L) with moderate increases in plasma levels of glutamine and alanine. Plasma concentrations of urea cycle intermediate amino acids are usually normal except for citrulline, which may be moderately elevated. The cause of the disorder is unknown. Urea cycle enzyme activities are normal. **Treatment** of hyperammonemia should be initiated promptly and continued vigorously. Recovery without sequelae is common, and hyperammonemia does
not recur even with a normal protein diet.

**Disorders of Ornithine Metabolism**

Ornithine, a key intermediate of the urea cycle, is not incorporated into natural proteins. Rather, it is generated in the cytosol from arginine and must be transported into mitochondria, where it becomes a substrate for the reaction catalyzed by OTC that forms citrulline. Excess ornithine is catabolized by 2 enzymes, ornithine aminotransferase, which is a mitochondrial enzyme converting ornithine to a proline precursor, and ornithine decarboxylase, which resides in the cytosol and converts ornithine to putrescine (see Fig. 103.12). Two genetic disorders feature hyperornithinemia: gyrate atrophy of the retina and hyperammonemia-hyperornithinemia-homocitrullinemia syndrome.

**Gyrate Atrophy of the Retina and Choroid**

This rare, autosomal recessive disorder is caused by deficiency of ornithine aminotransferase (see Fig. 103.12). Approximately 30% of the reported cases are from Finland. Clinical manifestations may include hyperammonemia in the 1st mo of life in some patients. Findings that define the phenotype of ornithine aminotransferase deficiency include night blindness, myopia, loss of peripheral vision, and posterior subcapsular cataracts. These eye changes start between 5 and 10 yr of age and progress to complete blindness by the 4th decade of life. Atrophic lesions in the retina resemble cerebral gyri. These patients usually have normal intelligence. Besides the characteristic 10-20–fold increase in plasma levels of ornithine (400–1,400 µmol/L), plasma levels of glutamate, glutamine, lysine, creatine, and creatinine can be moderately decreased. Some patients respond partially to high doses of pyridoxine. An arginine-restricted diet in conjunction with supplemental lysine, proline, and creatine has been successful in reducing plasma ornithine concentration and has produced some clinical improvement. The gene for ornithine aminotransferase (OAT) is mapped to chromosome 10q26.13. Many (at least 60) pathogenic variants have been identified in different families.

**Hyperammonemia-Hyperornithinemia-Homocitrullinemia Syndrome**
In this rare autosomal recessive disorder the defect is in the transport system of ornithine from the cytosol into the mitochondria, resulting in accumulation of ornithine in the cytosol and a depletion of this amino acid in mitochondria. The former causes hyperornithinemia, and the latter results in disruption of the urea cycle and hyperammonemia (see Fig. 103.12 ). Homocitrulline is presumably formed from the reaction of mitochondrial carbamoyl phosphate with lysine, which can become a substrate for the OTC reaction when ornithine is deficient. Clinical manifestations of hyperammonemia may develop shortly after birth or may be delayed until adulthood. Acute episodes of hyperammonemia manifest as refusal to feed, vomiting, and lethargy; coma may occur during infancy. Progressive neurologic signs, such as lower limb weakness, increased deep tendon reflexes, spasticity, clonus, seizures, and varying degrees of psychomotor retardation may develop if the condition remains undiagnosed. No clinical ocular findings have been observed in these patients. Laboratory findings reveal marked increases in plasma levels of ornithine and homocitrulline in addition to hyperammonemia (see Fig. 103.13 ). Acute episodes of hyperammonemia should be treated promptly (see earlier). Restriction of protein intake improves hyperammonemia. Oral supplementation with arginine (or citrulline) has produced clinical improvement in some patients. The gene for this disorder (SLC25A15) is located on chromosome 13q14.11.

**Congenital Glutamine Deficiency**

Glutamine is synthesized endogenously from glutamate and ammonia by a ubiquitous enzyme, glutamine synthetase (see Fig. 103.11 ). Glutamine is known to be involved in several important functions, including detoxification of ammonia. Deficiency of this enzyme, resulting in glutamine deficiency, has been reported in 3 infants from 3 unrelated families. All affected infants manifested multiorgan involvement, including significant brain malformations (abnormal gyrations, hypomyelination), facial abnormalities (broad nasal root, low-set ears), hypotonia and seizures at birth. Two of the patients died from multiorgan failure (respiratory and heart failure) in the neonatal period. One child was alive at 3 yr of age with severe developmental delay. Glutamine was absent in plasma, urine, and CSF, but plasma levels of glutamic acid were normal. Genetic defects of this enzyme underline the critical role of glutamine in embryogenesis, especially for normal brain development. The condition is inherited as an autosomal recessive trait; the gene for glutamine synthetase (GLUL) is mapped
to chromosome 1q25.3.

Histidine

Oleg A. Shchelochkov, Charles P. Venditti

Keywords

histidine
L-histidine decarboxylase
urocanic acid

Histidine is degraded through the urocanic acid pathway to glutamic acid. Several genetic biochemical aberrations involving the degradative pathway of histidine have been reported, but the clinical significance of elevated histidine levels has not been established.

Decarboxylation of histidine by histidine decarboxylase produces histamine. Deficiency of this enzyme has been implicated in the familial form of Tourette syndrome (see Chapter 103.11).

Bibliography

Lysine is catabolized through 2 pathways. In the 1st pathway, lysine is condensed with α-ketoglutaric acid to form saccharopine. Saccharopine is then
catabolized to α-aminoacidic semialdehyde and glutamic acid. These 1st 2 steps are catalyzed by α-aminoacidic semialdehyde synthase, which has 2 activities: lysine-ketoglutarate reductase and saccharopine dehydrogenase (Fig. 103.14). In the 2nd pathway, lysine is first transaminated and then condensed to its cyclic forms, piperolic acid and piperideine-6-carboxylic acid (P6C). P6C and its linear form, α-aminoacidic semialdehyde, are oxidized to α-aminoacidic acid by the enzyme antiquitin. This is the major pathway for D-lysine in the body and for the L-lysine in the brain.

**Hyperlysinemia-saccharopinuria** and **α-aminoacidic-α-ketoacidic acidemia** are biochemical conditions caused by inborn errors of lysine degradation. Individuals with these conditions are usually asymptomatic.

**Pyridoxine (Vitamin B₆)–Dependent**
Epilepsy

Pyridoxal 5′-phosphate (P5P), the active form of pyridoxine, is the cofactor for many enzymes including those involved in the metabolism of neurotransmitters. Intracellular P5P deficiency in the brain may result in a seizure disorder that is refractory to common anticonvulsant agents but is responsive to high doses of pyridoxine. These pyridoxine-responsive phenotypes are seen in the following genetic metabolic conditions:

Antiquitin (α-Aminoadipic Semialdehyde Dehydrogenase) Deficiency

This is the most common cause of pyridoxine-dependent epilepsy. Deficiency of antiquitin results in accumulation of P6C in brain tissue (see Fig. 103.14); P6C reacts with P5P and renders it inactive. Large doses of pyridoxine are therefore needed to overcome this inactivation. The condition is inherited as an autosomal recessive trait; the gene for antiquitin (ALDH7A1) is on chromosome 5q31.

Pyridox(am)ine 5′-Phosphate Oxidase (PNPO) Deficiency

PNPO deficiency clinically overlaps with antiquitin deficiency. PNPO-deficient patients often present with neonatal-onset seizures, developmental delays, spastic tetraplegia, and nonspecific findings on brain imaging (delayed myelination, cerebral atrophy, and abnormal signals in basal ganglia). Developmental regression, optic disc pallor, and retinopathy have been reported infrequently. Plasma and CSF amino acid analysis may reveal elevated glycine, prompting evaluation for nonketotic hyperglycinemia (see Chapter 103.7) and lead to a delay in initiating treatment with P5P. CSF neurotransmitter assay revealed inconsistent changes in the levels of 3-O -methyldopa, homovanillic acid, and 5-hydroxyindoleacetic acid. Normal CSF level of P5P was reported in one patient, suggesting that a therapeutic trial with P5P and molecular analysis may be a prudent strategy in some patients irrespective of the CSF studies. The lowest effective dose of P5P should be used to avoid toxicity. The disorder is caused by autosomal recessive pathogenic variants in PNPO.
Sulfite Oxidase Deficiency and Molybdenum Cofactor Deficiency

In this rare condition (see Chapter 103.4), accumulation of sulfites causes inhibition of enzymatic activity of antiquitin and accumulation of P6C, which in turn causes inactivation of P5P and vitamin B₆ dependency.

Hyperprolinemia Type II

In this condition, accumulation of Δ1-pyrroline-5-carboxylate (P5C) in brain tissue causes inactivation of P5P, leading to pyridoxine dependency (see Chapter 103.9 and Fig. 103.9).

Hypophosphatasia

Pyridoxal-5’-phosphate is the main circulating form of pyridoxine. Alkaline phosphatase (ALP) is required for dephosphorylation of P5P to generate free pyridoxine, which is the only form of vitamin B₆ that can cross the blood-brain barrier and enter the brain cells. Pyridoxine is rephosphorylated intracellularly to form P5P. In the infantile form of hypophosphatasia, P5P cannot be dephosphorylated to free pyridoxine because of marked deficiency of tissue-nonspecific ALP. This results in deficiency of pyridoxine in the brain and pyridoxine-dependent epilepsy (see Chapters 611 and 724).

The main clinical manifestation of pyridoxine-dependent epilepsy caused by antiquitin deficiency is generalized seizures, which usually occur in the first days of life and are unresponsive to conventional anticonvulsant therapies. Some mothers of affected fetuses report abnormal intrauterine fluttering movements. The seizures are usually tonic-clonic in nature but can be almost any type. Other manifestations such as dystonia, respiratory distress, and abdominal distention with vomiting, hepatomegaly, hypoglycemia and hypothermia may be present. Learning problems and speech delay are common sequelae. Late-onset forms of the condition (as late as 5 years of age) have been reported. Consequently, a trial with vitamin B₆ is recommended in any infant with intractable convulsions (see Chapters 611.04 and 611.06).

Laboratory findings show increased concentrations of α-amino adipic semialdehyde and pipecolic acid in the CSF, plasma, and urine. EEG abnormalities may normalize after treatment. Neuroimaging may be normal but
cerebellar and cerebral atrophy, periventricular hyperintensity, intracerebral hemorrhage, and hydrocephalus have been reported.

**Treatment** with vitamin B$_6$ (50-100 mg/day) usually results in a dramatic improvement of both seizures and the EEG abnormalities. High doses of pyridoxine can result in peripheral neuropathy, and doses $>$500 mg/day should be avoided. The pyridoxine dependency and thus the therapy are lifelong. The therapeutic benefit of a lysine-restricted diet is being evaluated.

### Glutaric Aciduria Type 1 (Glutaryl-CoA Dehydrogenase Deficiency)

Glutaric acid is an intermediate in the degradation of lysine (see Fig. 103.14), hydroxyllysine, and tryptophan. Glutaric aciduria **type 1**, a disorder caused by a deficiency of glutaryl-CoA dehydrogenase, should be differentiated from glutaric aciduria **type 2**, a distinct clinical and biochemical disorder caused by defects in the mitochondrial electron transport chain (see Chapter 104.1).

### Clinical Manifestations

Macrocephaly is a common but nonspecific finding in patients with glutaric aciduria type 1. It develops in the 1st yr of life but can also be present at birth and precede the onset of neurologic manifestations. Some affected infants may also show subtle neurologic symptoms, such as delayed onset of motor milestones, irritability, and feeding problems, during this seemingly asymptomatic period. The onset of the condition is usually heralded by **acute encephalopathic findings**, such as loss of normal developmental milestones (head control, rolling over, or sitting), seizures, generalized rigidity, opisthotonos, choreoathetosis, and dystonia caused by acute striatal injury. These symptoms may occur suddenly in an apparently normal infant after a minor infection. Brain imaging reveals increased extraaxial (particularly frontal) fluid with stretched bridging veins, striatal lesions, dilated lateral ventricles, cortical atrophy (mainly in frontotemporal region), and fibrosis. Recovery from the 1st attack usually occurs slowly, but some residual neurologic abnormalities may persist, especially dystonia and choreoathetosis. Without treatment, additional acute attacks resembling the first can occur during subsequent episodes of intercurrent infections or catabolic states. In some patients these signs and
symptoms may develop gradually in the 1st few yr of life. Hypotonia and choreoathetosis may gradually progress into rigidity and dystonia (insidious form). Acute episodes of metabolic decompensation with vomiting, ketosis, seizures, and coma also occur in this form after infection or other catabolic states. Without treatment, death may occur in the 1st decade of life during one of these episodes. Affected infants are prone to development of subdural hematoma and retinal hemorrhage following minor falls and head traumas. This can be misdiagnosed as child abuse. The intellectual abilities usually remain relatively normal in most patients.

**Laboratory Findings**

During acute episodes, mild to moderate metabolic acidosis and ketosis may occur. Hypoglycemia, hyperammonemia, and elevations of serum transaminases are seen in some patients. High concentrations of glutaric acid are usually found in urine, blood, and CSF. 3-Hydroxyglutaric acid may also be present in the body fluids. Acylcarnitine profile shows elevated glutaryl carnitine (C5-DC) in blood and urine. Plasma concentrations of amino acids are usually within normal limits. Laboratory findings may be unremarkable between attacks. Glutaric aciduria type 1 can be identified on the newborn screen by measuring glutaryl carnitine levels in blood spots. The sensitivity of this screening method depends on the cutoff value used by a newborn screen program, and some patients can be missed. For example, it can happen in a subset of patients with glutaric aciduria type 1 who may present with normal plasma and urinary levels of glutaric acid and variably elevated plasma glutaryl carnitine. This type of glutaric aciduria type 1 referred to as a “low-excretor” phenotype carries the same risk of developing brain injury as in a “high-excretor” phenotype. In some low-excreting patients, glutaric acid is elevated only in CSF. Urinary glutaryl carnitine appears to be a more sensitive screening method to identify affected low-excreting patients. In any child with progressive dystonia and dyskinesia, activity of the enzyme glutaryl-CoA dehydrogenase and molecular analysis of GCDH should be performed.

**Treatment**

Patients require lysine- and tryptophan-restricted diet while meeting physiologic requirements for protein, micronutrients, and vitamins. Increased dietary
arginine may decrease cellular uptake of lysine and decrease the endogenous formation of glutaryl-CoA. Patients should be routinely evaluated for lysine and tryptophan deficiency by monitoring plasma amino acids and growth. L-carnitine supplementation (50-100 mg/kg/24 hr orally) is recommended in all cases. Emergency treatment during acute illness, including temporary cessation of protein intake for 24 hr, replacement of lost calories using carbohydrates or lipids, IV L-carnitine, IV dextrose, prompt treatment of infection, and control of fever, is critical to decreasing the risk of striatal injury. All patients should be provided with an emergency letter describing the underlying diagnosis, recommended evaluation, and treatment. Early diagnosis through newborn screening with prevention and aggressive treatment of intercurrent catabolic states (infections) can help minimize striatal injury and ensure a more favorable prognosis. Patients with movement disorder and spasticity may require treatment with baclofen, diazepam, trihexyphenidyl, and injectable botulinum toxin A.

Glutaric aciduria type 1 is inherited as an autosomal recessive trait. The prevalence is estimated at 1 : 100,000 live births worldwide. The condition is more prevalent in some ethnic populations (Canadian Oji-Cree Indians, Irish Travelers, black South Africans, Swedes, and the Old Order Amish population in the United States). The gene for glutaryl-CoA dehydrogenase (GCDH) is located on chromosome 19p13.2. Molecular analysis of GCDH can aid in identifying patients with a low-excretor phenotype associated with specific pathogenic variants (e.g., p.M405V, p.V400M, p.R227P). High prevalence of known pathogenic variants in specific ethnic populations can enable a cost-effective molecular evaluation and counseling.

Prenatal diagnosis can be accomplished by demonstrating increased concentrations of glutaric acid in amniotic fluid, by assay of the enzyme activity in amniocytes or chorionic villus samples, or by identification of the known pathogenic variants in GCDH.

Lysinuric Protein Intolerance (Familial Protein Intolerance)

This rare autosomal recessive disorder is caused by a defect in the transport of the cationic amino acids lysine, ornithine, and arginine in both intestine and kidneys. Deficiency of the transporter protein (Y+L amino acid transporter 1) in this condition causes multisystem manifestations, which start initially with
gastrointestinal (GI) symptoms. The transport defect in this condition resides in the basolateral (antiluminal) membrane of enterocytes and renal tubular epithelia. This explains the observation that cationic amino acids are unable to cross these cells even when administered as dipeptides. Lysine in the form of dipeptide crosses the luminal membrane of the enterocytes but hydrolyzes to free lysine molecules in the cytoplasm. Free lysine, unable to cross the basolateral membrane of the cells, diffuses back into the lumen.

Refusal to feed, nausea, aversion to protein, vomiting, and mild diarrhea, which may result in failure to thrive, wasting, and hypotonia, may be seen shortly after birth. Breastfed infants usually remain asymptomatic until soon after weaning, possibly because of the low-protein content of breast milk. Episodes of hyperammonemia may occur after ingestion of a high-protein meal. Mild to moderate hepatosplenomegaly, osteoporosis, sparse brittle hair, thin extremities with moderate centripetal adiposity, and growth retardation are common physical findings in patients whose condition has remained undiagnosed. Neurocognitive status is usually normal, but moderate intellectual disability has been observed in some patients.

**Progressive interstitial pneumonitis** with bouts of acute exacerbation often occurs in these patients. This usually progresses to severe alveolar proteinosis. Clinical manifestations include progressive exertional dyspnea, fatigue, cough, diminished breath sound, and inspiratory rales; cyanosis may develop in older patients. Some patients have remained undiagnosed until the appearance of pulmonary manifestations. Radiographic evidence of pulmonary fibrosis has been observed in up to 65% of patients without clinical manifestations of pulmonary involvement.

**Renal involvement** is manifested initially by proteinuria, hematuria, and elevation of serum creatinine, which may progress to end-stage renal failure. Renal tubular involvement with laboratory findings of renal Fanconi syndrome may also be present. Renal biopsy reveals pathologic findings consistent with glomerulonephritis and tubulointerstitial nephritis. Hematologic findings of anemia, leukopenia, thrombocytopenia, and elevated ferritin may also be present. A condition resembling hemophagocytic lymphohistiocytosis/macrophage activation syndrome has also been reported. Immunologic abnormalities (impaired lymphocyte function, abnormalities in immune globulins, hypocomplementemia) and acute pancreatitis are frequent features of lysinuric protein intolerance.

**Laboratory findings** may reveal hyperammonemia and an elevated
concentration of urinary orotic acid, which develop after high-protein feeding. Plasma concentrations of lysine, arginine, and ornithine are usually mildly decreased, but urinary levels of these amino acids, especially lysine, are greatly increased. The pathogenesis of hyperammonemia is likely related to the depletion of urea cycle intermediates caused by poor absorption and the increased renal loss of ornithine and arginine. Plasma concentrations of alanine, glutamine, serine, glycine, and proline are usually increased. Anemia, increased serum levels of ferritin, lactate dehydrogenase (LDH), thyroxine-binding globulin, hypercholesterolemia, and hypertriglyceridemia are common findings. This condition should be differentiated from hyperammonemia caused by urea cycle defects (see Chapter 103.12), especially in heterozygous females with OTC deficiency, in whom increased urinary excretion of lysine, ornithine, and arginine is not seen.

**Treatment** with a low-protein diet providing the RDA of protein and supplemented with oral citrulline (50-100 mg/kg/day) can produce biochemical and clinical improvements. Episodes of hyperammonemia should be treated promptly (see Chapter 103.12). Supplementation with lysine (10-30 mg/kg/day) given in small and frequent doses helps improve plasma levels. The dose of lysine should be titrated down if patients develop abdominal pain and diarrhea. Treatment with high doses of prednisone has been effective in the management of acute pulmonary complications in some patients. **Bronchopulmonary lavage** is the treatment of choice for patients with alveolar proteinosis. The condition is more prevalent in Finland and Japan, where the prevalence is 1:60,000 and 1:57,000 live births, respectively.

The gene for lysinuric protein intolerance (*SLC7A7*) is mapped to chromosome 14q11.2. Pregnancies in affected mothers have been complicated by anemia, thrombocytopenia, toxemia, and bleeding, but offspring have been normal.

*N*-Acetylaspartic Acid (Canavan Disease)
Keywords

Canavan disease
atypical Canavan disease
N-acetylaspartic acid
NAA
ASPA
aspartoacylase
recombinant adeno-associated viruses
rAAVs
blood-brain barrier
leukodystrophy
progressive macrocephaly

N-Acetylaspartic acid (NAA), a derivative of aspartic acid, is synthesized in the brain and is found in a high concentration similar to glutamic acid. Studies suggest that NAA has multiple functions, such as serving as an acetate reservoir for myelin synthesis and being an organic osmolyte that helps regulate cerebral osmolality. However, the complete function of NAA is not yet fully understood. Aspartoacylase cleaves the N-acetyl group from NAA. Deficiency of aspartoacylase leads to Canavan disease, a severe leukodystrophy characterized by excessive excretion of NAA and spongy degeneration of the white matter of the brain. Canavan disease is an autosomal recessive disorder and is more prevalent in individuals of Ashkenazi Jewish descent than in other ethnic groups. The defective gene for Canavan disease (ASPA) is located on chromosome 17, and genetic testing can be offered for patients, family members, and at-risk populations.

Etiology and Pathology

The deficiency of the enzyme aspartoacylase leads to NAA accumulation in the brain, especially in white matter, and massive urinary excretion of this
compound. Excessive amounts of NAA are also present in the blood and CSF. Brain biopsies of patients with Canavan disease show spongy degeneration of the myelin fibers, astrocytic swelling, and elongated mitochondria. There is striking vacuolization and astrocytic swelling in white matter. Electron microscopy reveals distorted mitochondria. As the disease progresses, the ventricles enlarge because of cerebral atrophy.

**Clinical Manifestations**

The severity of Canavan disease covers a wide spectrum. Infants usually appear normal at birth and may not manifest symptoms of the disease until 3-6 mo of age, when they develop **progressive macrocephaly**, severe hypotonia, persistent head lag, and delayed milestones. As the disease progresses, there is spasticity, joint stiffness, and contractures. Optic atrophy and seizures develop. Feeding difficulties, poor weight gain, and gastroesophageal reflux may occur in the 1st yr of life; swallowing deteriorates, and nasogastric feeding or permanent gastrostomy may be required. In the past, most patients died in the 1st decade of life, but with the advances in medical technology and improved supportive care, now they often survive to the 2nd or 3rd decade.

**Atypical Canavan Disease**

**Juvenile** or **mild** Canavan disease is less common than **infantile** Canavan disease and is most prevalent in non-Ashkenazi Jews. Affected patients with juvenile Canavan disease usually present with mild speech and motor delay and may have **retinitis pigmentosa**. The other typical features of Canavan disease are usually not present. These children have moderately increased urinary excretion of NAA, which suggests Canavan disease. Brain MRI demonstrates increased signal intensity in the basal ganglia rather than global white matter disease, sometimes leading to confusion with mitochondrial disease.

**Diagnosis**

In a typical patient with Canavan disease, CT scan and MRI reveal diffuse white matter degeneration, primarily in the cerebral hemispheres, with less involvement of the cerebellum and brainstem ([Fig. 103.15](#)). Repeated
evaluations may be required. MRS performed at the time of MRI can be done to show the high peak of NAA, suggesting Canavan disease. The diagnosis can also be established by finding elevated amounts of NAA in the urine or blood. NAA is found only in trace amounts (24 ±16 µmol/mmol creatinine) in the urine of unaffected individuals, whereas in patients with Canavan disease its concentration is in the range of 1,440 ±873 µmol/mmol creatinine. High levels of NAA can also be detected in plasma, CSF, and brain tissue. Aspartoacylase in fibroblasts is often used to confirm the diagnosis but is not necessary. The activity of aspartoacylase in the fibroblasts of obligate carriers is half or less the activity found in normal individuals. Genotyping of patients with Canavan disease should always be done and will show mutations of ASPA. The differential diagnosis of Canavan disease should include Alexander disease, which is another leukodystrophy associated with macrocephaly. Alexander disease is caused by a defect in the synthesis of glial fibrillary acidic protein, and the diagnosis can be ruled out by molecular diagnosis on blood lymphocytes.
There are 2 predominant pathogenic variants leading to Canavan disease in the Ashkenazi Jewish population. The first is an amino acid substitution (E285A) in which glutamic acid is substituted for alanine. This mutation is the most frequent and encompasses 83% of 100 mutant alleles examined in Ashkenazi Jewish patients. The 2nd common pathogenic variant is a change from tyrosine to a nonsense mutation, leading to a stop in the coding sequence (Y231X). This accounts for 13% of mutant alleles. In the non-Jewish population, more diverse pathogenic variants have been observed, and the 2 variants common in Jewish people are rare. A different mutation (A305E), the substitution of alanine for glutamic acid, accounts for 40% of 62 mutant alleles in non-Jewish patients. More than 50 pathogenic variants are described in the non-Jewish population. With Canavan disease, it is important to obtain a molecular diagnosis because this will lead to accurate counseling and prenatal guidance for the family. If the mutations are not known, prenatal diagnosis relies on the NAA level in the amniotic fluid. In Ashkenazi Jewish patients, the carrier frequency can be as high as 1:40, which is close to that of Tay-Sachs disease. Carrier screening for Canavan disease is available for Jewish individuals. Genotype phenotype correlation and aspartoacylase expression show that expression studies may aid in understanding the disease.

Patients with juvenile or mild forms of Canavan disease have been compound heterozygotes with a mild pathogenic variant on one allele and a severe variant on the other allele. Mild variants include p.Tyr288Cys and p.Arg71His.

**Treatment and Prevention**

No specific treatment is currently available. Recent studies of gene therapy using recombinant adeno-associated viruses (rAAVs) have shown some positive results in rescuing knockout mice but have yet to be tested in humans. Feeding problems and seizures should be treated on an individual basis. Genetic counseling, carrier testing, and prenatal diagnosis are the only methods of prevention. Gene therapy attempts in children with Canavan disease have shown lack of long-term adverse events, some decrease in the brain elevation of N-acetylaspartic acid, improved seizure frequency, and stabilization of overall clinical status.
Bibliography

Mitochondrial β-oxidation of fatty acids is an essential energy-producing pathway. It is particularly important during prolonged periods of starvation and
during periods of reduced caloric intake caused by gastrointestinal illness or increased energy expenditure during febrile illness. Under these conditions, the body switches from using predominantly carbohydrate to predominantly fat as its major fuel. Fatty acids are also important fuels for exercising skeletal muscle and are the preferred substrate for normal cardiac metabolism. In these tissues, fatty acids are completely oxidized to carbon dioxide and water. The end products of hepatic fatty acid oxidation are the ketone bodies β-hydroxybutyrate and acetoacetate. These cannot be oxidized by the liver but are exported to serve as important fuels in peripheral tissues, particularly the brain, where ketone bodies can partially substitute for glucose during periods of fasting.

Genetic defects have been identified in almost all the known steps in the fatty acid oxidation pathway; all are recessively inherited (Table 104.1).

* Also known as glutaric acidemia type II or multiple acyl-CoA dehydrogenase defect (MADD).

Also known as glutaric acidemia type II or multiple acyl-CoA dehydrogenase defect (MADD).

AFLP, Acute fatty liver of pregnancy; CoA, coenzyme A; ETF, electron transport flavoprotein; HELLP, hemolysis, elevated liver enzymes, low platelets; MTP, mitochondrial trifunctional protein; NH3, ammonia.

Clinical manifestations characteristically involve tissues with a high β-oxidation flux, including liver, skeletal, and cardiac muscle. The most common presentation is an acute episode of life-threatening coma, hepatic encephalopathy, and hypoglycemia induced by a period of fasting resulting from defective hepatic ketogenesis. Other manifestations may include chronic cardiomyopathy and muscle weakness or exercise-induced acute rhabdomyolysis. The fatty acid oxidation defects can often be asymptomatic during periods when there is no fasting stress or increased energy demand. Acutely presenting disease may be misdiagnosed as Reye syndrome or, if fatal, as sudden unexpected infant death. Fatty acid oxidation disorders are easily overlooked because the only specific clue to the diagnosis may be the finding of inappropriately low concentrations of plasma or urinary ketones in an infant who has hypoglycemia, unless specialized metabolic testing is performed. Genetic defects in ketone body utilization may also be overlooked because ketonemia is an expected finding with fasting hypoglycemia. In some circumstances, clinical manifestations appear to arise from toxic effects of fatty acid metabolites rather than inadequate energy production. These circumstances include certain long-chain fatty acid oxidation disorders (deficiencies of long-chain 3-hydroxyacyl dehydrogenase [LCHAD], carnitine palmitoyltransferase-IA [CPT-IA], or mitochondrial trifunctional protein [MTP; also known as TFP]) in which the presence of a homozygous affected fetus increases the risk of a life-threatening
illness in the heterozygote mother, resulting in **acute fatty liver of pregnancy** (AFLP) or **preeclampsia with HELLP** (hemolysis, elevated liver enzymes, low platelets) syndrome. The mechanism of these obstetric complications is likely accumulation of toxic intermediates. Malformations of the brain and kidneys have been described in severe deficiencies of electron transfer flavoprotein (ETF), ETF dehydrogenase (ETF-DH), and carnitine palmitoyltransferase-II (CPT-II), which might reflect in utero toxicity of fatty acid metabolites or a developmental role for these enzymes. Progressive retinal degeneration, peripheral neuropathy, and chronic progressive liver disease have been identified in LCHAD and MTP deficiency. Newborn screening programs using tandem mass spectrometry detect characteristic plasma acylcarnitine profiles in most of these disorders, allowing early and presymptomatic diagnosis. Screening programs have demonstrated that all the fatty acid oxidation disorders combined are among the most common inborn errors of metabolism, at least in predominantly Caucasian populations.

Figs. 104.1 and 104.2 outline the steps involved in the oxidation of a typical long-chain fatty acid. In the **carnitine cycle**, long-chain fatty acids are transported across the barrier of the inner mitochondrial membrane as acylcarnitine esters. (Medium-chain fatty acids, which are commonly provided as medium-chain triglyceride supplementation in infants who are failing to thrive, can bypass the carnitine cycle and enter the mitochondrial β-oxidation cycle directly.) Within the mitochondria, successive turns of the 4-step β-oxidation cycle convert the **coenzyme A (CoA)**–activated fatty acids to acetyl-CoA units. Two or 3 different specific isoenzymes are needed for each of these β-oxidation steps to accommodate the different chain-length fatty acyl-CoA species. The electrons generated in the first β-oxidation step (acyl-CoA dehydrogenase) are carried by the **electron transfer pathway** to the **electron transport chain** at the level of coenzyme Q for adenosine triphosphate production; while electrons generated from the 3rd step (3-hydroxyacyl-CoA dehydrogenase) enter the **electron transport chain** at the level of complex 1. Most of the acetyl-CoA generated from fatty acid β-oxidation in the liver flows through the **pathway of ketogenesis** to form β-hydroxybutyrate and acetoacetate, whereas in muscle and heart the fatty acids are completely oxidized to CO₂ and water.
FIG. 104.1  Mitochondrial fatty acid oxidation. Carnitine enters the cell through the action of the organic cation/carnitine transporter (OCTN2). Palmitate, a typical 16-carbon long-chain fatty acid, is transported across the plasma membrane and can be activated to form a long-chain (LC) fatty acyl coenzyme A (CoA). It then enters into the carnitine cycle, where it is transesterified by carnitine palmitoyltransferase-I (CPT-I), translocated across the inner mitochondrial membrane by carnitine/acylcarnitine translocase (TRANS), and then reconverted into a long-chain fatty acyl-CoA by carnitine palmitoyltransferase-II (CPT-II) to undergo β-oxidation. Very-long-chain acyl-CoA dehydrogenase (VLCAD/LCAD) leads to the production of $\text{C}_{16}-\text{C}_{10}$ 2,3-enoyl CoA.

Mitochondrial trifunctional protein (MTP) contains the activities of enoyl CoA hydratase (hydratase), 3-OH-hydroxyacyl-CoA dehydrogenase (3-OH-ACD), and β-ketothiolase (thiolase). Acetyl-CoA, reduced form of flavin adenine dinucleotide (FADH), and reduced form of nicotinamide adenine dinucleotide (NADH) are produced. Medium- and short-chain fatty acids (C8-4) can enter the mitochondrial matrix independent of the carnitine cycle. Medium-chain acyl-CoA dehydrogenase (MCAD), short-chain acyl-CoA dehydrogenase (SCAD), and short-chain hydroxy acyl-CoA dehydrogenase (SCHAD) are required. Acetyl-CoA can then enter the Krebs (TCA) cycle. Electrons are transported from FADH to the respiratory chain via the electron transfer flavoprotein (ETF) and the electron transfer flavoprotein dehydrogenase (ETF-DH). NADH enters the electron transport chain through complex I. In liver, acetyl-CoA can be converted into hydroxymethylglutaryl (HMG) CoA by β-hydroxy-β-methylglutaryl-CoA synthase (HMG CoA synthase) and then the ketone body acetocacetate by the action of β-hydroxy-β-methylglutaryl-CoA lyase (HMG-CoA lyase).
FIG. 104.2  Pathway of mitochondrial oxidation of palmitate, a typical 16-carbon long-chain fatty acid. Enzyme steps include carnitine palmitoyltransferase (CPT) 1 and 2, carnitine/acylcarnitine translocase (TRANS), electron transfer flavoprotein (ETF), ETF dehydrogenase (ETF-DH), acyl-CoA dehydrogenase (ACD), enoyl-CoA hydratase (hydratase), 3-hydroxy-acyl-CoA dehydrogenase (3-OH-ACD), β-ketothiolase (thiolase), and others.
β-hydroxy-β-methylglutaryl-CoA (HMG-CoA) synthase, and lyase.

Defects in the β-Oxidation Cycle

Medium-Chain Acyl-CoA Dehydrogenase Deficiency

Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency is the most common fatty acid oxidation disorder. The disorder shows a strong founder effect; most patients have a northwestern European ancestry, and the majority of these patients are homozygous for a single common MCAD missense mutation, an A-G transition at cDNA position 985 (c.985A>G) that changes a lysine to glutamic acid at residue 329 (p.K329E).

Clinical Manifestations

Previously undiagnosed affected patients usually present in the 1st 3 mo to 5 yr of life with episodes of acute illness triggered by prolonged fasting (>12-16 hr). Signs and symptoms include vomiting and lethargy, which rapidly progress to coma or seizures and cardiorespiratory collapse. Sudden unexpected infant death may occur. The liver may be slightly enlarged with fat deposition. Attacks are rare until the infant is beyond the 1st few mo of life, presumably because of more frequent feedings at a younger age. Affected older infants are at higher risk of illness as they begin to fast through the night or are exposed to fasting stress during an intercurrent childhood illness. Presentation in the 1st days of life with neonatal hypoglycemia has been reported in newborns who were fasted inadvertently or were being breastfed. Diagnosis of MCAD has occasionally been documented in previously healthy teenage and adult individuals, indicating that even patients who have been asymptomatic in infancy are still at risk for metabolic decompensation if exposed to sufficient periods of fasting. An unknown number of patients may remain asymptomatic. Prior to routine newborn screening testing, as many as 25% of MCAD-deficient patients died or suffered severe brain damage from their first episode. Most patients are now diagnosed in the newborn period by blood spot acylcarnitine screening, allowing the initiation of early treatment and prevention of many of the severe signs and symptoms. In some reports, newborns with MCAD deficiency presented acutely before newborn screening results were obtained; neonates who
are exclusively breastfed are at higher risk because of early poor caloric intake.

**Laboratory Findings**

During acute episodes, hypoglycemia is usually present. Plasma and urinary ketone concentrations are inappropriately low (hypoketotic hypoglycemia). Because of the hypoketonemia, there is little or no metabolic acidosis, which is expected to be present in many children with hypoglycemia. Liver function tests (LFTs) are abnormal, with elevations of liver enzymes (alanine transaminase, aspartate transaminase), elevated blood ammonia, and prolonged prothrombin and partial thromboplastin times. Liver biopsy at times of acute illness shows microvesicular or macrovesicular steatosis from triglyceride accumulation. During fasting stress or acute illness, urinary organic acid profiles by gas chromatography/mass spectrometry show inappropriately low concentrations of ketones and elevated levels of medium-chain dicarboxylic acids (adipic, suberic, and sebacic acids) that derive from microsomal and peroxisomal omega oxidation of accumulated medium-chain fatty acids. Plasma and tissue concentrations of total carnitine are reduced to 25–50% of normal, and the fraction of total esterified carnitine is increased. This pattern of secondary carnitine deficiency is seen in most fatty acid oxidation defects and reflects competition between increased acylcarnitine levels and free carnitine for transport at the renal tubular plasma membrane. Significant exceptions to this rule are the plasma membrane carnitine transporter, CPT-IA, and β-hydroxy-β-methylglutaryl-CoA (HMG-CoA) synthase deficiencies, which do not manifest secondary carnitine deficiency.

Diagnostic metabolite patterns for MCAD deficiency include increased plasma C₆:0, C₈:0, C₁₀:0, and C₁₀:1 acylcarnitine species and increased urinary acylglycines, including hexanoylglycine, suberylglycine, and 3-phenylpropionylglycine. Newborn screening, which almost all babies born in the United States receive, can detect presymptomatic MCAD deficiency based on these abnormal acylcarnitines in filter paper blood spots. The diagnosis can be confirmed by finding the common A985G mutation or sequencing the *MCAD* gene. A 2nd common variant, T199C, has been detected in infants identified by newborn screening. Interestingly, this allele has not been seen to date in symptomatic MCAD patients; it may represent a milder mutation.

**Treatment**
Acute illnesses should be promptly treated with intravenous (IV) fluids containing 10% dextrose to correct or prevent hypoglycemia and to suppress lipolysis as rapidly as possible (see Chapter 111). Chronic therapy consists of avoiding fasting. This usually requires simply adjusting the diet to ensure that overnight fasting periods are limited to <10-12 hr. Restricting dietary fat or treatment with carnitine is controversial. The need for active therapeutic intervention for individuals with the T199C variant has not yet been established.

**Prognosis**
Up to 25% of unrecognized patients may die during their first attack of illness. There is frequently a history of a previous sibling death that is presumed to be from an unrecognized MCAD deficiency. Some patients may sustain permanent brain injury during an attack of profound hypoglycemia. For survivors without brain damage, the prognosis is excellent because progressive cognitive impairment or cardiomyopathy does not occur in MCAD deficiency. Fasting tolerance improves with age, and the risk of illness decreases. Because as many as 35% of affected patients have never had an episode, testing of siblings of affected patients is important to detect asymptomatic family members.

**Very-Long-Chain Acyl-CoA Dehydrogenase Deficiency**
Very-long-chain acyl-CoA dehydrogenase (VLCAD) deficiency is the second most commonly diagnosed disorder of fatty acid oxidation. It was originally termed “long-chain acyl-CoA dehydrogenase deficiency” before the existence of the inner mitochondrial membrane-bound VLCAD was known. *All patients previously diagnosed as having long-chain acyl-CoA dehydrogenase deficiency have VLCAD gene defects.* Patients with VLCAD deficiency have no ability to oxidize physiologic long-chain fatty acids and are usually more severely affected than those with MCAD deficiency, who have a milder oxidative defect. VLCAD deficiency presents earlier in infancy and has more chronic problems with muscle weakness or episodes of muscle pain and rhabdomyolysis. Cardiomyopathy may be present during acute attacks provoked by fasting. The left ventricle may be hypertrophic or dilated and may show poor contractility on echocardiography. Sudden unexpected death has occurred in several patients, but most who survive the initial episode show improvement, including normalization
of cardiac function. Other physical and routine laboratory features are similar to those of MCAD deficiency, including secondary carnitine deficiency. The urinary organic acid profile shows a nonketotic dicarboxylic aciduria with increased levels of C₆-₁₂ dicarboxylic acids. Diagnosis may be suggested by an abnormal acylcarnitine profile with plasma or blood spot C₁₄:0, 14:1, 14:2 acylcarnitine species. However, the specific diagnosis requires mutational analysis of the VLCAD gene. Treatment is based primarily on avoidance of fasts for >10-12 hr. Continuous intragastric feeding is useful in some patients.

**Short-Chain Acyl-CoA Dehydrogenase Deficiency**

A small number of patients with 2 null mutations in the short-chain acyl-CoA dehydrogenase (SCAD) gene have been described with variable phenotype. Most individuals classified as being SCAD deficient actually have polymorphic DNA changes in the SCAD gene; for example, 2 common polymorphisms are G185S and R147W, which are homozygously present in 7% of the population. Some investigators argue that these variants may be susceptibility factors, which require a 2nd, as yet unknown, genetic mutation to express a clinical phenotype; many other investigators believe that SCAD deficiency is a harmless biochemical condition. This autosomal recessive disorder presents with neonatal hypoglycemia and may have normal levels of ketone bodies. The diagnosis is indicated by elevated levels of butyrylcarnitine (C₄-carnitine) on newborn blood spots or plasma and increased excretion of urinary ethylmalonic acid and butyrylglycine. These metabolic abnormalities are most pronounced in patients with null mutations and are variably present in patients who are homozygous for the common polymorphisms.

The need for treatment in SCAD deficiency has not yet been established. It has been proposed that long-term evaluation of asymptomatic individuals is necessary to determine whether this is or is not a real disease. Most individuals with SCAD deficiency remain asymptomatic throughout life, but there may be a subset of individuals with severe manifestations, including dysmorphic facial features, feeding difficulties/failure to thrive, metabolic acidosis, ketotic hypoglycemia, lethargy, developmental delay, seizures, hypotonia, dystonia, and myopathy.
Long-Chain 3-Hydroxyacyl-CoA Dehydrogenase/Mitochondrial Trifunctional Protein Deficiency

The LCHAD enzyme is part of the MTP, which also contains 2 other steps in β-oxidation: long-chain 2,3-enoyl CoA hydratase and long-chain β-ketothiolase. MTP is a hetero-octameric protein composed of 4 α and 4 β chains derived from distinct contiguous genes sharing a common promoter region. In some patients, only the LCHAD activity of the MTP is affected (LCHAD deficiency), whereas others have deficiencies of all 3 activities (MTP deficiency).

Clinical manifestations include attacks of acute hypoketotic hypoglycemia similar to MCAD deficiency; however, patients often show evidence of more severe disease, including cardiomyopathy, muscle cramps and weakness, and abnormal liver function (cholestasis). Toxic effects of fatty acid metabolites may produce pigmented retinopathy leading to blindness, progressive liver failure, peripheral neuropathy, and rhabdomyolysis. Life-threatening obstetric complications (AFLP, HELLP syndrome) have been observed in heterozygous mothers carrying homozygous fetuses affected with LCHAD/MTP deficiency. Sudden unexpected infant death may occur. The diagnosis is indicated by elevated levels of blood spot or plasma 3-hydroxy acylcarnitines of chain lengths C_{16} -C_{18}. Urinary organic acid profile in patients may show increased levels of 3-hydroxydicarboxylic acids of chain lengths C_{6} -C_{14}. Secondary carnitine deficiency is common. A common mutation in the α subunit, E474Q, is seen in more than 60% of LCHAD-deficient patients. This mutation in the fetus is especially associated with the obstetric complications, but other mutations in either subunit may also be linked to maternal illness.

Treatment is similar to that for MCAD or VLCAD deficiency; that is, avoiding fasting stress. Some investigators have suggested that dietary supplements with medium-chain triglyceride oil to bypass the defect in long-chain fatty acid oxidation and docosahexaenoic acid (for protection against the retinal changes) may be useful. Liver transplantation has been attempted in patients with severe liver failure, but does not ameliorate the metabolic abnormalities or prevent the myopathic or retinal complications.

Short-Chain 3-Hydroxyacyl-CoA Dehydrogenase
Deficiency

Only 14 patients with proven mutations of short-chain 3-hydroxyacyl-CoA dehydrogenase (SCHAD) have been reported. Most cases with recessive mutations of the SCHAD gene have presented with episodes of hypoketotic hypoglycemia that was caused by hyperinsulinism. In contrast to those with other forms of fatty acid oxidation disorders, these patients required specific therapy with diazoxide for hyperinsulinism to avoid recurrent hypoglycemia. A single patient with compound heterozygous mutations presented with fulminant hepatic failure at age 10 mo. The SCHAD protein has a nonenzymatic function in which it directly interacts with glutamate dehydrogenase (GDH) to inhibit its activity. In the absence of SCHAD protein, this inhibition is removed, leading to upregulation of GDH enzyme activity, a recognized cause of hyperinsulinism usually from activating mutations of the GDH gene. Severe deficiency of SCHAD protein often presents predominantly as protein-sensitive hypoglycemia rather than as fasting hypoglycemia. It appears that if SCHAD protein is present, inhibition of GDH is maintained even when there is no SCHAD enzyme activity; these patients may present with a more traditional fatty acid oxidation defect. Specific metabolic markers for SCHAD deficiency include elevated plasma C4-hydroxy acylcarnitine and urine 3-hydroxyglutaric acid. Successful newborn screening for SCHAD deficiency has been recorded, but the sensitivity of the process has not yet been established.

**Treatment** of SCHAD-deficient patients with hyperinsulinism is with diazoxide. There is insufficient experience with the nonhyperinsulinemic form of SCHAD deficiency at present to recommend treatment modalities, but prevention of fasting seems advisable.

Short-Chain 2,3-Enoyl-CoA Hydratase Deficiency

This disorder, resulting from mutations in the ECHS1 gene, has only recently been defined. Many patients were identified through exome sequencing, and currently there are approximately 20 cases in the literature. The disorder affects a shared pathway of short-chain fatty acid and valine metabolism. The clinical phenotypes are more characteristic of mitochondrial disorders of pyruvate metabolism with predominantly a Leigh-like disease (see Chapter 616.2) with profound and often-fatal lactic acidosis. Currently, no treatment modalities or specific biomarkers have been established. Several patients were found to
excrete increased levels of methacrylylglycine, a highly reactive and potentially toxic intermediate; 2-methyl-2.3 dihydroxybutyrate; S-(2-carboxypropyl) cysteine; and S-(2-carboxpropyl) cysteamine.

**Defects in the Carnitine Cycle**

**Plasma Membrane Carnitine Transport Defect (Primary Carnitine Deficiency)**

Primary carnitine deficiency is the only genetic defect in which carnitine deficiency is the cause, rather than the consequence, of impaired fatty acid oxidation. The most common presentation is progressive cardiomyopathy with or without skeletal muscle weakness beginning at age 1-4 yr. A smaller number of patients may present with fasting hypoketotic hypoglycemia in the 1st yr of life, before the cardiomyopathy becomes symptomatic. The underlying defect involves the plasma membrane sodium gradient–dependent carnitine transporter that is present in heart, muscle, and kidney. This transporter is responsible both for maintaining intracellular carnitine concentrations 20-50–fold higher than plasma concentrations and for renal conservation of carnitine.

**Diagnosis** of the carnitine transporter defect is aided by patients having extremely reduced carnitine levels in plasma and muscle (1–2% of normal). Heterozygote parents have plasma carnitine levels approximately 50% of normal. Fasting ketogenesis may be normal because liver carnitine transport is normal, but it may become impaired if dietary carnitine intake is interrupted. The fasting urinary organic acid profile may show a hypoketotic dicarboxylic aciduria pattern if hepatic fatty acid oxidation is impaired, but is otherwise unremarkable. The defect in carnitine transport can be demonstrated clinically by the severe reduction in renal carnitine threshold or by in vitro assay of carnitine uptake using cultured fibroblasts or lymphoblasts. Mutations in the organic cation/carnitine transporter (OCTN2) underlie this disorder. **Treatment** with pharmacologic doses of oral carnitine (100-200 mg/kg/day) is highly effective in correcting the cardiomyopathy and muscle weakness, as well as any impairment in fasting ketogenesis. Muscle total carnitine concentrations remain <5% of normal on treatment.

**Carnitine Palmitoyltransferase-IA Deficiency**
Several dozen infants and children have been described with a deficiency of the liver and kidney CPT-I isozyme (CPT-IA). **Clinical manifestations** include fasting-induced hypoketotic hypoglycemia, occasionally with extremely abnormal LFTs and rarely with renal tubular acidosis. The heart and skeletal muscle are not involved because the muscle isozyme is unaffected. Fasting urinary organic acid profiles sometimes show a hypoketotic C₆-C₁₂ dicarboxylic aciduria but may be normal. Plasma acylcarnitine analysis demonstrates mostly free carnitine with very little acylated carnitine. This observation has been used to identify CPT-IA deficiency on newborn screening by tandem mass spectrometry. CPT-IA deficiency is the only fatty acid oxidation disorder in which plasma total carnitine levels may be elevated, often to 150–200% of normal. This phenomenon is explained by the absence of inhibitory effects of long-chain acylcarnitines on the renal tubular carnitine transporter in CPT-IA deficiency. The enzyme defect can be demonstrated in cultured fibroblasts or lymphoblasts. CPT-IA deficiency in the fetus has been associated in a single case report with AFLP in the mother. A common variant in the CPTIA gene (c.1436C>t, p.P479L) has been identified in individuals of Inuit background in the United States, Canada, and Greenland. This variant is associated with an increased risk for sudden infant death syndrome (SIDS) in the Inuit population. The variant can be detected by newborn screening; enzyme activity is reduced by 80%, and regulation by malonyl-CoA is lost. It has not been established whether CPT-IA (c.1436C>t, p.P479L) is a pathologic enzyme variant or an adaptation to ancient Inuit high-fat diets. **Treatment** for the severe form of CPT-IA deficiency that is found in non-Inuit populations is similar to that for MCAD deficiency, with avoidance of situations where fasting ketogenesis is necessary. The need for treatment of the Inuit variant has not yet been determined.

**Carnitine:Acylcarnitine Translocase Deficiency**

This defect of the inner mitochondrial membrane carrier protein for long-chain acylcarnitines blocks the entry of long-chain fatty acids into the mitochondria for oxidation. The clinical phenotype of this disorder is characterized by a severe and generalized impairment of fatty acid oxidation. Most newborn patients present with attacks of fasting-induced hypoglycemia, hyperammonemia, and cardiorespiratory collapse. All symptomatic newborns have had evidence of cardiomyopathy and muscle weakness. Several patients with a partial translocase deficiency and milder disease without cardiac involvement have also been
identified. No distinctive urinary or plasma organic acids are noted, although increased levels of plasma long-chain acylcarnitines of chain lengths C\textsubscript{16} - C\textsubscript{18} are reported. **Diagnosis** can be confirmed using genetic analysis. Functional carnitine:acylcarnitine translocase activity can be measured in cultured fibroblasts or lymphoblasts. **Treatment** is similar to that of other long-chain fatty acid oxidation disorders.

**Carnitine Palmitoyltransferase-II Deficiency**

Three forms of CPT-II deficiency have been described. A **severe neonatal lethal** presentation associated with a profound enzyme deficiency and early death has been reported in several newborns in association with dysplastic kidneys, cerebral malformations, and mild facial anomalies. A milder defect is associated with an **adult presentation** of episodic rhabdomyolysis. The first episode usually does not occur until late childhood or early adulthood. Attacks are frequently precipitated by prolonged exercise. There is aching muscle pain and myoglobinuria that may be severe enough to cause renal failure. Serum levels of creatine kinase are elevated to 5,000-100,000 units/L. Hypoglycemia has not been described, but fasting may contribute to attacks of myoglobinuria. Muscle biopsy shows increased deposition of neutral fat. This adult myopathic presentation of CPT-II deficiency is associated with a common mutation, c.338C>T, p.S113L. This mutation produces a heat-labile protein that is unstable to increased muscle temperature during exercise resulting in the myopathic presentation. The 3rd, **intermediate form** of CPT-II deficiency presents in infancy or early childhood with fasting-induced hepatic failure, cardiomyopathy, and skeletal myopathy with hypoketotic hypoglycemia, but is not associated with the severe developmental changes seen in the neonatal lethal presentation. This pattern of illness is similar to that seen in VLCAD deficiency, and management is identical.

**Diagnosis** of all forms of CPT-II deficiency can be made by a combination of molecular genetic analysis and demonstrating deficient enzyme activity in muscle or other tissues and in cultured fibroblasts.

**Defects in the Electron Transfer Pathway**

**Electron Transfer Flavoprotein** and **Electron...**
Transfer Flavoprotein Dehydrogenase Deficiencies (Glutaric Acidemia Type 2, Multiple Acyl-CoA Dehydrogenation Defects)

ETF and ETF-DH function to transfer electrons into the mitochondrial electron transport chain from dehydrogenation reactions catalyzed by VLCAD, MCAD, and SCAD, as well as by glutaryl-CoA dehydrogenase and 4 enzymes involved in branched-chain amino acid (BCAA) oxidation. Deficiencies of ETF or ETF-DH produce illness that combines the features of impaired fatty acid oxidation and impaired oxidation of several amino acids. Complete deficiencies of either protein are associated with severe illness in the newborn period, characterized by acidosis, hypoketotic hypoglycemia, coma, hypotonia, cardiomyopathy, and an unusual odor of sweaty feet caused by isovaleryl-CoA dehydrogenase inhibition. Some affected neonates have had congenital facial dysmorphism and polycystic kidneys similar to that seen in severe CPT-II deficiency, which suggests that toxic effects of accumulated metabolites may occur in utero.

**Diagnosis** can be made from the newborn blood spot acylcarnitine profile and urinary organic acids; both tests show abnormalities corresponding to blocks in the oxidation of fatty acids (ethylmalonate and C₆-C₁₀ dicarboxylic acids), lysine (glutarate), and BCAAs (isovaleryl-, isobutyryl-, and α-methylbutyryl-glycine). The diagnosis can be confirmed by genetic testing for ETF (2 genes, A and B) and ETF dehydrogenase. Most severely affected infants do not survive the neonatal period.

Partial deficiencies of ETF and ETF-DH produce a disorder that may mimic MCAD deficiency or other milder fatty acid oxidation defects. These patients have attacks of fasting hypoketotic coma. The urinary organic acid profile reveals primarily elevations of dicarboxylic acids and ethylmalonate, derived from short-chain fatty acid intermediates. Secondary carnitine deficiency is present. Some patients with mild forms of ETF/ETF-DH deficiency may benefit from treatment with high doses of riboflavin, a precursor of the various flavoproteins involved in electron transfer.

Defects in the Ketone Synthesis Pathway

The final steps in production of ketones from mitochondrial fatty acid β-oxidation convert acetyl-CoA to acetoacetate through 2 enzymes of the HMG-
β-Hydroxy-β-Methylglutaryl-CoA Synthase Deficiency

See Chapter 103.6.

HMG-CoA synthase is the rate-limiting step in the conversion of acetyl-CoA derived from fatty acid β-oxidation in the liver to ketones. Several patients with this defect have been identified. The presentation is one of fasting hypoketotic hypoglycemia without evidence of impaired cardiac or skeletal muscle function. Urinary organic acid profile shows only a nonspecific hypoketotic dicarboxylic aciduria. Plasma and tissue carnitine levels are normal, in contrast to all the other disorders of fatty acid oxidation. A separate synthase enzyme, present in cytosol for cholesterol biosynthesis, is not affected. The HMG-CoA synthase defect is expressed only in the liver (and kidney) and cannot be demonstrated in cultured fibroblasts. The diagnosis can be made by genetic mutation analysis. Avoiding fasting is usually a successful treatment.

β-Hydroxy-β-Methylglutaryl-CoA Lyase Deficiency (3 Hydroxy-3-Methylgutaric Aciduria)

See Chapter 103.6.

Defects in Ketone Body Utilization

The ketone bodies, β-hydroxybutyrate and acetoacetate, are the end products of hepatic fatty acid oxidation and are important metabolic fuels for the brain during fasting. Three defects in utilization of ketones in brain and other peripheral tissues present as episodes of hyperketotic coma, with or without hypoglycemia.

Monocarboxylate Transporter-1 Deficiency

About 10 patients have been described with recurrent episodes of potentially lethal ketoacidosis, with or without hypoglycemia, caused by deficiency of monocarboxylate transporter 1 (MCT1), a plasma membrane carrier encoded by
SLC16A1 that is required to transport ketones into tissues from plasma. Although the first cases identified were homozygous for inactivating mutations of MCT1, heterozygous carriers can also be affected. Affected patients developed severe ketoacidosis provoked by fasting or infections in their 1st years of life; hypoglycemia was not always present. The differential includes ketotic hypoglycemia associated with milder forms of glycogen storage disease, such as phosphorylase or phosphorylase kinase deficiency (see Chapter 105).

**Treatment** for acute episodes includes IV dextrose to suppress lipolysis and inhibit ongoing ketogenesis. Long-term treatment includes avoidance of prolonged fasting stress. The **diagnosis** can be suspected by unusually severe ketosis and delayed suppression of ketones after starting treatment with dextrose. There are no specific metabolic markers or newborn screening methods. The diagnosis can be established by genetic sequencing of SLC16A1.

**Succinyl-CoA:3-Ketoacid-CoA Transferase Deficiency**

See Chapter 103.6.

Several patients with succinyl-CoA:3-ketoacid-CoA transferase (SCOT) deficiency have been reported. The characteristic presentation is an infant with recurrent episodes of severe ketoacidosis induced by fasting. Plasma acylcarnitine and urine organic acid abnormalities do not distinguish SCOT deficiency from other causes of ketoacidosis. **Treatment** of episodes requires infusion of glucose and large amounts of bicarbonate until metabolically stable. Patients usually exhibit inappropriate hyperketonemia even between episodes of illness. SCOT is responsible for activating acetoacetate in peripheral tissues, using succinyl CoA as a donor to form acetoacetyl-CoA. Deficient enzyme activity can be demonstrated in the brain, muscle, and fibroblasts from affected patients. The gene has been cloned, and numerous mutations have been characterized.

**β-Ketothiolase Deficiency**

See Chapter 103.6.

**Bibliography**

104.2

Disorders of Very-Long-Chain Fatty Acids and Other Peroxisomal Functions

*Michael F. Wangler, Gerald V. Raymond*
Peroxisomal Disorders

Disorders of very-long-chain fatty acids (VLCFAs) fall within the broader group of peroxisomal diseases. The **peroxisomal diseases** are genetically determined disorders caused either by the failure to form or maintain the peroxisome or by a defect in the function of a single protein that is normally located in this organelle. These disorders cause serious disability in childhood and occur more frequently and present a wider range of phenotypes than recognized in the past. Many, but not all, peroxisomal disorders are associated with elevations of VLCFAs. This discussion addresses the broader group of peroxisomal disorders with a focus on pediatric presentations.

Etiology

Peroxisomal disorders are subdivided into two major categories (**Table 104.2**). In the **peroxisomal biogenesis disorders (PBDs)** the basic defect is the failure to import 1 or more proteins into the organelle. In the other group, defects affect a single peroxisomal protein (**single-enzyme defects**). The peroxisome is present in all cells except mature erythrocytes and is a subcellular organelle surrounded by a single membrane; >50 peroxisomal enzymes are identified. Some enzymes are involved in production and decomposition of hydrogen peroxide and others in lipid and amino acid metabolism. Most peroxisomal enzymes are first synthesized in their mature form on free polyribosomes and enter the cytoplasm. Proteins that are destined for the peroxisome contain specific **peroxisome targeting sequences** (PTSs). Most peroxisomal matrix proteins contain **PTS1**, a 3-amino acid sequence at the carboxyl terminus. **PTS2** is an aminoterminal sequence that is critical for the import of enzymes involved in plasmalogen and branched-chain fatty acid metabolism. Import of proteins
involves a complex series of reactions that involves at least 23 distinct proteins. These proteins, referred to as *peroxins*, are encoded by *PEX* genes.

**Epidemiology**

Except for X-linked adrenoleukodystrophy (ALD), all the peroxisomal disorders listed in Table 104.2 are **autosomal recessive diseases**. ALD is the most common peroxisomal disorder, with an estimated incidence of 1 in 17,000 live births. The combined incidence of the other peroxisomal disorders is estimated to be 1 in 50,000 live births, although with broader newborn screening it is expected that the actual incidences of all of the disorders of very-long-chain fatty acids will be more accurately established.

**Pathology**

Absence or reduction in the number of peroxisomes is pathognomonic for disorders of peroxisome biogenesis. In most disorders, membranous sacs contain peroxisomal integral membrane proteins, which lack the normal complement of matrix proteins; these are peroxisome “ghosts.” Pathologic changes are observed in most organs and include profound and characteristic defects in neuronal migration, micronodular cirrhosis of the liver, renal cysts, chondrodysplasia punctata, sensorineural hearing loss, retinopathy, congenital heart disease, and dysmorphic features.

**Pathogenesis**
All pathologic changes likely are secondary to the peroxisome defect. Multiple peroxisomal enzymes fail to function in the PBDs (Table 104.3). The enzymes that are diminished or absent are synthesized but are degraded abnormally fast because they may be unprotected outside the peroxisome. It is not clear how defective peroxisome functions lead to the widespread pathologic manifestations.

Mutations in 12 different *PEX* genes have been identified in PBDs. The pattern and severity of pathologic features vary with the nature of the import defects and the degree of import impairment. These gene defects lead to disorders that were named before their relationship to the peroxisome was recognized, namely, Zellweger syndrome, neonatal ALD, infantile Refsum disease, and rhizomelic chondrodysplasia punctata (RCDP). The first 3 disorders are considered to form a *clinical continuum*, with Zellweger syndrome the most severe, infantile Refsum disease the least severe, and neonatal ALD intermediate. They can be caused by mutations in any of the 11 genes involved in peroxisome assembly. The specific gene defects cannot be distinguished by clinical features. The clinical severity varies with the degree to which protein import is impaired. Mutations that abolish import completely are often associated with the Zellweger syndrome phenotype, whereas a missense mutation, in which some degree of import function is retained, leads to the
somewhat milder phenotypes. A defect in *PEX7*, which involves the import of proteins that utilize PTS2, is associated with RCDP. *PEX7* defects that leave import partially intact are associated with milder phenotypes, some of which resemble classic (adult) Refsum disease.

The genetic disorders that involve single peroxisomal enzymes usually have clinical manifestations that are more restricted and relate to the single biochemical defect. The primary adrenal insufficiency of ALD is caused by accumulation of VLCFAs in the adrenal cortex, and the peripheral neuropathy in adult Refsum disease is caused by the accumulation of phytanic acid in Schwann cells and myelin.

**Zellweger Spectrum Disorder**

Newborn infants with Zellweger syndrome show striking and consistent recognizable abnormalities. Of central diagnostic importance are the typical facial appearance (high forehead, unslanting palpebral fissures, hypoplastic supraorbital ridges, and epicanthal folds; Fig. 104.3), severe weakness and hypotonia, neonatal seizures, and eye abnormalities. Because of the hypotonia and craniofacial appearance, Down syndrome may be suspected. Infants with Zellweger syndrome rarely live more than a few months. More than 90% show postnatal growth failure. Table 104.4 lists the main clinical abnormalities.
FIG. 104.3 Zellweger syndrome. Three affected neonates. Note the hypotonia, high forehead with shallow supraorbital ridges, anteverted nares, and mild micrognathia, as well as the talipes equinovarus and contractures at the knees. (From Shaheen R, Al-Dirbashi OY, Al-Hassnan ZN, et al: Clinical, biochemical and molecular characterization of peroxisomal diseases in Arabs, Clin Genet 79(1):60–70, 2011.)

</tbody>
</table>

Patients with **neonatal ALD** show fewer, less prominent craniofacial features. Neonatal seizures occur frequently. Some degree of psychomotor developmental delay is present; function remains in the range of severe intellectual disability, and development may regress after 3-5 yr of age, probably from a progressive leukodystrophy. Hepatomegaly, impaired liver function, pigmentary degeneration of the retina, and severely impaired hearing are invariably present. Adrenocortical function is usually impaired and may require adrenal hormone replacement. Chondrodysplasia punctata and renal cysts are absent.

Patients with **infantile Refsum disease** have survived to adulthood. They can walk, although gait may be ataxic and broad based. Cognitive function is generally impaired, but accurate assessment is limited, usually by the presence of both vision and hearing impairment. Almost all have some degree of sensorineural hearing loss and pigmentary degeneration of the retina. They have moderately dysmorphic features that may include epicanthal folds, a flat nose bridge, and low-set ears. Early hypotonia and hepatomegaly with impaired function are common. Levels of plasma cholesterol and high-density and low-density lipoprotein are often moderately reduced. Chondrodysplasia punctata and renal cortical cysts are absent. Postmortem study in infantile Refsum disease reveals micronodular liver cirrhosis and small, hypoplastic adrenals. The brain shows no malformations, except for severe hypoplasia of the cerebellar granule
layer and ectopic locations of the Purkinje cells in the molecular layer. The mode of inheritance is autosomal recessive.

Some patients with PBDs have milder and atypical phenotypes. They may present with peripheral neuropathy or with retinopathy, impaired vision, or cataracts in childhood, adolescence, or adulthood and have been diagnosed to have Charcot-Marie-Tooth disease or Usher syndrome. Some patients have survived to the fifth decade. Defects in PEX7, which most frequently lead to the RCDP phenotype, may also lead to a milder phenotype with clinical manifestations similar to those of adult Refsum disease.

**Rhizomelic Chondrodysplasia Punctata**

RCDP is characterized by the presence of stippled foci of calcification within the hyaline cartilage and is associated with dwarfing, cataracts (72%), and multiple malformations caused by contractures. Vertebral bodies have a coronal cleft filled by cartilage that is a result of an embryonic arrest. Disproportionate short stature affects the proximal parts of the extremities (Fig. 104.4A). Radiologic abnormalities consist of shortening of the proximal limb bones, metaphyseal cupping, and disturbed ossification (Fig. 104.4B). Height, weight, and head circumference are less than the 3rd percentile, and these children have a severe intellectual disability. Skin changes such as those observed in ichthyosiform erythroderma are present in approximately 25% of patients.
Isolated Defects of Peroxisomal Fatty Acid Oxidation

In the group of single-enzyme defects, acyl-CoA oxidase and bifunctional enzyme deficiency involve a single enzymatic step in peroxisomal fatty acid oxidation. Defects of bifunctional enzyme are common and are found in approximately 15% of patients who are initially suspected of having Zellweger spectrum disorder. Patients with isolated acyl-CoA oxidase deficiency have a somewhat milder phenotype that resembles, and comes to attention because of the development of, an early childhood leukodystrophy.

Isolated Defects of Plasmalogen Synthesis

Plasmalogens are lipids in which the first carbon of glycerol is linked to an alcohol rather than a fatty acid. They are synthesized through a complex series of reactions, the first 2 steps of which are catalyzed by the peroxisomal enzymes dihydroxyacetone phosphate alkyl transferase (DHAPT) and synthase. Deficiency of either of these enzymes leads to a phenotype that is clinically
indistinguishable from the peroxisomal import disorder RCDP. This latter disorder is caused by a defect in PEX7, the receptor for PTS2. RCDP shares the severe deficiency of plasmalogens with these single-enzyme disorders but also has defects of phytanic oxidation. The fact that these single genetic disorders are associated with the full phenotype of RCDP suggests that a deficiency of plasmalogens is sufficient to produce it.

**Adult (Classic) Refsum Disease**

The defective enzyme (phytanoyl-CoA hydroxylase) is localized to the peroxisome. The manifestation of Refsum disease includes impaired vision from retinitis pigmentosa, anosmia, ichthyosis, peripheral neuropathy, ataxia, and occasionally cardiac arrhythmias. In contrast to infantile Refsum disease, cognitive function is normal, and there are no congenital malformations. Refsum disease often does not manifest until young adulthood, but visual disturbances such as night blindness, ichthyosis, and peripheral neuropathy may already be present in childhood and adolescence. Early diagnosis is important because institution of a phytanic acid–restricted diet can reverse the peripheral neuropathy and prevent the progression of the visual and central nervous system (CNS) manifestations. The adult Refsum disease phenotype may also be caused by defects in PEX7.

**2-Methylacyl-CoA Racemase Deficiency (AMACR)**

This disorder is caused by an enzyme defect that leads to the accumulation of the branched-chain fatty acids (phytanic and pristanic acid) and bile acids. Individuals present with typically an adult-onset peripheral neuropathy and may also have pigmentary degeneration of the retina.

**Laboratory Findings**

Diagnosis of a peroxisomal disorder often follows from a biochemical determination of an abnormality and then is confirmed through further genetic testing.

The biochemical characterization of peroxisomal disorders uses the generally available testing listed in Table 104.5. Measurement of plasma VLCFA levels is the most common assay. It must be emphasized that although plasma VLCFA levels are elevated in many patients with peroxisomal disorders, this is not always the case. The most important exception is RCDP, in which VLCFA levels
are normal, but plasma phytanic acid levels are increased and red blood cell (RBC) plasmalogen levels are reduced. In other peroxisomal disorders, the biochemical abnormalities are still more restricted. Therefore, a panel of tests is recommended and includes plasma levels of VLCFAs and phytanic, pristanic, and pipecolic acids and RBC levels of plasmalogens. Tandem mass spectrometry techniques also permit convenient quantitation of bile acids in plasma and urine. This panel of tests can be performed on very small amounts of venous blood and permits detection of most peroxisomal disorders. Furthermore, normal results make the presence of the typical peroxisomal disorder unlikely. Biochemical findings combined with the clinical presentation are often sufficient to arrive at a clinical diagnosis. *Methods using dried blood spots of filter paper have been developed and are being incorporated into newborn screening assays.*

* Phytanic acid and pristanic acid accumulation is age dependent, and normal (Nl) levels may be seen in infants and young children.

VLCFA, Very-long-chain fatty acids; ZSD, Zellweger spectrum disorder; RCDP, rhizomelic chondroplasia punctata; ALD, adrenoleukodystrophy; ACoX, acyl-CoA oxidase deficiency; AMACR, 2-methylacyl-CoA racemase deficiency.

The next step in diagnosis is generally to proceed to molecular DNA diagnosis, and many clinical laboratories provide a peroxisomal panel using next-generation technology. In some circumstances the diagnosis has been revealed through whole exome sequencing and the pathogenic nature of the alteration then confirmed through biochemical means.

Definition of the molecular defect in the *proband* is essential for carrier detection and speeds prenatal diagnosis. Characterization of the mutation may be of prognostic value in patients with *PEX1* defects. This defect is present in approximately 60% of PBD patients, and about half the *PEX1* defects have the
G843D allele, which is associated with a significantly milder phenotype than found in other mutations.

**Diagnosis**

Several noninvasive laboratory tests permit precise and early diagnosis of peroxisomal disorders (see Table 104.5). The challenge in PBDs is to differentiate them from the large variety of other conditions that can cause hypotonia, seizures, failure to thrive, or dysmorphic features. Experienced clinicians readily recognize classic Zellweger syndrome by its clinical manifestations. However, more mildly affected PBD patients often do not show the full clinical spectrum of disease and may be identifiable only by laboratory assays. Clinical features that warrant diagnostic assay include intellectual disability; weakness and hypotonia; dysmorphic features; neonatal seizures; retinopathy, glaucoma, or cataracts; hearing deficits; enlarged liver and impaired liver function; and chondrodysplasia punctata. The presence of 1 or more of these abnormalities increases the likelihood of this diagnosis. Atypical milder forms presenting as peripheral neuropathy have also been described.

Some patients with the isolated defects of peroxisomal fatty acid oxidation resemble those with Zellweger spectrum disorder and can be detected by the demonstration of abnormally high levels of VLCFAs.

Patients with RCDP must be distinguished from patients with other causes of chondrodysplasia punctata. RCDP is suspected clinically because of the shortness of limbs, developmental delays, and ichthyosis. The most decisive laboratory test is the demonstration of abnormally low plasmalogen levels in RBCs and an alteration in $\text{PEX7}$.

**Complications**

Patients with Zellweger syndrome have multiple disabilities involving muscle tone, swallowing, cardiac abnormalities, liver disease, and seizures. These conditions are treated symptomatically, but the prognosis is poor, and most patients succumb in the 1st yr of life. Similarly, individuals with RCDP have multiple systemic and neurologic issues. In addition, they may develop quadriplegia from compression at the base of the brain.

**Treatment**
The most effective therapy is the dietary treatment of adult Refsum disease with a phytanic acid–restricted diet. However, this only applies to this specific condition.

For patients with the somewhat milder variants of the peroxisome import disorders, success has been achieved with multidisciplinary early intervention, including physical and occupational therapy, hearing aids or cochlear implants, augmentative and alternative communication, nutrition, and support for the families. Although most patients continue to function in the impaired range, some make significant gains in self-help skills, and several are in stable condition in their teens or even early 20s.

Attempts to mitigate some of the secondary biochemical abnormalities include the oral administration of docosahexaenoic acid (DHA). DHA level is greatly reduced in patients with disorders of peroxisome biogenesis, and this therapy normalizes DHA plasma levels. Although there were anecdotal reports of clinical improvement with DHA therapy, a randomized placebo-controlled study failed to find benefit.

Genetic Counseling

All the discussed peroxisomal disorders can be diagnosed prenatally. Prenatal testing using chorionic villi sampling or amniocentesis will usually rely on genetic testing when the alteration is known, but biochemical measurements may be made using the same tests as described for postnatal diagnosis (see Table 104.5). Because of the 25% recurrence risk, couples with an affected child should be advised about the availability of prenatal diagnosis.

Adrenoleukodystrophy

ALD is an X-linked disorder associated with the accumulation of saturated VLCFAs and a progressive dysfunction of the adrenal cortex and nervous system. It is the most common peroxisomal disorder.

Etiology

The key biochemical abnormality in ALD is the tissue accumulation of saturated VLCFAs, with a carbon chain length of 24 or more. Excess hexacosanoic acid ($C_{26:0}$) is the most striking and characteristic feature. This accumulation of fatty
acids is caused by genetically deficient peroxisomal degradation of fatty acid. The defective gene \((ABCD1)\) codes for a peroxisomal membrane protein (ALDP, the ALD protein). Many alterations in \(ABCD1\) have been determined to be pathogenic, with over half these being private or unique to the kindred. A curated database of mutations is maintained (www.x-ald.nl). The mechanism by which the ALDP defect leads to VLCFA accumulation appears to be a disruption of transport of saturated fatty acids into the peroxisome, with resultant continued elongation of progressively longer fatty acids.

**Epidemiology**

The minimum incidence of ALD in males is 1 in 21,000, and the combined incidence of ALD males and heterozygous females in the general population is estimated to be 1 in 17,000. All races are affected. The various phenotypes often occur in members of the same kindred. Increased implementation of newborn screening in the United States and other countries is expected to improve the accuracy of these incidence estimates.

**Pathology**

Characteristic lamellar cytoplasmic inclusions can be demonstrated on electron microscopy in adrenocortical cells, testicular Leydig cells, and nervous system macrophages. These inclusions probably consist of cholesterol esterified with VLCFA. They are most prominent in cells of the zona fasciculata of the adrenal cortex, which at first are distended with lipid and later atrophy.

The nervous system displays 2 types of ALD lesions. In the severe cerebral form, demyelination is associated with an inflammatory response manifested by the accumulation of perivascular lymphocytes that is most intense in the involved region. In the slowly progressive adult form, adrenomyeloneuropathy, the main finding is a distal axonopathy that affects the long tracts in the spinal cord. In this form the inflammatory response is mild or absent.

**Pathogenesis**

The adrenal dysfunction is probably a direct consequence of the accumulation of VLCFAs. The cells in the adrenal zona fasciculata are distended with abnormal lipids. Cholesterol esterified with VLCFA is relatively resistant to
adrenocorticotropic hormone (ACTH)–stimulated cholesterol ester hydrolases, and this limits the capacity to convert cholesterol to active steroids. In addition, C_{26:0} excess increases the viscosity of the plasma membrane, which may interfere with receptor and other cellular functions.

There is no correlation between the neurologic phenotype and the nature of the mutation or the severity of the biochemical defect as assessed by plasma VLCFA levels or between the degree of adrenal involvement and nervous system involvement. The severity of the illness and rate of progression correlate with the intensity of the inflammatory response. The inflammatory response may be partially cytokine mediated and may involve an autoimmune response triggered in an unknown way by the excess of VLCFAs. Mitochondrial damage and oxidative stress also appear to contribute. Approximately half the patients do not experience the inflammatory response; this difference is not understood.

**Clinical Manifestations**

There are 5 relatively distinct ALD phenotypes, 3 of which are present in childhood with symptoms and signs. In all the phenotypes, development is usually normal in the 1st 3-4 yr of life.

In the childhood cerebral form of ALD, symptoms most often are first noted between ages 4 and 8 yr. The most common initial manifestations are hyperactivity, inattention, and worsening school performance in a child who had previously been a good student. Auditory discrimination is often impaired, although tone perception is preserved. This may be evidenced by difficulty in using the telephone and greatly impaired performance on intelligence tests in items that are presented verbally. Spatial orientation is often impaired. Other initial symptoms are disturbances of vision, ataxia, poor handwriting, seizures, and strabismus. Visual disturbances are often caused by involvement of the parietooccipital cortex rather than eye or optic tract abnormalities, which leads to variable and seemingly inconsistent visual capacity. Seizures occur in nearly all patients and may represent the first manifestation of the disease. Some patients present with increased intracranial pressure. Impaired cortisol response to ACTH stimulation is present in 85% of patients, and mild hyperpigmentation is noted. In most patients with this phenotype, adrenal dysfunction is recognized only after the condition is diagnosed because of the cerebral symptoms. Cerebral childhood ALD tends to progress rapidly with increasing spasticity and paralysis, visual and hearing loss, and loss of ability to speak or swallow. The
mean interval between the first neurologic symptom and an apparently vegetative state is 1.9 yr. Patients may continue in this apparently vegetative state for ≥10 yr.

Adolescent ALD designates patients who experience neurologic symptoms between ages 10 and 21 yr. The manifestations resemble those of childhood cerebral ALD except that progression is slower. Approximately 10% of patients present acutely with status epilepticus, adrenal crisis, acute encephalopathy, or coma.

Adrenomyeloneuropathy first manifests in late adolescence or adulthood as a progressive paraparesis caused by long tract degeneration in the spinal cord. Approximately half the affected men also have involvement of the cerebral white matter.

The Addison-only phenotype is an important condition. Of male patients with Addison disease, 25% may have the biochemical defect of ALD. Many of these patients have intact neurologic systems, whereas others have subtle neurologic signs. Many acquire adrenomyeloneuropathy in adulthood.

The term asymptomatic ALD is applied to persons who have the biochemical defect of ALD but are free of neurologic or endocrinial disturbances. Almost all persons with the gene defect eventually become neurologically symptomatic.

Approximately 50% of female heterozygotes acquire a syndrome that resembles adrenomyeloneuropathy but is milder and of later onset. Adrenal insufficiency and cerebral disease are rare.

Cases of typical ALD have occurred in relatives of those with adrenomyeloneuropathy. One of the most difficult problems in the management of ALD is the common observation that affected individuals in the same family may have quite different clinical courses. For example, in one family, an affected boy may have severe classic ALD culminating in death by age 10 yr, and another brother will have the later-onset adrenomyeloneuropathy.

Laboratory and Radiographic Findings

The most specific and important laboratory finding is the demonstration of abnormally high levels of VLCFAs in plasma, RBCs, or cultured skin fibroblasts. Positive results are obtained in all male patients with ALD and in approximately 85% of female carriers of ALD. Mutation analysis is the most reliable method for the identification of carriers. Simply finding a variation in ABCD1 is not adequate for making the diagnosis of ALD. It must be shown to
segregate with elevated VLCFA levels.

**Neuroimaging**

Patients with childhood cerebral or adolescent ALD have characteristic white matter lesions on MRI. In 80% of patients the lesions are symmetric and involve the splenium of the corpus callosum and periventricular white matter in the posterior parietal and occipital lobes. Many will show a garland of contrast enhancement adjacent and anterior to the posterior hypodense lesions (Fig. 104.5). This zone corresponds to the zones of intense perivascular lymphocytic infiltration where the blood-brain barrier breaks down. In 10–15% of patients, the initial lesions are frontal. Unilateral lesions that produce a mass effect suggestive of a brain tumor may occur rarely. MRI provides a clearer delineation of normal and abnormal white matter than does CT and is the preferred imaging modality.

![FIG. 104.5](image) Characteristic MRI findings in cerebral adrenoleukodystrophy. A, Symmetric T2-weighted MRI abnormalities involve the posterior white matter, including the corpus callosum. B, Contrast administration reveals a garland of enhancement.

**Impaired Adrenal Function**

More than 85% of patients with the childhood form of ALD have elevated levels of ACTH in plasma and a subnormal rise of cortisol levels in plasma after IV injection of 250 µg of ACTH (Cortrosyn).

**Diagnosis and Differential Diagnosis**

Diagnosis of asymptomatic males has become available by newborn screening
that has been added to the recommended uniform screening panel. After diagnosis, confirmatory testing and genetic counseling should be provided. Males then enter a program of surveillance for adrenal insufficiency and early detection of potential cerebral disease. Females identified through these programs should also have confirmatory testing, genetic counseling for the family, and screening of other at-risk males. Females do not generally require any other monitoring in childhood.

The earliest manifestations of childhood cerebral ALD are difficult to distinguish from the more common attention-deficit disorders or learning disabilities of school-age children. Rapid progression, signs of dementia, or difficulty in auditory discrimination suggest ALD. Even in early stages, neuroimaging shows abnormal changes. Other leukodystrophies or multiple sclerosis may sometimes mimic these radiographic findings, although early ALD has more of a predilection for the posterior brain than its mimics. Definitive diagnosis depends on demonstration of VLCFA excess, which occurs only in ALD and the other peroxisomal disorders.

Cerebral forms of ALD, especially if asymmetric, may be misdiagnosed as gliomas or other mass lesion. Individuals have received brain biopsy and rarely other therapies before the correct diagnosis was made. Measurement of VLCFAs in plasma is the most reliable differentiating test.

Adolescent or adult cerebral ALD can be confused with psychiatric disorders, dementing disorders, multiple sclerosis, or epilepsy. The first clue to the diagnosis of ALD may be the demonstration of characteristic white matter lesions by neuroimaging; VLCFA assays are confirmatory.

ALD cannot be distinguished clinically from other forms of Addison disease; it is recommended that assays of VLCFA levels be performed in all male patients with Addison disease. ALD patients do not usually have antibodies to adrenal tissue in their plasma.

**Complications**

An avoidable complication is the occurrence of **adrenal insufficiency**. The most difficult neurologic problems are those related to bed rest, contracture, coma, and swallowing disturbances. Other complications involve behavioral disturbances and injuries associated with defects of spatial orientation, impaired vision and hearing, and seizures.
Treatment

Corticosteroid replacement for adrenal insufficiency or adrenocortical hypofunction is effective. It may be lifesaving and may increase general strength and well-being, but it does not alter the course of the neurologic disability.

Bone Marrow Transplantation

Bone marrow transplantation (BMT) or hematopoietic stem cell therapy benefits patients who show early evidence of the inflammatory demyelination characteristic of the rapidly progressive neurologic disability in boys and adolescents with the cerebral ALD phenotype. BMT carries risk, and patients must be evaluated and selected with care. The mechanism of the beneficial effect is incompletely understood. Bone marrow–derived cells do express ALDP, the protein that is deficient in ALD; approximately 50% of brain microglial cells are bone marrow derived. The favorable effect may be caused by modification of the brain inflammatory response. Follow-up of boys and adolescents who had early cerebral involvement has shown stabilization. On the other hand, BMT does not arrest the course in those who already had severe brain involvement and may accelerate disease progression under these circumstances. The ALD MRI score and the use of performance measures on IQ testing have shown some predictive ability for boys likely to benefit from this procedure. Transplant is not recommended in patients with performance IQ significantly <80. Unfortunately, in more than half the patients who are diagnosed because of neurologic symptoms, the illness is so advanced at diagnosis that they are not candidates for transplant.

Consideration of BMT is most relevant in neurologically asymptomatic or mildly involved patients. Screening at-risk relatives of symptomatic patients identifies these patients most frequently. Screening by measurement of plasma VLCFA levels in patients with Addison disease may also identify candidates for BMT. Because of its risk (10–20% mortality) and because up to 50% of untreated patients with ALD do not develop inflammatory brain demyelination, transplant is not recommended in patients who are free of demonstrable brain involvement on MRI. MRI is also of key importance for the crucial decision of whether transplant should be performed. MRI abnormalities precede clinically evident neurologic or neuropsychologic abnormalities. The brain MRI should be monitored at 6 mo intervals in neurologically asymptomatic boys and adolescents age 3-15 yr. If the MRI is normal, BMT is not indicated. If brain
MRI abnormalities develop, the boy should be evaluated by a center familiar with transplant for ALD. This should include MRI, neurologic, and neuropsychologic evaluations. It is not known whether BMT has a favorable effect on the noninflammatory spinal cord involvement in adults with the adrenomyeloneuropathy phenotype.

**Lorenzo's Oil Therapy**

Lorenzo's oil (4 : 1 mixture of glycercyl trioleate and glycercyl trierucate) combined with a dietary regimen has been under investigation to prevent the development of various aspects of ALD. The compound does lower plasma levels of VLCFAs, but despite early enthusiasm, clinical trials have been equivocal. Lorenzo's oil has not been shown to alter disease progression in males with cerebral disease. Whether it or another agent that lowers VLCFA levels has disease-modifying effects is as yet uncertain.

**Supportive Therapy**

The progressive behavioral and neurologic disturbances associated with the childhood form of ALD are extremely difficult for the family. ALD patients require the establishment of a comprehensive management program and partnership among the family, physician, visiting nursing staff, school authorities, and counselors. In addition, parent support groups (e.g., United Leukodystrophy Foundation) are often helpful. Communication with school authorities is important because under the provisions of Public Law 94-142, children with ALD qualify for special services as “other health impaired” or “multi-handicapped.” Depending on the rate of progression of the disease, special needs might range from relatively low-level resource services within a regular school program to home- and hospital-based teaching programs for children who are not mobile.

Management challenges vary with the stage of the illness. The early stages are characterized by subtle changes in affect, behavior, and attention span. Counseling and communication with school authorities are of prime importance. Changes in the sleep–wake cycle can be benefited by the judicious use of nighttime sleep medications.

As the leukodystrophy progresses, the modulation of muscle tone and support of bulbar muscular function are major concerns. Baclofen in gradually increasing doses (5 mg twice a day to 25 mg 4 times a day) is an effective
pharmacologic agent for the treatment of acute episodic painful muscle spasms. Other agents may also be used, with care taken to monitor the occurrence of side effects and drug interactions. As the leukodystrophy progresses, bulbar muscular control is lost. Although initially this can be managed by changing the diet to soft and pureed foods, most patients eventually require a gastrostomy tube. At least 30% of patients have focal or generalized seizures that usually readily respond to standard anticonvulsant medications.

**Genetic Counseling and Prevention**

Genetic counseling and appropriate monitoring are of crucial importance. Extended-family screening should be offered to all at-risk relatives of symptomatic patients; one program led to the identification of >250 asymptomatic affected males and 1,200 women heterozygous for ALD. The plasma assay permits reliable identification of affected males in whom plasma VLCFA levels are increased already on the day of birth. Identification of asymptomatic males permits institution of steroid replacement therapy when appropriate and prevents adrenal crisis, which may be fatal. Monitoring of brain MRI also permits identification of patients who are candidates for BMT at a stage when this procedure has the greatest chance of success. Plasma VLCFA assay is recommended in all male patients with Addison disease. ALD has been shown to be the cause of adrenal insufficiency in >25% of boys with Addison disease of unknown cause. Identification of women heterozygous for ALD is more difficult than that of affected males. Plasma VLCFA levels are normal in 15–20% of heterozygous women, and failure to note this has led to serious errors in genetic counseling. DNA analysis permits accurate identification of carriers, provided that the mutation has been defined in a family member, and this is the procedure recommended for the identification of heterozygous women.

Prenatal diagnosis of affected male fetuses can be achieved by determination of the known mutation or by the measurement of VLCFA levels in cultured amniocytes or chorionic villus cells. Whenever a new patient with ALD is identified, a detailed pedigree should be constructed and efforts made to identify all at-risk female carriers and affected males. These investigations should be accompanied by careful and sympathetic attention to social, emotional, and ethical issues during counseling.

Epidemiology of Blood Lipids and Cardiovascular Disease

There is a strong association between average intake of saturated fats, plasma cholesterol, and mortality from coronary heart disease (CHD). Of all common chronic diseases, none is so clearly influenced by both environmental and genetic factors as CHD. This multifactorial disorder is strongly associated with
increasing age and male gender, although it is increasingly apparent that heart disease is underrecognized in women. Tobacco use confers a 2-fold higher lifetime risk. Sedentary activity and high intake of processed sugars leading to adiposity increase risk through differences in the plasma levels of atherogenic lipoproteins. Family history reflects the combined influence of lifestyle and genetic predisposition to early heart disease. Risk of premature heart disease associated with positive family history is 1.7 times higher than in families with no such history.

**Atherosclerosis** begins during childhood. The Johns Hopkins Precursors Study demonstrated that white male medical students with blood cholesterol levels in the lowest quartile showed only a 10% incidence of CHD 3 decades later, whereas those in the highest quartile had a 40% incidence. The Pathobiological Determinants of Atherosclerosis in Youth Study demonstrated a significant relationship between the weight of the abdominal fat pad and the extent of atherosclerosis found at autopsy on individuals 15-34 yr of age. The Bogalusa Heart Study of more than 3,000 black and white children and adolescents has provided the most comprehensive longitudinal data relating the presence and severity of CHD risk factors with semiquantifiable severity of atherosclerosis. Coronary atherosclerosis was present in 8.5% of military autopsies performed following combat or unintentional injuries.

The *fetal origins hypothesis* is based on the observation that infants born with low birthweight have a higher incidence of heart disease as adults. Epidemiologic studies support the idea that prenatal and early postnatal conditions may affect adult health status. Children who are large for gestational age at birth and exposed to an intrauterine environment of either diabetes or maternal obesity are at increased risk of eventually developing the **metabolic syndrome** (insulin resistance, type II diabetes, obesity, CHD). Breastfeeding preterm infants confers a long-term cardioprotective benefit 13-16 yr later. Those adolescents who were breastfed as infants had lower C-reactive protein (CRP) concentrations and a 14% lower low-density lipoprotein (LDL)/high-density lipoprotein (HDL) ratio than formula-fed infants. The impact of early nutrition and other lifestyle variables on gene expression, *epigenetics*, is one mechanism by which adult metabolism and body composition may be determined.

Secondary causes of hyperlipidemia may be the result of drugs (cyclosporine, corticosteroids, isotretinoin, protease inhibitors, alcohol, thiazide diuretics, β-blocking agents, valproate); or various diseases (nephrotic syndrome,
hypothyroidism, Cushing syndrome, anorexia nervosa, obstructive jaundice). Psychotropic medications, including second-generation antipsychotics such as olanzapine, are associated with dyslipidemia, obesity, and insulin resistance.

**Blood Lipids and Atherogenesis**

Numerous epidemiologic studies demonstrate the association of hypercholesterolemia, referring to elevated total and LDL blood cholesterol, with atherosclerotic disease. The ability to measure subcomponents within classes of lipid particles, as well as markers of inflammation, have further elucidated the process of atherogenesis and plaque rupture leading to acute coronary syndromes. Atherosclerosis affects primarily the coronary arteries but may also involve the aorta, arteries of the lower extremities, and carotid arteries.

The early stage of development of atherosclerosis is thought to begin with vascular endothelial dysfunction and intima-media thickness, which has been shown to occur in preadolescent children with risk factors such as obesity or familial hypercholesterolemia. The complex process of penetrating the intimal lining of the vessel may result from a variety of insults, including the presence of highly toxic oxidized LDL particles. Lymphocytes and monocytes penetrate the damaged endothelial lining, where they become macrophages laden with LDL lipids and then become foam cells. Such accumulation is counterbalanced by HDL particles capable of removing lipid deposits from the vessel wall. Fundamental to plaque formation is an inflammatory process (elevated CRP) involving macrophages and the arterial wall. The deposition of lipid within the subendothelial lining of the arterial wall appears macroscopically as fatty streaks, which may to some degree be reversible. A later stage of plaque development involves disruption of arterial smooth muscle cells stimulated by the release of tissue cytokines and growth factors. The *atheroma* is composed of a core of fatty substance separated from the lumen by collagen and smooth muscle ([Fig. 104.6](#)). Growth of the atherosclerotic plaque may result in ischemia of the tissue supplied by the artery. Chronic inflammation within the atheroma results in plaque instability and subsequent rupture. Platelet adherence leads to clot formation at the site of rupture, resulting in myocardial infarction (MI) or a cerebrovascular accident (CVA), depending on the site of thrombosis or thromboembolism.
The early stage of development of atherosclerosis begins with penetration of the intimal lining of the vessel by inflammatory cells. Deposition of lipid within the subendothelial lining of the arterial wall eventually leads to disruption of smooth muscle cells to form an atheromatous lipid core that impinges on the lumen. Chronic inflammation leads to plaque instability, setting the stage for plaque rupture and complete occlusion of the vessel lumen by clot formation.

Plasma Lipoprotein Metabolism and Transport

Abnormalities of lipoprotein metabolism are associated with diabetes mellitus and premature atherosclerosis. Lipoproteins are soluble complexes of lipids and proteins that effect transport of fat absorbed from the diet, or synthesis by the liver and adipose tissues, for utilization and storage. Dietary fat is transported from the small intestine as chylomicrons. Lipids synthesized by the liver as very-low-density lipoproteins (VLDLs) are catabolized to intermediate-density lipoproteins (IDLs) and LDLs. HDL is fundamentally involved in VLDL and chylomicron metabolism and cholesterol transport. Nonesterified free fatty acids are metabolically active lipids derived from lipolysis of triglycerides stored in adipose tissue and bound to albumin for circulation in the plasma (Fig. 104.7).
Lipoproteins consist of a central core of triglycerides and cholesteryl esters surrounded by phospholipids, cholesterol, and proteins (Fig. 104.8). The density of the several classes of lipoproteins is inversely proportional to the ratio of lipid to protein, which is generally denser (Fig. 104.9). Lipoproteins consist of a central core of triglycerides and cholesteryl esters surrounded by phospholipids, cholesterol, and proteins.
FIG. 104.8  Schematic of low-density lipoprotein. Lipoprotein consists of a central core of cholesteryl esters, surrounded by phospholipids, cholesterol, and protein.

FIG. 104.9  The density of the several classes of lipoprotein is inversely proportional to the ratio of lipid to protein. As lipid is less dense than protein, the more lipid contained in the particle increases its size and decreases its density. HDL, High-density lipoprotein; LDL, low-density lipoprotein; IDL, intermediate-density lipoprotein; VLDL, very-low-density lipoprotein.

Constituent proteins known as apolipoproteins are responsible for a variety of metabolic functions in addition to their structural role, including as cofactors or inhibitors of enzymatic pathways and mediators of lipoprotein binding to cell surface receptors (Table 104.6). ApoA is the major apolipoprotein (Apo) of HDL. ApoB is present in LDL, VLDL, IDL, and chylomicrons. ApoB-100 is derived from the liver, whereas apoB-48 comes from the small intestine. ApoC-I,
C-II, and C-III are small peptides important in triglyceride metabolism. Loss of function and disruptive mutations of the APOC3 gene are associated with low levels of triglycerides and a reduced risk of ischemic CHD. Likewise, apoE, which is present in VLDL, HDL, chylomicrons, and chylomicron remnants, plays an important role in the clearance of triglycerides.

### Transport of Exogenous (Dietary) Lipids

All dietary fat except medium-chain triglycerides is efficiently carried into the circulation by way of lymphatic drainage from the intestinal mucosa. Triglyceride and cholesteryl esters combine with apoA and apoB-48 in the intestinal mucosa to form chylomicrons, which are carried into the peripheral circulation via the lymphatic system. HDL particles contribute apoC-II to the chylomicrons, required for the activation of lipoprotein lipase (LPL) within the capillary endothelium of adipose, heart, and skeletal muscle tissue. Free fatty acids are oxidized, esterified for storage as triglycerides, or released into the circulation bound to albumin for transport to the liver. After hydrolysis of the triglyceride core from the chylomicron, apoC particles are recirculated back to HDL. The subsequent contribution of apoE from HDL to the remnant chylomicron facilitates binding of the particle to hepatic LDL receptor (LDL-R). Within the hepatocyte, the chylomicron remnant may be incorporated into membranes, resecreted as lipoprotein back into the circulation, or secreted as
bile acids. Normally, all dietary fat is disposed of within 8 hr after the last meal, an exception being individuals with a disorder of chylomicron metabolism. **Postprandial hyperlipidemia** is a risk factor for atherosclerosis. Abnormal transport of chylomicrons and their remnants may result in their absorption into the blood vessel wall as foam cells, caused by the ingestion of cholesteryl esters by macrophages, the earliest stage in the development of fatty streaks.

**Transport of Endogenous Lipids From the Liver**

The formation and secretion of VLDL from the liver and its catabolism to IDL and LDL particles describe the endogenous lipoprotein pathway. Fatty acids used in the hepatic formation of VLDL are derived primarily by uptake from the circulation. VLDL appears to be transported from the liver as rapidly as it is synthesized, and it consists of triglycerides, cholesteryl esters, phospholipids, and apoB-100. Nascent particles of VLDL secreted into the circulation combine with apoC and apoE. The size of the VLDL particle is determined by the amount of triglyceride present, progressively shrinking in size as triglyceride is hydrolyzed by the action of LPL, yielding free fatty acids for utilization or storage in muscle and adipose tissue. Hydrolysis of approximately 80% of the triglyceride present in VLDL particles produces IDL particles containing an equal amount of cholesterol and triglyceride. The remaining remnant IDL is converted to LDL for delivery to peripheral tissues or to the liver. ApoE is attached to the remnant IDL particle to allow binding to the cell and subsequent incorporation into the lysosome. Individuals with deficiency of either apoE2 or hepatic triglyceride lipase accumulate IDL in the plasma.

LDL particles account for approximately 70% of the plasma cholesterol in normal individuals. LDL receptors are present on the surfaces of nearly all cells. Most LDL is taken up by the liver, and the rest is transported to peripheral tissues such as the adrenal glands and gonads for steroid synthesis. Dyslipidemia is greatly influenced by LDL-R activity. The efficiency with which VLDL is converted into LDL is also important in lipid homeostasis. The normal newborn LDL level of 50 mg/dL is probably adequate for steroid synthesis throughout the life cycle.

**High-Density Lipoprotein and Reverse Cholesterol Transport**
Because hepatic secretion of lipid particles into the bile is the only mechanism by which cholesterol can be removed from the body, transport of excess cholesterol from the peripheral cells is a vitally important function of HDL. HDL is heavily laden with apoA-I–containing lipoproteins, which is nonatherogenic, in contrast to B lipoproteins. Cholesterol-poor nascent HDL particles secreted by the liver and small intestine are esterified to more mature HDL-2 particles by the action of the enzyme lecithin-cholesterol acyltransferase (LCAT), which facilitates movement of chylomicrons and VLDL into the HDL core. HDL-2 may transfer cholesteryl esters back to apoB lipoproteins mediated by cholesteryl ester transfer protein (CETP), or the cholesterol-rich particle may be removed from the plasma by endocytosis, completing reverse cholesterol transport. Low HDL may be genetic (deficiency of apoA-I) or secondary to increased plasma triglyceride.

**LCAT deficiency** results in diminished maturation of HDL particles, affecting their ability to do reverse cholesterol transport. This reduces its protective effect on atherosclerosis. There are rare reports, however, of less-than-expected severity of atherosclerosis despite low HDL secondary to LCAT deficiency, suggesting that the relationship may, for unknown reasons, be variable.

Familial Hypercholesterolemia

Familial hypercholesterolemia (FH) is a monogenic autosomal co-dominant disorder characterized by strikingly elevated LDL cholesterol (LDL-C), premature cardiovascular disease (CVD), and tendon xanthomas. In the past, FH referred to defects of LDL-R activity. The etiology of this lipoprotein abnormality also includes defects in the genes for apoB (as well as PCSK-9). Of the almost 1200 mutations described, some result in failure of synthesis of the LDL-R (receptor negative), and others cause defective binding or release at the lipoprotein-receptor interface. Receptor-negative mutations result in more severe phenotypes than receptor-defective mutations.

Homozygous Familial Hypercholesterolemia

FH homozygotes inherit 2 abnormal LDL receptor genes, resulting in markedly elevated plasma cholesterol levels ranging between 500 and 1,200 mg/dL. Triglyceride levels are normal to mildly elevated, and HDL levels may be slightly decreased. The condition occurs in 1 in 500,000 persons. Receptor-negative patients have <2% normal LDL-R activity, whereas those who are receptor defective may have as much as 25% normal activity and a better prognosis.

The prognosis is poor regardless of the specific LDL-R aberration. Severe atherosclerosis involving the aortic root and coronary arteries is present by early to middle childhood. These children usually present with xanthomas, which may cause thickening of the Achilles tendon or extensor tendons of the hands, or cutaneous lesions on the hands, elbows, knees, or buttocks (Figs. 104.10 to 104.12). Corneal arcus may be present. Family history is informative because premature heart disease is strongly prevalent among relatives of both parents.
The diagnosis may be confirmed genetically or by measuring LDL-R activity in cultured skin fibroblasts. Phenotypic expression of the disease may also be assessed by measuring receptor activity on the surface of lymphocytes by using cell-sorting techniques.

**FIG. 104.10**  Homozygous familial hypercholesterolemia. Tendon xanthomas in a 5 yr old male with homozygous FH noted at the knee (A), wrist (B), and Achilles (C).

**FIG. 104.11**  Striate palmar xanthomata. (From Durrington P: Dyslipidaemia, Lancet 362:717–731, 2003.)
Untreated homozygous patients rarely survive to adulthood. Symptoms of coronary insufficiency may occur; sudden death is common. LDL apheresis to remove LDL particles selectively from the circulation is recommended for many children because it slows the progression of atherosclerosis. Liver transplantation is also successful in decreasing LDL-C levels, but complications related to immunosuppression are common. HMG-CoA reductase inhibitors may be modestly effective depending on the specific class of LDL-R defect present. Combination therapy with ezetimibe, selectively blocking cholesterol adsorption in the gut, usually results in further decline in LDL levels; it has largely replaced the use of bile acid sequestrants. Early clinical trials using microsomal triglyceride transfer protein inhibition with lomitapide (oral agent) resulted in a significant reduction in all apoB lipoproteins, including LDL, but hepatic fat deposition as a side effect limits consideration of this pharmacologic approach.
Mipomersen (subcutaneous injection), an antisense oligonucleotide that binds to the sequence that encodes apolipoprotein B, reduces the synthesis of apoB and thus also VLDL and LDL; LDL cholesterol levels may decline approximately 25% with this treatment. Adverse effects include flulike symptoms, hepatic steatosis, and cirrhosis.

**Heterozygous Familial Hypercholesterolemia**

Heterozygous FH is the most common single-gene mutations associated with acute coronary syndromes and atherosclerotic CHD in adults. Its prevalence is approximately 1 in 250 individuals worldwide, but the frequency may be greater in select populations, such as French Canadians, Afrikaners, and Christian Lebanese, as a result of the founder effect of unique new mutations. The founder effect noted in Ashkenazi Jews can be traced through gene disequilibrium analysis to an initial mutation in Lithuania in the 1400s.

Heart disease accounts for more than half of all deaths in Western society. The pathogenesis of CHD is both environmental and genetic, and the complex interrelationship determines the phenotypic expression of disease.

Because heterozygous FH is a co-dominant condition with nearly full penetrance, 50% of first-degree relatives of affected individuals will have the disease, as will 25% of second-degree relatives. An estimated 20 million people have FH worldwide. Symptoms of CHD usually occur at the mean age of 45-48 yr in males and a decade later in females. Genetic testing of individuals who fulfill clinical criteria for the diagnosis of heterozygous FH is variably positive dependent on the population under investigation, including pediatric vs adult participants.

The World Health Organization (WHO) has targeted FH for individualized intervention strategies because of its large effect on morbidity and mortality. A relatively small percentage of the population accounts for a disproportionately high share of the burden of CVD. The clinical expression of the disease is straightforward, and treatment is effective.

One cannot overemphasize the importance of family history for suspecting the possibility of FH, especially given the 3% cholesterol screening rate for children in primary care offices. American Academy of Pediatrics (AAP) and National Heart, Lung, and Blood Institute (NHLBI) guidelines advocate for universal screening for cholesterol in childhood, but with poor acceptance and disagreement. There is an increased interest in genetic testing for persons with suspected FH because of variability in phenotype based on genotype. In fact, the
risk of CHD in individuals with FH can be up to 20 times greater than in the general population.

Plasma levels of LDL-C do not allow unequivocal diagnosis of FH heterozygotes, but values are generally twice normal for age because of 1 absent or dysfunctional allele. The U.S. MED-PED (Make Early Diagnosis–Prevent Early Death) Program has formulated diagnostic criteria. Similar criteria with minor variations exist in the United Kingdom (Simon Broome criteria) and Holland (Dutch Lipid Clinic Network criteria). Within well-defined FH families, the diagnosis is reliably established according to LDL cutoff points. More stringent criteria are required to establish the diagnosis in previously undiagnosed families, requiring strong evidence of an autosomal inheritance pattern and higher LDL cutoff points. At a total cholesterol level of 310 mg/dL, only 4% of adults in the general population would have FH, whereas 95% of adults who were first-degree relatives of known cases would have the disease. The mathematical probability of FH in MED-PED, verified by molecular genetics, is derived from a U.S. population cohort and may not be applicable to other countries.

Very high cholesterol levels in children should prompt extensive screening of adult first- and second-degree relatives (“reverse cascade” cholesterol screening). In the general population, a child younger than age 18 yr with total plasma cholesterol of 270 mg/dL and/or LDL-C of 200 mg/dL has an 88% chance of having FH (Table 104.8). Formal clinical diagnosis of FH is based on the presence of 2 or more family members having elevated LDL-C levels (the 95th percentile LDL-C level cutoff points for children vary with age and are lower than for adults; see Table 104.9). Thus the criteria for probable FH in a child whose first-degree relative has known FH require only modest elevation of total cholesterol to 220 mg/dL (LDL-C 160 mg/dL; Table 104.8). The challenge of childhood FH diagnosis is heightened by the lack of clinical stigmata such as xanthomata that are employed in the Simon Broome and Dutch Lipid Clinic Network schema and highlights the shift toward genetic diagnosis.

* Note that different percentiles are listed for high-density lipoprotein (HDL) cholesterol. LDL, Low-density lipoprotein.

Treatment of children with FH should begin with a rather rigorous low-fat diet. Diet alone is rarely sufficient for decreasing blood cholesterol levels to acceptable levels (LDL-C < 130 mg/dL). Ezetimibe blocks cholesterol adsorption in the gastrointestinal (GI) tract and has a low risk of side effects. Data suggest that ezetimibe will lower total cholesterol by 20-30 mg/dL. HMG-CoA reductase inhibitors (statins) are the drug of choice for treatment of FH because of their remarkable effectiveness and acceptable risk profile. There is sufficient clinical experience with this class of drugs in children over age 10 yr to document that they are as effective in children as in adults, and the risks of elevated hepatic enzymes and myositis are no greater than in adults. Another class of drugs, the proprotein convertase subtilisin/kexin type 9 (PCSK-9) inhibitors, are monoclonal antibodies (mAbs) that block the action of PCSK-9 to downregulate the LDL-R. These agents boost LDL-R levels and result in a marked decrease in plasma LDL-C levels. PCSK-9 inhibitors have a role in adults intolerant of statins and those with subtherapeutic statin effect. Use in children is experimental.

Familial Defective ApoB-100

Familial defective apoB-100 is an autosomal dominant condition that is indistinguishable from heterozygous FH. LDL cholesterol levels are increased, triglycerides are normal, adults often develop tendon xanthomas, and premature CHD occurs. Familial defective apoB-100 is caused by mutation in the receptor-binding region of apoB-100, the ligand of the LDL receptor, with an estimated frequency of 1 in 700 people in Western cultures. It is usually caused by substitution of glutamine for arginine in position 3500 in apoB-100, which results in reduced ability of the LDL-R to bind LDL-C, thus impairing its removal from the circulation. Specialized laboratory testing can distinguish familial defective apoB-100 from FH, but this is not necessary, except in research settings, because treatment is the same.

Autosomal Recessive Hypercholesterolemia

This rare condition, caused by a defect in LDL-R–mediated endocytosis in the liver, clinically presents with severe hypercholesterolemia at levels intermediate between those found in homozygous and heterozygous FH. It is
disproportionately present among Sardinians and is modestly responsive to treatment with HMG-CoA reductase inhibitors.

**Sitosterolemia**

A rare autosomal recessive condition characterized by excessive intestinal adsorption of plant sterols, sitosterolemia is caused by mutations in the adenosine triphosphate (ATP)–binding cassette transporter system (ABCG5 or ABCG8), which is responsible for limiting adsorption of plant sterols in the small intestine and promotes biliary excretion of the small amounts adsorbed. Plasma cholesterol levels may be severely elevated, resulting in tendon xanthomas and premature atherosclerosis. Other features include hemolytic anemia, macrothrombocytopenia (large platelets, reduced number), and hemorrhage. Diagnosis can be confirmed by measuring elevated plasma sitosterol levels. Treatment with HMG-CoA reductase inhibitors is not effective, but cholesterol adsorption inhibitors, such as ezetimibe, and bile acid sequestrants are effective.

**Polygenic Hypercholesterolemia**

Primary elevation in LDL-C among children and adults is most often polygenic; the small effects of many genes are impacted by environmental influences (diet). Plasma cholesterol levels are modestly elevated; triglyceride levels are normal. Polygenic hypercholesterolemia aggregates in families sharing a common lifestyle but does not follow predictable hereditary patterns found in single-gene lipoprotein defects. Treatment of children with polygenic hypercholesterolemia is directed toward adoption of a healthy lifestyle: reduced total and saturated fat consumption and at least 1 hr of physical activity daily. Cholesterol-lowering medication is rarely necessary.

**Hypercholesterolemia With Hypertriglyceridemia**

**Familial Combined Hyperlipidemia**

This autosomal dominant condition is characterized by moderate elevation in plasma LDL-C and triglycerides and reduced plasma HDL-C. Familial combined hyperlipidemia (FCHL) is the most common primary lipid disorder, affecting approximately 1 in 200 people. Family history of premature heart disease is typically positive; the formal diagnosis requires that at least 2 first-degree
relatives have evidence of 1 of 3 variants of dyslipidemia: (1) >90th percentile plasma LDL-C; (2) >90th percentile LDL-C and triglycerides; and (3) >90th percentile triglycerides. Individuals switch from one phenotype to another. Xanthomas are not a feature of FCHL. Elevated plasma apoB levels with increased small, dense LDL particles support the diagnosis.

Children and adults with FCHL have coexisting adiposity, hypertension, and hyperinsulinemia, suggesting the presence of the metabolic syndrome. Formal diagnosis in adults, as defined by the National Cholesterol Education Program (NCEP) Adult Treatment Panel III, identifies 6 major components: abdominal obesity, atherogenic dyslipidemia, hypertension, insulin resistance with or without impaired glucose tolerance, evidence of vascular inflammation, and prothrombotic state. An estimated 30% of overweight adults fulfill criteria for the diagnosis of metabolic syndrome, including 65% of those with FCHL. Hispanics and South Asians from the Indian subcontinent are especially susceptible. There is no official definition of metabolic syndrome for children. Absolute cutoffs for diagnosis in children do not account for continuous variables in aging, sexual maturation, and race/ethnicity.

FCHL and type 2 diabetes share many features of the metabolic syndrome, suggesting that they are less distinct entities than originally conceptualized. Genetic association studies reveal evidence for a common genetic background. The resultant metabolic overlap is associated with ectopic fat accumulation and insulin resistance. The mechanisms associating visceral adiposity with the metabolic syndrome and type 2 diabetes are not fully understood. A plausible unifying principle is that obesity causes endoplasmic reticulum stress, leading to suppression of insulin receptor signaling and thus insulin resistance and heightened inflammatory response. How this relates to atherogenesis is unclear. It is assumed that hypercholesterolemia and, with less certainty, hypertriglycerideremia confer risk for CVD in patients with FCHL. When features of the metabolic syndrome are included in logistic models, shared etiologic features such as increased visceral adiposity become apparent. Visceral adiposity increases with age, and its importance in children as a risk factor for heart disease and diabetes is limited by the relative paucity of data. Although longitudinal measurement of waist circumference and the presence of intraabdominal fat as determined by MRI is being conducted in the research setting, body mass index (BMI) remains the surrogate for adiposity in the pediatric clinical setting.

The metabolic syndrome is a dramatic illustration of the interaction of
genetics and the environment. Genetic susceptibility is essential as an explanation for premature heart disease in individuals with FCHL. Unhealthy lifestyle, poor diet, and physical inactivity contribute to obesity and attendant features of the metabolic syndrome.

*The cornerstone of management is lifestyle modification.* This includes a diet low in saturated fats, *trans* fats, and cholesterol, as well as reduced consumption of processed sugars. Increased dietary intake of fruits and vegetables is important, as is 1 hr of moderate physical activity daily. Compliance among children and their parents is often a problem, but small incremental steps are more likely to succeed than aggressive weight loss strategies. It is very important that the child’s caregivers participate in the process. Plasma triglyceride levels are usually quite responsive to dietary restriction, especially reduction in the amount of sweetened drinks consumed. Blood cholesterol levels may decrease by 10–15%, but if LDL-C remains >160 mg/dL, drug therapy should be considered.

**Familial Dysbetalipoproteinemia (Type III Hyperlipoproteinemia)**

Familial dysbetalipoproteinemia (FDBL) is caused by mutations in the gene for apoE, which when exposed to environmental influences (e.g., high-fat high-caloric diet, excessive alcohol intake) results in a mixed type of hyperlipidemia. Patients tend to have elevated plasma cholesterol and triglycerides to a relatively similar degree. HDL-C is typically normal, in contrast to other causes of hypertriglyceridemia associated with low HDL. This rare disorder affects approximately 1 in 10,000 persons. ApoE mediates removal of chylomicron and VLDL remnants from the circulation by binding to hepatic surface receptors. The polymorphic *APOE* gene expresses in 3 isoforms: *apoE3*, *apoE2*, and *apoE4*. *E4* is the “normal” allele present in the majority of the population. The *apoE2* isoform has lower affinity for the LDL receptor, and its frequency is approximately 7%. Approximately 1% of the population is homozygous for *apoE2/E2*, the most common mutation associated with FDBL, but only a minority expresses the disease. Expression requires precipitating illnesses such as diabetes, obesity, renal disease, or hypothyroidism. Individuals homozygous for *apoE4/E4* are at risk for late-onset Alzheimer disease and dementia from repeated sports-related head injuries.

Most patients with FDBL present in adulthood with distinctive xanthomas. Tuberoeruptive xanthomas resemble small, grapelike clusters on the knees,
buttocks, and elbows. Prominent orange-yellow discoloration of the creases of the hands (palmar xanthomas) is also typically present. Atherosclerosis, often presenting with peripheral vascular disease, usually occurs in the 4th or 5th decade. Children may present with a less distinctive rash and generally have precipitating illnesses.

The diagnosis of FDBL is established by lipoprotein electrophoresis, which demonstrates a broad beta band containing remnant lipoproteins. Direct measurement of VLDL by ultracentrifugation can be performed in specialized lipid laboratories. A VLDL/total triglyceride ratio >0.30 supports the diagnosis. APOE genotyping for apoE2 homozygosity can be performed, confirming the diagnosis in the presence of the distinctive physical findings. A negative result does not necessarily rule out the disease as other mutations in APOE may cause even more serious manifestations.

Pharmacologic treatment of FDBL is necessary to decrease the likelihood of symptomatic atherosclerosis in adults. HMG-CoA reductase inhibitors, nicotinic acid, and fibrates are all effective. FDBL is quite responsive to recommended dietary restriction.

**Hypertriglycerideremias**

The familial disorders of triglyceride-rich lipoproteins include both common and rare variants of the Frederickson classification system. These include familial chylomicronemia (type I), familial hypertriglyceridemia (type IV), and the more severe combined hypertriglyceridemia and chylomicronemia (type V). Hepatic lipase deficiency also results in a similar combined hyperlipidemia.

**Familial Chylomicronemia (Type I Hyperlipidemia)**

This rare single-gene defect, like FH, is caused by mutations affecting clearance of apoB-containing lipoproteins. Deficiency or absence of LPL or its cofactor apoC-II, which facilitates lipolysis by LPL, causes severe elevation of triglyceride-rich plasma chylomicrons. HDL-C levels are decreased. Clearance of these particles is greatly delayed, so the plasma is noted to have a turbid appearance even after prolonged fasting (Fig. 104.13). Chylomicronemia caused by LPL deficiency is associated with modest elevation in triglycerides, whereas this is not the case when the cause is deficient or absent apoC-II. Both are autosomal recessive conditions with a frequency of approximately 1 in 1 million population. The disease usually presents during childhood with acute
pancreatitis. Eruptive xanthomas on the arms, knees, and buttocks may be present, and there may be hepatosplenomegaly. The diagnosis is established by assaying triglyceride lipolytic activity. **Treatment** of chylomicronemia is by vigorous dietary fat restriction supplemented by fat-soluble vitamins. Medium-chain triglycerides that are adsorbed into the portal venous system may augment total fat intake, and administration of fish oils may also be beneficial.

**Familial Hypertriglyceridemia (Type IV Hyperlipidemia)**

Familial hypertriglyceridemia (FHTG) is an autosomal dominant disorder of unknown etiology that occurs in approximately 1 in 500 individuals. It is characterized by elevation of plasma triglycerides >90th percentile (250-1,000
mg/dL range), often accompanied by slight elevation in plasma cholesterol and low HDL. FHTG does not usually manifest until adulthood, although it is expressed in approximately 20% of affected children. In contrast to FCHL, FHTG is not thought to be highly atherogenic. It is most likely caused by defective breakdown of VLDL, or less often by overproduction of this class of lipoproteins.

The diagnosis should include the presence of at least 1 first-degree relative with hypertriglyceridemia. FHTG should be distinguished from FCHL and FDBL, which require more vigorous treatment to prevent coronary or peripheral vascular disease. The differentiation is usually possible on clinical grounds, in that lower LDL-C levels accompany FHTG, but measurement of normal apoB levels in FHTG may be helpful in ambiguous situations.

A more severe hypertriglyceridemia characterized by increased levels of chylomicrons as well as VLDL particles (Frederickson type V) may occasionally be encountered. Triglyceride levels are often >1,000 mg/dL. The disease is rarely seen in children. In contrast to chylomicronemia (Frederickson type I), LPL or apoC-II deficiency is not present. These patients often develop eruptive xanthomas in adulthood, whereas type IV hypertriglyceridemia individuals do not. Acute pancreatitis may be the presenting illness. As with other hypertriglyceridemias, excessive alcohol consumption and estrogen therapy can exacerbate the disease.

Secondary causes of transient hypertriglyceridemia should be ruled out before making a diagnosis of FHTG. A diet high in simple sugars and carbohydrates or excessive alcohol consumption, as well as estrogen therapy, may exacerbate hypertriglyceridemia. Adolescents and adults should be questioned about excessive consumption of soda and other sweetened drinks, as it is common to encounter people who drink supersized drinks or multiple 12 oz cans of sweetened drinks daily. Cessation of this practice often results in dramatic fall in triglyceride levels as well as weight among those who are obese. HDL-C levels will tend to rise as BMI stabilizes.

Pediatric diseases associated with hyperlipidemia include hypothyroidism, nephrotic syndrome, biliary atresia, glycogen storage disease, Niemann-Pick disease, Tay-Sachs disease, systemic lupus erythematosus, hepatitis, and anorexia nervosa (Table 104.10). Certain medications exacerbate hyperlipidemia, including isotretinoin (Accutane), thiazide diuretics, second-generation antipsychotic agents, oral contraceptives, corticosteroids, β blockers, immunosuppressants, and protease inhibitors used in HIV treatment.
### Table 104.10

**Secondary Causes of Hyperlipidemia**

**Hypercholesterolemia**

- Hypothyroidism
- Nephrotic syndrome
- Cholestasis
- Anorexia nervosa
- Drugs: progesterone, thiazides, carbamazepine (Tegretol), cyclosporine

**Hypertriglyceridemia**

- Obesity
- Type 2 diabetes
- Alcohol
- Renal failure
- Sepsis
- Stress
- Cushing syndrome
- Pregnancy
- Hepatitis
- AIDS, protease inhibitors
- Drugs: anabolic steroids, β-blockers, estrogen, thiazides

**Reduced High-Density Lipoprotein**

- Smoking
- Obesity
- Type 2 diabetes
- Malnutrition
- Drugs: β-blockers, anabolic steroids

Treatment of hypertriglyceridemia in children rarely requires medication unless levels >1,000 mg/dL persist after dietary restriction of fats, sugars, and
carbohydrates, accompanied by increased physical activity. In such patients the aim is to prevent episodes of pancreatitis. The common use of fibrates (fenofibric acid) and niacin in adults with hypertriglyceridemia is not recommended in children. HMG-CoA reductase inhibitors are variably effective in lowering triglyceride levels, and there is considerably more experience documenting the safety and efficacy of this class of lipid-lowering medications in children. In adults, the U.S. Food and Drug Administration (FDA) has approved prescription (Lovaza, Vascepa) and nonprescription fish oils as adjuncts to diet in the treatment of severe hypertriglyceridemias.

**Hepatic Lipase Deficiency**

Hepatic lipase deficiency is a very rare autosomal recessive condition causing elevation in both plasma cholesterol and triglycerides. Hepatic lipase hydrolyzes triglycerides and phospholipids in VLDL remnants and IDL, preventing their conversion to LDL. HDL-C levels tend to be increased rather than decreased, suggesting the diagnosis. Laboratory confirmation is established by measuring hepatic lipase activity in heparinized plasma.

**Disorders of High-Density Lipoprotein Metabolism**

**Primary Hypoalphalipoproteinemia**

Isolated low HDL cholesterol is a familial condition that often follows a pattern suggestive of autosomal dominant inheritance but may occur independent of family history. It is the most common disorder of HDL metabolism. It is defined as HDL-C <10th percentile for gender and age with normal plasma triglycerides and LDL-C. Whether it is associated with more rapid atherosclerosis is uncertain. Primary hypoalphalipoproteinemia appears to be related to a reduction in apoA-I synthesis and increased catabolism of HDL. Secondary causes of low HDL-C, such as the metabolic syndrome, and rare diseases such as LCAT deficiency and Tangier disease must be ruled out.

**Familial Hyperalphalipoproteinemia**

This is an unusual condition conferring decreased risk for CHD among family members. Plasma levels of HDL-C exceed 80 mg/dL.
Familial Apolipoprotein A-I Deficiency

Mutations in the \textit{apoA-I} gene may result in complete absence of plasma HDL. Nascent HDL is produced in the liver and small intestine. Free cholesterol from peripheral cells is esterified by LCAT, enabling formation of mature HDL particles. ApoA-I is required for normal enzymatic functioning of LCAT. The resultant accumulation of free cholesterol in the circulation eventually leads to corneal opacities, planar xanthomas, and premature atherosclerosis. Some patients, however, may have mutations of \textit{apoA-I} that result in very rapid catabolism of the protein not associated with atherogenesis, despite HDL-C levels in the 15-30 mg/dL range.

Tangier Disease

This autosomal co-dominant disease is associated with HDL-C levels <5 mg/dL. It is caused by mutations in ABCA1, a protein that facilitates the binding of cellular cholesterol to apoA-I. This results in free cholesterol accumulation in the reticuloendothelial system, manifested by tonsillar hypertrophy of a distinctive orange color and hepatosplenomegaly. Intermittent peripheral neuropathy may occur from cholesterol accumulation in Schwann cells. Diagnosis should be suspected in children with enlarged orange tonsils and extremely low HDL-C levels.

Familial Lecithin–Cholesterol Acyltransferase (LCAT) Deficiency

Mutations affecting LCAT interfere with the esterification of cholesterol, thereby preventing formation of mature HDL particles. This is associated with rapid catabolism of apoA-I. Free circulating cholesterol in the plasma is greatly increased, which leads to corneal opacities and HDL-C levels <10 mg/dL. Partial LCAT deficiency is known as “fish-eye” disease. Complete deficiency causes hemolytic anemia and progressive renal insufficiency early in adulthood. This rare disease is not thought to cause premature atherosclerosis. Laboratory confirmation is based on demonstration of decreased cholesterol esterification in the plasma.

Cholesteryl Ester Transfer Protein Deficiency

Mutations involving the \textit{CETP} gene are localized to chromosome 16y21. Cholesteryl ester transfer protein (CETP) facilitates the transfer of lipoproteins
from mature HDL to and from VLDL and chylomicron particles, thus ultimately regulating the rate of cholesterol transport to the liver for excretion in the bile. About half of mature HDL-2 particles are directly removed from the circulation by HDL receptors on the surface of the liver. The other half of cholesteryl esters in the core of HDL exchange with triglycerides in the core of apoB lipoproteins (VLDL, IDL, LDL) for transport to the liver. Homozygous deficiency of CETP has been observed in subsets of the Japanese population with extremely high HDL-C levels (>150 mg/dL).

**Conditions Associated With Low Cholesterol**

Disorders of apoB-containing lipoproteins and intracellular cholesterol metabolism are associated with low plasma cholesterol.

**Abetalipoproteinemia**

This rare autosomal recessive disease is caused by mutations in the gene encoding microsomal triglyceride transfer protein necessary for the transfer of lipids to nascent chylomicrons in the small intestine and VLDL in the liver. This results in absence of chylomicrons, VLDL, LDL, and apoB and very low levels of plasma cholesterol and triglycerides. Fat malabsorption, diarrhea, and failure to thrive present in early childhood. Spinocerebellar degeneration, secondary to vitamin E deficiency, manifests in loss of deep tendon reflexes progressing to ataxia and lower-extremity spasticity by adulthood. Patients with abetalipoproteinemia also acquire a progressive pigmented retinopathy associated with decreased night and color vision and eventual blindness. The neurologic symptoms and retinopathy may be mistaken for Friedreich ataxia. Differentiation from Friedreich ataxia is suggested by the presence of malabsorption and acanthocytosis on peripheral blood smear in abetalipoproteinemia. Many of the clinical manifestations of the disease are a result of malabsorption of fat-soluble vitamins, such as vitamins E, A, and K. *Early treatment with supplemental vitamins, especially E, may significantly slow the development of neurologic sequelae.* Vitamin E is normally transported from the small intestine to the liver by chylomicrons, where it is dependent on the endogenous VLDL pathway for delivery into the circulation and peripheral tissues. Parents of children with abetalipoproteinemia have normal blood lipid and apoB levels.
Familial Hypobetalipoproteinemia

Familial homozygous hypobetalipoproteinemia is associated with symptoms very similar to those of abetalipoproteinemia, but the inheritance pattern is autosomal co-dominant. The disease is caused by mutations in the gene encoding apoB-100 synthesis. It is distinguishable from abetalipoproteinemia in that heterozygous parents of probands have plasma LDL-C and apoB levels less than half normal. There are no symptoms or sequelae associated with the heterozygous condition.

The selective inability to secrete apoB-48 from the small intestine results in a condition resembling abetalipoproteinemia or homozygous hypobetalipoproteinemia. Sometimes referred to as Anderson disease, the failure of chylomicron absorption causes steatorrhea and fat-soluble vitamin deficiency. The blood level of apoB-100, derived from normal hepatocyte secretion, is normal in this condition.

Smith-Lemli-Opitz Syndrome

Patients with Smith-Lemli-Opitz syndrome (SLOS) often have multiple congenital anomalies and developmental delay caused by low plasma cholesterol and accumulated precursors (Tables 104.11 and 104.12) (see Chapter 606.2). Family pedigree analysis has revealed its autosomal recessive inheritance pattern. Mutations in the DHCR7 (7-dehydrocholesterol-Δ7 reductase) gene result in deficiency of the microsomal enzyme DHCR7, which is necessary to complete the final step in cholesterol synthesis. It is not known why defects in cholesterol synthesis result in congenital malformations, but since cholesterol is a major component of myelin and a contributor to signal transduction in the developing nervous system, neurodevelopment is severely impaired. The incidence of SLOS is estimated to be 1 in 20,000-60,000 births among whites, with a somewhat higher frequency in Hispanics and lower incidence in individuals of African descent.

Table 104.11

Major Clinical Characteristics of Smith-Lemli-Opitz Syndrome: Frequent Anomalies (>50% of Patients)

| Craniofacial |
Microcephaly
Blepharoptosis
Anteverted nares
Retromicrognathia
Low-set, posteriorly rotated ears
Midline cleft palate
Broad maxillary alveolar ridges
Cataracts (<50%)

**Skeletal Anomalies**

Syndactyly of toes II/III
Postaxial polydactyly (<50%)
Equinovarus deformity (<50%)

**Genital Anomalies**

Hypospadias
Cryptorchidism
Sexual ambiguity (<50%)

**Development**

Prenatal and postnatal growth retardation
Feeding problems
Mental impairment
Behavioral abnormalities

**Table 104.12**

**Characteristic Malformations of Internal Organs in Severely Affected Smith-Lemli-Opitz Patients**
Central Nervous System

- Frontal lobe hypoplasia
- Enlarged ventricles
- Agenesis of corpus callosum
- Cerebellar hypoplasia
- Holoprosencephaly

Cardiovascular

- Atrioventricular canal
- Secundum atrial septal defect
- Patent ductus arteriosus
- Membranous ventricular septal defect

Urinary Tract

- Renal hypoplasia or aplasia
- Renal cortical cysts
- Hydronephrosis
- Ureteral duplication

Endocrine

Adrenal insufficiency

Spontaneous abortion of SLOS fetuses may occur. **Type II** SLOS often leads to death by the end of the neonatal period. Survival is unlikely when the plasma cholesterol level is <20 mg/dL. Laboratory measurement should be performed by gas chromatography, because standard techniques for lipoprotein assay include measurement of cholesterol precursors, which may yield a false-positive result. Milder cases may not present until late childhood. Phenotypic variance ranges from microcephaly, cardiac and brain malformation, and multiorgan system failure to only subtle dysmorphic features and mild developmental delay. **Treatment** includes supplemental dietary cholesterol (egg yolk) and HMG-CoA reductase inhibition to prevent the synthesis of toxic precursors proximal to the enzymatic block.

**Disorders of Intracellular Cholesterol Metabolism**

**Cerebrotendinous Xanthomatosis**

This autosomal recessive disorder presents clinically in late adolescence with tendon xanthomas, cataracts, and progressive neurodegeneration. It is caused by tissue accumulation of bile acid intermediates shunted into cholestanol, resulting from mutations in the gene for sterol 27-hydroxylase. This enzyme is necessary for normal mitochondrial synthesis of bile acids in the liver. Early treatment with chenodeoxycholic acid reduces cholesterol levels and prevents the development of symptoms.

**Wolman Disease and Cholesterol Ester Storage Disease**

These autosomal recessive disorders are caused by lack of lysosomal acid lipase. After LDL cholesterol is incorporated into the cell by endocytosis, it is delivered to lysosomes, where it is hydrolyzed by lysosomal lipase. Failure of hydrolysis
because of complete absence of the enzyme causes accumulation of cholesteryl esters within the cells. Hepatosplenomegaly, steatorrhea, and failure to thrive occur during early infancy, leading to death by age 1 yr. In cholesterol ester storage disease, a less severe form than Wolman disease, there is low but detectable acid lipase activity (see Chapter 104.4).

**Niemann-Pick Disease Type C**

This disorder of intracellular cholesterol transport is characterized by accumulation of cholesterol and sphingomyelin in the CNS and reticuloendothelial system. Death from this autosomal recessive neurologic disease usually occurs by adolescence (see Chapter 104.4).

**Lipoprotein Patterns in Children and Adolescents**

Derived primarily from the Lipid Research Clinics Population Studies, Table 104.9 shows the distribution of lipoprotein levels in American youth at various ages. Total plasma cholesterol rises rapidly from a mean of 68 mg/dL at birth to a level approximately twice that by the end of the neonatal period. A very gradual rise in total cholesterol level occurs until puberty, when the mean level reaches 160 mg/dL. Total cholesterol falls transiently during puberty, in males because of a small decrease in HDL-C, and in females secondary to a slight fall in LDL-C. Blood cholesterol levels track reasonably well as individuals age.

High blood cholesterol tends to aggregate in families, a reflection of genetic and environmental influences.

Acceptable total cholesterol among children and adolescents is <170 mg/dL; borderline is 170-199 mg/dL; and high >200 mg/dL. Acceptable LDL-C is <110 mg/dL; borderline 110-129 mg/dL; and high >130 mg/dL. HDL-C should be >40 mg/dL.

**Blood Cholesterol Screening**

The AAP began recommending a universal approach for cholesterol screening to all children in 2011. A lipid profile should be checked for all children between ages 9 and 11 yr and then another between ages 17 and 21 yr, because cholesterol levels may vary after puberty. However, if a child would have met the selective criteria from the previous risk-based guidelines (premature
coronary artery disease in parent or grandparent, parent with cholesterol >240 mg/dL), screening can occur as early as age 2 yr. Data also suggest that obtaining a nonfasting lipid profile can be just as useful in detecting severe genetic dyslipidemias as a fasting lipid profile, and thus can be used as first-line screening in children. Fasting lipid profiles may also be used depending on parental, child, and clinician preference, especially if there is concern for hypertriglyceridemia, since triglycerides are affected more by fasting status. Abnormal lipid panels should be repeated, and especially when the concern is the triglycerides, the 2nd panel should be obtained ≥2 wk later in the fasted state. Treatment other than lifestyle modification is not initiated based on a single lipid panel determination.

**Risk Assessment and Treatment of Hyperlipidemia**

The NCEP recommends a population-based approach toward healthy lifestyle applicable to all children, and an individualized approach directed at those children at high risk (Fig. 104.14 ). The important focus on maintenance of a healthy lifestyle rather than aggressive weight reduction is recommended by the AAP.
All children with dyslipidemias are stratified according to the presence of high-level or moderate-level risk factors to determine their ultimate treatment. **High-level risk factors** are defined as hypertension requiring drug therapy (blood pressure ≥99th percentile + 5 mm Hg), current cigarette smoker, BMI at
the \( \geq 97 \)th percentile, presence of type 1 or type 2 diabetes mellitus, chronic kidney disease, postorthoptic heart transplant, and/or Kawasaki disease with current aneurysms. **Moderate-level risk factors** are defined as hypertension that does not require drug therapy, BMI at the \( \geq 95 \)th percentile but \(< 97 \)th percentile, HDL-C \(< 40 \) mg/dL, Kawasaki disease with regressed coronary aneurysms, chronic inflammatory disease, HIV infection, and/or presence of nephrotic syndrome.

The initial treatment for dyslipidemia in a child always begins with a 6-mo trial of lifestyle modification, namely, improvements in dietary and physical activity patterns. Being overweight confers special risk of CVD because of the strong association with the insulin resistance syndrome (metabolic syndrome). Although there is no standardized definition of metabolic syndrome defined for youth, it is likely that half of all severely obese children are insulin resistant. Data from the CARDIAC project noted that 49\% of 5th grade children with the hyperpigmented rash, acanthosis nigricans, had 3 or more factors for the insulin resistance syndrome when using the definition classically used for adults, including evidence of insulin resistance, hypertension, HDL-C \(< 40 \) mg/dL, and triglycerides \( \geq 150 \) mg/dL, in addition to obesity.

The Cardiovascular Health Integrated Lifestyle Diet-1 (CHILD-1) diet is the first level of dietary change to be recommended for all children with dyslipidemias. The CHILD-1 diet is specially designed for children with risk factors for coronary artery disease and focuses on limiting dietary cholesterol to 300 mg/day, limiting sugary drink consumption, using reduced-fat/skim milk, avoiding foods high in trans-type fats, limiting foods high in sodium, and encouraging consumption of foods high in fiber. Specific recommendations depend on the child's age.

The use of the Cardiovascular Health Integrated Lifestyle Diet-2 (CHILD-2) diet is recommended if the CHILD-1 diet alone is unsuccessful. Although similar in many aspects to the CHILD-1 diet, the CHILD-2 diet is geared toward a specific dyslipidemia type; the CHILD-2 LDL diet is recommended for children with elevated LDL levels and the CHILD-2 TG diet for those presenting with elevated triglycerides. The basic recommendations of calorie consumption for the CHILD-2 diet are as follows: only 25–30\% of calories from fat, \( \leq 7 \)\% of calories from saturated fat, 10\% of calories from monounsaturated fat, and \(< 200 \) mg/day of cholesterol. If the CHILD-2 LDL diet is recommended, the use of plant sterols and water-soluble fiber is emphasized. If the CHILD-2 TG diet is recommended, the increasing consumption of omega-3 fatty acids and
complex rather than simple carbohydrates is emphasized. If followed, these dietary recommendations will provide adequate calories for optimal growth and development without promoting obesity. Compliance on the part of children and their caregivers is challenging. Children learn eating habits from their parents. Successful adoption of a healthier lifestyle is much more likely to occur if meals and snacks in the home are applicable to the entire family rather than an individual child. A regular time for meals together as a family is desirable. Grandparents and other nonparental caregivers sometimes need to be reminded not to indulge the child who is on a restricted diet. Additionally, the rise in obesity is prompting some school districts to restrict sweetened drink availability and offer more nutritious cafeteria selections.

Changes in physical activity habits are also an important part of the initial lifestyle modification. The National Association for Sport and Physical Education recommends that children should accumulate at least 60 min of age-appropriate physical activity on most days of the week. Extended periods (≥2 hr) of daytime inactivity are discouraged, as is >2 hr of television and other forms of screen time.

**Pharmacologic Therapy.**

**Rare:** Dry eyes, hyperpigmentation

**Fish Oil**

Euructation, dyspepsia, unpleasant aftertaste

Pharmacologic therapy with cholesterol-lowering medication is the cornerstone of therapy for children who fail to respond to 6 mo of rigorous lifestyle modification. Drug therapy should be considered when 1 of the following conditions are met (also shown in Fig. 104.14):

- LDL cholesterol remains >190 mg/dL
- LDL cholesterol remains >160 mg/dL with presence of 1 high-level risk factor and/or at least 2 moderate-level risk factors
- LDL cholesterol remains >130 mg/dL with presence of at least 2 high-level risk factors, 1 high-level risk factor, and at least 2 moderate-level risk factors, or evidence of coronary artery disease (CAD)

**HMG-CoA reductase inhibitors**, also known as “statins” are remarkably effective in lowering LDL cholesterol levels and reducing plaque inflammation, thereby reducing the likelihood of a sudden coronary event in an at-risk adult within weeks of starting the medication. As a class, they work by blocking the intrahepatic biosynthesis of cholesterol, thereby stimulating the production of more LDL receptors on the cell surface and facilitating the uptake of LDL-C.
from the bloodstream. The NCEP Adult Treatment Panel advocates aggressive lowering of LDL to <70 mg/dL in individuals with known CAD. This information is relevant because a child who fulfills criteria for consideration of cholesterol-lowering medication will almost always have inherited the condition from one of the child's parents. Not infrequently, when providing care for the child, questions arise about screening and treatment of parents or grandparents. Statins are equally effective in children, capable of lowering LDL-C levels by 50% when necessary. They are considered first-line therapy for children who meet criteria for pharmacologic therapy. They also will affect a modest reduction in triglycerides and an inconsistent increase in HDL-C. Their side effect profile, mainly liver dysfunction and rarely rhabdomyolysis with secondary renal failure, should be taken into consideration before prescribing the drug. However, there has been no evidence that complications are any more frequent in children than adults, and skeletal muscle discomfort seems to be somewhat less of a problem. Drug interactions may occur as well, so careful attention should be paid to a child's active prescriptions to avoid potentiation of the side effects. Children should have liver enzymes monitored regularly, and creatine phosphokinase measured if muscle aches or weakness occurs. Liver (muscle) enzymes may be allowed to rise 3-fold before discontinuing the drug. There is a suggested link between the use of statins and increased risk of developing type 2 diabetes mellitus in adults, but these results have not been replicated in children. Sex hormones have been measured in children receiving statins and are unchanged. It should be reemphasized that children with modest elevations in cholesterol, such as that seen in polygenic hypercholesterolemia, are not, as a rule, candidates for statins because of their side effect profile and the childhood response to lifestyle modifications. Statins should be started at the lowest effective dose and allowed at least 8 wk to achieve their peak effect. If LDL levels are not at goal, which in children who are treated is generally established to be <130 mg, the medication may be titrated upward with careful monitoring of side effects.

Other cholesterol-lowering medications, such as nicotinic acid and fibrates, have been used far less often in children than bile acid sequestrants and statins. Nicotinic acid and fibrates have been used selectively in children with marked hypertriglyceridemia (>500 mg/dL) at risk for acute pancreatitis, though dietary restriction of complex sugars (stressing elimination of sugar-sweetened beverages) and carbohydrates will usually result in significant lowering of triglyceride levels. Current guidelines recommend treatment of LDL-C as the initial priority and after LDL levels are at goal, then if triglycerides remain
between 200 and 499 mg/dL and non-HDL cholesterol ≥145 mg/dL, pharmacologic treatment to reduce triglyceride levels is indicated. Omega-3 fatty acid supplementation, available in both over-the-counter and prescription form, is a safe and useful treatment thought to reduce triglyceride levels by decreasing the hepatic synthesis of triglycerides. LDL-C levels in adults of about 70 mg/dL were recently associated with coronary artery atheromatous plaque reduction and reversal of CAD. Knowledge in this area will continue to evolve.

Ezetimibe has proved to be useful in the pediatric population because of its efficacy and low side effect profile. Ezetimibe reduces plasma LDL-C by blocking sterol absorption in enterocytes. The drug is marketed as an adjunct to statins when adults are not achieving sufficient blood lipid lowering with statins alone. Sufficient reports documenting its effectiveness without side effects support recommending ezetimibe instead of a statin when moderate hypercholesterolemia is encountered, or apprehension from parents makes using a statin difficult.

The lysosomal lipid storage diseases are diverse disorders, each caused by an inherited deficiency of a specific lysosomal hydrolase leading to the intralysosomal accumulation of the enzyme's particular substrate (Tables 104.15 and 104.16). Except for Wolman disease and cholesterol ester storage disease, the lipid substrates share a common structure that includes a ceramide backbone (2-N-acylsphingosine) from which the various sphingolipids are derived by substitution of hexoses, phosphorylcholine, or 1 or more sialic acid residues on the terminal hydroxyl group of the ceramide molecule. The pathway of sphingolipid metabolism in nervous tissue (Fig. 104.15) and in visceral organs (Fig. 104.16) is known; each catabolic step, with the exception of the catabolism of lactosylceramide, has a genetically determined metabolic defect and a resultant disease. Because sphingolipids are essential components of all cell membranes, the inability to degrade these substances and their subsequent accumulation results in the physiologic and morphologic alterations and characteristic clinical manifestations of the lipid storage disorders (Table 104.15). Progressive lysosomal accumulation of glycosphingolipids in the CNS leads to neurodegeneration, whereas storage in visceral cells can lead to organomegaly, skeletal abnormalities, pulmonary infiltration, and other manifestations. The storage of a substrate in a specific tissue depends on its normal distribution in the body.

FIG. 104.15 Pathways in the metabolism of sphingolipids found in nervous tissues. The name of the enzyme catalyzing each reaction is given with the name of the substrate that it hydrolyzes. Inborn errors are depicted as bars crossing the reaction arrows, and the name of the associated defect or defects is given in the nearest box. The gangliosides are named according to the nomenclature of Svennerholm. Anomeric configurations are given only at the largest starting compound. Gal, Galactose; glc, glucose; NAcgal, N-acetylgalactosamine; NANA, N-acetyleneuraminic acid; PC, phosphorylcholine.
Diagnostic assays for the identification of affected individuals rely on the measurement of the specific enzymatic activity, typically in isolated leukocytes. Fig. 104.17 shows an approach to differentiating these disorders. For most, carrier identification and prenatal diagnosis are available; a specific diagnosis is essential to permit genetic counseling. Neonatal screening using dried blood spots and performing enzyme assays and mutational analysis for Gaucher, Pompe, Fabry, and Niemann-Pick diseases are undergoing pilot studies, and the FDA has approved the Seeker System for detection of Gaucher and Fabry diseases. The characterization of the genes that encode the specific enzymes required for sphingolipid metabolism permit the development of therapeutic
options, such as recombinant enzyme replacement therapy, as well as the potential of cell or gene therapy. Identification of specific disease-causing mutations improves diagnosis, prenatal detection, and carrier identification. For several disorders (Gaucher, Fabry, Niemann-Pick types A and B), it has been possible to make genotype-phenotype correlations that predict disease severity and allow more precise genetic counseling. Inheritance is autosomal recessive except for X-linked Fabry disease.

![Algorithm of the clinical evaluation recommended for an infant with a suspected lysosomal storage disease. GAGs, Glycosaminoglycans; ISSD, infantile sialic acid storage disease; NIHF, nonimmune hydrops fetalis. (From Staretz-Chacham O, Lang TC, LaMarca ME, et al: Lysosomal...)](image-url)
GM₁ Gangliosidosis

GM₁ gangliosidosis most frequently presents in early infancy but has been described in patients with juvenile- and adult-onset subtypes. Inherited as an autosomal recessive trait, each subtype results from a different gene mutation that leads to the deficient activity of β-galactosidase, a lysosomal enzyme encoded by a gene on chromosome 3 (3p21.33). Although the disorder is characterized by the pathologic accumulation of GM₁ gangliosides in the lysosomes of both neural and visceral cells, GM₁ ganglioside accumulation is most marked in the brain. In addition, keratin sulfate, a mucopolysaccharide, accumulates in liver and is excreted in the urine of patients with GM₁ gangliosidosis. The β-galactosidase gene has been isolated and sequenced; mutations causing the disease subtypes have been identified.

The clinical manifestations of the **infantile** form of GM₁ gangliosidosis may be evident in the newborn as hepatosplenomegaly, edema, and skin eruptions (angiokeratoma). It most frequently presents in the 1st 6 mo of life with developmental delay followed by progressive psychomotor retardation and the onset of tonic-clonic seizures. Typical facies is characterized by low-set ears, frontal bossing, a depressed nasal bridge, and an abnormally long philtrum. Up to 50% of patients have a macular cherry-red spot. Hepatosplenomegaly and skeletal abnormalities are present, such as those of the mucopolysaccharidoses, including anterior beaking of the vertebrae, enlargement of the sella turcica, and thickening of the calvarium. By the end of the 1st yr of life, most patients are blind and deaf, with severe neurologic impairment characterized by decerebrate rigidity. Death usually occurs by 3-4 yr of age. The **juvenile-onset** form of GM₁ gangliosidosis is clinically distinct, with a variable age at onset. Affected patients present primarily with neurologic symptoms, including ataxia, dysarthria, intellectual disability, and spasticity. Deterioration is slow; patients may survive through the 4th decade of life. These patients lack the visceral involvement, facial abnormalities, and skeletal features seen in type 1 disease. Adult-onset patients have been described who present with gait and speech abnormalities, dystonia and mild skeletal abnormalities. **There is no specific treatment** for either form of GM₁ gangliosidosis.
The diagnosis of GM<sub>1</sub> gangliosidosis should be suspected in infants with typical clinical features and is confirmed by the demonstration of the deficiency of β-galactosidase activity in peripheral leukocytes. Other disorders that share some of the features of the GM<sub>1</sub> gangliosidoses include Hurler disease (mucopolysaccharidosis type I), I-cell disease, and Niemann-Pick disease type A, each of which can be distinguished by the demonstration of their specific enzymatic deficiencies. Carriers of the disorder are detected by the measurement of the enzymatic activity in peripheral leukocytes or by identifying the specific gene mutations; prenatal diagnosis is accomplished by determination of the enzymatic activity in cultured amniocytes or chorionic villi or identification of the specific disease-causing mutations. Only supportive therapy is available for patients with GM<sub>1</sub> gangliosidosis. However, studies in mice with GM<sub>1</sub> gangliosidosis have demonstrated that oral N-octyl-4-epi-β-valienamine (NOEV), which stabilizes the mutant enzyme protein produced by the affected animals, crossed the brain and improved neurologic deterioration, suggesting that this approach may be useful in human study.

**The GM<sub>2</sub> Gangliosidoses**

The GM<sub>2</sub> gangliosidoses include Tay-Sachs disease and Sandhoff disease; each results from deficiency of β-hexosaminidase activity and lysosomal accumulation of GM<sub>2</sub> gangliosides, particularly in the CNS. Both disorders have been classified into infantile-, juvenile-, and adult-onset forms based on the age at onset and clinical features. β-Hexosaminidase occurs as 2 isozymes: β-hexosaminidase A, which is composed of 1 α and 1 β subunit, and β-hexosaminidase B, which has 2 β subunits. B-Hexosaminidase A deficiency results from mutations in the α subunit and causes Tay-Sachs disease, whereas mutations in the β subunit result in the deficiency of both β-hexosaminidases A and B and cause Sandhoff disease. Both are autosomal recessive traits, with Tay-Sachs disease being more common in the Ashkenazi Jewish population, in whom the carrier frequency is approximately 1 in 25.

More than 50 mutations have been identified; most are associated with the infantile forms of disease. Three mutations account for >98% of mutant alleles among Ashkenazi Jewish carriers of Tay-Sachs disease, including one allele associated with the adult-onset form. Mutations that cause the subacute or adult-onset forms result in enzyme proteins with residual enzymatic activities, the
levels of which correlate with the severity of the disease.

Patients with the infantile form of **Tay-Sachs disease** have clinical manifestations in infancy such as loss of motor skills, increased startle reaction, and macular pallor and retinal cherry-red spots (see **Table 104.15**). Affected infants usually develop normally until 4-5 mo of age, when decreased eye contact and an exaggerated startle response to noise (**hyperacusis**) are noted. **Macrocephaly**, not associated with hydrocephalus, may develop. In the 2nd yr of life, seizures develop, which may be refractory to anticonvulsant therapy. Neurodegeneration is relentless, with death occurring by age 4 or 5 yr. The juvenile- and later-onset forms initially present with ataxia and dysarthria and may not be associated with a macular cherry-red spot.

The clinical manifestations of **Sandhoff disease** are similar to those of Tay-Sachs disease. Infants with Sandhoff disease have hepatosplenomegaly, cardiac involvement, and mild bony abnormalities. The **juvenile** form of this disorder presents as ataxia, dysarthria, and mental deterioration, but without visceral enlargement or a macular cherry-red spot. **No treatment is available** for Tay-Sachs disease or Sandhoff disease, although experimental approaches are being evaluated.

The diagnosis of **infantile** Tay-Sachs disease and Sandhoff disease is usually suspected in an infant with neurologic features and a cherry-red spot. Definitive diagnosis is made by determination of β-hexosaminidase A and B activities in peripheral leukocytes. The 2 disorders are distinguished by the enzymatic assay, because in Tay-Sachs disease only the β-hexosaminidase A isozyme is deficient, whereas in Sandhoff disease both the β-hexosaminidase A and B isozymes are deficient. At-risk pregnancies for both disorders can be prenatally diagnosed by determining the enzyme levels in fetal cells obtained by amniocentesis or chorionic villus sampling. Identification of carriers in families is also possible by β-hexosaminidases A and B determination. Indeed, for Tay-Sachs disease, carrier screening of all couples in which at least 1 member is of Ashkenazi Jewish descent is recommended before the initiation of pregnancy to identify couples at risk. These studies can be conducted by the determination of the level of β-hexosaminidase A activity in peripheral leukocytes or plasma. Molecular studies to identify the exact molecular defect in enzymatically identified carriers should also be performed to permit more specific identification of carriers in the family and to allow prenatal diagnosis in at-risk couples by both enzymatic and genotype determinations. The incidence of Tay-Sachs disease has been greatly reduced since the introduction of carrier screening programs in the Ashkenazi
Jewish population. Newborn screening may be possible by measuring specific glycosphingolipid markers or the relevant enzymatic activities in dried blood spots.

**Gaucher Disease**

Gaucher disease is a multisystemic lipidosis characterized by hematologic abnormalities, organomegaly, and skeletal involvement, the latter usually manifesting as bone pain and pathologic fractures (see Table 104.15). It is one of the most common lysosomal storage diseases and the most prevalent genetic defect among Ashkenazi Jews. There are 3 clinical subtypes, delineated by the absence or presence and progression of neurologic manifestations: **type 1**, or the adult, nonneuronopathic form; **type 2**, the infantile or acute neuronopathic form; and **type 3**, the juvenile or subacute neuronopathic form. All are autosomal recessive traits. Type 1, which accounts for 99% of cases, has a striking predilection for Ashkenazi Jews, with an incidence of approximately 1 in 1,000 live births and a carrier frequency of approximately 1 in 18 adults.

Gaucher disease results from the deficient activity of the lysosomal hydrolase, acid β-glucosidase, which is encoded by a gene located on chromosome 1q21-q31. The enzymatic defect results in the accumulation of undegraded glycolipid substrates, particularly glucosylceramide, in cells of the reticuloendothelial system (RES). This progressive deposition results in infiltration of the bone marrow, progressive hepatosplenomegaly, and skeletal complications. Four mutations—N370S, L444P, 84insG, and IVS2+2—account for approximately 95% of mutant alleles among Ashkenazi Jewish patients, permitting screening for this disorder in this population. Genotype-phenotype correlations have been noted, providing the molecular basis for the clinical heterogeneity seen in Gaucher disease type 1. Patients who are homozygous for the N370S mutation tend to have a later onset of clinical manifestations, with a more indolent course than patients with 1 copy of N370S and another common allele.

Clinical manifestations of **type 1 Gaucher disease** have a variable age at onset, from early childhood to late adulthood, with most symptomatic patients presenting by adolescence. At presentation, patients may have bruising from thrombocytopenia, chronic fatigue secondary to anemia, hepatomegaly with or without elevated LFT results, splenomegaly, and bone pain. Occasional patients have pulmonary involvement at presentation. Patients presenting in the 1st decade frequently are not Jewish and have growth retardation and a more
malignant course. Other patients may be discovered fortuitously during evaluation for other conditions or as part of routine examinations; these patients may have a milder or even a benign course. In symptomatic patients, splenomegaly is progressive and can become massive. Most patients develop radiologic evidence of skeletal involvement, including an Erlenmeyer flask deformity of the distal femur. Clinically apparent bony involvement, which occurs in most patients, can present as bone pain, a pseudoosteomyelitis pattern, or pathologic fractures. Lytic lesions can develop in the long bones, including the femur, ribs, and pelvis; osteosclerosis may be evident at an early age. Bone crises with severe pain and swelling can occur. Bleeding secondary to thrombocytopenia may manifest as epistaxis or bruising and is frequently overlooked until other symptoms become apparent. With the exception of the severely growth-retarded child, who may experience developmental delay secondary to the effects of chronic disease, development and intelligence are normal.

The pathologic hallmark of Gaucher disease is the Gaucher cell in the RES, particularly in the bone marrow (Fig. 104.18). These cells, which are 20-100 μm in diameter, have a characteristic wrinkled-paper appearance resulting from the presence of intracytoplasmic substrate inclusions. The cytoplasm of the Gaucher cell reacts strongly positive with the periodic acid–Schiff (PAS) stain. The presence of this cell in bone marrow and tissue specimens is highly suggestive of Gaucher disease, although it also may be found in patients with granulocytic leukemia and myeloma.

![Cells from the spleen of a patient with Gaucher disease. A characteristic spleen cell is shown engorged with glucocerebroside.](image_url)
**Gaucher disease type 2** is a rare form and does not have an ethnic predilection. It is characterized by a rapid neurodegenerative course with extensive visceral involvement and death early in life. It presents in infancy with increased tone, strabismus, and organomegaly. Failure to thrive and stridor caused by laryngospasm are typical. After a several-year period of psychomotor regression, death typically occurs secondary to respiratory compromise.

**Gaucher disease type 3** presents with clinical manifestations that are intermediate to those seen in types 1 and 2, with presentation in childhood and death by age 10-15 yr. It has a predilection for the Swedish Norrbottian population, in whom the incidence is approximately 1 in 50,000. Neurologic involvement is present. Type 3 disease is further classified as types 3a and 3b based on the extent of neurologic involvement and whether there is progressive myotonia and dementia (type 3a) or isolated supranuclear gaze palsy (type 3b).

Gaucher disease should be considered in the differential diagnosis of patients with unexplained organomegaly, who bruise easily, who have bone pain, or who have a combination of these conditions. Bone marrow examination usually reveals the presence of Gaucher cells. All suspected diagnoses should be confirmed by determination of the acid β-glucosidase activity in isolated leukocytes or cultured fibroblasts, as well as by identification of their specific acid β-glucosidase gene mutations. In Ashkenazi Jewish individuals the identification of carriers can be achieved best by molecular testing for the common Ashkenazi mutations. Testing should be offered to all family members, keeping in mind that heterogeneity, even among members of the same kindred, can be so great that nonsymptomatic affected individuals may be diagnosed.

**Prenatal diagnosis** is available by determination of enzyme activity and/or the specific family mutations in chorionic villi or cultured amniotic fluid cells.

**Treatment** of patients with Gaucher disease type 1 includes enzyme replacement therapy (ERT). The efficacy of ERT with mannose-terminated recombinant human acid β-glucosidase (*imiglucerase* [Cerezyme, Genzyme]), *velaglucerase alfa* [VPRIV, Shire HGT]), or *taliglucerase alfa* (Uplyso, Protalix Biotherapeutics) is the standard of care for the treatment of patients with type 1 disease. Most symptoms (organomegaly, hematologic indices, bone pain) are reversed by ERT (60 IU/kg) administered by IV infusion every other week, and the bone involvement can be stabilized or improved. Although ERT does not alter the neurologic progression of patients with Gaucher disease types 2 and 3, it has been used in selected patients as a palliative measure, particularly in type 3 patients with severe visceral involvement. Alternative treatment with oral
substrate reduction agents designed to decrease the synthesis of glucosylceramide by chemical inhibition of glucosylceramide synthase include miglustat (Zavesca, Actelion), although its efficacy on hematologic parameters is not as great as ERT. A 2nd, more effective substrate inhibitor, eliglustat (Cerdelga, Sanofi-Genzyme), has demonstrated significant efficacy versus placebo and is not inferior to imiglucerase making this an alternative first-line oral treatment for patients with type 1 disease. A small number of patients have undergone bone marrow transplantation (BMT), which is curative but is associated with significant morbidity and mortality from the procedure, limiting the selection of appropriate candidates.

Niemann-Pick Disease

The original description of Niemann-Pick disease (NPD) was what is now known as type A NPD, a fatal disorder of infancy characterized by failure to thrive, hepatosplenomegaly, and a rapidly progressive neurodegenerative course that leads to death by 2-3 yr of age. Type B disease is a nonneuronopathic form observed in children and adults. Type C disease is a neuronopathic form that results from defective cholesterol transport. All subtypes are inherited as autosomal recessive traits and display variable clinical features (see Table 104.15).

NPD types A and B result from the deficient activity of acid sphingomyelinase (ASM), a lysosomal enzyme encoded by a gene on chromosome 11 (11p15.1-p15.4). The enzymatic defect results in the pathologic accumulation of sphingomyelin, a ceramide phospholipid, and other lipids in the monocyte-macrophage system, the primary pathologic site. The progressive deposition of sphingomyelin in the CNS results in the neurodegenerative course seen in type A and in nonneural tissue in the systemic disease manifestations of type B, including progressive lung disease in some patients. A variety of mutations in the acid sphingomyelinase gene that cause types A and B NPD have been identified.

The clinical manifestations and course of type A NPD are uniform and characterized by a normal appearance at birth followed by hepatosplenomegaly, moderate lymphadenopathy, and psychomotor retardation evident by 6 mo of age. Over time, the loss of motor function and the deterioration of intellectual capabilities are progressively debilitating; spasticity and rigidity develop; and death occurs by 3 yr of age. In contrast to the stereotyped type A phenotype, the
clinical presentation and course of patients with type B disease are more variable. Most are diagnosed in infancy or childhood when enlargement of the liver or spleen, or both, is detected during a routine physical examination. At diagnosis, type B NPD patients usually have evidence of mild pulmonary involvement, usually detected as a diffuse reticular or finely nodular infiltration on the chest radiograph. Pulmonary symptoms may present in adults. In most patients, hepatosplenomegaly is particularly prominent in childhood, but with increasing linear growth, the abdominal protuberance decreases and becomes less conspicuous. In mildly affected patients the splenomegaly may not be noted until adulthood, and disease manifestations may be minimal.

Severely affected patients may have liver involvement leading to life-threatening cirrhosis, portal hypertension, and ascites. Clinically significant pancytopenia caused by secondary hypersplenism may require partial or complete splenectomy; this should be avoided if possible because splenectomy frequently causes progression of pulmonary disease, which can be life threatening. In general, type B patients do not have neurologic involvement and have a normal IQ. Some patients with type B disease have cherry-red maculae or haloes and subtle neurologic symptoms (peripheral neuropathy). In some type B patients, decreased pulmonary diffusion caused by alveolar infiltration becomes evident in late childhood or early adulthood and progresses with age. Severely affected individuals may experience significant pulmonary compromise by 15-20 yr of age. Such patients have low oxygen tension (Po2) values and dyspnea on exertion. Life-threatening bronchopneumonia may occur, and cor pulmonale has been described.

Type C NPD patients often present with prolonged neonatal jaundice, appear normal for 1-2 yr, and then experience a slowly progressive and variable neurodegenerative course. Their hepatosplenomegaly is less severe than that of patients with types A or B NPD, and they may survive into adulthood. The underlying biochemical defect in type C patients is an abnormality in cholesterol transport, leading to the accumulation of sphingomyelin and cholesterol in their lysosomes and a secondary partial reduction in ASM activity (see Chapter 104.3).

In type B NPD patients, splenomegaly is usually the first manifestation detected. The splenic enlargement is noted in early childhood; in very mild disease the enlargement may be subtle and detection delayed until adolescence or adulthood. The presence of the characteristic NPD cells in bone marrow aspirates supports the diagnosis of type B NPD. Patients with type C NPD,
however, also have extensive infiltration of NPD cells in the bone marrow, and thus all suspected cases should be evaluated enzymatically to confirm the clinical diagnosis by measuring the ASM activity level in peripheral leukocytes. Patients with types A and B NPD have greatly decreased ASM levels (1–10%), whereas patients with type C NPD have normal or somewhat decreased ASM activities. The enzymatic identification of NPD carriers is problematic. For families in whom the specific molecular lesion has been identified, however, family members can be accurately tested for heterozygote status by DNA analysis. Prenatal diagnosis of types A and B NPD can be made reliably by the measurement of ASM activity in cultured amniocytes or chorionic villi; molecular analysis of fetal cells to identify the specific ASM mutations can provide the specific diagnosis or serve as a confirmatory test. The clinical diagnosis of type C NPD can be supported by filipin stain positivity in cultured fibroblasts and identification of a specific mutation in the NPC1 or NPC2 gene.

There is no specific treatment for NPD. Orthotopic liver transplantation in an infant with type A disease and cord blood transplantation in several type B NPD patients have been attempted with little or no success. BMT in a small number of type B NPD patients has been successful in reducing the spleen and liver volumes, the sphingomyelin content of the liver, the number of Niemann-Pick cells in the marrow, and radiologically detected infiltration of the lungs. In one patient, liver biopsies taken up to 33 mo after transplant showed only a moderate reduction in stored sphingomyelin. ERT with recombinant human ASM is currently in clinical trials for the treatment of type B patients. A 26-wk phase 1b study in adult patients with NPD type B established initial proof of concept in this patient group, and a phase 1/2 clinical trial in pediatric patients and a phase 2/3 trial in adult patients with ASM deficiency are ongoing. Clinical trials of miglustat have been performed, and the drug has been approved in Europe for the treatment of type C disease. Treatment of type A disease by BMT has not been successful, presumably because of the severe neurologic involvement.

**Fabry Disease**

Fabry disease is an X-linked inborn error of glycosphingolipid metabolism caused by the absent or extremely deficient activity of α-galactosidase A (α-gal A). There are 2 major phenotypes. Affected males with the classic phenotype present in childhood with angiokeratomas (telangiectatic skin lesions), hypohidrosis, corneal and lenticular opacities, and painful acroparesthesias. With
advancing age, they develop kidney failure, heart disease, and stroke (see Table 104.15). This classic phenotype is caused by the absent activity of the α-gal A and has an estimated prevalence of approximately 1 in 40,000 males. The later-onset phenotype occurs in affected males with residual α-gal A activity and presents in the 4th to 8th decades with cardiac disease and renal failure. This phenotype is more prevalent than the classic phenotype. Heterozygous females for the classic phenotype can be asymptomatic or as severely affected as the males, the variability a result of random X-chromosomal inactivation. The enzyme deficiency results from mutations in the α-gal A gene located on the long arm of the X chromosome (Xq22). The enzymatic defect leads to the systemic accumulation of neutral glycosphingolipids, primarily globotriaosylceramide, particularly in the plasma and lysosomes of vascular endothelial and smooth muscle cells, cardiac myocytes, and renal podocytes. The progressive vascular glycosphingolipid deposition in classically affected males results in small-vessel occlusion and ischemia, leading to the major disease manifestations. The complementary DNA (cDNA) and genomic sequences encoding α-gal A have been characterized, and >900 different mutations in the α-gal A gene are responsible for this lysosomal storage disease.

The angiokeratomas usually occur in childhood and may lead to early diagnosis (Fig. 104.19). They increase in size and number with age and range from barely visible to several millimeters in diameter. The lesions are punctate, dark red to blue-black, and flat or slightly raised. They do not blanch with pressure, and the larger ones may show a slight hyperkeratosis. Characteristically, the lesions are densest between the umbilicus and knees, in the “bathing trunk area,” but may occur anywhere, including the oral mucosa. The hips, thighs, buttocks, umbilicus, lower abdomen, scrotum, and glans penis are common sites, and there is a tendency toward symmetry. Variants without skin lesions have been described. Sweating is usually decreased or absent. Corneal opacities and characteristic lenticular lesions, observed under slit-lamp examination, are present in affected males, as well as in approximately 90% of heterozygotes from families with the classic phenotype. Conjunctival and retinal vascular tortuosity is common and results from the systemic vascular involvement.
Pain is the most debilitating symptom in childhood and adolescence. **Fabry crises**, lasting from hours to several days, consist of agonizing, burning pain in the hands, feet, and proximal extremities and are usually associated with exercise, fatigue, fever, or a combination of these factors. These painful acroparesthesias usually become less frequent in the 3rd and 4th decades, although in some men these may become more frequent and severe. Attacks of abdominal or flank pain may simulate appendicitis or renal colic. Pain may suggest other diagnoses (Table 104.17).

The major morbid symptoms in classically affected males result from the progressive involvement of the vascular system. Early in the course of the classic phenotype, casts, RBCs, and lipid inclusions with characteristic birefringent “Maltese crosses” appear in the urinary sediment. Proteinuria, isosthenuria, and gradual deterioration of renal function and development of azotemia occur in the 2nd to 4th decades in the classic phenotype and in the 4th to 8th decades in the later-onset form. Cardiovascular findings may include arrhythmias, hypertrophic cardiomyopathy, and heart failure. Mitral insufficiency is the most common valvular lesion. Cerebrovascular manifestations, including transient ischemic attack (TIA) and stroke (CVA), result secondary to cardiac arrhythmias as well as multifocal small-vessel involvement, other features may include chronic bronchitis and dyspnea, lymphedema of the legs without hypoproteinemia, episodic diarrhea, osteoporosis, impaired growth, and delayed puberty. Death most often results from renal failure, cardiac disease, or stroke. Before hemodialysis or renal transplantation, the mean age at death for affected men was about 40 yr. Patients with the later-onset phenotype with residual α-gal A activity have cardiac and/or renal disease. The cardiac manifestations include hypertrophy of the left ventricular wall and interventricular septum, and electrocardiographic abnormalities consistent with cardiomyopathy. Hypertrophic cardiomyopathy may lead to ventricular tachycardia as a cause of death.

The diagnosis of Fabry disease in classically affected males is most readily made from the history of painful acroparesthesias, hypohidrosis, the presence of the characteristic skin lesions, and the observation of the corneal opacities and lenticular lesions. The disorder is often misdiagnosed as rheumatic fever, erythromelalgia, or neurosis. The skin lesions must be differentiated from the benign angiokeratomas of the scrotum (Fordyce disease) or from angiokeratoma circumscriptum. Angiokeratomas identical to those of Fabry disease have been reported in fucosidosis, aspartylglycosaminuria, late-onset GM₁ gangliosidosis, galactosialidosis, α-N-acetylgalactosaminidase deficiency, and sialidosis. Later-onset patients have been identified among patients on hemodialysis and patients with hypertrophic cardiomyopathy or who had cryptogenic strokes. Later-onset patients lack the early classic manifestations previously described. The diagnosis of classic and later-onset Fabry disease is
confirmed biochemically by the demonstration of greatly decreased α-gal A activity in plasma, isolated leukocytes, or cultured fibroblasts or lymphoblasts. The specific α-gal A mutation can be determined by gene sequencing. Heterozygous females from classic families may have corneal opacities, isolated skin lesions, and intermediate activities of α-gal A in plasma or cells. Rare female heterozygotes may have manifestations as severe as those in affected males. Asymptomatic at-risk females in classic and later-onset families affected by Fabry disease, however, should be optimally diagnosed by the direct analysis of their family's specific mutation. Prenatal detection of affected males can be accomplished by demonstrating deficient α-gal A activity and the family's specific gene mutation in chorionic villi obtained in the 1st trimester or in cultured amniocytes obtained by amniocentesis in the 2nd trimester of pregnancy. Fabry disease can be detected by newborn screening, and pilot studies have been conducted in Europe, Asia, and North America.

**Treatment** for Fabry disease may include the use of phenytoin and carbamazepine to decrease the frequency and severity of the chronic acroparesthesias and the periodic crises of excruciating pain. Renal transplantation and long-term hemodialysis are lifesaving procedures for patients with renal failure.

Enzyme replacement therapy (ERT) for Fabry patients using recombinant human α-gal A preparations produced in Chinese hamster ovary cells (agalsidase beta, Fabrazyme, Genzyme) and in human fibrosarcoma cells (agalsidase alfa, Replagal, Shire HGT) is available. Both Fabrazyme and Replagal were approved by the European Medicines Agency in the European Union, but only Fabrazyme is approved by the U.S. FDA. The effectiveness of ERT with Fabrazyme has been demonstrated in stabilization of renal disease, regression of hypertrophic cardiomyopathy, reduction of pain, and improvement in quality of life. Because most classically affected males produce no enzyme protein, these patients can produce immunoglobulin G (IgG) antibodies in response to the infused enzyme, which does not reduce the effectiveness of substrate clearance unless the antibody titer is very high. Treatment of classically affected males should begin in childhood.

**Fucosidosis**

Fucosidosis is a rare autosomal recessive disorder caused by the deficient activity of α-fucosidase and the accumulation of fucose-containing
glycosphingolipids, glycoproteins, and oligosaccharides in the lysosomes of the liver, brain, and other organs (see Table 104.15). The α-fucosidase gene is on chromosome 1 (1p24), and specific mutations are known. Although the disorder is panethnic, most reported patients are from Italy and the United States. There is wide variability in the clinical phenotype, with the most severely affected patients presenting in the 1st yr of life with developmental delay and somatic features similar to those of the mucopolysaccharidoses. These features include frontal bossing, hepatosplenomegaly, coarse facial features, and macroglossia. The CNS storage results in a relentless neurodegenerative course, with death in childhood. Patients with milder disease have angiokeratomas and longer survival. No specific therapy exists for fucosidosis. The disorder can be diagnosed by the demonstration of deficient α-fucosidase activity in peripheral leukocytes or cultured fibroblasts. Carrier identification and prenatal diagnosis are possible by determination of the enzymatic activity or the specific family mutations.

Schindler Disease

This autosomal recessive neurodegenerative disorder results from the deficient activity of α-N-acetylgalactosaminidase and the accumulation of asialoglycopeptides and sialyloligosaccharides (see Table 104.15). The gene for the enzyme is located on chromosome 22 (22q11). Schindler disease is clinically heterogeneous, and 2 major phenotypes have been identified. Type I disease is an infantile-onset neuroaxonal dystrophy. Affected infants have normal development for the 1st 9-15 mo of life followed by a rapid neurodegenerative course that results in severe psychomotor retardation, cortical blindness, and frequent myoclonic seizures. Type II disease is characterized by a variable age at onset, mild intellectual disability, and angiokeratomas. There is no specific therapy for either form of the disorder. The diagnosis is by demonstration of the enzymatic deficiency in leukocytes or cultured skin fibroblasts or specific gene mutations.

Metachromatic Leukodystrophy

This autosomal recessive white matter disease is caused by a deficiency of arylsulfatase A (ASA), which is required for the hydrolysis of sulfated
glycosphingolipids. Another form of metachromatic leukodystrophy (MLD) is caused by a deficiency of a sphingolipid activator protein (SAP1), which is required for the formation of the substrate-enzyme complex. The deficiency of this enzymatic activity results in the white matter storage of sulfated glycosphingolipids, which leads to demyelination and a neurodegenerative course. The ASA gene is on chromosome 22 (22q13.31qter); specific mutations tend to fall into 2 groups that correlate with disease severity.

The clinical manifestations of the late-infantile form of MLD, which is most common, usually present between 12 and 18 mo of age as irritability, inability to walk, and hyperextension of the knee, causing genu recurvatum. The clinical progression of the disease relates to the pathologic involvement of both central and peripheral nervous systems, giving a mixture of upper and lower motor neuron and cognitive and psychiatric signs. Deep tendon reflexes are diminished or absent. Gradual muscle wasting, weakness, and hypotonia become evident and lead to a debilitated state. As the disease progresses, nystagmus, myoclonic seizures, optic atrophy, and quadriaparesis appear, with death in the 1st decade of life (see Table 104.15). The juvenile form of MLD has a more indolent course, with onset that may occur as late as 20 yr of age. This form of the disease presents with gait disturbances, mental deterioration, urinary incontinence, and emotional difficulties. The adult form, which presents after the 2nd decade, is similar to the juvenile form in its clinical manifestations, although emotional difficulties and psychosis are more prominent features. Dementia, seizures, diminished reflexes, and optic atrophy also occur in both juvenile and adult forms. The pathologic hallmark of MLD is the deposition of metachromatic bodies, which stain strongly positive with PAS and Alcian blue, in the white matter of the brain. Neuronal inclusions may be seen in the midbrain, pons, medulla, retina, and spinal cord; demyelination occurs in the peripheral nervous system. The diagnosis of MLD should be suspected in patients with the clinical features of leukodystrophy. Decreased nerve conduction velocities, increased cerebrospinal fluid protein, metachromatic deposits in sampled segments of sural nerve, and metachromatic granules in urinary sediment are all suggestive of MLD. Confirmation of the diagnosis is based on the demonstration of the reduced activity of ASA in leukocytes or cultured skin fibroblasts. SAP deficiency is diagnosed by measuring the concentration of SAP1 in cultured fibroblasts using a specific antibody to the protein. The diagnosis, identification of carriers, and prenatal diagnosis are available for both forms of MLD by detection of the causative mutations in the ASA or SAP genes.
Unrelated-donor umbilical cord blood transplantation has been undertaken in some pediatric patients with MLD. A longitudinal study of 6 patients with late-infantile onset and 14 with juvenile onset revealed that motor deficits present at the time of transplant did not improve, and that neurologic symptoms continued to progress in those with late-infantile presentation. In contrast, in juvenile patients the brainstem auditory evoked responses, visual evoked potentials, electroencephalogram, and/or peripheral nerve conduction velocities stabilized or improved. Therefore, consideration of umbilical cord blood transplantation for children with presymptomatic late-infantile MLD or minimally symptomatic juvenile MLD may be indicated. Clinical trials of a recombinant human arylsulfatase A (rhARSA) enzyme (Metazym, Shire HGT) demonstrated its safety in children with late-infantile MLD, but a lack of efficacy. A multicenter phase I/II clinical trial to evaluate the safety and efficacy of rhARSA administered intrathecally is ongoing.

Multiple-Sulfatase Deficiency

This autosomal recessive disorder results from the enzymatic deficiency of at least 9 sulfatases, including arylsulfatases A, B, and C and iduronate-2-sulfatase. The specific defect is an enzyme in the C-α-formylglycine–generating system (the gene for which is located at 3p26), which introduces a common posttranslational modification in all the affected sulfatases and explains the occurrence of these multiple enzyme defects. Because of the deficiency of these enzymes, sulfatides, mucopolysaccharides, steroid sulfates, and gangliosides accumulate in the cerebral cortex and visceral tissues, resulting in a clinical phenotype with features of a leukodystrophy as well as those of the mucopolysaccharidoses. Severe ichthyosis may also occur. Carrier testing and prenatal diagnosis can be done by measurement of the enzymatic activities or the specific gene defects. There is no specific treatment for multiple sulfatase deficiency other than supportive care.

Krabbe Disease

Also called globoid cell leukodystrophy, Krabbe disease is an autosomal recessive fatal disorder of infancy. It results from the deficient activity of galactocerebrosidase and the white matter accumulation of galactosylceramide
which is normally found almost exclusively in the myelin sheath. Both peripheral and central myelin is affected, resulting in spasticity and cognitive impairment coupled with deceptively normal or even absent deep tendon reflexes. The galactocerebrosidase gene is on chromosome 14 (14q31), and specific disease-causing mutations are known. The infantile form of Krabbe disease is rapidly progressive, and patients present in early infancy with irritability, seizures, and hypertonia (see Table 104.15). Optic atrophy is evident in the 1st yr of life, and mental development is severely impaired. As the disease progresses, optic atrophy and severe developmental delay become apparent; affected children exhibit opisthotonos and die before 3 yr of age. A late-infantile form of Krabbe presents after age 2 yr. Affected individuals have a course similar to that of the early-infantile form.

The diagnosis of Krabbe disease relies on the demonstration of the specific enzymatic deficiency in white blood cells or cultured skin fibroblasts. Causative gene mutations have been identified. Carrier identification and prenatal diagnosis are available. The development of methods to measure galactocerebrosidase activity on dried blood spots has led to the inclusion of Krabbe disease in the newborn screening programs of some states. Treatment of infants with Krabbe disease with umbilical cord blood transplantation has been reported in prenatally identified asymptomatic newborns and symptomatic infants. Transplanted infants appear to develop neurologic manifestations at a slower rate but succumb to a neurologic demise.

Farber Disease

This rare autosomal recessive disorder results from the deficiency of the lysosomal enzyme acid ceramidase and the accumulation of ceramide in various tissues, especially the joints. Symptoms can begin in the 1st yr of life with painful joint swelling and nodule formation (Fig. 104.20), which is sometimes diagnosed as rheumatoid arthritis. As the disease progresses, nodule or granulomatous formation on the vocal cords can lead to hoarseness and breathing difficulties; failure to thrive is common. In some patients, moderate CNS dysfunction is present (see Table 104.15). Patients may die of recurrent pneumonias in their teens. There is currently no specific therapy. The diagnosis of Farber disease should be suspected in patients who have nodule formation over the joints but no other findings of rheumatoid arthritis. In such patients, acid ceramidase activity should be determined in cultured skin fibroblasts or
Peripheral leukocytes. Various disease-causing mutations have been identified in the acid ceramidase gene. Carrier detection and prenatal diagnosis are available.

**FIG. 104.20** Forearm of an 18 mo old girl with Farber disease. Note the painful joint swelling and the nodule formation. The infant was suspected of having rheumatoid arthritis.

**Wolman Disease and Cholesterol Ester Storage Disease**

These autosomal recessive lysosomal storage diseases result from deficiency of *lysosomal acid lipase (LAL)* and accumulation of cholesterol esters and triglycerides in histiocytic foam cells of most visceral organs. The *LAL* gene is on chromosome 10 (10q24-q25). **Wolman disease** is the more severe clinical phenotype and is a fatal disorder of infancy. Clinical features become apparent in the 1st weeks of life and include failure to thrive, relentless vomiting, abdominal distention, steatorrhea, and hepatosplenomegaly (see Table 104.15). There usually is hyperlipidemia. Hepatic dysfunction and fibrosis may occur. **Calcification of the adrenal glands** occurs in about 50% of patients. Death usually occurs within the 1st 6 mo of life.
**Cholesterol ester storage disease** is less severe than Wolman disease and may not be diagnosed until adulthood. Hepatomegaly can be the only detectable abnormality, but affected individuals are at significant risk for premature cirrhosis and atherosclerosis. Adrenal calcification can occur in patients with severe early onset.  

**Diagnosis** and carrier identification are based on measuring LAL activity in peripheral leukocytes or cultured skin fibroblasts. Disease-causing mutations have been identified in the *LAL* gene. Prenatal diagnosis depends on measuring decreased enzyme levels or identifying specific mutations in cultured chorionic villi or amniocytes. Pharmacologic agents to suppress cholesterol synthesis, in combination with cholestyramine and diet modification, have been used in patients, but with little to no clinical benefit. *Sebelipase alfa* (Kanuma, Alexion) is a recombinant form of LAL approved by the FDA in 2015. In a clinical study, 67% of infants with LAL deficiency survived beyond 12 mo of age, compared with 0% of untreated infants in a historical cohort, all of whom died by 8 mo. In a study of 66 pediatric and adult patients with cholesteryl ester storage disease, those treated with Kanuma had demonstrated significant reductions in serum alanine transaminase (ALT) levels and liver fat and improvements in LDL-C, triglycerides, and HDL-C, compared to placebo-treated patients (see **Chapter 104.3**).

I-cell disease (mucolipidosis II [ML-II]) and pseudo-Hurler polydystrophy (mucolipidosis III [ML-III]) are rare autosomal recessive disorders that share some clinical features with Hurler syndrome (see Chapter 107). These diseases result from the abnormal targeting of newly synthesized lysosomal enzymes that normally have phosphorylated mannose residues for binding to the mannose-6-phosphate receptors that transport the enzymes to the lysosomes. These mannose-6-phosphate residues are synthesized in a 2-step reaction that occurs in the Golgi apparatus and is mediated by 2 enzymatic activities. The enzyme that catalyzes the first step, the lysosomal enzyme N-acetylglucosamine-1-phosphotransferase, is defective in both ML-II and ML-III, which are allelic disorders resulting from mutations in the GlcNAc-phosphotransferase α/β-subunits precursor gene (GNPTAB). This enzyme deficiency results in abnormal targeting of the lysosomal enzymes, which are consequently secreted into the extracellular matrix. Because the lysosomal enzymes require the acidic environment of the lysosome to function, patients with this defect accumulate a variety of different substrates because of the intracellular deficiency of most lysosomal enzymes. The diagnosis of ML-II and ML-III can be made by the determination of the serum lysosomal enzymatic activities, which are markedly elevated, or by the demonstration of their reduced enzymatic activity levels in cultured skin fibroblasts. Direct measurement of the phosphotransferase activity is possible as well. Prenatal diagnosis is available for both disorders by measurement of lysosomal enzymatic activities in amniocytes or chorionic villus
cells. Carrier identification is available for both disorders by measurement of enzymatic activities using cultured skin fibroblasts or by mutation analysis of the causative gene. Neonatal screening by tandem mass spectroscopy may detect I-cell disease.

I-Cell Disease

I-cell disease, or ML-II, shares many of the clinical manifestations of Hurler syndrome (see Chapter 107), although there is no mucopolysacchariduria, and the presentation is earlier (see Table 104.15). Some patients have clinical features evident at birth, including coarse facial features, craniofacial abnormalities, restricted joint movement, and hypotonia. Nonimmune hydrops may be present in the fetus. The remainder of patients present in the 1st yr with severe psychomotor retardation, coarse facial features, and skeletal manifestations that include kyphoscoliosis and a lumbar gibbus. Patients may also have congenital dislocation of the hips, inguinal hernias, and gingival hypertrophy. Progressive, severe psychomotor impairment leads to death in early childhood. No treatment is available for I-cell disease.

Pseudo-Hurler Polydystrophy

Pseudo-Hurler polydystrophy, or ML-III, is a less severe disorder than I-cell disease, with later onset and survival to adulthood reported. Affected children may present around age 4 or 5 yr with joint stiffness and short stature. Progressive destruction of the hip joints and moderate dysostosis multiplex are evident. Radiographic evidence of low iliac wings, flattening of the proximal femoral epiphyses with valgus deformity of the femoral head, and hypoplasia of the anterior third of the lumbar vertebrae are characteristic findings. Ophthalmic findings include corneal clouding, retinopathy, and astigmatism; visual complaints are uncommon (see Table 104.15). Some patients have learning disabilities or intellectual disability. Treatment, which should include orthopedic care, is symptomatic.

Carbohydrate synthesis and degradation provide the energy required for most metabolic processes. The important carbohydrates include 3 monosaccharides—glucose, galactose, and fructose—and a polysaccharide, glycogen. Fig. 105.1 shows the relevant biochemical pathways of these carbohydrates. **Glucose** is the principal substrate of energy metabolism, continuously available through dietary intake, gluconeogenesis (glucose made de novo from amino acids, primarily alanine), and glycogenolysis (breakdown of glycogen). Metabolism of glucose generates adenosine triphosphate (ATP) via glycolysis (conversion of glucose or glycogen to pyruvate), mitochondrial oxidative phosphorylation (conversion of pyruvate to carbon dioxide and water), or both. Dietary sources of glucose come from polysaccharides, primarily starch, and the disaccharides lactose, maltose, and sucrose. However, oral intake of glucose is intermittent and unreliable. Gluconeogenesis contributes to maintaining euglycemia (normal levels of glucose in the blood), but this process requires time. Hepatic glycogenolysis provides the rapid release of glucose, and is the most significant factor in maintaining euglycemia. **Glycogen** is also the primary stored energy source in muscle, providing glucose for muscle activity during exercise. Galactose and fructose are monosaccharides that provide fuel for cellular metabolism, though their role is less significant than that of glucose. **Galactose** is derived from lactose (galactose + glucose), which is found in milk and milk products. Galactose is an important energy source in infants, but it is first metabolized to glucose. Galactose (exogenous or endogenously synthesized from glucose) is also an important component of certain glycolipids, glycoproteins, and glycosaminoglycans. The dietary sources of **fructose** are sucrose (fructose + glucose, sorbitol) and fructose itself, which is found in fruits, vegetables, and
FIG. 105.1 Pathway related to glycogen storage diseases and galactose and fructose disorders. G, Glycogen, the primer for glycogen synthesis; GLUT-2, glucose transporter 2; GSA, active glycogen synthase; GSb, inactive glycogen synthase; NAD/NADH, nicotinamide adenine dinucleotide; Pa, active phosphorylase; PaP, phosphorylase a
Defects in glycogen metabolism typically cause an accumulation of glycogen in the tissues, thus the name glycogen storage disease (Table 105.1). Defects in gluconeogenesis or the glycolytic pathway, including galactose and fructose metabolism, do not result in an accumulation of glycogen (Table 105.1). The defects in pyruvate metabolism in the pathway of the conversion of pyruvate to carbon dioxide and water via mitochondrial oxidative phosphorylation are more often associated with lactic acidosis and some tissue glycogen accumulation.

enzyme replacement therapy

The disorders of glycogen metabolism, the glycogen storage diseases (GSDs), result from deficiencies of various enzymes or transport proteins in the pathways of glycogen metabolism (see Fig. 105.1). Glycogen found in these disorders is abnormal in quantity, quality, or both. GSDs are categorized by numerical type in accordance with the chronological order in which these enzymatic defects were identified. This numerical classification is still widely used, at least up to number VII. The GSDs can also be classified by organ involvement into liver and muscle glycogenoses (see Table 105.1).

There are more than 12 forms of GSDs. Glucose-6-phosphatase deficiency (type I), lysosomal acid α-glucosidase deficiency (type II), debrancher deficiency (type III), and liver phosphorylase kinase deficiency (type IX) are the most common of those that typically present in early childhood; myophosphorylase deficiency (type V, McArdle disease) is the most common in adolescents and adults. The cumulative frequency of all forms of GSD is
Liver Glycogenoses

The GSDs that principally affect the liver include glucose-6-phosphatase deficiency (type I), debranching enzyme deficiency (type III), branching enzyme deficiency (type IV), liver phosphorylase deficiency (type VI), phosphorylase kinase deficiency (type IX, formerly GSD VIa), glycogen synthase deficiency (type 0), and glucose transporter-2 defect. Because hepatic carbohydrate metabolism is responsible for plasma glucose homeostasis, this group of disorders typically causes fasting hypoglycemia and hepatomegaly. Some (types III, IV, IX) can be associated with liver cirrhosis. Other organs can also be involved and may manifest as renal dysfunction in type I, myopathy (skeletal and/or cardiomyopathy) in types III and IV, as well as in some rare forms of phosphorylase kinase deficiency, and neurologic involvement in types III (peripheral nerves) and IV (diffuse central and peripheral nervous system dysfunction).

Type I Glycogen Storage Disease (Glucose-6-Phosphatase or Translocase Deficiency, Von Gierke Disease)

Type I GSD is caused by the absence or deficiency of glucose-6-phosphatase activity in the liver, kidney, and intestinal mucosa. It has 2 subtypes: type Ia, in which the defective enzyme is glucose-6-phosphatase, and type Ib, in which the defective enzyme is a translocase that transports glucose-6-phosphate across the microsomal membrane. Deficiency of the enzymes in both type Ia and type Ib lead to inadequate hepatic conversion of glucose-6-phosphate to glucose through normal glycogenolysis and gluconeogenesis, resulting in fasting hypoglycemia.

Type I GSD is an autosomal recessive disorder. The gene for glucose-6-phosphatase (G6PC) is located on chromosome 17q21; the gene for translocase (SLC37A4) is on chromosome 11q23. Common pathogenic variants have been identified. Carrier detection and prenatal diagnosis are possible with DNA-based methodologies.

Clinical Manifestations
Patients with type I GSD may present in the neonatal period with hypoglycemia and lactic acidosis but more often present at 3-4 mo of age with hepatomegaly, hypoglycemic seizures, or both. Affected children often have a doll-like face with fat cheeks, relatively thin extremities, short stature, and a protuberant abdomen that is a consequence of massive hepatomegaly. The kidneys are also enlarged, whereas the spleen and heart are not involved.

The biochemical characteristics of type I GSD are hypoglycemia, lactic acidosis, hyperuricemia, and hyperlipidemia. Hypoglycemia and lactic acidosis can develop after a short fast. Hyperuricemia is present in young children; it rarely progresses to symptomatic gout before puberty. Despite marked hepatomegaly, the liver transaminase levels are usually normal or only slightly elevated. Intermittent diarrhea may occur in GSD I. In patients with GSD Ib, the loss of mucosal barrier function as a result of inflammation, which is likely related to the disturbed neutrophil function, seems to be the main cause of diarrhea. Easy bruising and epistaxis are common and are associated with a prolonged bleeding time as a result of impaired platelet aggregation and adhesion.

The plasma may be “milky” in appearance due to strikingly elevated triglyceride levels. Cholesterol and phospholipids are also elevated, but less prominently. The lipid abnormality resembles type IV hyperlipidemia and is characterized by increased levels of very-low-density lipoprotein, low-density lipoprotein, and a unique apolipoprotein profile consisting of increased levels of apolipoproteins B, C, and E, with relatively normal or reduced levels of apolipoproteins A and D. The histologic appearance of the liver is characterized by a universal distention of hepatocytes by glycogen and fat. The lipid vacuoles are particularly large and prominent. There is no associated liver fibrosis.

Although type I GSD affects mainly the liver, multiple organ systems are involved. Delayed puberty is often seen. Females can have ultrasound findings consistent with polycystic ovaries even though other features of polycystic ovary syndrome (acne, hirsutism) are not seen. Nonetheless, fertility appears to be normal, as evidenced in several reports of successful pregnancy in women with GSD I. Increased bleeding during menstrual cycles, including life-threatening menorrhagia, has been reported and could be related to the impaired platelet aggregation. Symptoms of gout usually start around puberty from long-term hyperuricemia. There is an increased risk of pancreatitis, secondary to the lipid abnormalities. The dyslipidemia, together with elevated erythrocyte aggregation, could predispose these patients to atherosclerosis, but premature
Atherosclerosis has not yet been clearly documented except for rare cases. Impaired platelet aggregation and increased antioxidative defense to prevent lipid peroxidation may function as a protective mechanism to help reduce the risk of atherosclerosis. Frequent fractures and radiographic evidence of osteopenia are common; bone mineral content is reduced, even in prepubertal patients.

By the 2nd or 3rd decade of life, some patients with type I GSD develop hepatic adenomas that can hemorrhage and turn malignant in some cases. Pulmonary hypertension has been seen in some long-term survivors of the disease. Iron-refractory anemia and an increased prevalence of thyroid autoimmunity are also being recognized.

Renal disease is another late complication, and most patients with type I GSD >20 yr of age have proteinuria. Many also have hypertension, renal stones, nephrocalcinosis, and altered creatinine clearance. Glomerular hyperfiltration, increased renal plasma flow, and microalbuminuria are often found in the early stages of renal dysfunction and can occur before the onset of proteinuria. In younger patients, hyperfiltration and hyperperfusion may be the only signs of renal abnormalities. With the advancement of renal disease, focal segmental glomerulosclerosis and interstitial fibrosis become evident. In some patients, renal function has deteriorated and progressed to failure, requiring dialysis and transplantation. Other renal abnormalities include amyloidosis, a Fanconi-like syndrome, hypocitraturia, hypercalciuria, and a distal renal tubular acidification defect.

Patients with GSD Ib can have additional features of recurrent bacterial infections from neutropenia and impaired neutrophil function. Oral involvement including recurrent mucosal ulceration, gingivitis, and rapidly progressive periodontal disease may occur in type Ib. Intestinal mucosa ulceration culminating in GSD enterocolitis is also common. Type 1b is also associated with a chronic inflammatory bowel disease (IBD)–like picture involving the colon that may be associated with neutropenia and/or neutrophil dysfunction; it may resemble ulcerative colitis or Crohn disease.

**Diagnosis**

The clinical presentation and laboratory findings of hypoglycemia, lactic acidosis, hyperuricemia, and hyperlipidemia lead to a suspected diagnosis of type I GSD. Neutropenia is noted in GSD Ib patients, typically before 1 yr of age. Neutropenia has also been noted in some patients with GSD Ia, especially
those with the p.G188A variant. Administration of glucagon or epinephrine leads to a negligible increase, if any, in blood glucose levels, but the lactate level rises significantly. Before the availability of genetic testing, a definitive diagnosis required a liver biopsy. Gene-based variant analysis by single-gene sequencing or gene panels provides a noninvasive way to diagnose most patients with GSD types Ia and Ib.

**Treatment**

Treatment focuses on maintaining normal blood glucose levels and is achieved by continuous nasogastric (NG) infusion of glucose or oral administration of uncooked cornstarch. In infancy, overnight NG drip feeding may be needed to maintain normoglycemia. NG feedings can consist of an elemental enteral formula or only glucose or a glucose polymer to provide sufficient glucose to maintain euglycemia. During the day, frequent feedings with high-carbohydrate content are typically sufficient.

Uncooked cornstarch acts as a slow-release form of glucose and can be introduced at a dose of 1.6 g/kg every 4 hr for children <2 yr of age. The response of young children is variable. For older children, the cornstarch regimen can be changed to every 6 hr at a dose of 1.6-2.5 g/kg body weight and can be given orally as a liquid. Newer starch products, such as extended-release waxy maize starch, are thought to be longer acting, better tolerated, and more palatable. Medium-chain triglyceride (MCT) supplementation improves metabolic control, leading to improved growth in children. Since fructose and galactose cannot be converted directly to glucose in GSD type I, these sugars should be restricted in the diet. Sucrose (table sugar, cane sugar, other ingredients), fructose (fruit, juice, high-fructose corn syrup), lactose (dairy foods), and sorbitol should be avoided or limited. As a result of these dietary restrictions, vitamins and minerals such as calcium and vitamin D may be deficient, and supplementation is required to prevent nutritional deficiencies.

Dietary therapy improves hyperuricemia, hyperlipidemia, and renal function, slowing the development of renal failure. This therapy fails, however, to normalize blood uric acid and lipid levels completely in some individuals, despite good metabolic control, especially after puberty. The control of hyperuricemia can be further augmented by the use of allopurinol, a xanthine oxidase inhibitor. The hyperlipidemia can be reduced with lipid-lowering drugs such as β-hydroxy-β-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors and fibrate (see Chapter 104). **Microalbuminuria**, an early indicator
of renal dysfunction in type I disease, is treated with angiotensin-converting enzyme (ACE) inhibitors. Citrate supplements can be beneficial for patients with hypocitraturia by preventing or ameliorating nephrocalcinosis and development of urinary calculi. Thiazide diuretics increase renal reabsorption of filtered calcium and decrease urinary calcium excretion, thereby preventing hypercalciuria and nephrocalcinosis. Growth hormone (GH) should be used with extreme caution and limited to only those with a documented GH deficiency. Even in those patients, there should be close monitoring of metabolic parameters and for the presence of adenomas.

In patients with type Ib GSD, granulocyte and granulocyte-macrophage colony-stimulating factors are successful in correcting the neutropenia, decreasing the number and severity of bacterial infections, and improving the chronic IBD. The minimum effective dose should be used because side effects are noted on these agents, including splenomegaly, hypersplenism, and bone pain. Bone marrow transplantation has been reported to correct the neutropenia of type Ib GSD.

Orthotopic liver transplantation is a potential cure of type I GSD, especially for patients with liver malignancy, multiple liver adenomas, metabolic derangements refractory to medical management, and liver failure. However, this should be considered as a last resort because of the inherent short- and long-term complications. Large adenomas (>2 cm) that are rapidly increasing in size and/or number may necessitate partial hepatic resection. Smaller adenomas (<2 cm) may be treated with percutaneous ethanol injection or transcatheter arterial embolization. Recurrence of liver adenomas is a challenge and may potentiate malignant transformation in these patients, ultimately requiring a liver transplant.

Before any surgical procedure, the bleeding status must be evaluated and good metabolic control established. Prolonged bleeding times can be normalized by the use of intensive intravenous (IV) glucose infusion for 24-48 hr before surgery. DDAVP (1-deamino-8-D-arginine vasopressin) can reduce bleeding complications, but it should be used with caution because of the risk of fluid overload and hyponatremia when administered as an IV infusion. Lactated Ringer solution should be avoided because it contains lactate and no glucose. Glucose levels should be maintained in the normal range throughout surgery with the use of 10% dextrose. Overall, metabolic control is assessed by growth, improvement, and correction of the metabolic abnormalities, such as elevated lactate, glucose, triglyceride, cholesterol, and uric acid levels.
Prognosis
Previously, type I GSD was associated with a high mortality at a young age, and even for those who survived, the prognosis was guarded. Inadequate metabolic control during childhood can lead to long-term complications in adults. Clinical outcomes have improved dramatically with early diagnosis and effective treatment. However, serious complications such as renal disease and formation of hepatic adenomas with potential risk for malignant transformation persist. The ability to identify transformation to hepatocellular carcinoma in the liver adenomas remains a challenge: α-fetoprotein (AFP) and carcinoembryonic antigen (CEA) levels often remain normal in the setting of hepatocellular carcinoma.

Type III Glycogen Storage Disease (Debrancher Deficiency, Limit Dextrinosis)
Type III GSD is caused by deficient activity of the glycogen debranching enzyme. Debranching enzyme, together with phosphorylase, is responsible for complete degradation of glycogen. When debranching enzyme is defective, glycogen breakdown is incomplete, resulting in the accumulation of an abnormal glycogen with short outer-branch chains, which resemble limit dextrin. Symptoms of glycogen debranching enzyme deficiency include hepatomegaly, hypoglycemia, short stature, variable skeletal myopathy, and variable cardiomyopathy. GSD type IIIa usually involves both liver and muscle, whereas in type IIIb, seen in approximately 15% of patients, the disease appears to involve only liver.

Type III GSD is an autosomal recessive disease that has been reported in many different ethnic groups. The frequency is relatively high in Sephardic Jews from North Africa, inhabitants of the Faroe Islands, and in Inuits. The gene for debranching enzyme (AGL) is located on chromosome 1p21. More than 130 different pathogenic variants have been identified; 2 pathogenic variants in exon 3, c.18_19delGA (previously described as c.17_18delAG) and p.Gln6X, are specifically associated with glycogenosis IIIb. Carrier detection and prenatal diagnosis are possible using DNA-based methodologies.

Clinical Manifestations
In infancy and childhood, GSD type III may be indistinguishable from type I
GSD because of overlapping features such as hepatomegaly, hypoglycemia, hyperlipidemia, and growth retardation (Fig. 105.2). Splenomegaly may be present, but the kidneys are typically not affected. Hepatomegaly in most patients with type III GSD improves with age; however, liver fibrosis, cirrhosis progressing to liver failure, and hepatocellular carcinoma (HCC) are noted in many in late adulthood. Hepatic adenomas occur less often in individuals with GSD III than those with GSD I. The relationship between hepatic adenomas and malignancy in GSD III remains unclear. AFP and CEA levels are not good predictors of the presence of hepatocellular adenomas or malignant transformation. A single case of malignant transformation at the site of adenomas has been noted.

FIG. 105.2 Growth and development in a patient with type IIIb glycogen storage disease. The patient has debrancher deficiency in the liver but normal activity in muscle. As a child, he had hepatomegaly, hypoglycemia, and growth retardation. After puberty, he no longer had hepatomegaly or hypoglycemia, and his final adult height is normal. He had no muscle weakness or atrophy; this is in contrast to type IIIa patients, in whom a progressive myopathy is seen in adulthood.

In patients with GSD type IIIa, the muscle weakness is slowly progressive and associated with wasting. The weakness is less remarkable in childhood but
can become severe after the 3rd or 4th decade of life. Low bone mineral density in patients with GSD III put them at an increased risk of potential fractures. Myopathy does not follow any particular pattern of involvement; both proximal and distal muscles are involved. Electromyography reveals a widespread myopathy; nerve conduction studies are often abnormal.

Although overt cardiac dysfunction is rare, ventricular hypertrophy is a frequent finding. **Cardiac pathology** has shown diffuse involvement of various cardiac structures, including vacuolation of myocytes, atrioventricular conduction, and hyperplasia of smooth muscles. Life-threatening arrhythmia and the need for heart transplant have been reported in some GSD III patients. Hepatic symptoms in some patients may be so mild that the diagnosis is not made until adulthood, when the patients show symptoms and signs of neuromuscular disease.

The initial diagnosis has been confused with Charcot-Marie-Tooth disease (see Chapter 631.1). Polycystic ovaries are noted; some patients can develop hirsutism, irregular menstrual cycles, and other features of polycystic ovarian syndrome. Fertility does not appear to be affected; successful pregnancies have been reported.

Hypoglycemia and hyperlipidemia are common. In contrast to type I GSD, elevation of liver transaminase levels and fasting ketosis are prominent, but blood lactate and uric acid concentrations are usually normal. Glucagon administration 2 hr after a carbohydrate meal provokes a normal increase in blood glucose; after an overnight fast, however, glucagon may provoke no change in blood glucose level. Serum creatine kinase levels can be useful to identify patients with muscle involvement, although normal levels do not rule out muscle enzyme deficiency.

**Diagnosis**

The histologic appearance of the liver is characterized by a universal distention of hepatocytes by glycogen and the presence of fibrous septa. The fibrosis and the paucity of fat distinguish type III glycogenosis from type I. The fibrosis, which ranges from minimal periportal fibrosis to micronodular cirrhosis, appears in most cases to be nonprogressive. Overt cirrhosis has been seen in some patients with GSD III.

Patients with myopathy and liver symptoms have a generalized enzyme defect (type IIIa). The deficient enzyme activity can be demonstrated not only in liver and muscle, but also in other tissues such as heart, erythrocytes, and cultured
fibroblasts. Patients with hepatic symptoms without clinical or laboratory evidence of myopathy have debranching enzyme deficiency only in the liver, with enzyme activity retained in the muscle (type IIIb). Before the availability of genetic testing, a definitive diagnosis required enzyme assay in liver, muscle, or both. Gene sequencing now allows for diagnosis and subtype assignment in the majority of patients.

**Treatment**

The mainstay of treatment of GSD III is dietary management, as in GSD I, although it is less demanding. Patients do not need to restrict dietary intake of fructose and galactose, although simple sugars should be avoided to prevent sudden spikes in blood glucose levels. Hypoglycemia is treated with small, frequent meals high in complex carbohydrates, such as cornstarch supplements or nocturnal gastric drip feedings. Additionally, a high-protein diet during the daytime as well as overnight protein enteral infusion is effective in preventing hypoglycemia. The exogenous protein can be used as a substrate for gluconeogenesis which helps to meet energy needs and prevent endogenous protein breakdown. Protein in the diet also reduces the overall starch requirement. Overtreatment with cornstarch should be avoided as it can result in excessive glycogen buildup, which is detrimental and can lead to excessive weight gain. MCT supplementation is being considered as an alternative source of energy. There is no satisfactory treatment for the progressive myopathy other than recommending a high-protein diet and a submaximal exercise program. Close monitoring with abdominal MRI is needed to detect progression of liver fibrosis to cirrhosis and further to HCC. Liver transplantation has been performed in GSD III patients with progressive cirrhosis and/or HCC. There are reports of cardiac transplant in GSD III patients with end stage cardiac disease.

**Type IV Glycogen Storage Disease (Branching Enzyme Deficiency, Amylopectinosis, Polyglucosan Disease, or Andersen Disease)**

Type IV GSD is caused by the deficiency of branching enzyme activity, which results in the accumulation of an abnormal glycogen with poor solubility. The disease is also known as amylopectinosis because the abnormal glycogen has fewer branch points, more α1-4 linked glucose units, and longer outer chains,
resulting in a structure resembling amylopectin. Accumulation of polyglucosan, which is positive on periodic acid–Schiff (PAS) and partially resistant to diastase digestion, is seen in all tissues of patients, but to different degrees.

Type IV GSD is an autosomal recessive disorder. The glycogen branching enzyme (GBE) gene is located on chromosome 3p21. More than 20 pathogenic variants responsible for type IV GSD have been identified, and their characterization in individual patients can be useful in predicting clinical outcome. The nearly complete absence of GBE activity with null variants has been associated with perinatal death and fatal neonatal hypotonia. Residual GBE enzyme activity >5% and presence of at least 1 missense variant are associated with a nonlethal hepatic cirrhosis phenotype and, in some situations, a lack of progressive liver disease.

**Clinical Manifestations**

There is a high degree of clinical variability associated with type IV GSD. The most common and classic form is characterized by progressive cirrhosis of the liver and manifests in the 1st 18 mo of life as hepatosplenomegaly and failure to thrive. Cirrhosis may present with portal hypertension, ascites, and esophageal varices and may progress to liver failure, usually leading to death by 5 yr of age. Rare patients survive without progression of liver disease; they have a milder hepatic form and do not require a liver transplant. Extrahepatic involvement in some patients with GSD IV consists of musculoskeletal involvement, particularly cardiac and skeletal muscles, as well as central nervous system (CNS) involvement.

A **neuromuscular** form of type IV GSD has been reported, with 4 main variants recognized based on age at presentation. The **perinatal** form is characterized by a *fetal akinesia deformation sequence* (FADS) and death in the perinatal period. The **congenital** form presents at birth with severe hypotonia, muscle atrophy, and neuronal involvement, with death in the neonatal period; some patients have cardiomyopathy. The **childhood** form presents primarily with myopathy or cardiomyopathy. The **adult** form, *adult polyglucosan body disease* (APBD), presents as an isolated myopathy or with diffuse CNS and peripheral nervous system dysfunction, accompanied by accumulation of polyglucosan material in the nervous system. Symptoms of neuronal involvement include peripheral neuropathy, neurogenic bladder, and leukodystrophy, as well as mild cognitive decline in some patients. For APBD, a leukocyte or nerve biopsy is needed to establish the diagnosis because branching
enzyme deficiency is limited to those tissues.

**Diagnosis**
Deposition of amylopectin-like materials can be demonstrated in liver, heart, muscle, skin, intestine, brain, spinal cord, and peripheral nerve in type IV GSD. Liver histology shows micronodular cirrhosis and faintly stained basophilic inclusions in the hepatocytes. The inclusions are composed of coarsely clumped, stored material that is PAS positive and partially resistant to diastase digestion. Electron microscopy (EM) shows, in addition to the conventional α and β glycogen particles, accumulation of the fibrillar aggregations that are typical of amylopectin. The distinct staining properties of the cytoplasmic inclusions, as well as EM findings, could be diagnostic. However, polysaccharides with histologic features reminiscent of type IV disease, but without enzymatic correlation, have been observed. The definitive diagnosis rests on the demonstration of the deficient branching enzyme activity in liver, muscle, cultured skin fibroblasts, or leukocytes, or on the identification of pathogenic variants in the *GBE* gene. Prenatal diagnosis is possible by measuring enzyme activity in cultured amniocytes, chorionic villi, or DNA-based methodologies.

**Treatment**
There is no specific treatment for type IV GSD. Nervous system involvement, such as gait problems and bladder involvement, requires supportive, symptomatic management. Unlike patients with the other liver GSDs (I, III, VI, IX), those with GSD IV do not have hypoglycemia, which is only seen when there is overt liver cirrhosis. Liver transplantation has been performed for patients with progressive liver disease, but patients must be carefully selected as this is a multisystem disease, and in some patients, extrahepatic involvement may manifest after transplant. The long-term success of liver transplantation is unknown. Individuals with significant diffuse reticuloendothelial involvement may have greater risk for morbidity and mortality, which may impact the success rate for liver transplant.

**Type VI Glycogen Storage Disease (Liver Phosphorylase Deficiency, Hers Disease)**
Type VI GSD is caused by deficiency of liver glycogen phosphorylase.
Relatively few patients are documented, likely because of underreporting of this disease. Patients usually present with hepatomegaly and growth retardation in early childhood. Hypoglycemia, hyperlipidemia, and hyperketosis are of variable severity. Ketotic hypoglycemia may present after overnight or prolonged fasting. Lactic acid and uric acid levels are normal. Type VI GSD presents within a broad spectrum of involvement, some with a more severe clinical presentation. Patients with severe hepatomegaly, recurrent severe hypoglycemia, hyperketosis, and postprandial lactic acidosis have been reported. Focal nodular hyperplasia of liver and hepatocellular adenoma with malignant transformation into carcinoma is reported in some patients. While cardiac muscle was thought to be unaffected, recently mild cardiomyopathy has been reported in a patient with GSD VI.

**Treatment** is symptomatic and aims to prevent hypoglycemia while ensuring adequate nutrition. A high-carbohydrate, high-protein diet and frequent feeding are effective in preventing hypoglycemia. Blood glucose and ketones should be monitored routinely, especially during periods of increased activity/illness. Long-term follow-up of these patients is needed to expand the understanding of the natural history of this disorder.

GSD VI is an autosomal recessive disease. **Diagnosis** can be confirmed through molecular testing of the liver phosphorylase gene (*PYGL*), which is found on chromosome 14q21-22 and has 20 exons. Many pathogenic variants are known in this gene; a splice-site variant in intron 13 has been identified in the Mennonite population. A liver biopsy showing elevated glycogen content and decreased hepatic phosphorylase enzyme activity can also be used to make a diagnosis. However, with the availability of DNA analysis and next-generation sequencing panels, liver biopsies are considered unnecessary.

**Type IX Glycogen Storage Disease (Phosphorylase Kinase Deficiency)**

Type IX GSD represents a heterogeneous group of glycogenoses. It results from deficiency of the enzyme **phosphorylase kinase** (PhK), which is involved in the rate-limiting step of glycogenolysis. This enzyme has 4 subunits (α, β, γ, δ), each encoded by different genes on different chromosomes and differentially expressed in various tissues. Pathogenic variants in the *PHKA1* gene cause muscle PhK deficiency; pathogenic variants in the *PHKA2* and *PHKG2* genes cause liver PhK deficiency; pathogenic variants in the *PHKB* gene cause PhK deficiency in liver and muscle. Pathogenic variants in the *PHKG1* gene have not
been identified. Defects in subunits $\alpha$, $\beta$, and $\gamma$ are responsible for liver presentation.

**Clinical manifestations** of liver PhK deficiency are usually recognizable within the 1st 2 yr of life and include short stature and abdominal distention from moderate to marked hepatomegaly. The clinical severity of liver PhK deficiency varies considerably. Hyperketotic hypoglycemia, if present, can be mild but may be severe in some cases. Ketosis may occur even when glucose levels are normal. Some children may have mild delays in gross motor development and hypotonia. It is becoming increasingly clear that GSD IX is not a benign condition. Severe phenotypes are reported, with liver fibrosis progressing to cirrhosis and HCC, particularly in patients with $\text{PHKG2}$ variants. Progressive splenomegaly and portal hypertension are reported secondary to cirrhosis. Mild cardiomyopathy has been reported in a patient with GSD IX ($\text{PHKB variant}$). Cognitive and speech delays have been reported in a few individuals, but it is not clear whether these delays are caused by PhK deficiency or coincidental. Renal tubular acidosis has been reported in rare cases. Unlike in GSD I, lactic acidosis, bleeding tendency, and loose bowel movements are not characteristic. Although growth is retarded during childhood, normal height and complete sexual development are eventually achieved. As with debrancher deficiency, abdominal distention and hepatomegaly usually decrease with age and may disappear by adolescence. Most adults with liver PhK deficiency are asymptomatic, although further long-term studies are needed to fully assess the impact of this disorder in adults.

Phenotypic variability within each subtype is being uncovered with the availability of molecular testing. The incidence of all subtypes of PhK deficiency is approximately 1 : 100,000 live births.

**X-Linked Liver Phosphorylase Kinase Deficiency (From $\text{PHKA2}$ Variants)**

X-linked liver PhK deficiency is one of the most common forms of liver glycogenosis in males. In addition to liver, enzyme activity can also be deficient in erythrocytes, leukocytes, and fibroblasts; it is normal in muscle. Typically, a 1-5 yr old boy presents with growth retardation, an incidental finding of hepatomegaly, and a slight delay in motor development. Cholesterol, triglycerides, and liver enzymes are mildly elevated. Ketosis may occur after fasting. Lactate and uric acid levels are normal. Hypoglycemia is typically mild, if present, but can be severe. The response in blood glucose to glucagon is
normal. Hepatomegaly and abnormal blood chemistries gradually improve and can normalize with age. Most adults achieve a normal final height and are usually asymptomatic despite a persistent PhK deficiency. It is increasingly being recognized that this disorder is not benign as previously thought, and there are patients with severe disease and long-term hepatic sequelae. In rare cases, liver fibrosis can occur and progress to cirrhosis.

Liver histology shows glycogen-distended hepatocytes, steatosis, and potentially mild periportal fibrosis. The accumulated glycogen (β particles, rosette form) has a frayed or burst appearance and is less compact than the glycogen seen in type I or III GSD. Fibrous septal formation and low-grade inflammatory changes may be seen.

The gene for the common liver isoform of the PhK α subunit, PHKA2, is located on the X chromosome (αL at Xp22.2). Mutations in the PHKA2 gene account for 75% of all PhK cases. X-linked liver PhK deficiency is further subdivided into 2 biochemical subtypes: XLG1, with measurable deficiency of PhK activity in both blood cells and liver, and XLG2, with normal in vitro PhK activity in blood cells and variable activity in liver. It is suspected that XLG2 may be caused by missense variants that affect enzyme regulation, whereas nonsense variants affecting the amount of protein result in XLG1. Female carriers are unaffected.

**Autosomal Liver and Muscle Phosphorylase Kinase Deficiency (From PHKB Variants)**

PhK deficiency in liver and blood cells with an autosomal recessive mode of inheritance has been reported. Similar to the X-linked form, chief symptoms in early childhood include hepatomegaly and growth retardation. Some patients also exhibit muscle hypotonia. In a few cases where enzyme activity has been measured, reduced PhK activity has been demonstrated in muscle. Mutations are found in PHKB (chromosome 16q12-q13), which encodes the β subunit, and result in liver and muscle PhK deficiency. Several nonsense variants, a single-base insertion, a splice-site mutation, and a large intragenic mutation have been identified. In addition, a missense variant was discovered in an atypical patient with normal blood cell PhK activity.

**Autosomal Liver Phosphorylase Kinase Deficiency (From PHKG2 Variants)**
This form of PhK deficiency is caused by pathogenic variants in the testis/liver isoform (TL) of the γ subunit gene \((PHKG2)\). In contrast to X-linked PhK deficiency, patients with variants in \(PHKG2\) typically have more severe phenotypes, with recurrent hypoglycemia, prominent hepatomegaly, significant liver fibrosis, and progressive cirrhosis. Liver involvement may present with cholestasis, bile duct proliferation, esophageal varices, and splenomegaly. Other reported presentations include delayed motor milestones, muscle weakness, and renal tubular damage. The spectrum of involvement continues to evolve as more cases are recognized. \(PHKG2\) maps to chromosome 16p12.1-p11.2; many pathogenic variants are known for this gene.

**Phosphorylase Kinase Deficiency Limited to Heart**

These patients have been reported with cardiomyopathy in infancy and rapidly progress to heart failure and death. Recent studies have shown that this is not a case of cardiac-specific primary PhK deficiency as suspected previously, but rather linked to the \(γ_2\) subunit of adenosine monophosphate (AMP)–activated protein kinase (see later). The \(γ_2\) subunit is encoded by the \(PRKAG2\) gene.

**Diagnosis**

PhK deficiency may be diagnosed by demonstration of the enzymatic defect in affected tissues. PhK can be measured in leukocytes and erythrocytes, but because the enzyme has many isozymes, the diagnosis can be easily missed without studies of liver, muscle, or heart. Individuals with liver PhK deficiency also usually have elevated transaminases, mildly elevated triglycerides and cholesterol, normal uric acid and lactic acid concentrations, and normal glucagon responses. Gene sequencing is used for diagnostic confirmation and subtyping of GSD IX.

The \(PHKA2\) gene encoding the α subunit is most frequently involved, followed by the \(PHKB\) gene encoding the β subunit. Variants in the \(PHKG2\) gene underlying γ-subunit deficiency are typically associated with severe liver involvement with recurrent hypoglycemia and liver fibrosis.

**Treatment and Prognosis**

The treatment for liver PhK deficiency is symptomatic. It includes a diet high in complex carbohydrates and proteins and small, frequent feedings to prevent hypoglycemia. Cornstarch can be administered with symptom-dependent dosage
and timing (0.6-2.5 g/kg every 6 hr). Oral intake of glucose, if tolerated, should be used to treat hypoglycemia. If not, IV glucose should be given.

Prognosis for the X-linked and certain autosomal forms is typically good; however, long term complications are being recognized. Patients with mutations in the γ subunit typically have a more severe clinical course with progressive liver disease. Liver involvement needs to be monitored in all patients with GSD IX by periodic imaging (abdominal ultrasound or MRI every 6-12 mo) and serial hepatic function tests.

Liver Glycogen Synthase Deficiency

Liver glycogen synthase deficiency type 0 (GSD 0) is caused by deficiency of hepatic glycogen synthase (GYS2) activity, leading to a marked decrease of glycogen stored in the liver. The gene GYS2 is located at 12p12.2. Several pathogenic variants have been identified in patients with GSD 0. The disease appears to be rare in humans, and in the true sense, this is not a type of GSD because the deficiency of the enzyme leads to decreased glycogen stores. Patients present in infancy with early-morning (prebreakfast) drowsiness, pallor, emesis, and fatigue and sometimes convulsions associated with hypoglycemia and hyperketonemia. Blood lactate and alanine levels are low, and there is no hyperlipidemia or hepatomegaly. Prolonged hyperglycemia, glycosuria, lactic acidosis, and hyperalaninemia, with normal insulin levels after administration of glucose or a meal, suggest a deficiency of glycogen synthase. Definitive diagnosis may be by a liver biopsy to measure the enzyme activity or identification of pathogenic variants in GYS2.

Treatment consists of frequent meals, rich in protein and nighttime supplementation with uncooked cornstarch to prevent hypoglycemia and hyperketonemia. Most children with GSD 0 are cognitively and developmentally normal. Short stature and osteopenia are common features. The prognosis seems good for patients who survive to adulthood, including resolution of hypoglycemia, except during pregnancy.

Hepatic Glycogenosis With Renal Fanconi Syndrome (Fanconi-Bickel Syndrome)

Fanconi-Bickel Syndrome is a rare autosomal recessive disorder is caused by defects in the facilitative glucose transporter 2 (GLUT-2), which transports
glucose in and out of hepatocytes, pancreatic β cells, and the basolateral membranes of intestinal and renal epithelial cells. The disease is characterized by proximal renal tubular dysfunction, impaired glucose and galactose utilization, and accumulation of glycogen in liver and kidney.

The affected child typically presents in the 1st yr of life with failure to thrive, rickets, and a protuberant abdomen from hepatomegaly and nephromegaly. The disease may be confused with GSD I because a Fanconi-like syndrome can also develop in type I patients. Adults typically present with short stature, dwarfism, and excess fat in the abdomen and shoulders. Patients are more susceptible to fractures because of early-onset generalized osteopenia. In addition, intestinal malabsorption and diarrhea may occur.

Laboratory findings include glucosuria, phosphaturia, generalized aminoaciduria, bicarbonate wasting, hypophosphatemia, increased serum alkaline phosphatase levels, and radiologic findings of rickets. Mild fasting hypoglycemia and hyperlipidemia may be present. Liver transaminase, plasma lactate, and uric acid levels are usually normal. Oral galactose or glucose tolerance tests show intolerance, which could be explained by the functional loss of GLUT-2 preventing liver uptake of these sugars. Tissue biopsy results show marked accumulation of glycogen in hepatocytes and proximal renal tubular cells, presumably from the altered glucose transport out of these organs. Diffuse glomerular mesangial expansion along with glomerular hyperfiltration and microalbuminuria similar to nephropathy in GSD Ia and diabetes have been reported.

This condition is rare, and 70% of patients with Fanconi-Bickel syndrome have consanguineous parents. Most patients have homozygous pathogenic variants; some patients are compound heterozygotes. The majority of variants detected thus far predict a premature termination of translation. The resulting loss of the C-terminal end of the GLUT-2 protein predicts a nonfunctioning glucose transporter with an inward-facing substrate-binding site.

There is no specific treatment. Symptom-dependent treatment with phosphate and bicarbonate can result in growth improvement. Growth may also improve with symptomatic replacement of water, electrolytes, and vitamin D; restriction of galactose intake; and a diet similar to that used for diabetes mellitus, with small, frequent meals and adequate caloric intake.

Muscle Glycogenoses
The role of glycogen in muscle is to provide substrates for the generation of ATP for muscle contraction. The muscle GSDs are broadly divided into 2 groups. The first group is characterized by hypertrophic cardiomyopathy, progressive skeletal muscle weakness and atrophy, or both, and includes deficiencies of acid α-glucosidase, a lysosomal glycogen-degrading enzyme (type II GSD), lysosomal-associated membrane protein 2 (LAMP2), and AMP-activated protein kinase γ2 (PRKAG2). The 2nd group comprises muscle energy disorders characterized by muscle pain, exercise intolerance, myoglobinuria, and susceptibility to fatigue. This group includes myophosphorylase deficiency (McArdle disease, type V GSD) and deficiencies of phosphofructokinase (type VII), phosphoglycerate kinase, phosphoglycerate mutase, lactate dehydrogenase, and muscle-specific phosphorylase kinase. Some of these latter enzyme deficiencies can also be associated with compensated hemolysis, suggesting a more generalized defect in glucose metabolism.

Type II Glycogen Storage Disease (Lysosomal Acid α-1,4-Glucosidase Deficiency, Pompe Disease)

Pompe disease, also referred to as GSD type II or acid maltase deficiency, is caused by a deficiency of acid α-1,4-glucosidase (acid maltase), an enzyme responsible for the degradation of glycogen in lysosomes. This enzyme defect results in lysosomal glycogen accumulation in multiple tissues and cell types, predominantly affecting cardiac, skeletal, and smooth muscle cells. In Pompe disease, glycogen typically accumulates within lysosomes, as opposed to its accumulation in cytoplasm in the other glycogenoses. However, as the disease progresses, lysosomal rupture and leakage lead to the presence of cytoplasmic glycogen as well.

Pompe disease is an autosomal recessive disorder. The incidence was thought to be approximately 1 in 40,000 live births in Caucasians and 1 in 18,000 live births in Han Chinese. Newborn screening for Pompe disease in the United States suggests that the prevalence is much higher than previously thought (between 1 in 9,132 and 1 in 24,188). The gene for acid α-glucosidase (GAA) is on chromosome 17q25.2. More than 500 pathogenic variants have been identified that could be helpful in delineating the phenotypes. A splice-site variant (IVS1-13T → G; c.-32-13T>G) is commonly seen in late-onset Caucasian
Clinical Manifestations

Pompe disease is broadly classified into infantile and late-onset forms. Infantile Pompe disease (IPD) is uniformly lethal without enzyme replacement therapy (ERT) with alglucosidase alfa. Affected infants present in the 1st day to weeks of life with hypotonia, generalized muscle weakness with a floppy infant appearance, neuropathic bulbar weakness, feeding difficulties, macroglossia, hepatomegaly, and hypertrophic cardiomyopathy, which if untreated leads to death from cardiorespiratory failure or respiratory infection, usually by 1 yr of age.

Late-onset Pompe disease (LOPD; juvenile-, childhood-, and adult-onset disease) is characterized by proximal limb girdle muscle weakness and early involvement of respiratory muscles, especially the diaphragm. Cardiac involvement ranges from cardiac rhythm disturbances to cardiomyopathy and a less severe, short-term prognosis. Symptoms related to progressive dysfunction of skeletal muscles can start as early as within 1 yr of age to as late as the 6th decade of life. The clinical picture is dominated by slowly progressive proximal muscle weakness with truncal involvement and greater involvement of the lower limbs than the upper limbs. The pelvic girdle, paraspinal muscles, and diaphragm are the muscle groups most seriously affected in patients with LOPD. Other symptoms may include lingual weakness, ptosis, and dilation of blood vessels (e.g., basilar artery, ascending aorta). With disease progression, patients become confined to a wheelchair and require artificial ventilation. The initial symptoms in some patients may be respiratory insufficiency manifested by somnolence, morning headache, orthopnea, and exertional dyspnea, which eventually lead to sleep-disordered breathing and respiratory failure. Respiratory failure is the cause of significant morbidity and mortality in LOPD. Basilar artery aneurysms with rupture also contribute to mortality in some cases. Small-fiber neuropathy presenting as painful paresthesia has been identified in some LOPD patients. Gastrointestinal disturbances such as postprandial bloating, dysphagia, early satiety, diarrhea, chronic constipation, and irritable bowel disease have been reported. Genitourinary tract involvement is not uncommon and may present as bladder and bowel incontinence, weak urine stream or dribbling. If untreated, the age of death varies from early childhood to late adulthood, depending on the rate of disease progression and the extent of respiratory muscle involvement. With the advent of ERT, a new natural history is
emerging for both survivors of infantile and LOPD.

**Laboratory Findings**

These include elevated levels of serum creatine kinase (CK), aspartate transaminase (AST), alanine transaminase (ALT), and lactate dehydrogenase (LDH). Urine glucose tetrasaccharide, a glycogen breakdown metabolite, is a reliable biomarker for disease severity and treatment response. In the infantile form a chest x-ray film showing massive cardiomegaly is frequently the first symptom detected. **Electrocardiographic findings** include a high-voltage QRS complex, Wolff-Parkinson-White (WPW) syndrome, and a shortened PR interval. Echocardiography reveals thickening of both ventricles and/or the intraventricular septum and/or left ventricular outflow tract obstruction. Muscle biopsy shows the presence of vacuoles that stain positively for glycogen; acid phosphatase is increased, presumably from a compensatory increase of lysosomal enzymes. EM reveals glycogen accumulation within a membranous sac and in the cytoplasm. Electromyography reveals myopathic features with excessive electrical irritability of muscle fibers and pseudomyotonic discharges. Serum CK is not always elevated in adult patients. Depending on the muscle sampled or tested, the muscle histologic appearance and electromyography may not be abnormal.

Some patients with infantile Pompe disease who had peripheral nerve biopsies demonstrated glycogen accumulation in the neurons and Schwann cells.

**Diagnosis**

Diagnosis of Pompe disease can be made by enzyme assay in dried blood spots, leukocytes, blood mononuclear cells, muscle, or cultured skin fibroblasts demonstrating deficient acid α-glucosidase activity. Gene sequencing showing 2 pathogenic variants in the GAA gene is confirmatory. The enzyme assay should be done in a laboratory with experience using maltose, glycogen, or 4-methylumbelliferyl-α-D-glucopyranoside (4MUG) as a substrate. The infantile form has a more severe enzyme deficiency than the late-onset forms. Detection of percent residual enzyme activity is captured in skin fibroblasts and muscle. Blood-based assays, especially dried blood spots, have the advantage of a rapid turnaround time and are being increasingly used as the first-line tissue to make a diagnosis. A muscle biopsy is often done with suspected muscle disease and a broad differential; it yields faster results and provides additional information
about glycogen content and site of glycogen storage within and outside the lysosomes of muscle cells. However, a normal muscle biopsy *does not* exclude a diagnosis of Pompe disease. Late-onset patients show variability in glycogen accumulation in different muscles and within muscle fibers; muscle histology and glycogen content can vary depending on the site of muscle biopsy. There is also a high risk from anesthesia in infantile patients. An electrocardiogram can be helpful in making the diagnosis in suspected cases of the infantile form and should be done for patients suspected of having Pompe disease before any procedure requiring anesthesia, including muscle biopsy, is performed. Urinary glucose tetrasaccharides can be elevated in the urine of affected patients, and levels are extremely high in infantile patients. Availability of next-generation sequencing panels and whole exome sequencing allows for identification of additional patients with Pompe disease, especially when the diagnosis is ambiguous. **Prenatal diagnosis** using amniocytes or chorionic villi is available.

**Treatment**

Enzyme replacement therapy with recombinant human acid α-glucosidase (alg glucosidase alfa) is available for treatment of Pompe disease. Recombinant acid α-glucosidase is capable of preventing deterioration or reversing abnormal cardiac and skeletal muscle functions (Fig. 105.3). ERT should be initiated as soon as possible across the disease spectrum, especially for babies with the infantile form, because the disease is rapidly progressive. Infants who are negative for cross-reacting immunologic material (CRIM) develop a high-titer antibody against the infused enzyme and respond to the ERT less favorably. Treatment using immunomodulating agents such as methotrexate, rituximab, and intravenous immune globulin (IVIG) have demonstrated efficacy in preventing the development of an immune response to ERT and immune tolerance. Nocturnal ventilatory support, when indicated, should be used; it has been shown to improve the quality of life and is particularly beneficial during a period of respiratory decompensation.
In addition to ERT, other adjunctive therapies have demonstrated benefit in Pompe patients. For patients with the late-onset disease, a high-protein diet may be beneficial. Respiratory muscle strength training has demonstrated improvements in respiratory parameters when combined with ERT. Submaximal exercise regimens are of assistance to improve muscle strength, pain, and fatigue. Other approaches are under clinical development to improve the safety and efficacy of enzyme delivery to affected tissues. These include use of chaperone molecules to enhance rhGAA delivery, and neoGAA, which is a second-generation ERT with a high number of mannose-6-phosphate (M6P) tags that enhances M6P receptor targeting and enzyme uptake. Gene therapy studies to correct the endogenous enzyme production pathways have shown promise.

Early diagnosis and treatment are necessary for optimal outcomes. Newborn
screening using blood-based assays in Taiwan has resulted in early identification of Pompe cases and thus improved disease outcomes through the early initiation of ERT.

**Glycogen Storage Diseases Mimicking Hypertrophic Cardiomyopathy (Danon Disease)**

Danon disease is caused by pathogenic variants in the *LAMP2* gene, which leads to a deficiency of **lysosomal-associated membrane protein 2** (LAMP2). This leads to accumulation of glycogen in the heart and skeletal muscle, which presents primarily with hypertrophic cardiomyopathy and skeletal muscle weakness. Danon disease can be distinguished from the usual causes of hypertrophic cardiomyopathy (defects in sarcomere-protein genes) by their electrophysiologic abnormalities, particularly ventricular preexcitation and conduction defects. Patients present with cardiac symptoms, including chest pain, palpitations, syncope, and cardiac arrest, usually between ages 8 and 15 yr. Other clinical manifestations in Danon disease include peripheral pigmentary retinopathy, lens changes, and abnormal electroretinograms. This disorder is inherited in an X-linked dominant pattern. Diagnosis can be done by genetic testing for the *LAMP2* gene. The prognosis for LAMP2 deficiency is poor, with progressive end-stage heart failure early in adulthood. **Treatment** is directed toward management of symptoms in affected individuals, including management of cardiomyopathy, correction of arrhythmias, and physical therapy for muscle weakness. Cardiac transplantation has been tried successfully in some patients.

**Adenosine Monophosphate–Activated Protein Kinase γ2 Deficiency (PRKAG2 Deficiency)**

AMP-activated protein kinase γ2 (PRKAG2) deficiency is caused by pathogenic variants in the *PRKAG2* gene mapped to chromosome 7q36. *PRKAG2* is required for the synthesis of the enzyme AMP-activated protein kinase (AMPK), which regulates cellular pathways involved in ATP metabolism. Common presentations include hypertrophic cardiomyopathy and electrophysiologic abnormalities such as WPW syndrome, atrial fibrillation, and progressive atrioventricular block. Cardiac involvement is variable and includes supraventricular tachycardia, sinus bradycardia, left ventricular dysfunction, and
even sudden cardiac death in some cases. In addition to cardiac involvement, there is a broad spectrum of phenotypic presentations including myalgia, myopathy, and seizures. Cardiomyopathy caused by PRKAG2 variants usually allows for long-term survival, although a rare congenital form presenting in early infancy is associated with a rapidly fatal course. Cardiomyopathy in PRKAG2 syndrome often mimics that in other conditions, especially Pompe disease, and should be considered as a differential diagnosis in infants presenting with severe hypertrophic cardiomyopathy. **Treatment** is primarily symptomatic, including management of cardiac failure and correction of conduction defects.

**Muscle Glycogen Synthase Deficiency**

This GSD results from muscle glycogen synthase (glycogen synthase 1, GYS1) deficiency. The gene GYS1 has been localized to chromosome 19q13.3. In the true sense, this is not a type of GSD because the deficiency of the enzyme leads to decreased glycogen stores. The disease is extremely rare and has been reported in 3 children of consanguineous parents of Syrian origin. Muscle biopsies showed lack of glycogen, predominantly oxidative fibers, and mitochondrial proliferation. Glucose tolerance was normal. Molecular study revealed a homozygous stop mutation (R462→ter) in the muscle glycogen synthase gene. The phenotype was variable in the 3 siblings and ranged from sudden cardiac arrest, muscle fatigability, hypertrophic cardiomyopathy, an abnormal heart rate, and hypotension while exercising, to mildly impaired cardiac function at rest.

**Late-Onset Polyglucosan Body Myopathy (From GYG1 Variants)**

Late-onset polyglucosan body myopathy is an autosomal recessive, slowly progressive skeletal myopathy caused by pathogenic variants in the GYG1 gene blocking glycogenin-1 biosynthesis. There is a reduced or complete absence of glycogenin-1, which is a precursor necessary for glycogen formation. Polyglucosan accumulation in skeletal muscles causes adult-onset proximal muscle weakness, prominently affecting hip and shoulder girdles. Cardiac involvement is not seen. Compared with GSD IV–APBD, nervous system involvement is uncommon, although polyglucosan deposition is seen in both disorders. GYG1 is mapped to chromosome 3q24. Muscle biopsies show PAS-
positive storage material in 30–40% of muscle fibers. EM reveals the typical polyglucosan structure, consisting of ovoid form composed of partly filamentous material.

**Type V Glycogen Storage Disease (Muscle Phosphorylase Deficiency, McArdle Disease)**

GSD type V is caused by deficiency of myophosphorylase activity. Lack of this enzyme limits muscle ATP generation by glycogenolysis, resulting in muscle glycogen accumulation, and is the prototype of muscle energy disorders. A deficiency of myophosphorylase impairs the cleavage of glucosyl molecules from the straight chain of glycogen.

**Clinical Manifestations**

Symptoms usually first develop in late childhood or in the 2nd decade of life. Clinical heterogeneity is uncommon, but cases suggesting otherwise have been documented. Studies have shown that McArdle disease can manifest in individuals as old as 74, as well as in infancy in a fatal, early-onset form characterized by hypotonia, generalized muscle weakness, and respiratory complication. Symptoms are generally characterized by exercise intolerance with muscle cramps and pain. Symptoms are precipitated by 2 types of activity: brief, high-intensity exercise, such as sprinting or carrying heavy loads, and less intense but sustained activity, such as climbing stairs or walking uphill. Most patients can perform moderate exercise, such as walking on level ground, for long periods. Many patients experience a characteristic “second wind” phenomenon, with relief of muscle pain and fatigue after a brief period of rest. As a result of the underlying myopathy, these patients may be at risk for statin-induced myopathy and rhabdomyolysis. While patients typically experience episodic muscle pain and cramping from exercise, 35% of patients with McArdle disease report permanent pain that has a serious impact on sleep and other activities. Studies also suggest that there may also be a link between GSD V and variable cognitive impairment.

Approximately 50% of patients report burgundy-colored urine after exercise as a result of exercise-induced myoglobinuria secondary to rhabdomyolysis. Excessive myoglobinuria after intense exercise may precipitate acute renal failure.
Lab findings show elevated levels of serum CK at rest, which further increases after exercise. Exercise also elevates the levels of blood ammonia, inosine, hypoxanthine, and uric acid, which may be attributed to accelerated recycling of muscle purine nucleotides caused by insufficient ATP production. Type V GSD is an autosomal recessive disorder. The gene for muscle phosphorylase (PYGM) has been mapped to chromosome 11q13.

**Diagnosis**

The standard diagnosis for GSD V includes a muscle biopsy to measure glycogen content as well as enzyme and sequencing of *PYGM*. An ischemic exercise test offers a rapid diagnostic screening for patients with a metabolic myopathy. Lack of an increase in blood lactate levels and exaggerated blood ammonia elevations indicate muscle glycogenosis and suggest a defect in the conversion of muscle glycogen or glucose to lactate. The abnormal ischemic exercise response is *not limited* to type V GSD. Other muscle defects in glycogenolysis or glycolysis produce similar results (deficiencies of muscle phosphofructokinase, phosphoglycerate kinase, phosphoglycerate mutase, or LDH). An ischemic exercise test was once used to be a rapid diagnostic screening for suspected patients but was associated with severe complications and false-positive results. A nonischemic forearm exercise test with high sensitivity that is easy to perform and cost-effective has been determined to be indicative of muscle glycogenosis. However, as with the ischemic test, it cannot differentiate between abnormal exercise responses due to type V disease versus other defects in glycogenolysis or glycolysis or debranching enzyme (noted when the test is done after fasting).

The diagnosis is confirmed by molecular genetic testing of PYGM. A common nonsense variant, p.R49X in exon 1, is found in 90% of Caucasian patients, and a deletion of a single codon in exon 17 is found in 61% of Japanese patients. The p.R49X variant represents 55% of alleles in Spanish patients, whereas the p.W797R variant represents 14% and the p.G204S 9% of pathogenic alleles in the Spanish population. There seems to be an association between clinical severity of GSD V and presence of the D allele of the ACE insertion/deletion polymorphism. This may help explain the spectrum of phenotypic variability manifested in this disorder.

**Treatment**
Avoidance of strenuous exercise prevents the symptoms; regular and moderate exercise is recommended to improve exercise capacity. Glucose or sucrose given before exercise or injection of glucagon can greatly improve tolerance in these patients. A high-protein diet may increase muscle endurance, and low-dose creatine supplement has been shown to improve muscle function in some patients. The clinical response to creatine is dose dependent; muscle pain may increase on high doses of creatine supplementation. Vitamin B₆ supplementation reduces exercise intolerance and muscle cramps. Longevity is not generally affected.

**Type VII Glycogen Storage Disease (Muscle Phosphofructokinase Deficiency, Tarui Disease)**

Type VII GSD is caused by pathogenic variants in the *PFKM* gene, located on chromosome 12q13.1, which results in a deficiency of muscle phosphofructokinase enzyme. This enzyme is a key regulatory enzyme of glycolysis and is necessary for the ATP-dependent conversion of fructose-6-phosphate to fructose-1,6-diphosphate. Phosphofructokinase is composed of 3 isoenzyme subunits according to the tissue type and are encoded by different genes: (*PFKM* [M: muscle], *PFKL* [L: liver], and *PFKP* [P: platelet]). Skeletal muscle has only the M subunit, whereas red blood cells (RBCs) express a hybrid of L and M forms. In type VII GSD the M isoenzyme is defective, resulting in complete deficiency of enzyme activity in muscle and a partial deficiency in RBCs.

Type VII GSD is an autosomal recessive disorder with increased prevalence in individuals of Japanese ancestry and Ashkenazi Jews. A splicing defect and a nucleotide deletion in *PFKM* account for 95% of pathogenic variants in Ashkenazi Jews. Diagnosis based on molecular testing for the common variants is thus possible in this population.

**Clinical Manifestations**

Although the clinical picture is similar to that of type V GSD, the following features of type VII GSD are distinctive:

1. Exercise intolerance, which usually commences in childhood, is more severe than in type V disease and may be associated with nausea,
vomiting, and severe muscle pain; vigorous exercise causes severe muscle cramps and myoglobinuria.

2. Compensatory hemolysis occurs, as indicated by an increased level of serum bilirubin and an elevated reticulocyte count.

3. Hyperuricemia is common and exaggerated by muscle exercise to a greater degree than that observed in type V or III GSD.

4. An abnormal polysaccharide is present in muscle fibers; it is PAS positive but resistant to diastase digestion.

5. Exercise intolerance is especially worse after carbohydrate-rich meals because the ingested glucose prevents lipolysis, thereby depriving muscle of fatty acid and ketone substrates. This is in contrast to patients with type V disease, who can metabolize blood borne glucose derived from either endogenous liver glycogenolysis or exogenous glucose; indeed, glucose infusion improves exercise tolerance in type V patients.

6. The “second wind” phenomenon is absent because of the inability to break down blood glucose.

Several rare type VII variants occur. One variant presents in infancy with hypotonia and limb weakness and proceeds to a rapidly progressive myopathy that leads to death by 4 yr of age. A 2nd variant occurs in infancy and results in congenital myopathy and arthrogryposis with a fatal outcome. A 3rd variant presents in infancy with hypotonia, mild developmental delay, and seizures. An additional presentation is hereditary nonspherocytic hemolytic anemia. Although these patients do not experience muscle symptoms, it remains unclear whether these symptoms will develop later in life. One variant presents in adults and is characterized by a slowly progressive, fixed muscle weakness rather than cramps and myoglobinuria. It may also cause mitral valve thickening from glycogen buildup.

**Diagnosis**

To establish a diagnosis, a biochemical or histochemical demonstration of the enzymatic defect in the muscle is required. The absence of the M isoenzyme of phosphofructokinase can also be demonstrated in muscle, blood cells, and fibroblasts. Gene sequencing can identify pathogenic variants for the phosphofructokinase gene.
Treatment

There is no specific treatment. Strenuous exercise should be avoided to prevent acute episodes of muscle cramps and myoglobinuria. Consuming simple carbohydrates before strenuous exercise may benefit by improving exercise tolerance. A ketogenic diet has been reported to show clinical improvement in a patient with infantile GSD VII. Drugs such as statins should be avoided. Precautionary measures should be taken to avoid hyperthermia while undergoing anesthesia. Carbohydrate meals and glucose infusions have demonstrated worsening symptoms because of the body's inability to utilize glucose. The administered glucose tends to lower the levels of fatty acids in the blood, a primary source of muscle fuel.

Muscle-Specific Phosphorylase Kinase Deficiency (From PHKA1 Variants)

A few cases of PhK deficiency restricted to muscle are known. Patients, both male and female, present either with muscle cramps and myoglobinuria with exercise or with progressive muscle weakness and atrophy. PhK activity is decreased in muscle but normal in liver and blood cells. There is no hepatomegaly or cardiomegaly. This is inherited in an X-linked or autosomal recessive manner. The gene for the muscle-specific form α subunit (αM) is located at Xq12. Pathogenic variants of the gene have been found in some male patients with this disorder. The gene for muscle γ subunit (γM, PHKG1) is on chromosome 7p12. No pathogenic variants in this gene have been reported so far.

Other Muscle Glycogenoses With Muscle Energy Impairment

Six additional defects in enzymes—phosphoglycerate kinase, phosphoglycerate mutase, lactate dehydrogenase, fructose-1,6-bisphosphate aldolase A, muscle pyruvate kinase, and β-enolase in the pathway of the terminal glycolysis—cause symptoms and signs of muscle energy impairment similar to those of types V and VII GSD. The failure of blood lactate to increase in response to exercise is a useful diagnostic test and can be used to differentiate muscle glycogenoses from disorders of lipid metabolism, such as carnitine palmitoyltransferase II
deficiency and very-long-chain acyl-CoA dehydrogenase deficiency, which also cause muscle cramps and myoglobinuria. Muscle glycogen levels can be normal in the disorders affecting terminal glycolysis, and assaying the muscle enzyme activity is needed to make a definitive diagnosis. There is no specific treatment (see preceding Treatment section).

### Defects in Galactose Metabolism

*Priya S. Kishnani, Yuan-Tsong Chen*

### Keywords

galactose
lactose
galactosemia
transferase
Milk and dairy products contain lactose, the major dietary source of galactose. The metabolism of galactose produces fuel for cellular metabolism through its conversion to glucose-1-phosphate (see Table 105.1). Galactose also plays an important role in the formation of galactosides, which include glycoproteins, glycolipids, and glycosaminoglycans. Galactosemia denotes the elevated level of galactose in the blood and is found in 3 distinct inborn errors of galactose metabolism in 1 of the following enzymes: galactose-1-phosphate uridyl transferase, galactokinase, and uridine diphosphate galactose-4-epimerase. The term galactosemia, although adequate for the deficiencies in any of these disorders, generally designates the transferase deficiency.

**Galactose-1-Phosphate Uridyl Transferase Deficiency Galactosemia**

Two forms of the deficiency exist: infants with complete or near-complete deficiency of the enzyme (classic galactosemia) and those with partial transferase deficiency. Classic galactosemia is a serious disease with onset of symptoms typically by the 2nd half of the 1st wk of life. The incidence is predicted to be 1 in 60,000 live births. The newborn infant receives high amounts of lactose (up to 40% in breast milk and certain formulas), which consists of equal parts of glucose and galactose. Without the transferase enzyme, the infant is unable to metabolize galactose-1-phosphate, the accumulation of which results in injury to kidney, liver, and brain. This injury may begin prenatally in the affected fetus by transplacental galactose derived from the diet of the heterozygous mother or by endogenous production of galactose in the fetus.

**Clinical Manifestations**

The diagnosis of uridyl transferase deficiency should be considered in newborn or young infants with any of the following features within a few days or weeks after birth: jaundice, hepatomegaly, vomiting, hypoglycemia, seizures, lethargy,
irritability, feeding difficulties, poor weight gain or failure to regain birthweight, and aminoaciduria. Untreated children may show nuclear cataracts, vitreous hemorrhage, hepatic failure, cirrhosis, ascites, splenomegaly, or intellectual disability. Patients with galactosemia are at increased risk for *Escherichia coli* neonatal sepsis; the onset of sepsis often precedes the diagnosis of galactosemia. Pseudotumor cerebri can occur and cause a bulging fontanel. Complete withdrawal of lactose from the diet results in improvement of the acute symptoms. If untreated, death from liver and kidney failure and sepsis may follow within days. When the diagnosis is not made at birth, damage to the liver (cirrhosis) and brain (intellectual disability) becomes increasingly severe and irreversible.

**Partial transferase deficiency** is generally asymptomatic. It is more common than classic galactosemia and is diagnosed in newborn screening because of moderately elevated blood galactose and/or low transferase activity. Galactosemia should be considered for the newborn or young infant who is not thriving or who has any of the preceding findings. Light and electron microscopy of hepatic tissue reveals fatty infiltration, the formation of pseudoacini, and eventual macronodular cirrhosis. These changes are consistent with a metabolic disease but do not indicate the precise enzymatic defect.

**Diagnosis**

The *initial* diagnosis of galactosemia is done by demonstration of a **reducing substance** in several urine specimens collected while the patient is on a diet containing human milk, cow's milk, or any other formula containing lactose. The reducing substance detected in urine by Clinitest (e.g., glucose, galactose) can be identified by chromatography or an enzymatic test specific for galactose. Galactose can be detected in urine, provided the milk feeding was within the last few hours and the child is not vomiting excessively. Clinistix urine test results are usually negative because the test relies on the action of glucose oxidase, which is specific for glucose but is nonreactive with galactose. Amino acids may be detected in urine since they are excreted together with glucose because of a proximal renal tubular syndrome. Since galactose is injurious to persons with galactosemia, diagnostic challenge tests dependent on administering galactose orally or intravenously should not be used. **Direct enzyme assay using erythrocytes establishes the diagnosis.** The clinician needs to confirm that the patient did not receive a blood transfusion before the collection of the blood
sample, because a diagnosis could be missed. A novel method utilizes nonradioactive ultraviolet (UV) light and high-performance liquid chromatography (HPLC) to accurately detect levels of galactose-1-phosphate uridyl transferase in erythrocytes.

**Genetics**

Transferase deficiency is an autosomal recessive disorder. Based on newborn screening in the United States, the frequency of the disease is approximately 1 in 47,000 live births. There are several enzymatic variants of galactosemia. The *Duarte variant*, a single–amino acid substitution (p.N314D), has diminished RBC enzyme activity (50% of normal), but usually is of no clinical significance. This variant is the most common, with a carrier frequency of 12% in the general population. Those who are heterozygous for the Duarte variant of galactosemia typically have 25% of normal galactose activity, few symptoms, elevated metabolites, and no need for intervention. Other similar variants expressing little enzyme activity typically require no intervention. Some black patients have milder symptoms despite the absence of measurable transferase activity in erythrocytes; these patients retain 10% enzyme activity in liver and intestinal mucosa, whereas most white patients have no detectable activity in any of these tissues. More than 230 identifiable pathogenic variants have been associated with transferase deficiency. In blacks, 62% of alleles are represented by the p.S135L variant, a variant that is responsible for a milder disease course. In the white population, 70% of alleles are represented by the p.Q188R and p.K285N missense variants and are associated with severe disease. Carrier testing and prenatal diagnosis can be performed by direct enzyme analysis of amniocytes or chorionic villi; testing can also be DNA based.

**Treatment and Prognosis**

With the availability of newborn screening for galactosemia, it is possible to identify and treat patients earlier than before. All galactose-containing foods should be removed from the diet on initial suspicion of galactosemia. Various non–lactose-containing milk substitutes are available (casein hydrolysates, soybean-based formula). Elimination of galactose from the diet along with adequate calcium supplementation reverses growth failure and renal and hepatic dysfunction. Cataracts regress, and most patients have no impairment of vision.
Early diagnosis and treatment have improved the prognosis of galactosemia. On long-term follow-up, however, patients still manifest ovarian failure with primary or secondary amenorrhea, decreased bone mineral density, developmental delay, and learning disabilities that increase in severity with age. Hypergonadotropic hypogonadism is reported in 80% to >90% of female patients with classic galactosemia. Although most women with classic galactosemia are infertile when they reach childbearing age, a small number have given birth. Most patients manifest speech disorders, whereas a smaller number demonstrate poor growth and impaired motor function and balance (with or without overt ataxia). The relative control of galactose-1-phosphate levels does not always correlate with long-term outcome, leading to the belief that other factors, such as elevated galactitol, decreased uridine diphosphate galactose (a donor for galactolipids and proteins), and endogenous galactose production may be responsible.

### Galactokinase Deficiency

The deficient enzyme is galactokinase, which normally catalyzes the phosphorylation of galactose. The principal metabolites accumulated are galactose and galactitol. Two genes are reported to encode galactokinase: GK1 on chromosome 17q24 and GK2 on chromosome 15. Cataracts are usually the sole manifestation of galactokinase deficiency; pseudotumor cerebri is a rare complication. The affected infant is otherwise asymptomatic. Heterozygous carriers may be at risk for presenile cataracts. Lab findings show an increased concentration of blood galactose levels, provided the infant has been fed a lactose-containing formula. The diagnosis is made by demonstrating an absence of galactokinase activity in erythrocytes or fibroblasts. Transferase activity is normal. Treatment is dietary restriction of galactose.

### Uridine Diphosphate Galactose-4-Epimerase Deficiency

There are 2 distinct forms of epimerase deficiency. The first is a benign form that is diagnosed incidentally through newborn screening programs. Affected individuals are asymptomatic because the enzyme deficiency is limited to leukocytes and erythrocytes. This form does not require treatment. The second
variety is **severe** because the epimerase deficiency is more generalized. Clinical manifestations resemble transferase deficiency, with the additional symptoms of hypotonia and nerve deafness. Clinical symptoms improve with restriction of galactose in diet. Although the severe form of galactosemia is rare, it must be considered in a symptomatic patient with measurable galactose-1-phosphate who has normal transferase activity. The abnormally accumulated metabolites are similar to those in transferase deficiency; however, there is also an increase in cellular uridine diphosphate (UDP) galactose. Diagnosis is confirmed by the assay of epimerase in erythrocytes.

Patients with the severe form of epimerase deficiency cannot synthesize UDP galactose from UDP glucose and are galactose dependent. Because galactose is an essential component of many nervous system structural proteins, patients are placed on a galactose-restricted diet rather than a galactose-free diet.

Infants with the mild form of epimerase deficiency have not required treatment. It is advisable to follow urine specimens for reducing substances and exclude aminoaciduria within a few weeks of diagnosis while the infant is still on lactose-containing formula.

The gene for UDP galactose-4-epimerase (GALE) is located on chromosome 1 at 1p36. Carrier detection is possible by measurement of epimerase activity in the erythrocytes. **Prenatal diagnosis** for the severe form of epimerase deficiency can be done using an enzyme assay of cultured amniotic fluid cells.

Defects in Fructose Metabolism

Priya S. Kishnani, Yuan-Tsong Chen

Keywords

fructose
fructosuria
hereditary fructose intolerance
fructokinase
aldolase
hypoglycemia

Two inborn errors are known in the specialized pathway of fructose metabolism: benign or essential fructosuria and hereditary fructose intolerance. Fructose-1,6-bisphosphatase deficiency, although strictly speaking not a defect of the specialized fructose pathway, is discussed in Chapter 105.4.

Deficiency of Fructokinase (Essential or Benign Fructosuria)

Deficiency of fructokinase is not associated with any clinical manifestations. Fructosuria is an accidental finding usually made because the asymptomatic patient's urine contains a reducing substance. No treatment is necessary, and the prognosis is excellent. Inheritance is autosomal recessive with an incidence of 1 in 120,000 live births. The gene encoding fructokinase (KHK) is located on chromosome 2p23.3.

Fructokinase catalyzes the first step of metabolism of dietary fructose: conversion of fructose to fructose-1-phosphate (see Fig. 105.1). Without this enzyme, ingested fructose is not metabolized; its level is increased in the blood,
and it is excreted in urine because practically no renal threshold exists for fructose. Clinitest results reveal the urinary reducing substance, which can be identified as fructose by chromatography.

**Deficiency of Fructose-1,6-Bisphosphate Aldolase (Aldolase B, Hereditary Fructose Intolerance)**

Deficiency of fructose-1,6-bisphosphate aldolase (aldolase-B) is a severe condition of infants caused by a deficiency of aldolase B activity in the liver, kidney, and intestine. This enzyme catalyzes the hydrolysis of fructose-1,6-bisphosphate into triose phosphate and glyceraldehyde phosphate. The same enzyme also hydrolyzes fructose-1-phosphate. In the absence of enzyme activity, there is a rapid accumulation of fructose-1-phosphate, which presents with severe symptoms when fructose-containing food is ingested.

**Epidemiology and Genetics**

The exact incidence of hereditary fructose intolerance (HFI) is unknown but is estimated to be as high as 1 in every 26,000 live births. HFI is inherited in an autosomal recessive manner. The ALDOB gene is mapped to chromosome 9q22.3. At least 40 pathogenic variants causing HFI are known. The most common pathogenic variant identified in northern Europeans is a single missense variant, a G→C transversion in exon 5 resulting in the normal alanine at position 149 being replaced by proline. This variant, along with 2 other missense variants (p.A174D and p.N334K), account for 80–85% of HFI in Europe and the United States. Diagnosis of HFI can be made by direct DNA analysis for the common variants and phosphorus magnetic resonance spectroscopy.

**Clinical Manifestations**

Affected individuals remain asymptomatic until fructose or sucrose (table sugar) is introduced in diet (usually from fruit, fruit juice, or sweetened cereal). Signs and symptoms typically manifest in infancy when foods or formulas containing these sugars are introduced. Certain patients are very sensitive to fructose, whereas others can tolerate moderate intakes (up to 250 mg/kg/day). The
average intake of fructose in Western societies is 1-2 g/kg/day. Early clinical manifestations resemble galactosemia and include jaundice, hepatomegaly, vomiting, lethargy, irritability, and convulsions. There may also be a higher incidence of celiac disease in HFI patients (>10%) than in the general population (1–3%). As they grow older, patients usually develop an aversion to fructose-containing foods due to associated symptoms of nausea, vomiting, and abdominal pain.

Characteristic lab findings include lactic acidosis, hypophosphatemia, hyperuricemia, and hypermagnesemia. A prolonged clotting time, hypoalbuminemia, elevation of bilirubin and transaminase levels, and proximal tubular dysfunction are also seen. Acute fructose ingestion produces symptomatic hypoglycemia; the higher the intake, the more severe the clinical picture. Chronic ingestion results in failure to thrive and hepatic disease. If the intake of fructose persists, hypoglycemic episodes recur, leading to progressive renal and hepatic failure and eventually death.

Diagnosis

The presence of a reducing substance in urine during an acute episode raises the possibility of HFI. Oral fructose challenge is no longer considered a diagnostic approach because of high risk to the patient, who can become acutely ill after the test. Definitive diagnosis is made by demonstration of 2 pathogenic variants in ALDOB on molecular genetic testing. A common pathogenic variant (substitution of Pro for Ala at position 149) accounts for 53% of HFI alleles worldwide. An alternative is to show deficient hepatic fructose 1-phosphate aldolase (aldolase B) activity on liver biopsy.

Treatment

Acute episodes are managed symptomatically by correcting hypoglycemia with IV glucose (dextrose) administration, providing supportive treatment of hepatic insufficiency, and correcting metabolic acidosis. Complete elimination of fructose usually rapidly reverses symptoms and results in normalization of related metabolic disturbances. The cornerstone of long-term treatment is the complete restriction of all sources of sucrose, fructose, and sorbitol from the diet. It may be difficult because these sugars are widely used additives, found even in most medicinal preparations. With treatment, liver and kidney
dysfunction improves, and catch-up in growth is common. Intellectual development is usually unimpaired. As the patient matures, symptoms become milder even after fructose ingestion; the long-term prognosis is good. Because of voluntary dietary avoidance of sucrose, affected patients have few dental caries. Care should be taken to avoid fructose-containing IV fluids during hospitalizations.

Bibliography

105.4
Defects in Intermediary Carbohydrate Metabolism Associated With Lactic Acidosis

Priya S. Kishnani, Yuan-Tsong Chen
Lactic acidosis (type B3) occurs with defects of carbohydrate metabolism that interfere with the conversion of pyruvate to glucose via the pathway of gluconeogenesis or to carbon dioxide and water via the mitochondrial enzymes of the Krebs cycle. Fig. 105.4 depicts the relevant metabolic pathways. Type I GSD, fructose-1,6-diphosphatase deficiency, and phosphoenolpyruvate carboxylase deficiency are disorders of gluconeogenesis associated with lactic acidosis. Pyruvate dehydrogenase complex deficiency, respiratory chain defects, and pyruvate carboxylase deficiency are disorders in the pathway of pyruvate metabolism causing lactic acidosis. Lactic acidosis (type B3) can also occur in defects of fatty acid oxidation, organic acidurias (see Chapters 103.6, 103.10, and 104.1), or biotin utilization diseases (type B3) (Table 105.2). These disorders are easily distinguishable by the presence of abnormal acyl carnitine profiles, amino acids in the blood, and unusual organic acids in the urine. Blood lactate, pyruvate, and acyl carnitine profiles, and the presence of these unusual urine organic acids should be determined in infants and children with unexplained acidosis, especially if there is an increase of anion gap.
FIG. 105.4 Enzymatic reactions of carbohydrate metabolism, deficiencies of which can give rise to lactic acidosis, pyruvate elevations, or hypoglycemia. The pyruvate dehydrogenase complex comprises, in addition to \( E_1 \), \( E_2 \), and \( E_3 \), an extra lipoate-containing protein (not shown), called protein X, and pyruvate dehydrogenase phosphatase.

Mitochondrial DNA depletion syndromes
Nuclear DNA respiratory chain defects
Mitochondrial DNA respiratory defects
Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS)
Myoclonic epilepsy with ragged red fibers (MERRF)
Lactic acidosis unrelated to an enzymatic defect occurs in hypoxemia (type A lactic acidosis). In this case, as well as in defects in the respiratory chain, the serum pyruvate concentration may remain normal (<1.0 mg/dL, with increased lactate:pyruvate ratio), whereas pyruvate is usually increased when lactic acidosis results from an enzymatic defect in gluconeogenesis or pyruvate dehydrogenase complex (both lactate and pyruvate are increased, and the ratio is normal). Lactate and pyruvate should be measured in the same blood specimen and on multiple blood specimens obtained when the patient is symptomatic because lactic acidosis can be intermittent. Fig. 105.5 is an algorithm for the differential diagnosis of lactic acidosis. Lactic acidosis is also noted with various underlying diseases (type B1) and drugs or toxins (type B2) (Table 105.2).
Disorders of Gluconeogenesis

Deficiency of Glucose-6-Phosphatase (Type I Glycogen Storage Disease)

Type I GSD is the only glycogenosis associated with significant lactic acidosis. The chronic metabolic acidosis predisposes these patients to osteopenia; after prolonged fasting, the acidosis associated with hypoglycemia is a life-threatening condition (see Chapter 105.1).

Fructose-1,6-Diphosphatase Deficiency

Fructose-1,6-diphosphatase deficiency impairs the formation of glucose from all gluconeogenic precursors, including dietary fructose. Hypoglycemia occurs when glycogen reserves are limited or exhausted. The clinical manifestations are characterized by life-threatening episodes of acidosis, hypoglycemia, hyperventilation, convulsions, and coma. In about half the cases, the deficiency presents in the 1st wk of life. In infants and small children, episodes are triggered by febrile infections and gastroenteritis if oral food intake decreases. The frequency of the attacks decreases with age. Laboratory findings include low blood glucose, high lactate and uric acid levels, and metabolic acidosis. In contrast to HFI, there is usually no aversion to sweets; renal tubular and liver function is normal.

The diagnosis is established by demonstrating an enzyme deficiency in either liver or intestinal biopsy. The enzyme defect can also be demonstrated in leukocytes in some cases. The gene coding for fructose-1,6-diphosphatase (FBP1) is located on chromosome 9q22; pathogenic variants are characterized, making carrier detection and prenatal diagnosis possible. Treatment of acute attacks consists of correction of hypoglycemia and acidosis by IV glucose infusion; the response is usually rapid. Avoidance of fasting, aggressive management of infections, and restriction of fructose and sucrose from the diet can prevent further episodes. For long-term prevention of hypoglycemia, a slowly released carbohydrate such as cornstarch is useful. Patients who survive childhood develop normally.
Phosphoenolpyruvate Carboxykinase Deficiency

Phosphoenolpyruvate carboxykinase (PEPCK) is a key enzyme in gluconeogenesis. It catalyzes the conversion of oxaloacetate to phosphoenolpyruvate (see Fig. 105.4). PEPCK deficiency is both a mitochondrial enzyme deficiency and a cytosolic enzyme deficiency, encoded by 2 distinct genes.

PEPCK deficiency has been reported in only a few cases. The clinical features are heterogeneous, with hypoglycemia, lactic acidemia, hepatomegaly, hypotonia, developmental delay, and failure to thrive as the major manifestations. There may be multisystem involvement, with neuromuscular deficits, hepatocellular damage, renal dysfunction, and cardiomyopathy. The diagnosis is based on the reduced activity of PEPCK in liver, fibroblasts, or lymphocytes. Fibroblasts and lymphocytes are not suitable for diagnosing the cytosolic form of PEPCK deficiency because these tissues possess only mitochondrial PEPCK. To avoid hypoglycemia, patients should receive treatment with slow-release carbohydrates such as cornstarch, and fasting should be avoided.

Disorders of Pyruvate Metabolism

Pyruvate is formed from glucose and other monosaccharides, from lactate, and from alanine. It is metabolized through 4 main enzyme systems: lactate dehydrogenase, alanine transaminase, pyruvate carboxylase, and pyruvate dehydrogenase complex. Deficiency of the M subunit of LDH causes exercise intolerance and myoglobinuria (see Chapter 105.1).

Pyruvate Dehydrogenase Complex Deficiency

After entering the mitochondria, pyruvate is converted into acetyl-CoA by the pyruvate dehydrogenase complex (PDHC), which catalyzes the oxidation of pyruvate to acetyl-CoA, which then enters the tricarboxylic acid cycle for ATP production. The complex comprises 5 components: $E_1$, an $\alpha$-ketoacid decarboxylase; $E_2$, a dihydrolipoyl transacylase; $E_3$, a dihydrolipoyl dehydrogenase; protein X, an extra lipoate-containing protein; and pyruvate dehydrogenase phosphatase. The most common is a defect in the $E_1$ (see Fig. 105.4).
Deficiency of the PDHC is the most common of the disorders leading to lactic acidemia and CNS dysfunction. The CNS dysfunction occurs because the brain obtains its energy primarily from oxidation of glucose. Brain acetyl-CoA is synthesized almost exclusively from pyruvate.

The E₁ defects are caused by pathogenic variants in the gene coding for E₁ α subunit, which is X-linked dominant. Although X-linked, its deficiency is a problem in both male and female patients, despite only one E₁ α allele in females carrying a variant.

**Clinical Manifestations**

PDHC deficiency has a wide spectrum of presentations, from the most severe neonatal presentation to a mild late-onset form. The neonatal onset is associated with lethal lactic acidosis, white matter cystic lesions, agenesis of the corpus callosum, and the most severe enzyme deficiency. Infantile onset can be lethal or associated with psychomotor delay and chronic lactic acidosis, cystic lesions in the brainstem and basal ganglia, and pathologic features resembling Leigh disease (see later and Chapter 616.2). Neurologic symptoms in PDHC can be categorized into 2 groups: abnormal brain development, seen in both males and females, and brain lesions and epilepsy, seen in male patients only. Older children, usually boys, may have less acidosis, have greater enzyme activity, and manifest ataxia with high-carbohydrate diets. Intelligence may be normal. Patients of all ages may have facial dysmorphology, features similar to those of fetal alcohol syndrome.

The E₂ and protein X–lipoate defects are rare and result in severe psychomotor retardation. The E₃ lipoamide dehydrogenase defect leads to deficient activity not only in the PDHC, but also in the α-ketoglutarate and branched-chain ketoacid dehydrogenase complexes. This deficiency is more common in the Ashkenazi Jewish population. The reactive oxygen species generated by the pathogenic variants responsible for lipoamide dehydrogenase deficiency may in fact explain certain disease characteristics and suggest the utility of antioxidant therapy. Pyruvate dehydrogenase phosphatase deficiency has also been reported. These other PDHC defects have clinical manifestations within the variable spectrum associated with PDHC deficiency caused by E₁ deficiency.

**Treatment**
The general prognosis is poor, except in rare patients in whom variants are associated with altered affinity for thiamine pyrophosphate, who may respond to thiamine supplementation. Because carbohydrates can aggravate lactic acidosis, a ketogenic diet is recommended. The diet has been found to lower the blood lactate level; the long-term benefit to patient outcome is unclear. A potential treatment strategy is to maintain any residual PDHC in its active form by oral administration of dichloroacetate, an inhibitor of E₁ kinase. Beneficial effects of controlling postprandial lactic acidosis have been shown in some patients. Young children with congenital acidosis generally tolerate dichloroacetate well, but continued exposure is associated with peripheral neuropathy, a condition that could be attributable to the drug or the disease.

**Deficiency of Pyruvate Carboxylase**

Pyruvate carboxylase is a mitochondrial, biotin-containing enzyme essential in the process of gluconeogenesis; it catalyzes the conversion of pyruvate to oxaloacetate. The enzyme is also essential for Krebs cycle function as a provider of oxaloacetate and is involved in lipogenesis and formation of nonessential amino acids. Clinical manifestations of this deficiency have varied from neonatal severe lactic acidosis accompanied by hyperammonemia, citrullinemia, and hyperlysinemia (type B) to late-onset mild to moderate lactic acidosis and developmental delay (type A). In both types, patients who survived usually had severe psychomotor retardation with seizures, spasticity, and microcephaly. Some patients have pathologic changes in the brainstem and basal ganglia that resemble Leigh disease. The clinical severity appears to correlate with the level of the residual enzyme activity. A “benign” form of pyruvate carboxylase deficiency has also been described, characterized by recurrent attacks of lactic acidosis and mild neurologic deficits (type C). Laboratory findings are characterized by elevated levels of blood lactate, pyruvate, alanine, and ketonuria. In the case of type B, blood ammonia, citrulline, and lysine levels are also elevated, which might suggest a primary defect of the urea cycle. The mechanism is likely caused by depletion of oxaloacetate, which leads to reduced levels of aspartate, a substrate for argininosuccinate synthase in the urea cycle (see Chapter 103.12). The gene for pyruvate carboxylase (PC) is located on chromosome 11q13.4-q13.5, and about 15 pathogenic variants have been identified.

**Treatment** consists of avoidance of fasting and eating a carbohydrate meal.
before bedtime. During acute episodes of lactic acidosis, patients should receive continuous IV glucose. Aspartate and citrate supplements restore the metabolic abnormalities; whether this treatment can prevent the neurologic deficits is not known. Liver transplantation has been attempted; its benefit remains unknown. **Diagnosis** of pyruvate carboxylase deficiency is made by the measurement of enzyme activity in liver or cultured skin fibroblasts and must be differentiated from holocarboxylase synthase or biotinidase deficiency.

**Deficiency of Pyruvate Carboxylase Secondary to Deficiency of Holocarboxylase Synthase or Biotinidase**

Deficiency of either holocarboxylase synthase (HCS) or biotinidase, which are enzymes of biotin metabolism, result in multiple-carboxylase deficiency (pyruvate carboxylase and other biotin-requiring carboxylases and metabolic reactions) and in **clinical manifestations** associated with the respective deficiencies, as well as rash, lactic acidosis, and alopecia (see **Chapter 103.6** ). The course of HCS or biotinidase deficiency can be protracted, with intermittent exacerbation of chronic lactic acidosis, failure to thrive, seizures, and hypotonia leading to spasticity, lethargy, coma, and death. Auditory and optic nerve dysfunction can lead to deafness and blindness, respectively. Late-onset milder forms have also been reported. Laboratory findings include metabolic acidosis and abnormal organic acids in the urine. In HCS deficiency, biotin concentrations in plasma and urine are normal. **Diagnosis** can be made in skin fibroblasts or lymphocytes by assay for HCS activity, and in the case of biotinidase, in the serum by a screening blood spot. **Treatment** consists of biotin supplementation, 5-20 mg/day, and is generally effective if treatment is started before the development of brain damage. Patients identified through newborn screening and treated with biotin have remained asymptomatic.

Both enzyme deficiencies are autosomal recessive disorders. The incidence of HCS deficiency is approximately 1 in 87,000 live births. HCS and biotinidase (BTD) are located on chromosome 21q22 and 3p25, respectively. Ethnic-specific pathogenic variants in the HCS gene have been identified. Two common pathogenic variants (del7/ins3 and p.R538C) in the BTD account for 52% of all pathogenic alleles in symptomatic patients with biotinidase deficiency.
Mitochondrial Respiratory Chain Defects (Oxidative Phosphorylation Disease)

The mitochondrial respiratory chain catalyzes the oxidation of fuel molecules and transfers the electrons to molecular oxygen with concomitant energy transduction into adenosine triphosphate (oxidative phosphorylation) (see Chapter 106). The respiratory chain produces ATP from adenosine diphosphate and inorganic phosphate utilizing the energy from electrons transferred from nicotinamide adenine dinucleotide (NADH) or flavin adenine dinucleotide and includes 5 specific complexes (I: NADH–coenzyme Q reductase; II: succinate–coenzyme Q reductase; III: coenzyme QH$_2$ cytochrome-c reductase; IV: cytochrome-c oxidase; V: ATP synthase). Each complex is composed of 4-35 individual proteins and, with the exception of complex II (which is encoded solely by nuclear genes), is encoded by nuclear or mitochondrial DNA (inherited only from the mother by mitochondrial inheritance). Defects in any of these complexes or assembly systems produce chronic lactic acidosis, presumably because of a change of the reduction-oxidation state with increased concentrations of NADH (see Table 105.3).

In contrast to PDHC or pyruvate carboxylase deficiency, skeletal muscle and heart are usually involved in the respiratory chain disorders. On muscle biopsy, ragged red fibers indicating mitochondrial proliferation are very suggestive when present (see Fig. 105.5). Because of the ubiquitous nature of oxidative phosphorylation, a defect of the mitochondrial respiratory chain accounts for a vast array of clinical manifestations and should be considered in patients in all age-groups presenting with multisystem involvement. Some deficiencies resemble Leigh disease, whereas others cause infantile myopathies such as MELAS (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes), MERRF (myoclonic epilepsy and ragged red fibers), and Kearns-Sayre syndrome (external ophthalmoplegia, acidosis, retinal degeneration, heart block, myopathy, and high cerebrospinal fluid protein) (Table 105.3) (see Chapters 616.2 and 629.4). There is a higher incidence of psychiatric disorders in adults with a primary oxidative phosphorylation disease than in the general population. Elevated serum growth and differentiation factor (GDF)-15 levels help screen for mitochondrial disorders.

* Characteristic constellations of symptoms and signs are in bold.

+, Presence of a symptom, sign, or finding; −, absence of a symptom, sign, or finding; ±, possible presence of a symptom, sign, or finding; AID, aminoglycoside-induced deafness; KSS, Kearns-Sayre syndrome; LHON, Leber hereditary optic neuropathy; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes; MERRF, myoclonic epilepsy with ragged-red fibers; MILS, maternally inherited Leigh syndrome; NARP, neuropathy, ataxia, and retinitis pigmentosa; PEO, progressive external ophthalmoplegia; PS, Pearson syndrome.

**Diagnosis** requires demonstration of abnormalities of oxidative phosphorylation enzyme complex activities in tissues or of mitochondrial DNA or a nuclear gene coding for mitochondrial functions, or both (Fig. 105.6). Muscle histology, including EM, can detect ragged red fibers and other abnormalities typical of mitochondrial myopathies. Analysis of oxidative phosphorylation complexes I-IV from intact mitochondria isolated from fresh skeletal muscle is the most sensitive assay for mitochondrial disorders; however, electron transport chain testing of flash-frozen muscle provides an alternative approach when fresh muscle testing is not available. Next-generation sequencing of mitochondrial DNA and panels of nuclear genes provides a noninvasive alternative to diagnosis. Specific criteria may assist in making a diagnosis (Table 105.4). Table 105.5 lists clues to the diagnosis of mitochondrial diseases.
FIG. 105.6 Mutations in the human mitochondrial genome that are known to cause disease. Disorders that are frequently or prominently associated with mutations in a particular gene are shown in bold. ### Table 105.5

**Clues to the Diagnosis of Mitochondrial Disease**

**Neurologic**

- Cerebral stroke-like lesions in a nonvascular pattern
- Basal ganglia disease
- Encephalopathy: recurrent or with low/moderate dosing of valproate
Neurodegeneration
Epilepsia partialis continua
Myoclonus
Ataxia
MRI findings consistent with Leigh disease
Characteristic MRS peaks
Lactate peak at 1.3 ppm TE (time to echo) at 35 and 135
Succinate peak at 2.4 ppm

Cardiovascular

Hypertrophic cardiomyopathy with rhythm disturbance
Unexplained heart block in a child
Cardiomyopathy with lactic acidosis (>5 mM)
Dilated cardiomyopathy with muscle weakness
Wolff-Parkinson-White arrhythmia

Ophthalmologic

Retinal degeneration with signs of night blindness, color vision deficits,
decreased visual acuity, or pigmentary retinopathy
Ophthalmoplegia/paresis
Fluctuating, dysconjugate eye movements
Ptosis
Sudden- or insidious-onset optic neuropathy/atrophy

Gastroenterologic

Unexplained or valproate-induced liver failure
Severe dysmotility
Pseudoobstructive episodes

Other

A newborn, infant, or young child with unexplained hypotonia, weakness,
failure to thrive, and a metabolic acidosis (particularly lactic acidosis)
Exercise intolerance that is not in proportion to weakness
Hypersensitivity to general anesthesia
Episodes of acute rhabdomyolysis
Elevated GDF-15 level

MRI, Magnetic resonance imaging, MRS, magnetic resonance spectroscopy;
GDF, growth and differentiation factor.

The majority of mitochondrial disorders are caused by nuclear genes involved in mitochondrial function, and >300 genes have been included in nuclear gene panels for mitochondrial disorder diagnosis. However, pathogenic variants can be identified in 50% or fewer of patients diagnosed clinically with a mitochondrial disorder. An important consideration is that many genetic and multifactorial conditions have been associated with defects in 1 or more of the 4 complexes assayed in mitochondrial oxidative phosphorylation testing. These latter conditions feature so-called secondary mitochondrial dysfunction, because the conditions are not considered to be mitochondrial disorders per se.

**Treatment** remains largely symptomatic and does not significantly alter the outcome of disease. Some patients appear to respond to cofactor supplements, typically coenzyme Q_{10} ± L-carnitine at pharmacologic doses. The addition of creatine monohydrate and α-lipoic acid supplementation may add a significant benefit. EPI-743 is a parobenzoquinone like agent that has protective activity against oxidative injury; it is a promising agent in the treatment of mitochondrial disorders, including Leigh syndrome.

**Leigh Disease (Subacute Necrotizing Encephalomyelopathy)**

Leigh disease is a heterogeneous neurologic disease characterized by demyelination, gliosis, necrosis, relative neuronal sparing, and capillary proliferation in specific brain regions (see Chapter 616.2). Patients with Leigh
disease frequently present with feeding and swallowing problems, failure to thrive, and developmental delay. The presentation is highly variable and may include seizures, altered consciousness, pericardial effusion, and dilated cardiomyopathy. **Diagnosis** is usually confirmed by radiologic or pathologic evidence of symmetric lesions affecting the basal ganglia, brainstem, and subthalamic nuclei. Patients with Leigh disease have defects in several enzyme complexes. Dysfunction in cytochrome-c oxidase (complex IV) is the most commonly reported defect, followed by NADH–coenzyme Q reductase (complex I), PDHC, and pyruvate carboxylase (see **Chapter 106**). Pathogenic variants in the nuclear **SURF1** gene, which encodes a factor involved in the biogenesis of cytochrome-c oxidase and mitochondrial DNA variants in the adenosine triphosphatase 6 coding region, have been reported in patients with Leigh disease in association with complex IV deficiency. The most common mitochondrial DNA variant in Leigh disease is the T8993G variant in **MT-ATP6**. The **prognosis** for Leigh syndrome is poor. In a study of 14 cases, there were 7 fatalities before age 1.5 yr.

Lactic acidosis, hypoglycemia, and encephalopathy have also been reported in patients with thiamine transporter deficiency and with pyridoxine-dependent epilepsy. Both disorders should improve by the provision of thiamine and pyridoxine, respectively.

Defects in Pentose Metabolism

Priya S. Kishnani, Yuan-Tsong Chen

Keywords

- hexose monophosphate
- pentosuria
- xylulose
- transaldolase
- ribose
- urine reducing substance

Approximately 90% of glucose metabolism in the body is via the glycolytic pathway, with the remaining 10% via the hexose monophosphate pathway. The hexose monophosphate shunt leads to formation of pentoses, as well as providing NADH. One of the metabolites is ribose-5-phosphate, which is used in the biosynthesis of ribonucleotides and deoxyribonucleotides. Through the transketolase and transaldolase reactions, the pentose phosphates can be converted back to fructose-6-phosphate and glucose-6-phosphate.

Essential Pentosuria

Essential pentosuria is a benign disorder encountered principally in Ashkenazi Jews and is an autosomal recessive trait. The urine contains \( \text{L-xylulose} \), which is excreted in increased amounts because of a block in the conversion of \( \text{L-xylulose} \) to xylitol as a result of \text{xylitol dehydrogenase deficiency}. The condition is usually discovered accidentally in a urine test for reducing substances. No treatment is required.
Transaldolase Deficiency

Few patients have reported symptoms that include liver cirrhosis, hepatosplenomegaly, severe neonatal hepatopathy, and cardiomyopathy. Biochemical abnormalities revealed elevated levels of arabitol, ribitol, and erythritol in the urine. Erythronic acid has been identified by urine nuclear magnetic resonance spectroscopy as another hallmark metabolite. Enzyme assay in the lymphoblasts and fibroblasts demonstrated low transaldolase activity, which was confirmed by pathogenic variants in the transaldolase gene. In addition, measurement of transaldolase activity in fibroblasts, lymphoblasts, or liver tissue, as well as assessing urinary concentrations of polyols, also can be used to confirm the diagnosis.

Ribose-5-Phosphate Isomerase Deficiency

Only one case of this disorder has been reported. The affected male had psychomotor delay from early in life and developed epilepsy at 4 yr of age. Thereafter, a slow neurologic regression developed, with prominent cerebellar ataxia, some spasticity, optic atrophy, and a mild sensorimotor neuropathy. MRI of the brain at ages 11 and 14 yr showed extensive abnormalities of the cerebral white matter. Proton magnetic resonance spectroscopy (MRS) of the brain revealed elevated levels of ribitol and D-arabitol. These pentitols were also increased in urine and plasma similar to the patient found in transaldolase deficiency. Enzyme assays in cultured fibroblasts showed deficient ribose-5-phosphate isomerase activity, which was confirmed by a molecular study. These results, combined with a study of ribose-5-phosphate isomerase–deficient mice, demonstrated that the specific genetic pairing of a null allele with an allele coding for a form of the enzyme that is only partly active, allowing for cell type–dependent expression deficits, is a contributing factor to the rarity of the disease. Ribose-5-phosphate isomerase deficiency may represent an example of a single-gene disease that appears seldom because of its complex molecular etiology.

Disorders of Glycoprotein Degradation and Structure

Margaret M. McGovern, Robert J. Desnick

The disorders of glycoprotein degradation and structure include several lysosomal storage diseases that result from defects in glycoprotein degradation, and the congenital disorders of glycosylation (see Chapter 105.7). Glycoproteins are macromolecules composed of oligosaccharide chains linked to a peptide backbone. They are synthesized by 2 pathways: the glycosyltransferase pathway, which synthesizes oligosaccharides linked $O$-glycosidically to serine or threonine residues; and the dolichol, lipid-linked pathway, which synthesizes oligosaccharides linked $N$-glycosidically to asparagine.
The **glycoprotein lysosomal storage diseases** result from the deficiency of the enzymes that normally participate in the degradation of oligosaccharides and include sialidosis, galactosialidosis, aspartylglucosaminuria, and α-mannosidosis. In some instances the underlying abnormality that leads to glycoprotein accumulation also results in abnormal degradation of other classes of macromolecules that contain similar oligosaccharide linkages, such as certain glycolipids and proteoglycans. In these cases the underlying enzymatic deficiency results in the accumulation of both glycoproteins and *glycolipids*. The classification of these types of disorders as *lipidoses* or *glycoproteinoses* depends on the nature of the predominantly stored substance. In general, the glycoprotein disorders are characterized by autosomal recessive inheritance and a progressive disease course with clinical features that resemble those seen in the mucopolysaccharidoses.

### Sialidosis and Galactosialidosis

**Sialidosis** is an autosomal recessive disorder that results from the primary deficiency of neuraminidase because of mutations in the gene (*NEU1*) that encodes this protein, located on chromosome 6p21.33. In contrast, **galactosialidosis** is caused by the deficiency of 2 lysosomal enzymes—neuraminidase and β-galactosidase. The loss of these enzymatic activities results from mutations in a single gene, *CTSA*, located on chromosome 20q13.12, that encodes the protective protein cathepsin A, which functions to stabilize these enzymatic activities. Neuraminidase normally cleaves terminal sialyl linkages of several oligosaccharides and glycoproteins. Its deficiency results in the accumulation of oligosaccharides, and the urinary excretion of sialic acid terminal oligosaccharides and sialylglycopeptides. Examination of tissues from affected individuals reveals pathologic storage of substrate in many tissues, including liver, bone marrow, and brain.

The clinical phenotype associated with neuraminidase deficiency is variable and includes **type I** sialidosis, which usually presents in the 2nd decade of life with myoclonus and cherry-red spots in the macula. These patients typically present secondary to gait disturbances, myoclonus, or visual complaints. In contrast, **type II** sialidosis occurs at several ages of onset (congenital, infantile, and juvenile), depending on the severity of the gene mutation. The **congenital** and **infantile** forms result from isolated neuraminidase deficiency, whereas the **juvenile** form results from both neuraminidase and β-galactosidase deficiency.
The congenital type II disease is characterized by hydrops fetalis, neonatal ascites, hepatosplenomegaly, stippling of the epiphyses, periosteal cloaking, and stillbirth or death in infancy. The type II infantile form presents in the 1st yr of life with dysostosis multiplex, moderate global developmental delays, visceromegaly, corneal clouding, cherry-red maculae, and seizures. The juvenile type II form of sialidosis, which is sometimes designated galactosialidosis, has a variable age of onset ranging from infancy to adulthood. In infancy, the phenotype is similar to that of GM1 gangliosidosis, with edema, ascites, skeletal dysplasia, and cherry-red spots. Patients with later-onset disease have dysostosis multiplex, visceromegaly, intellectual disability, dysmorphism, corneal clouding, progressive neurologic deterioration, and cherry-red spots.

No specific therapy exists for any form of the disease, although studies in animal models have demonstrated improvement in the phenotype after bone marrow transplantation. The diagnosis of sialidosis and galactosialidosis is achieved by the demonstration of the specific enzymatic deficiency or by mutations in the responsible gene. Prenatal diagnosis using cultured amniotic cells or chorionic villi is available by demonstrating the enzyme defect and/or specific gene mutations.

Aspartylglucosaminuria

This is a rare autosomal recessive lysosomal storage disorder, except in Finland, where the carrier frequency is estimated at 1 in 36 adults, the high frequency due to a founder gene. The disorder results from the deficient activity of aspartylglycosaminidase and the subsequent accumulation of aspartylglycosamine, particularly in the liver, spleen, and thyroid. The gene for the enzyme (AGA) has been localized to chromosome 4q32-33, and the DNA and gene have been isolated and sequenced. In the Finnish population, a single AGA mutation encoding p.C163S accounts for most mutant alleles, whereas outside of Finland, a large number of private mutations have been described.

Affected individuals with aspartylglucosaminuria typically present in the 1st yr of life with recurrent infections, diarrhea, and umbilical hernias. Coarsening of the facies and short stature usually develop later. Other features include joint laxity, macroglossia, hoarse voice, crystal-like lens opacities, hypotonia, and spasticity. Psychomotor development is usually near normal until age 5 yr, when a decline is noted. Behavioral abnormalities are typically seen, and IQ values in
affected adults are usually<40 (severe intellectual disability). Survival to adulthood is common, with most early deaths attributable to pneumonia or other pulmonary causes. Definitive diagnosis requires demonstration of markedly deficient aspartylglucosaminidase in peripheral blood leukocytes, and/or the specific AGA mutation(s). Several patients have undergone allogeneic bone marrow transplants, but this approach has not proved effective, and no specific treatment is available. Prenatal diagnosis is available by the determination of aspartylglucosaminidase deficiency and/or the specific AGA mutations in cultured amniocytes or chorionic villi.

**α-Mannosidosidosis**

This autosomal recessive disorder results from the deficient activity of α-mannosidase and the accumulation of mannose-rich compounds. The gene MAN2B1 encoding the enzyme has been localized to chromosome 19p13.2-q12, and the cDNA and gene sequence have been determined. To date >140 gene mutations have been reported. Affected patients display clinical heterogeneity. There is a severe infantile form, or type I disease, and a milder juvenile variant, type II disease. All patients have psychomotor retardation, facial coarsening, and dysostosis multiplex. The infantile form of the disorder, however, is characterized by more rapid cognitive deterioration, with death occurring between ages 3 and 10 yr. Patients with the infantile form also have more severe skeletal involvement and hepatosplenomegaly. The juvenile disorder is characterized by onset of symptoms in early childhood or adolescence, with milder somatic features and survival to adulthood. Hearing loss, destructive synovitis, pancytopenia, and spastic paraplegia have been reported in type II patients. The diagnosis is made by the demonstration of the marked deficiency of α-mannosidase activity in white blood cells or cultured fibroblasts. Clinical trials of ERT with recombinant human α-mannosidase are underway. Prenatal diagnosis can be made by demonstrating the enzyme defect and/or the specific gene mutations in cultured amniocytes or chorionic villi.

Congenital Disorders of Glycosylation

Eva Morava, Peter Witters

Keywords

glycosylation
deglycosylation
glycans
transferrin isoelectric focusing
TIEF
cerebro-ocular dysplasia–muscular dystrophy
Glycosylation is the complex multistep metabolic process of adding (oligo)saccharides to proteins and lipids. The classification of disorders of hypoglycosylation is based on biochemical structures: (1) defects in protein N-linked glycosylation, (2) defects in protein O-linked glycosylation, (3) defects in glycosphingolipid and in glycosylphosphatidylinositol-anchor glycosylation, and (4) defects in multiple glycosylation pathways and in other pathways (Fig. 105.7). No disorders are known to result from abnormal C-linked glycosylation. Congenital disorders of glycosylation are labeled based on their genetic defect (CDG).
Protein glycosylation is an essential pathway. Most functional proteins are glycosylated, including serum proteins (e.g., transferrin, ceruloplasmin, TBG), hormones (e.g., TSH, FSH, FH, ACTH, IGFBP3), and clotting and anticoagulation factors (e.g., factors IX and XI, antithrombin). Membrane proteins are also highly glycosylated. Important intracellular glycoproteins include enzymes such as glycosyltransferases or lysosomal enzymes.

N-glycans are linked to the amide group of asparagine. They are synthetized in a complicated process throughout the cytoplasm, endoplasmic reticulum (ER), and Golgi complex, starting with sugar activation and nucleotide sugar synthesis, then oligosaccharide assembly, and finally glycan processing (Fig. 105.8). The majority of the pediatric disorders are N-glycosylation disorders. O-glycans are linked to the hydroxyl group of serine or threonine. These diverse glycoproteins are mostly formed in the Golgi complex; their defects can involve xylosylation, fucosylation, mannosylation, or other modifications. An important focus is O-
mannosylation defects because of their relevance for dystroglycanopathies.
Lipid glycosylation is an essential process for the synthesis of ceramide and ganglioside synthesis. **Glycosylphosphatidylinositol**s (GPIs) are very special glycolipids that link various proteins to the plasma membrane, as complex lipid-sugar anchors (GPI anchors, see Fig. 105.7).
**Congenital disorders of glycosylation (CDG)** are predominantly multisystem diseases, caused by >140 different genetic defects in glycoprotein and glycolipid glycan synthesis. This rapidly growing group is one of the newest and largest metabolic disorder groups. Most patients described with CDG have N-glycosylation defects, followed by the fastest-growing group of CDGs, involving multiple glycosylation pathways and dolicholphosphate synthesis. Smaller groups are O-glycosylation disorders and disorders of glycosylphosphatidylinositol. The “oldest” CDG is PMM2-CDG, in which the genetic defect leads to the loss of **phosphomannomutase 2** (PMM2), the enzyme that catalyzes the conversion of mannose-6-phosphate into mannose-1-phosphate. The majority of CDGs have an autosomal recessive inheritance. Only 2 N-linked CDGs are autosomal dominant, GANAB-CDG and PRKCSH-CDG. The dominantly inherited O-linked CDGs include EXT1/EXT2-CDG, POFUT1-CDG, and POGLUT1-CDG. X-linked CDGs include ALG13-CDG, SSR4-CDG, PIGA-CDG, SLC35A2-CDG, ATP6AP2-CDG and ATP6AP1-CDG.

Some CDGs are lethal; 20% of PMM2-CDG patients die in the 1st 2 yr of life. Some patients, however, stabilize throughout young adulthood. Almost any clinical phenotype can be present in a patient with CDG. It can affect any organ or organ system and most often includes the central nervous system (CNS). The most common clinical features include developmental and speech delay, seizures, ataxia, spasticity, peripheral neuropathy, hypotonia, strabismus, abnormal fat distribution, visual loss, cardiomyopathy, feeding difficulties, liver dysfunction, endocrine abnormalities, bleeding diathesis, and thrombosis (Fig. 105.9 and Table 105.6). Single-organ presentations are rare in CDGs (e.g., TUSC3-CDG and ST3GAL3-CDG: brain; DHDDS-CDG: retina; ALG14-CDG: neuromuscular junction; POFUT1-CDG and POGLUT1-CDG: skin; SEC23B-CDG: red cell lineage; EXT1/EXT2-CDG: cartilage; TMEM199-CDG: liver). Many CDGs are recognizable syndromes. CDG should be considered in any patient with a developmental disability or an unexplained clinical condition, especially in multisystem disease with neurologic involvement.
FIG. 105.9 Patients with phosphomannomutase-2 deficiency (PMM2-CDG) and recognizable clinical features. A, Inverted nipples. B and C, Abnormal fat distribution. </table>
There are also **congenital disorders of deglycosylation**, including known lysosomal disorders and a severe neurologic condition caused by defective $N$-glycanase function ($NGLY1$ defect).

Laboratory evaluations in most $N$-linked CDGs rely on a primary screening method called serum **transferrin isoelectric focusing** (TIEF). Transferrin isoforms, which are hyposialylated (missing terminal sialic acid residues), show different cathodal shifts depending on either missing glycan chains or truncated glycans. A **type 1 pattern** suggests an early metabolic defect in the cytosolic-ER–related glycan synthesis and assembly. A **type 2 pattern** suggests Golgi-related glycan-processing defects (Fig. 105.10).
Isoelectric focusing of apolipoprotein C-III (IEF apoC-III), a serum mucine type O-glycosylated protein, can detect some O-glycosylation disorders (combined N- and O-linked glycosylation defects). Mass spectrometry in serum for type 1 defects is highly sensitive for mild glycosylation abnormalities. Glycomics by matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) can be diagnostic in specific types of CDG (mostly Golgi related with a type 2 pattern). Dolichol-linked glycan or lipid-linked oligosaccharide (LLO) analysis is a complicated but sensitive method to detect ER-related N-linked glycan assembly (CDG type 1) defects in patient fibroblasts. GPI-anchor defects can be suspected based on recurrent elevation of alkaline phosphatase levels in blood.
**Dystroglycanopathies** can be confirmed based on abnormal immunohistochemistry in muscle biopsy. Fluorescence-activated cell sorting (FACS) analysis of the membrane-anchored markers CD16 and CD24 in leukocytes is highly suggestive for a GPI-anchor abnormality, especially when alkaline phosphatase in blood is significantly elevated. Enzyme analysis in blood is only available for a few, more common CDGs (PMM2-CDG, MPI-CDG, PGM1-CDG); it is more reliable in fibroblasts.

With an abnormal TIEF pattern result or clinical suspicion of any type of CDG, most metabolic centers use a direct CDG gene panel analysis or next-generation sequencing (NGS; whole exome sequencing) (see Fig. 105.10).

**Congenital Disorders of Protein N-Glycosylation**

**Phosphomannomutase-2 Deficiency (PMM2-CDG)**

**Clinical Manifestations**

PMM2-CDG is the most common and easily recognizable CDG. Most patients have alternating strabismus, characteristic facial features (short nose, long philtrum, large ears) (Fig. 105.9E), inverted nipples and/or abnormal fat pads (Fig. 105.9A-C), feeding difficulties, axial hypotonia, and decreased reflexes, already in the 1st few mo of life. Nystagmus (caused by pontocerebellar and vermis hypoplasia; Fig. 105.9F) is also common. Psychomotor disability is present in most patients, but normal intellectual development has been described in a few patients. Most patients develop a multisystem disease, and <25% show an isolated neurologic phenotype without other organ involvement, normal endocrine regulation, and no coagulopathy. The neurologic involvement is quite diverse, with ataxia, seizures, spasticity, and peripheral neuropathy (Fig. 105.9D) the most common features. Dystonia, stroke-like episodes, and proximal myopathy can also occur. PMM2-CDG is not a progressive disease, but certain features, when present, typically appear at different ages during the disease. From birth, pericardial fluid collection, cardiomyopathy, or chronic vomiting/diarrhea can occur; after 7 yr, retinitis pigmentosa and cataract; and after puberty, scoliosis, neuropathy, and recurrent thrombotic events. Liver function anomalies are mild, and only a few patients develop cholestasis or liver
fibrosis. Most patients have a hypergonadotropic hypogonadism; no successful pregnancies have been reported. Intellectual disability can be mild to severe; speech development is frequently delayed and can even be absent. Autistic behavior is common, although patients usually have a cheerful personality.

Pathophysiology
Phosphomannomutase 2 catalyzes the conversion of mannose-6-phosphate to mannose-1-phosphate, essential for the formation of activated mannose units used in the synthesis of the growing glycan chain in the ER. Hypoglycosylation leads to abnormal function affecting many essential glycoproteins, such as coagulation and anticoagulation factors, endocrine regulation, transport proteins, liver function, and immune, membrane, and receptor proteins.

Diagnosis
The primary screening method for PMM2-CDG is serum transferrin glycoform analysis, which is most frequently performed by TIEF. Intact transferrin has 4 negatively charged sialic acid residues (tetrasialotransferrin). Transferrin glycoforms, missing terminal sialic acid residues, show different cathodal shifts, less abundant tetrasialotransferrin, increased disialotransferrin, and some a-sialotransferrin (see Fig. 105.10). This is the so-called type 1 pattern, suggestive of a defect in glycan assembly in the cytosol-ER. Transferrin isoforms are also detectable by mass spectrometry. Certain other disorders can cause a false-positive transferrin isoform pattern, including galactosemia, hereditary fructose intolerance, and excessive alcohol use. PMM enzyme analysis is available in leukocytes and fibroblasts. The presence of elevated serum transaminases, hypoalbuminemia, decreased factor IX and XI and antithrombin activity, or low ceruloplasmin or thyroxine-binding globulin (TBG) level is highly suggestive of CDG, including the most common type, PMM2-CDG.

PMM2-CDG is autosomal recessive. Genetic testing is mostly performed by direct sequencing. The most frequent pathogenic variant (c.422G>A; R141H) is present in 75% of patients of Caucasian origin. The exact incidence of PMM2-CDG is not known, but it is estimated to be as high as 1 in 40,000-80,000 in Europe. Prenatal diagnosis is only reliable by genetic testing.

Treatment
The therapy in PMM2-CDG relies on supportive treatment. Even with the best treatment, mortality is about 20% in the 1st 2 yr of life, mostly from cardiac or kidney involvement and severe infections. Current recommended therapy includes adequate nutrition, diet or tube feeding if needed, cardiac support, hormone supplements, physical and occupational therapy, speech therapy, seizure management, and strabismus surgery. Therapeutic developments include targeted mannose-phosphate treatment, and chaperone therapy; these are only in preclinical trial phases.

**Mannosephosphoisoisomerase Deficiency (MPI-CDG)**

**Clinical Manifestations**

MPI deficiency is a recognizable and treatable CDG. Most patients show early symptoms of liver disease (cholestasis, elevated transaminases) and feeding difficulties, with recurrent vomiting and chronic diarrhea, most frequently with protein-losing enteropathy. Life-threatening episodes might appear as early as the 1st few mo of life with recurrent thrombosis and severe gastrointestinal bleeding because of severe coagulation abnormalities. Hypoglycemia is usually caused by hyperinsulinism. Hypoalbuminemia can be severe; patients might develop visible abdominal distention from a combination of ascites and hepatomegaly. Patients with MPI-CDG have no other organ involvement, and the CNS is not affected. There are no dysmorphic features. The liver disease frequently progresses to fibrosis or cirrhosis.

**Pathophysiology**

Mannosephosphoisoisomerase (MPI) catalyzes the conversion of fructose-6-phosphate to mannose-6-phosphate, 1 step before PMM2, therefore blocking the formation of activated mannose units (GDP mannose) for oligosaccharide synthesis. Hypoglycosylation leads to abnormal glycoprotein function the same as in PMM2-CDG, especially coagulation and anticoagulation factors, liver function, and hormone receptors.

**Diagnosis**

The primary screening method in a suspected MPI-CDG patient is serum transferrin isoform analysis by TIEF (see Fig. 105.10) or MS analysis. MPI
deficiency leads to a type 1 pattern, as seen in PMM2 deficiency. MPI enzyme analysis is available in leukocytes and fibroblasts. The presence of elevated serum transaminases, hypoalbuminemia, decreased factor IX and XI and antithrombin activity, hyperinsulinism, and nonketotic hypoglycemia are highly suggestive for MPI-CDG.

MPI-CDG is autosomal recessive. Genetic testing is mostly performed by direct sequencing. The exact incidence of MPI-CDG is not known, but it is estimated at 1 : 800 000 in Europe. Prenatal diagnosis is only reliable by genetic testing. Although this is a rare CDG, early diagnosis is imperative because it is treatable.

**Treatment**

MPI-CDG is the first CDG type treatable by dietary therapy. Mannose therapy is clinically effective by both IV and oral supplementation of 1 g/kg/day divided into 3-4 doses. A known side effect is hemolysis. The treatment uses an alternative pathway: mannose can be phosphorylated by hexokinases to mannose 6-phosphate, bypassing the MPI defect. The clinical symptoms improve rapidly, but liver function might further deteriorate. Liver fibrosis and cirrhosis might necessitate liver transplantation, which will resolve the metabolic disease. The oldest patient known with MPI-CDG has survived into her late 30s.

**Glucosyltransferase-1 Deficiency (ALG6-CDG)**

**Clinical Manifestations**

ALG6-CDG is the 2nd most common CDG. Most patients have hypotonia, muscle weakness, seizures, and ataxia. To date, no patient with ALG6-CDG has normal intelligence. Speech delay and nystagmus are common neurologic signs. Brachydactyly, skeletal abnormalities, and transverse limb defects have been observed. Strabismus and characteristic facial dysmorphism are rare (hypertelorism, oval face, short nose). Inverted nipples and/or abnormal fat pads are exceptional in ALG6-CDG.

The most severe ALG6-CDG patients show a multisystem phenotype in the 1st few mo of life, including severe infections, protein-losing enteropathy, hypoalbuminemia, anemia, and failure to thrive. Autistic behavior and mood changes have been observed in several patients. The oldest patient to date is almost 45 yr.
**Pathophysiology**

The metabolic problem is caused by defective binding of the 1st of 3 glucose to the lipid-linked oligosaccharide in the ER. This glucose binding is essential for attachment of the oligosaccharyltransferase enzyme complex to the newly built oligosaccharide chain and the ability to transfer it to the protein. This leads to protein hypoglycosylation and abnormal glycoprotein function similar to PMM2-CDG and MPI-CDG. Laboratory abnormalities are also similar, including abnormalities in coagulation and anticoagulation factors, liver function, thyroid hormones, and immunoglobulins (IgG).

**Diagnosis**

The primary screening method in a suspected ALG6-CDG patient is serum transferrin glycoform analysis by TIEF or MS analysis. ALG6 deficiency leads to a type 1 pattern (see Fig. 105.10), as seen in PMM2 and MPI deficiency. There is no available enzyme analysis, although lipid-linked oligosaccharides could be evaluated in patient fibroblasts.

ALG6-CDG is autosomal recessive. Genetic testing is mostly performed by direct sequencing. The most common mutations are p.A333V and p.I299Del. Prenatal diagnosis is only reliable by genetic testing. The exact incidence of ALG6-CDG is not known.

**Treatment**

The current therapy in ALG6-CDG relies on supportive treatment. Mortality is about 10% in the 1st years of life, mostly from protein-losing enteropathy and severe infections.

**UDP-GlcNAc:Dol-P-GlcNAc-P Transferase Deficiency (DPAGT1-CDG)**

**Clinical Manifestations**

DPAGT1 deficiency is a recognizable and potentially treatable CDG. About one third of patients show the *congenital myasthenia* phenotype, indistinguishable from other genetic congenital myasthenias. Creatine kinase (CK) levels are normal. These patients have a relatively good prognosis, especially with early myasthenia therapy. The other patients show a multisystem phenotype with
microcephaly, brain malformations, hypotonia, severe psychomotor disability, seizures, spasticity, failure to thrive, joint contractures, and cataracts.

**Pathophysiology**

DPAGT1 defect leads to very early arrest of glycan synthesis outside the ER membrane, by slowing down the addition of the 2nd GlcNAc sugar to the phosphorylated dolichol arm. Abnormal receptor glycosylation in the **neuromuscular junction** leads to myasthenia. Hypoglycosylation in the multisystem type leads to abnormal glycoprotein function similar to that in PMM2-CDG, especially involving the anticoagulation factors, and interestingly leading to high serum CK (in contrast to the congenital myasthenia phenotype) and hypoalbuminemia.

**Diagnosis**

The primary screening method is serum transferrin glycoform analysis or MS analysis. Most patients show a type 1 pattern (see Fig. 105.10), but patients with the congenital myasthenia phenotype can show normal screening. There is no clinically available enzyme analysis.

DPAGT1-CDG is autosomal recessive. Genetic testing is mostly performed by direct sequencing. The exact incidence is not known. Prenatal diagnosis is only reliable by genetic testing. Because of the false-negative TIEF results in several patients with the myasthenic phenotype, congenital myasthenia panel testing is suggested in suspected cases, especially for determining the potential therapy.

**Treatment**

The congenital myasthenia phenotype is frequently treatable by high-dose pyridostigmine, eventually enhanced with salbutamol. In the multisystem phenotype of DPAGT1-CDG, treatment is supportive.

**Congenital Disorders of Protein O-Glycosylation**

**Cerebro-Ocular Dysplasia–Muscular Dystrophy and Muscle-Eye-Brain Disease**
Spectrum (POMT1-CDG, POMT2-CDG, POMGNT1-CDG)

From isolated muscular dystrophy to Walker Warburg syndrome, this group of O-linked glycosylation disorders presents with severe muscle weakness, congenital eye malformations, and neuronal migration defects. Pachygyria, cobblestone dysgenesis, hydrocephalus, polymicrogyria, heterotopias, and corpus callosum agenesis are variably present. Eye malformations include anophthalmia, microphthalmia, congenital cataract, or colobomas. Congenital muscular dystrophy is associated with significant CK level elevations. There is severe psychomotor disability.

The underlying metabolic defect is the abnormal synthesis of the O-mannosylglycan core, which is essential for the proper glycosylation of α-dystroglycan. The α-dystroglycan is heavily O-glycosylated with mannose residues and is expressed in both muscle and brain. Defective mannosylation of α-dystroglycan leads to muscle degeneration and migration defects. Muscle biopsy shows abnormal α-dystroglycan staining on immunohistochemistry.

Transferrin isoelectric focusing is normal in patients with isolated O-mannosylation defects. There is also no clinically available enzyme analysis. Diagnosis is based on histology (muscle biopsy) and genetic analysis.

POMT1-CDG, POMT2-CDG, POMGNT1-CDG are the most common autosomal recessive α-dystroglycanopathies. Additional gene defects occur in the pathway; POMK, FKTN, FKRP, LARGE, B4GAT1, TMEM5, and ISPD have been described in association with human disease. The exact incidence of α-dystroglycanopathies is not known.

In α-dystroglycanopathies the treatment is supportive.

Defects in Lipid Glycosylation and in Glycosylphosphatidylinositol Anchor Biosynthesis

Hyperphosphatasia–Intellectual Disability Syndromes: PIGA Deficiency (PIGA-CDG)

This clinically recognizable syndrome is an epilepsy syndrome with intellectual
disability, hypotonia, dysmorphic facial features, skin anomalies, congenital brain malformations, and behavioral abnormalities, including autism. Other organ malformations, including cardiac and renal defects, have also been reported. (Note that somatic mutations with PIGA defect can also lead to paroxysmal nocturnal hemoglobinuria."

$\text{N}$-acylglucosamine (GlcNAc) cannot be efficiently transferred to phosphatidylinositol for glycoprophosphatidylinositol synthesis. Abnormal anchoring of alkaline phosphatase leads to hyperphosphatasemia in blood and loss of specific surface antigens on blood cells.

Transferrin isoform analysis is normal in GPI-anchor defects. FACS analysis of the membrane-anchored markers CD16 and CD24 in leukocytes is highly suggestive for a GPI-anchor abnormality, especially in association with increased levels of serum alkaline phosphatase. Mutation analysis confirms the defect.

PIGA-CDG is X-linked. The exact incidence is not known. A similar phenotype has been described in PIGO, PIGV, PIGY, PIG, PGAP2, and PGAP3 defects.

In PIGA-CDG the treatment is supportive.

**Defects in Multiple Glycosylation Pathways and in Other Pathways, Including Dolicholphosphate Biosynthesis Defects**

**Steroid 5α-Reductase Deficiency (SRD5A3-CDG)**

**Clinical Manifestations**

SRD5A3 deficiency is a clinically recognizable CDG, originally described as a multiple–congenital malformation syndrome. About 20 patients have been diagnosed at different ages, including one at 45 yr. Patients have hypotonia, ataxia, and eye abnormalities, including congenital cataract, retinal and iridic colobomas, glaucoma, optic nerve dysplasia, and visual loss. Cerebellar vermis hypoplasia can be variable. Intellectual disability has been described in all
affected patients thus far. About one third of patients have severe congenital ichthyosis. Hypertrichosis and dysmorphic facial features are common, including squared face, high forehead, large ears, and coarsening. Some children with SRD5A3-CDG have a severe autism spectrum disorder. Skeletal abnormalities (scoliosis) and cardiac malformations are less common.

**Pathophysiology**
SRD5A3 deficiency leads to abnormal dolichol synthesis affecting early glycan synthesis outside the ER membrane and affects O-mannosylation and GPI-anchor synthesis. Hypoglycosylation affects anticoagulation factors and leads to increased serum transaminases.

**Diagnosis**
The primary screening method in a suspected SRD5A3-CDG patient is serum transferrin glycoform analysis or MS analysis. Most patients show a type 1 pattern (see Fig. 105.10), but several false-negative cases have been described. There is no clinically available enzyme analysis.

SRD5A3-CDG is autosomal recessive. Genetic testing is mostly performed by direct sequencing. The exact incidence is not known.

**Treatment**
In SRD5A3-CDG the treatment is supportive.

**Autosomal Recessive Cutis Laxa Type 2 (ARCL-2A or ATP6V0A2-CDG, ATP6V1A-CDG and ATP6V1E1-CDG)**

**Clinical Manifestations**
ATP6V02-CDG is a multiple-malformation syndrome originally described as cutis laxa syndrome and recently discovered to be a combined N- and O-linked glycosylation disorder. Patients show generalized cutis laxa with inelastic, sagging skin at birth, hypotonia, strabismus, myopia, characteristic facial features, and joint laxity. The facial features include hypertelorism, short nose, long philtrum, down-slanting palpebral fissures with sagging eyelids, and sagging cheeks. Cardiovascular involvement is rare, and there is variable CNS
involvement. Seizures and motor and language developmental disability are common, but normal intelligence has been described as well. Sensorineural hearing loss is sometimes observed. Some patients have vermis hypoplasia, and several children have been described with cobblestone like dysgenesis and partial pachygyria on brain MRI. Skeletal abnormalities and short stature are common, as well as late-closing fontanels, and/or brachydactyly and scoliosis. There is frequently enamel dysplasia. The skin features spontaneously improve with age. ATP6V1A-CDG and ATP6V1E1-CDG show a highly overlapping phenotype with associated cardiovascular symptoms and hypercholesterolemia.

**Pathophysiology**

ATP6V0A2 is a membrane subunit of the proton pump of the vesicular adenosine triphosphatase (V-ATPase) complex. Abnormal function of the V-ATPase complex alters the pH gradient in the secretory pathway and affects the maturation and transport of several glycosyltransferases and elastic fibers (e.g., elastin). ATP6V1A and ATP6V1E1 are other complex subunits affecting ATP6V0A2 function and cause secondary ATPase deficiency. Both N- and O-linked glycosylation are affected. There are mild coagulation abnormalities and high serum transaminase levels in some patients.

**Diagnosis**

The primary screening method in a suspected ATP6V0A2-CDG patient is serum transferrin glycoform analysis or MS analysis. Most patients show a type 2 pattern (see Fig. 105.10), but false-negative cases have been described before age 6 wk. Apolipoprotein III-C (apoC-III) is a mucin-type secretory glycoprotein that is only O-glycosylated. ApoC-III IEF shows a hypoglycosylation pattern in patients, even when the TIEF is falsely negative. Skin biopsy in patients show classic histologic changes of cutis laxa with diminished, short, abnormal, and fuzzy elastic fibers.

ATP6V0A2-CDG is autosomal recessive. Genetic testing is mostly performed by direct sequencing. The exact incidence is not known. ATP6V1A and ATP6V1E1 defects have been recently described.

**Treatment**

In autosomal recessive cutis laxa type 2, the treatment is supportive. There is continuous and spontaneous improvement of skin symptoms throughout the
disease course, especially in ATP6V0A2-CDG.

**Golgi-α_{1-2} Mannosidase-1 Deficiency (MAN1B1-CDG)**

**Clinical Manifestations**

*MANN1B1* defect was originally described as an intellectual disability syndrome in association with dysmorphic features. Additional patients were recognized with psychomotor disability, muscle hypotonia, and inverted nipples in association with truncal obesity. The degree of intellectual disability is quite variable. Autistic behaviors, eating disorders, and aggressive behavior are frequent features. More than 30 patients have been reported.

**Pathophysiology**

*MANN1B1* codes for a Golgi mannosidase, which is essential for the final “trimming” of mannose units during the glycan processing in the Golgi. Hypermannosylation leads to abnormal, truncated glycans and CDG-II. The glycosylation abnormality in serum is relatively mild. Increased serum transaminases and abnormal coagulation are uncommon.

**Diagnosis**

Most patients show a mild type 2 pattern by TIEF, but false-negative cases have been described. MALDI-TOF analysis shows characteristic, hybrid glycans in serum. In suspected cases, direct sequence analysis is recommended, even if the TIEF is normal.

*MAN1B1*-CDG is autosomal recessive. The exact incidence is unknown; several adult patients are known.

**Treatment**

Only supportive treatment is available.

**Phosphoglucomutase-1 Deficiency (PGM1-CDG)**

**Clinical Manifestations**

PGM1-CDG is a disorder presenting with midline malformations (cleft palate,
Pierre Robin sequence, bifid uvula), liver dysfunction, hypoglycemia, and short stature in almost all patients. Hypoglycemia is usually caused by hyperinsulinism in the 1st years of life. It can resolve with aging; ketotic hypoglycemia has also been observed. Cholestasis, liver fibrosis, and even cirrhosis have been described in a few patients. About one third of patients also show proximal muscle weakness and dilated cardiomyopathy; the latter led to mortality in at least 7 reported cases. Other malformations, including cardiac and skeletal anomalies, have also been described. Wound healing is frequently abnormal, and there is a very high risk for bleeding during surgery. Intelligence is normal.

**Pathophysiology**

Phosphoglucomutase 1 (PGM1) is an essential enzyme for glycogenolysis and glycolysis. It also provides substrates for nucleotide sugars needed for normal glycosylation. PGM1 regulates the bidirectional conversion of glucose-1-phosphate and glucose-6-phosphate. During fasting it leads to a glycogenosis-like phenotype (also called GSD XIV, MIM 614921). PGM1-CDG affects both the ER- and Golgi-related glycosylation and causes a mixed type 1/type 2 hypoglycosylation pattern. Abnormal serum proteins include coagulation and anticoagulation factors, insulin-like growth factor–binding protein 3 (IGFBP3), TBG, and thyroid-stimulating hormone (TSH), in addition to serum transaminases, hypoglycemia, and elevated CK.

**Diagnosis**

The primary screening method in a suspected PGM1-CDG is serum transferrin glycoform analysis or MS analysis. Patients show a mixed type 1/type 2 pattern. PGM1-CDG is autosomal recessive. It is among the relatively common CDGs; >40 patients have been described. Enzyme testing is possible in blood, but is more reliable in fibroblasts. Direct sequencing is available for testing.

**Treatment**

PGM1-CDG seems to be the 2nd treatable CDG besides MPI-CDG. D-Galactose is hypothesized to restore the balance in the availability of different nucleotide sugars. Adding 1 g/kg/day D-galactose for a few weeks to the diet improves glycosylation significantly, although the TIEF pattern does not fully normalize. This treatment improves liver transaminases and antithrombin levels and in some patients the hormonal status. The effect of D-galactose on
hypoglycemic episodes and the myopathy is not yet clear. Larger, long-term dietary trials are ongoing.

**Disorders of Golgi Homeostasis: TMEM199-, CCDC115-, ATP6AP2-CDG, and ATP6AP1-CDG**

**Clinical Manifestations**

These 4 disorders are clinically and biochemically indistinguishable. They have been described with liver function anomalies, cholestasis, fibrosis, and cirrhosis with liver failure, necessitating liver transplantation in a few patients. The phenotype resembles ***Wilson disease***, especially because of low serum ceruloplasmin and copper levels, but there is no Kayser-Fleischer ring. In CCDC115-CDG there are frequently also neurologic features. The intellectual outcome is variable. Additional abnormalities include hypercholesterolemia and elevated alkaline phosphatase. In ATP6AP1-CDG there is also immunologic involvement.

**Pathophysiology**

TMEM199-, CCDC115-, ATP6AP1-CDG, and ATP6AP2-CDG are important for Golgi homeostasis. The exact pathologic mechanism is not yet known, but it is hypothesized that the secondary Golgi dysfunction affects and delays the normal glycosylation process.

**Diagnosis**

The primary screening method in a patient with suspected PGM1-CDG is serum transferrin glycoform analysis or MS analysis. Patients show a type 2 pattern (see Fig. 105.10). ApoC-III IEF is abnormal. Glycomics results by MALDI-TOF analysis are characteristic but cannot discriminate between the 3 defects. Final diagnosis requires mutation analysis.

TMEM199-CDG and CCDC115-CDG are autosomal recessive, whereas ATP6AP1-CDG, and ATP6AP2-CDG are X-linked.

**Treatment**

Treatment is supportive; 2 patients successfully underwent liver transplantation.
Manganese Transporter Defect: SLC39A8-CDG

Clinical Manifestations

This intriguing disorder was originally described as a neurologic disease with hypotonia, seizures (hypsarrhythmia), and developmental disability. Some of the later-described patients had severe skeletal dysplasia with rhizomelic chondrodysplasia, craniosynostosis, and dwarfism. Mitochondrial dysfunction (Leigh disease, cerebral lactic acidemia, dystonia) may also be present.

Pathophysiology

SLC39A8 is a membrane transporter, responsible for the manganese (Mn) transmembrane transport. SLC39A8 deficiency affects all Mn-dependent enzymes and therefore different parts of the metabolism. Since several glycosyltransferases (e.g. β-1,4-galactosyltransferase) are Mn dependent, a secondary Golgi glycosylation occurs with a type 2 glycosylation defect. Low serum Mn levels are suggestive but not always present in patients.

Diagnosis

The primary screening method in a suspected SLC39A8-CDG is serum transferrin glycoform analysis or MS analysis. Patients show a type 2 pattern (see Fig. 105.10). MALDI-TOF analysis is suggestive, but not discriminative. Final diagnosis requires mutation analysis.

SLC39A8-CDG is an autosomal recessive disease. Its incidence is unknown.

Treatment

Besides supportive treatment, a few patients showed biochemical and clinical improvement (better seizure control) with oral D-galactose (1-3 g/kg/day) therapy.

Congenital Disorders of Deglycosylation

N-Glycanase 1 Deficiency (NGLY1 Defect)

Clinical Manifestations

Patients with NGLY1 deficiency do have a glycosylation disorder, but not from the deficient synthesis; rather, it is caused by deficient breakdown of...
glycoproteins. The phenotype comprises severe CNS involvement, microcephaly, intellectual disability, seizures, neuropathy, movement disorders, and hypotonia. The presence of alacrimia, hypolacrimation, or chalazion is highly suggestive for the diagnosis, but not all patients have problems with tearing. Other features include failure to thrive, intrauterine growth restriction, and liver involvement. Some patients have a recognizable oval face with a short nose, flat profile, and hypertelorism. Masklike face also occurs, imitating the phenotype of mitochondrial disorders, especially when serum lactic acid levels are also elevated.

**Pathophysiology**

N-glycanase is responsible for the deglycosylation of misfolded N-linked glycoproteins. The enzyme is essential for cutting off the glycans before the proteins are degraded in the ER. The increased abundance of misfolded N-glycans increases ER stress, which has been suggested as a possible reason for lactate elevation in several patients. Serum transaminase and α-fetoprotein levels are also frequently increased.

**Diagnosis**

Serum transferrin isoform analysis shows a normal pattern. Final diagnosis requires mutation analysis.

NGLY1-CDG is an autosomal recessive disease. The most common mutation is c.1201A>T/p.R401X. The exact incidence of the condition is unknown, but >20 patients have been reported in a few years since the discovery of the disease.

**Treatment**

Only supportive treatment is available for the patient with NGLY1 deficiency.

**Therapeutic Summary**

Most CDGs are only treatable with supportive therapy. The initially discovered oral mannose treatment in MPI-CDG (1 g/kg/day) has proved to be efficient for coagulation problems and protein-losing enteropathy but cannot prevent liver fibrosis in all patients. Liver transplantation in MPI-CDG has been successful in a few patients. Oral D-galactose in PGM1-CDG (1g/kg/day) improves serum transaminases and coagulation, and has a positive effect on endocrine function,
but cannot restore glycosylation fully. Seizure frequency improved in patients with SLC39A8-CDG receiving oral β -galactose treatment (1 g/kg/day) and oral Mn intake. The congenital myasthenic syndrome in DPAGT1-CDG, GFPT1-CDG and GMPPB-CDG has been successfully treated with high dose of cholinesterase inhibitors. Several CDG have been positively controlled by transplantation; including DOLK-CDG (DK1-CDG; heart transplantation) PGM3-CDG (hematopoietic stem cell transplantation), CCDC155-CDG (liver transplantation).

Additional CDG treatment options are available for disorders not described in this chapter. Patients with CAD-CDG show significant clinical improvement on receiving oral uridine therapy, especially with seizure control. Two children with SLC35C1-CDG–defective immune function improved on oral fucose therapy. GNE-CDG patients showed significant improvement in muscle strength on N -acetylmannosamine therapy. Several dietary trials are currently ongoing in different CDG.

Overview of Mitochondrial Disease

Mitochondrial diseases are multisystemic energy failure states with extensive clinical and genetic heterogeneity. Their common basis is best understood through recognition that mitochondria function as biologic “fuel cells” or “batteries,” producing chemical energy in the form of adenosine triphosphate (ATP) by aerobic metabolism of nutrient-derived reducing equivalents, through the integrated function of the 5-complex mitochondrial respiratory chain (RC) (Fig. 106.1). Mitochondria also play other essential roles that can be variably disrupted in disease states, such as regulating calcium homeostasis, diverse aspects of intermediary nutrient metabolism, nucleotide metabolism, and oxidative stress. Primary mitochondrial disease results from deficient RC function, which can be caused by mutations in genes that encode RC subunits, assembly factors or cofactors, components of mitochondrial DNA (mtDNA) metabolism and maintenance, or a host of other basic metabolic processes ongoing within mitochondria. Approximately 1,500 proteins exist within the mitochondrial proteome of different tissues, with variants in more than 350 unique genes across both the nuclear and the mitochondrial genomes already implicated as causal in human mitochondrial disease.
Collectively recognized as the most common group of inherited metabolic diseases, **primary** (genetic-based) mitochondrial disease has a combined minimal prevalence of 1 in 4,300 individuals across all ages. In addition, **secondary** mitochondrial dysfunction is broadly implicated in the pathogenesis of a host of complex diseases, ranging from metabolic syndrome to ischemia-
reperfusion injury after stroke, to neurodegenerative diseases. Failure of high-energy demand organs in mitochondrial diseases may clinically present as severe neurodevelopmental, cardiac, myopathic, renal, hepatic, endocrine, immune, gastrointestinal, hearing, and vision disabilities, as well as global metabolic instability with lactic acidosis (Fig. 106.2) (see Tables 105.2 and 105.3). In most mitochondrial disorders, the phenotype may vary depending on the patient's age or the specific gene or genetic variant. Particularly common mitochondrial disease clinical syndromes that present in children include Leigh syndrome (for which there are more than 90 causal genes), mtDNA depletion syndrome (MDS, for which there are dozens of causal genes), mtDNA deletion syndromes (Pearson, Kearns Sayre), primary lactic acidosis, and pyruvate dehydrogenase deficiency. Common clinical features in children present in at least 90 percent of patients include fatigue, exercise intolerance, weakness, gastrointestinal problems, ataxia, and developmental delay. Thus, mitochondrial diseases present to and must be considered by clinicians across every medical specialty.

FIG. 106.2 Mitochondrial disease subject cohort, experienced symptoms. Frequency of experienced symptoms as reported by the RDCRN self-reported cohort revealed muscle weakness, chronic fatigue, exercise.

Subjects affected (%)
intolerance, imbalance, and gastrointestinal problems to be the top 5 common symptoms. (Modified from Zolkipli-Cunningham Z, Xiao R, Stoddart A, et al: Mitochondrial disease patient motivations and barriers to participate in clinical trials. PLoS ONE 13(5):e0197513 [Fig. 2].)

Patients with suspected mitochondrial disease may frequently experience a diagnostic odyssey, both clinically and genetically. Their extensive phenotypic heterogeneity without a common biomarker (GDF-15 may be one screening test that may be elevated in some mitochondrial myopathies particularly involving mtDNA deletions or depletion, along with lactic acidosis) presents a challenge to the readily available and accurate clinical diagnosis of mitochondrial disorders in many medical settings. Similarly, their extensive genetic heterogeneity involving known etiologies in >300 nuclear genes and all 37 mitochondrial DNA (mtDNA) genes, with likely dozens to hundreds more causative nuclear disease genes awaiting discovery, can make the accurate genetic diagnosis of an individual patient challenging. The diagnostic uncertainty can be further compounded by poor genotype-phenotype correlations and variable clinical presentations of individual gene disorders, high locus heterogeneity (i.e., multiple different causal disease genes) for similar clinical phenotypes, incomplete penetrance for some gene disorders, variable life stressors or environmental exposures that may exacerbate a given child's disease, and the unique biologic aspects of maternal inheritance for the subset of mitochondrial diseases caused by mtDNA gene mutations.

When to Suspect Mitochondrial Disease

Because of failure in the ability to generate cellular energy, mitochondrial diseases can involve any organ system at any age (see Fig. 106.2). Mitochondrial disease should be suspected when classic symptoms are present or if unexplained symptoms occur in 3 or more apparently unrelated organs. Individuals may present with a vast array of symptoms, including fatigue, muscle weakness, exercise intolerance, metabolic strokes, seizures, cardiomyopathy, arrhythmias, developmental or cognitive disabilities, autism, diabetes mellitus, other endocrinopathies (adrenal, thyroid), dysautonomia, and autoimmune disorders, as well as impairment of hearing, vision, growth, liver, gastrointestinal (GI), or kidney function. Although individuals may have just one or a few symptoms and a fluctuating disease course in terms of symptom severity, most patients with primary mitochondrial disease tend to develop
progressive symptoms over time. A study of patients with mitochondrial diseases showed an average of 16 different clinically significant symptoms per patient, with a range of 7-35. When considering the diagnosis, it is helpful to recognize that most symptoms of mitochondrial disease involve functional, rather than structural, problems.

When mitochondrial disease is considered in the differential diagnosis, it is often helpful to obtain several laboratory screening studies for common biochemical features of mitochondrial disease and overlapping disorders, both at baseline and if unrevealing, during an acute illness or period of decompensation. Blood-based metabolic screening studies include comprehensive chemistry panel, complete blood count with differential, plasma amino acid quantitative analysis, carnitine analysis (total, free, acyl-carnitine profile), ammonia, creatine kinase, and testing for common secondary manifestations of mitochondrial disease (e.g., thyroid screen, lipoprotein profile, hemoglobin A1c). Urine-based metabolic screening studies include urinalysis, urine organic acid quantitative analysis, and urine amino acid quantitative analysis. Consideration should also be given for screening for congenital disorders of glycosylation or vitamin deficiencies, which may have overlapping clinical features in some cases with mitochondrial disease. Lactic acidemia is neither highly sensitive nor specific for primary mitochondrial disease, but laboratory findings suggestive of primary mitochondrial disease include elevations of blood lactate, pyruvate, lactate:pyruvate ratio, alanine, ratios of alanine to lysine (>3) and alanine to sum of phenylalanine and tyrosine (>4), and anion gap. Biochemical alterations further suggestive of mitochondrial disease may include secondary impairment of fatty acid oxidation with elevation of dicarboxylic acids on acyl-carnitine profile, increased branched-chain amino acids and proline on plasma amino acid analysis, increased tricarboxylic acid cycle intermediates and lactate excretion on urine organic acid analysis, and generalized aminoaciduria on urine amino acid analysis. Growth and differentiation factor 15 (GDF-15) may be a useful screening test for mitochondrial depletion based myopathies.

Similarly, when mitochondrial disease is considered in the differential diagnosis, obtaining additional clinical evaluations to carefully phenotype the patient for prevalent or highly morbid and potentially modifiable features of mitochondrial disease is important. Because many individuals with mitochondrial disease develop problems with their vision (reduced visual acuity not correctable with glasses, photophobia or nyctalopia with reduced peripheral vision associated with retinal disease or optic atrophy, ophthalmoplegia, ptosis),
hearing (high-frequency sensorineural hearing loss), and heart (arrhythmia, conduction block, cardiomyopathy), carefully evaluating for involvement of these high-energy systems is indicated. **Neurologic** evaluation is essential because many mitochondrial disease patients experience a range of **central** (metabolic stroke in cortical or deep gray matter including basal ganglia, midbrain, and/or brainstem, white matter changes, seizures, ataxia, movement disorder, migraine, cognitive changes), **peripheral** (axonal sensorimotor neuropathy), or **autonomic** nervous system dysfunction; brain imaging (MRI), spectroscopy (MRS), and on occasion electromyogram or nerve conduction velocity (EMG/NCV) studies can be helpful to support the diagnosis. Formal **exercise physiology** evaluation can also be useful to quantify and advise patients on their exercise capacity and safety, with some specific features (e.g., reduced $\text{VO}_2$ maximal capacity) suggestive of quantifiable mitochondrial dysfunction. **Sleep** study may be useful for individuals with sleep dysfunction because sleep disorders may mimic mitochondrial disease symptoms, and sleep problems are common and potentially treatable in mitochondrial disease. **Gastrointestinal** symptoms are common and underrecognized in mitochondrial disease patients, usually involving dysmotility of any portion of the GI tract with reflux, swallowing dysfunction, delayed gastric emptying, feeding and/or growth problems, pseudoobstruction, malabsorption, and constipation. **Endocrine** abnormalities are also common but underappreciated in many patients, including pituitary, adrenal, thyroid, and pancreatic dysfunction. Such careful phenotyping of patients with suspected mitochondrial disease can thus provide reassurance that the common, and potentially treatable, clinical aspects of mitochondrial disease are not present although they may develop over time, or conversely if identified, increase diagnostic suspicion and direct further diagnostic evaluation.

**Mitochondrial Disease Inheritance**

Primary mitochondrial disease may result from variants in either nuclear genes or mtDNA genes, which may be inherited from a parent or occur de novo in an affected individual. Thus, all **mendelian** (autosomal recessive, autosomal dominant, X-linked) or **maternal** (mtDNA) inheritance patterns can be consistent with mitochondrial diseases (Table 106.1). Obtaining a detailed, three-generation pedigree is important to potentially highlight the specific inheritance pattern in a given family. Individuals with inherited mtDNA disorders may
report family members related through their maternal lineage (both males and females may be affected, but only affected individuals will be connected through the female germline), with a range of functional problems in different organs, such as migraines, fatigue, exercise intolerance, stroke, diabetes mellitus, thyroid dysfunction, irritable bowel spectrum, mood disorder, or vision and hearing problems. Inherited X-linked disorders typically present with symptoms only, or more severely, in males related through unaffected or minimally affected females. **Autosomal recessive** disorders are common in pediatric mitochondrial disease, particularly in consanguineous pedigrees, where a rare variant in the general population becomes enriched and passed down through both maternal and paternal lineages to become homozygous in the affected proband and also affect multiple individuals in a given generation without having affected individuals in earlier generations. **Autosomal dominant** variants may occur de novo or are passed on from either parent to their child, although many disorders may have reduced penetrance, which may make the genetic disorder appear to skip a generation. Identifying a likely inheritance pattern through pedigree analysis can inform accurate interpretation of large-scale genetic diagnostic evaluations, such as multigene sequencing and deletion/duplication analysis panels and exome or genome sequencing. Establishing a correct genetic diagnosis for mitochondrial disease in an affected individual is essential to enable reliable recurrence risk counseling and testing options in a given family, whether in a future pregnancy by chorionic villus sampling (CVS, typically performed at 10-12 weeks’ gestation) or amniocentesis (typically performed at 16-20 weeks’ gestation) or in the in vitro fertilization (IVF) setting with preimplantation genetic diagnosis (PGD) for a specific disease-causing variant.

Special mention is warranted to consider the unique aspects of *maternal inheritance* that typify mtDNA disorders. More than 300 disease-causing mtDNA variants have been identified, with extensive variation in disease manifestations and features. Most disease-causing variants are present in only a portion of an individual's mtDNA genomes, a concept known as *heteroplasmy*. For heteroplasmic mtDNA variants, the precise mutation level (percent) can vary between an individual's different tissues and can change over time, with symptom severity corresponding to different threshold mutation levels that can be difficult to define and that typically vary between organs. An individual's mtDNA genome background set of fixed sequence variants, known as a *haplogroup*, can also influence the penetrance or severity of a mtDNA disease. When a novel or rare mtDNA variant is identified in a given individual, it may be useful to use highly sensitive sequencing methods to test the levels of that mutation (which may be accurate to detect 1% mutation levels) in their different tissues (blood, urine, buccal, skin cells, muscle), as well as tissues from their mother or maternal relatives, to accurately determine whether it may be causal of disease in that family. Research-based functional testing may also be necessary to characterize fully the effects of a newly recognized mtDNA variant. When it is not known whether an mtDNA variant is maternally inherited or occurs de novo, the recurrence risk to future offspring of their asymptomatic parent is empirically estimated at 1 in 25 (4%), although the empirical recurrence risk
rises to 1 in 2 (50%) when the mother is symptomatic.

**Diagnostic Testing for Mitochondrial Disease**

The diagnosis of mitochondrial disease relies foremost on genetic testing (genomic analysis), with biochemical screens useful in blood or urine and invasive tissue testing often seen as secondary, or sometimes not required at all (Fig. 106.3).

When the clinical evaluation—medical history; detailed review of systems; careful physical, neurologic, and dysmorphic examinations; pedigree-, blood-, and urine-based biochemical screening studies; and additional phenotyping
clinical evaluations—is suggestive of mitochondrial disease, a range of clinical diagnostic testing options can be pursued. Absent a known molecular etiology in an affected family member, first-line genetic diagnostic testing may involve a focused panel of hundreds to thousands of known nuclear genes and the mtDNA genome using next-generation sequencing (NGS) methodologies that will detect both single-nucleotide variants and larger-scale gene deletions and duplications. If such testing is unrevealing, clinically based whole exome sequencing (WES) may be pursued. The standard of care is moving to pursue initial diagnostic testing by WES, which is more comprehensive for genes known not only to cause mitochondrial disease, but also to cause all human genetic diseases. The rationale for this evolution in diagnostic testing approach includes the following factors:

1. An increasingly similar cost and turnaround-time for panel-based and WES-based massively parallel NGS studies.
2. The common genetic diagnostic laboratory practice of generating WES data for all tests ordered, but only evaluating and reporting variants in specific gene subsets when panel-based testing is requested, leaving the remaining genes uninterpreted.
3. The mtDNA genome sequence is often included at no extra cost when clinical WES is ordered in blood, but may need to be repeated in a symptomatic tissue (e.g., muscle, liver) to detect heteroplasmic mtDNA variants that may not be present in blood.
4. The utility of performing concurrent proband and both parental sample sequencing (trio-based testing), as usually pursued with WES but not panel-based testing, thereby allowing concurrent segregation analysis of a suspected pathogenic variants as well as ready identification of de novo dominant variants in the proband.
5. The improved diagnostic yield of exome relative to panel-based testing increasingly being reported by clinical diagnostic laboratories, given the highly heterogeneous nature of mitochondrial disease, rapid rate of change in the recognition of new gene diagnoses making prior established gene panels obsolete, and the extensive phenotypic overlap with non-mitochondrial diseases.
6. The ability to utilize WES raw data (either on a research basis or for reanalysis at a later date by the clinical diagnostic laboratory) to highlight and/or identify “novel” gene disorders not previously
recognized or associated with human disease.

A mitochondrial disease community resource to centrally curate all mitochondrial disease, gene, and variant knowledge across both genomes is publicly accessible at www.mseqdr.org. Exome sequencing including mtDNA is estimated to identify the definitive genetic etiology for mitochondrial disease in at least 60% of patients in whom it is strongly suspected, reducing the diagnostic odyssey in many patients from decades or years to months.

Tissue-based diagnostic testing has decreased in frequency as a front-line test in all patients with suspected mitochondrial disease, although it still has clinical utility in some cases. These include (1) in the setting of rapidly deteriorating clinical status when genetic testing results may not be available in a timely fashion; (2) when a variant of uncertain significance identified on genomic testing has unclear biochemical consequences; and (3) when uninformative genomic sequencing in blood in an individual with myopathy or muscle symptoms raises concern for other disease processes that may be evident on histology, electron microscopy, immunohistochemistry or enzymatic tissue testing. In addition, some mitochondrial diseases are only evident by tissue-based diagnostic testing. These include mtDNA deletion disorders (typically involving several-thousand nucleotides) not present in blood that cause chronic progressive external ophthalmoplegia (CPEO) or Kearns-Sayre syndrome (KSS) spectrum disorder, as well as different tissue (muscle or liver)-specific mtDNA depletion disorders (e.g., reduced mtDNA tissue content) that confirm a mitochondrial pathophysiology in a given patient and highlight a likely underlying nuclear gene cause for their disease, since mtDNA maintenance requires a host of nuclear-encoded proteins. Muscle analysis for integrated RC oxidative phosphorylation capacity assessment requires analysis of a fresh muscle biopsy only available at a very limited number of sites worldwide, whereas electron transport chain enzyme activity analyses are the accepted gold standard to evaluate for mitochondrial dysfunction in a previously frozen tissue sample, often shipped elsewhere for diagnostic analysis. Skin biopsies are useful to establish fibroblast cell lines in which these same studies of mitochondrial function can be clinically performed. If detected, abnormalities can be revealing of a specific type of mitochondrial disorder, although not all mitochondrial diseases may be expressed or detectable in skin analysis. Thus, if fibroblast testing is unrevealing, more invasive tissue studies may subsequently need to be pursued. Fibroblast cell lines, and occasionally blood-based
lymphoblastoid cell lines, also provide a minimally invasive cell source to allow other clinical enzymatic analyses to be performed, as well as novel disease gene validation and research-based therapeutic modeling.

**Treatment Principles for Mitochondrial Disease**

Effective therapies for both primary and secondary mitochondrial diseases are lacking, because little has been known about the biochemical and physiologic abnormalities that contribute to their diverse clinical manifestations. Clinical complexity and imprecisely defined or understood biochemical phenotypes of different mitochondrial disease subtypes have made it difficult for clinicians to effectively apply or monitor targeted therapies for RC disease. **Mitochondrial cocktails** of vitamins and supplements variably include vitamins \(B_1, B_2, C\), antioxidants \(\text{CoQ}_{10}, \text{lipoic acid, vitamin E}\), and metabolic modifiers \((\text{creatine, L-carnitine, L-arginine, folinic acid})\). Although the efficacy, toxicity, and optimal dose of these drugs are not known and have not been objectively assessed in human RC disease patients, they continue to be empirically prescribed in hopes of enhancing residual RC enzymatic function or quenching toxic metabolites theorized to accumulate in RC dysfunction, and because of patient-based reports of improved well-being. However, provision of these therapies has often adopted a one-size-fits-all approach, ignoring the inherent variation in primary mitochondrial disease subtypes, the tissue-specific manifestations, and the major pathogenic factors, such as the predominant downstream metabolic and signaling alterations that occur in different disease subclasses.

Although no cure or U.S. Food and Drug Administration (FDA)–approved therapy yet exists for any mitochondrial disease, improved molecular delineation has enabled selected therapies to advance from the theoretical, empirical, and largely ineffective stage to a promising horizon of rational, personalized, and effective interventions. An increasing number of mitochondrial disease diagnoses have interventions involving the initiation or avoidance of specific medications \((\text{corticosteroids, valproic acid, phenytoin, barbiturates, propofol for prolonged duration beyond 30-60 min, certain anesthetics, statins, β-blocking agents, amiodarone, nucleoside reverse transcriptase inhibitors})\), provision of cofactors or diets, and screening regimens for progressive clinical involvement
of modifiable manifestations. General therapies for Leigh syndrome such as L-arginine and citrulline may prevent or reverse neurodevelopmental sequelae from a metabolic stroke. Nutritional therapies in these disorders are tailored to specific disease genes, such as thiamine and biotin for SLC19A3 disease, ubiquinol for PDSS2 (CoQ10 deficiency) disease, and thiamine and the ketogenic diet for PDHA1 (pyruvate dehydrogenase) deficiency. Establishing the precise molecular diagnosis can further be lifesaving by avoiding fasting and mitochondrial-toxic medicines or general anesthetics in specific mitochondrial disease subsets, improving recurrence risk counseling and prevention, enabling targeted screening for reported medical complications, and in some cases providing necessary cofactors or vitamins that may not otherwise have been considered. In addition, reproductive methodologies emerging in some countries for mitochondrial disease prevention, such as mitochondrial replacement technologies (MRTs), are only appropriate to consider in the setting of known pathogenic, inherited mtDNA variants. Finally, the ability to molecularly identify primary mitochondrial disease patients has enabled the design of an increasing number of clinical treatment trials now being planned or underway for a diverse range of symptoms that occur in primary mitochondrial diseases (see www.clinicaltrials.gov).

Parikh S, et al. A modern approach to the treatment of

Mucopolysaccharidoses are hereditary, progressive diseases caused by mutations of genes coding for lysosomal enzymes needed to degrade glycosaminoglycans (acid mucopolysaccharides). Glycosaminoglycans (GAGs) are long-chain complex carbohydrates composed of uronic acids, amino sugars, and neutral sugars. The major GAGs are chondroitin-4-sulfate, chondroitin-6-sulfate, heparan sulfate, dermatan sulfate, keratan sulfate, and hyaluronan. These substances are synthesized and, with the exception of hyaluronan, linked to proteins to form proteoglycans, major constituents of the ground substance of connective tissue and of nuclear and cell membranes. Degradation of proteoglycans starts with the proteolytic removal of the protein core, followed by the stepwise degradation of the GAG moiety. Failure of this degradation because of absent or grossly reduced activity of mutated lysosomal enzymes results in the intralysosomal accumulation of GAG fragments (Fig. 107.1). Distended lysosomes accumulate in the cell, interfere with cell function, and lead to characteristic patterns of clinical, radiologic, and biochemical abnormalities (Table 107.1 and Fig. 107.2). Within these patterns, specific diseases can be recognized that evolve from the intracellular accumulation of different degradation products (Table 107.2). As a general rule, the impaired degradation of heparan sulfate is more closely associated with mental deficiency, and that of dermatan, chondroitin, and keratan sulfate with mesenchymal abnormalities. Variable expression within a given entity results from allelic mutations and varying residual activity of mutated enzymes. For instance, allelic mutations of the gene encoding L-iduronidase may result in severe Hurler disease (Hurler syndrome) with early death or in mild Scheie disease (Scheie syndrome) manifesting only with limited joint mobility, mild skeletal abnormalities, and corneal opacities.
FIG. 107.1 Degradation of heparan sulfate and mucopolysaccharidoses resulting from the deficiency of individual enzymes. Some of the enzymes are also involved in the degradation of other glycosaminoglycans (not shown).

Mucopolysaccharidoses are autosomal recessive disorders, with the exception of **Hunter disease** (Hunter syndrome), which is X-linked recessive. Their birth prevalence varies between 1.2 per 100,000 births (United States) and 16.9 per 100,000 births (Saudi Arabia). In the United States the most common subtype is MPS-III, followed by MPS-I and MPS-II.

### Disease Entities

#### Mucopolysaccharidosis I

Mucopolysaccharidosis I (MPS-I) is caused by mutations of the *IUA* gene on
chromosome 4p16.3 encoding α-L-iduronidase. Mutation analysis has revealed 2 major alleles, W402X and Q70X, which account for more than half the MPS-I alleles in the white population. The mutations that introduce stop codons with ensuing absence of functional enzyme (null alleles), and in homozygosity or compound heterozygosity, give rise to Hurler syndrome. Other mutations occur in only one or a few individuals.

Deficiency of α-L-iduronidase results in a wide range of clinical involvement, from severe Hurler syndrome to mild Scheie syndrome, which are ends of a broad clinical spectrum. Homozygous nonsense mutations result in severe forms of MPS-I, whereas missense mutations are more likely to preserve some residual enzyme activity associated with a milder form of the syndrome.

**Hurler Syndrome**

The Hurler form of MPS-I (MPS I-H) is a severe, progressive disorder with involvement of multiple organs and tissues that results in premature death, usually by 10 yr of age. An infant with Hurler syndrome appears normal at birth, but inguinal hernias and failed neonatal hearing tests may be early signs. Diagnosis is usually made at 6-24 mo, with evidence of hepatosplenomegaly, coarse facial features, corneal clouding, large tongue, enlarged head circumference, joint stiffness, short stature, and skeletal dysplasia. Acute cardiomyopathy has been found in some infants <1 yr. Most patients have recurrent upper respiratory tract and ear infections, noisy breathing, and persistent copious nasal discharge. Valvular heart disease, notably with incompetence of the mitral and aortic valves, regularly develops, and narrowing of the coronary arteries occurs. Obstructive airway disease, especially during sleep, may necessitate tracheotomy. Obstructive airway disease, respiratory infection, and cardiac complications are the common causes of death (Table 107.3).

OSA, Obstructive sleep apnea.

Most children with Hurler syndrome acquire only limited language skills because of intellectual disability, combined conductive and neurosensory hearing loss, and an enlarged tongue. Progressive ventricular enlargement with increased intracranial pressure caused by communicating hydrocephalus also occurs. Corneal clouding, glaucoma, and retinal degeneration are common. Radiographs show a characteristic skeletal dysplasia known as dysostosis multiplex (Figs. 107.3 and 107.4). The earliest radiographic signs are thick ribs and ovoid vertebral bodies. Skeletal abnormalities (in addition to those shown in the figures) include enlarged, coarsely trabeculated diaphyses of the long bones with irregular metaphyses and epiphyses. With disease progression, macrocephaly develops with thickened calvarium, premature closure of lambdoid and sagittal sutures, shallow orbits, enlarged J-shaped sella, and abnormal spacing of teeth with dentigerous cysts.
FIG. 107.3  Dysostosis multiplex. A, Sanfilippo syndrome, patient age 4 yr; the ribs are wide. B, Sanfilippo syndrome, age 4 yr; immature, ovoid configuration of the vertebral bodies. C, Hurler syndrome, age 18 mo; anterosuperior hypoplasia of 1st lumbar vertebra (L1) resulting in hook-shaped appearance.

FIG. 107.4  Dysostosis multiplex. A, Mucopolysaccharidosis I-H, patient age 10 yr. The inferior portions of the ilia are hypoplastic, with resulting iliac flare and shallow acetabular fossae. The femoral necks are in valgus position. B, MPS I-H, age 4 yr. Metacarpals and phalanges are abnormally short, wide, and deformed with proximal pointing of the metacarpals and bullet-shaped phalanges. Bone trabeculation is coarse, and the cortices are thin. C, MPS I-S, age 13 yr. The carpal bones are small, leading to a V-shaped configuration of the digits. The short, tubular bones are well modeled. Flexion of the middle and distal phalanges II-V is caused by joint contractures.
Hurler-Scheie Syndrome

The clinical phenotype of the Hurler-Scheie form of MPS-I (MPS I-H/S) is intermediate between Hurler and Scheie syndromes and is characterized by progressive somatic involvement, including dysostosis multiplex with little or no intellectual dysfunction. The onset of symptoms is usually observed between 3 and 8 yr of age. Survival to adulthood is common. Cardiac involvement and upper airway obstruction contribute to clinical morbidity. Some patients have spondylolisthesis, which may cause cord compression.

Scheie Syndrome

The Scheie form of MPS-I (MPS I-S) is a comparatively mild disorder characterized by joint stiffness, aortic valve disease, corneal clouding, and mild dysostosis multiplex. Onset of significant symptoms is usually after age 5 yr, with diagnosis made between 10 and 20 yr. Patients with Scheie syndrome have normal intelligence and stature but have significant joint and ocular involvement. A carpal tunnel syndrome often develops. Ophthalmic features include corneal clouding, glaucoma, and retinal degeneration. Obstructive airway disease, causing sleep apnea, develops in some patients, necessitating tracheotomy. Aortic valve disease is common and has required valve replacement in some patients.

Mucopolysaccharidosis II

Hunter syndrome (MPS-II) is an X-linked disorder caused by the deficiency of iduronate 2-sulfatase. The IDS gene is mapped to Xq28. Point mutations of IDS have been detected in about 80% of patients with MPS-II. Major deletions or rearrangements of IDS have been found in the rest, and these are usually associated with a more severe clinical phenotype. As an X-linked recessive disorder, Hunter syndrome manifests almost exclusively in males. However, it has been observed in females, because of skewed inactivation of the X-chromosome carrying the normal gene.

Marked molecular heterogeneity explains the wide clinical spectrum of Hunter syndrome. Patients with severe MPS-II have features similar to those of Hurler syndrome, except for the lack of corneal clouding and the somewhat slower progression of somatic and central nervous system (CNS) deterioration. Coarse facial features, short stature, dysostosis multiplex, joint stiffness, and
intellectual disability manifest between 2 and 4 yr of age. Grouped skin papules are present in some patients. Extensive mongolian spots have been observed in African and Asian patients and may be an early marker of the disease. Gastrointestinal (GI) storage may produce chronic diarrhea. Communicating hydrocephalus and spastic paraplegia may result from thickened meninges. In severely affected patients, extensive, slowly progressive neurologic involvement precedes death, which usually occurs at age 10-15 yr.

Patients with the mild form have a near-normal or normal life span, minimal CNS involvement, and slow progression of somatic deterioration with preservation of cognitive function in adult life. Survival to ages 65 and 87 yr has been reported, and some patients have had children. Somatic features are Hurler-like but milder with a greatly reduced rate of progression. Adult height may exceed 150 cm (60 inches). Airway involvement, valvular cardiac disease, hearing impairment, carpal tunnel syndrome, and joint stiffness are common and can result in significant loss of function in both the mild and severe forms.

**Mucopolysaccharidosis III**

**Sanfilippo syndrome (MPS-III)** is a genetically heterogeneous but clinically similar group of 4 recognized types (IIIA-IIID). Each type is caused by a different enzyme deficiency involved in the degradation of heparan sulfate (see [Fig. 107.1](#)). Genes encoding these enzymes are listed in [Table 107.2](#).

Sanfilippo syndrome is characterized by slowly progressive, severe CNS degeneration with mild somatic disease. Onset of clinical features usually occurs at age 2–6 yr in a child who previously appeared normal. Presenting features include delayed cognitive development, hyperactivity with aggressive behavior, coarse hair, hirsutism, sleep disorders, and mild hepatosplenomegaly. Delay in diagnosis of MPS-III is common because of the mild physical features, hyperactivity, and slowly progressive neurologic disease. Severe neurologic deterioration occurs in most patients by age 6-10 yr, accompanied by rapid deterioration of social and adaptive skills. Severe behavior problems are common, such as sleep disturbance, uncontrolled hyperactivity, temper tantrums, destructive behavior, and physical aggression. Profound intellectual disability and behavior problems often occur in patients with normal physical strength, making management particularly difficult.

**Mucopolysaccharidosis IV**
Morquio syndrome (MPS-IV) is caused by a deficiency of N-acetylgalactosamine-6-sulfatase (MPS-IVA) or of β-galactosidase (MPS-IVB). Both result in the defective degradation of keratan sulfate. The gene encoding N-acetylgalactosamine-6-sulfatase is GALNS on chromosome 16q24.3, and the gene encoding β-galactosidase is GLB1 on chromosome 3p21.33. β-Galactosidase catalyzes GM1 ganglioside in addition to endohydrolysis of keratan sulfate, and most mutations of GLB1 result in generalized gangliosidosis, a spectrum of neurodegenerative disorders associated with dysostosis multiplex. A W273L mutation of the GLB1 gene, either in the homozygous state or as part of compound heterozygosity, usually results in Morquio B syndrome.

Both types of Morquio syndrome are characterized by short-trunk dwarfism, a skeletal dysplasia that is distinct from other mucopolysaccharidoses, and preservation of intelligence. MPS-IVA is usually more severe than MPS-IVB, with adult height of <125 cm (50 inches) and >150 cm, respectively. However, there is considerable variability of expression in both subtypes. The appearance of genu valgum, kyphosis, growth retardation with short trunk and neck, and waddling gait with a tendency to fall are early symptoms of MPS-IV. Extraskeletal manifestations include mild corneal clouding, small teeth with abnormally thin enamel, frequent caries formation, and occasionally hepatomegaly and cardiac valvular lesions. Instability of the odontoid process and ligamentous laxity are invariably present and can result in life-threatening atlantoaxial instability and dislocation. Thickened anterior extradural tissue contributes to spinal cord compression. Regular neurologic assessment and radiologic imaging are imperative. Surgery to stabilize the upper cervical spine, usually by posterior spinal fusion, before the development of cervical myelopathy, can be lifesaving.

Mucopolysaccharidosis VI

Maroteaux-Lamy syndrome (MPS-VI) is caused by mutations of the ARSB gene on chromosome 5q11-13 encoding N-acetylgalactosamine-4-sulfatase (arylsulfatase B). It is characterized by severe to mild somatic involvement, as seen in MPS-I, but with preservation of intelligence. The somatic involvement of the severe form of MPS-IV is characterized by corneal clouding, coarse facial features, joint stiffness, valvular heart disease, communicating hydrocephalus, and dysostosis multiplex. In the severe form, growth can be normal for the 1st few years of life but seems to virtually stop after age 6-8 yr. The mild to
intermediate forms of Maroteaux-Lamy syndrome can be easily confused with Scheie syndrome. Spinal cord compression from thickening of the dura in the upper cervical canal with resultant myelopathy is common in patients with MPS-VI.

**Mucopolysaccharidosis VII**

*Sly syndrome* (MPS-VII) is caused by mutations of the *GUSB* gene located on chromosome 7q21.11. Mutations result in a deficiency of β-glucuronidase, intracellular storage of GAG fragments, and extensive clinical involvement. The most severe form presents as lethal nonimmune fetal hydrops and may be detected in utero by ultrasound. Some severely affected newborns survive for months and have, or develop, signs of lysosomal storage disease, including thick skin, visceromegaly, and dysostosis multiplex. Less severe forms of MPS-VII present during the 1st years of life with features of MPS-I but slower progression. Corneal clouding varies. Patients with manifestation after 4 yr of life have skeletal abnormalities of dysostosis multiplex but normal intelligence and usually clear corneas. They may be found incidentally on the basis of a blood smear that shows coarse granulocytic inclusions.

**Mucopolysaccharidosis IX**

*MPS-IX* is caused by a mutation in the *HYAL1* gene on chromosome 3p21.2-21.2 encoding 1 of 3 hyaluronidases. Clinical findings in the only known patient, a 14 yr old girl, were bilateral nodular soft tissue periarticular masses, lysosomal storage of GAGs in histiocytes, mildly dysmorphic craniofacial features, short stature, normal joint movement, and normal intelligence. Small erosions in both acetabula were the only radiographic findings.

**Mucopolysaccharidosis Plus Syndrome**

Coarse facial features, organomegaly, joint contractures, dysostosis multiplex, cognitive deficiency, increased mucopolysacchariduria, and massive intracellular accumulation of heparin sulfate were found in 13 children in Northeastern Siberia and 2 Turkish children. Further findings were optic atrophy, intracerebral calcifications, pancytopenia, and renal insufficiency. Most patients died within the 1st 2 yr of life from cardiorespiratory failure.
Lysosomal enzyme activities were normal in children with MPS plus syndrome. This autosomal recessive multisystem disorder is caused by homozygous mutations of VPS33A encoding a protein involved in lysosomal fusion processes.

**Diagnosis and Differential Diagnosis**

Clinical suspicion of a MPS justifies a skeletal survey. Radiographs of chest, spine, pelvis, and hands may show signs of dysostosis multiplex. The next diagnostic step is to assay the urinary excretion of GAGs. Semiquantitative spot tests for increased urinary GAG excretion are quick, inexpensive, and useful for initial evaluation but are subject to both false-positive and false-negative results. Quantitative analysis of single GAG and/or oligosaccharides by mass spectrometry detection tests reveals type-specific profiles in urine, serum, plasma, and dried blood spots.

Any individual with a suspected MPS disorder based on clinical features, radiographic results, or urinary GAG screening tests should have a definitive diagnosis established by enzyme assay. Serum, leukocytes, or cultured fibroblasts are used as the tissue source for measuring lysosomal enzymes (see Table 107.2).

Molecular analysis is typically performed using appropriate gene panels. In many cases the type and location of the mutation are related to the future course of the disease and thus have a predictive value. The specific mutation is also needed if prenatal diagnosis on fetal cells from a subsequent pregnancy is considered. Carrier testing in Hunter syndrome, an X-linked disorder, requires analysis of IDS once the specific mutation or chromosome arrangement in the family is known. Prenatal molecular analysis must be offered in a male fetus of a proven female carrier of the IDS gene. His risk to be affected is 50%. In a female fetus the risk is small, but not zero, as a result of skewed maternal X-chromosome inactivation.

**Newborn screening** for mucopolysaccharidoses is available from dried blood spots and is essential for their early detection and therapeutic intervention.

**Mucolipidoses** and **oligosaccharidoses** manifest with the same clinical and radiographic features as mucopolysaccharidoses. In these conditions the urinary excretion of GAGs is not elevated. Hurler-like facial features, joint contractures, dysostosis multiplex, and elevated urinary GAG excretion differentiate the mucopolysaccharidoses from other neurodegenerative and dwarfing conditions.
**Treatment**

**Hematopoietic stem cell transplantation** has resulted in significant clinical improvement of somatic disease in patients with MPS I, II, and VI (Table 107.4). Clinical effects are increased life expectancy with resolution or improvement of growth, hepatosplenomegaly, joint stiffness, facial appearance, skin changes, obstructive sleep apnea, heart disease, communicating hydrocephalus, and hearing loss. Enzyme activity in serum and urinary GAG excretion normalize. This is true for MPS I-H, II, and III. Patients with MPS-I who have undergone transplantation before 9 mo of age may show normal cognitive development. Transplantation before 24 mo and with a baseline mental development index >70 have improved long-term outcome. Transplantation does not significantly improve the neuropsychological outcome of MPS patients with impaired cognition at transplantation. Early transplantation in the MPS-II patient may have the same effect. Transplantation in the MPS-VI patient stabilizes or improves cardiac manifestations, posture, and joint mobility. Stem cell transplantation does not correct skeletal or ocular anomalies.

**Enzyme replacement therapy** (ERT) using recombinant α-L-iduronidase has been approved for patients with MPS-I (Table 107.4). It reduces organomegaly and ameliorates rate of growth, improves joint mobility, and reduces the number
of episodes of sleep apnea and urinary GAG excretion. The enzyme does not cross the blood-brain barrier and does not prevent deterioration of neurocognitive function. Consequently, ERT is appropriate for patients with mild CNS involvement or to stabilize extraneural manifestations in young patients before stem cell transplantation. Recombinant iduronate-2-sulfatase is the treatment of choice for MPS-II to ameliorate nonneural manifestations. ERT with recombinant human GALNS improves physical endurance, respiratory function, and daily living activity of patients with MPS-IV. Similar effects produce recombinant \( N \)-acetylgalactosamine-4-sulfatase in patients with MPS-VI.

Symptomatic therapy focuses on respiratory and cardiovascular complications, hearing loss, carpal tunnel syndrome, spinal cord compression, hydrocephalus, and other problems (Table 107.5). The multisystem involvement and progressive nature of MPS syndromes usually requires the complex care provided by medical centers.

## Bibliography

Jameson E, Jones S, Remmington T. Enzyme replacement therapy with laronidase (Aldurozyme) for treating
mucopolysaccharidosis type I. *Cochrane Database Syst Rev*. 2016;(4) [CD009354].

Triggs-Raine B, Salo TJ, Zhang H, et al. Mutations in *HYAL1*, a member of a tandemly distributed multigene family encoding
disparate hyaluronidase activities, cause a newly described lysosomal disorder, mucopolysaccharidosis IX. *Proc Natl Acad Sci USA*. 1999;96:6296–6300.

The inherited disorders of purine and pyrimidine metabolism cover a broad spectrum of illnesses with various presentations. These include hyperuricemia, acute renal failure, renal stones, gout, unexplained neurologic deficits (seizures, muscle weakness, choreoathetoid and dystonic movements), intellectual and developmental disabilities, acrofacial dysostosis, compulsive self-injury and aggression, autistic-like behavior, unexplained anemia, failure to thrive, susceptibility to recurrent infection (immune deficiency), and deafness. When identified, all family members should be screened.

Purines and pyrimidines form the basis of nucleotides and nucleic acids (DNA and RNA) and thus are involved in all biologic processes. Metabolically active nucleotides are formed from heterocyclic nitrogen-containing purine bases (guanine and adenine) and pyrimidine bases (cytosine, uridine, and thymine): all cells require a balanced supply of nucleotides for growth and survival. Purines provide the primary source of cellular energy through adenosine triphosphate (ATP) and the basic coenzymes (nicotinamide adenine dinucleotide and its reduced form) for metabolic regulation and play a major role in signal transduction (guanosine triphosphate [GTP], cyclic adenosine monophosphate, cyclic guanosine monophosphate). **Fig. 108.1** shows the early steps in the biosynthesis of the purine ring. Purines are primarily produced from endogenous sources, and in usual circumstances, dietary purines have a small role. The end product of purine metabolism in humans is uric acid (2,6,8-trioxypurine).
Uric acid is not a specific disease marker, so the cause of its elevation must be determined. The serum level of uric acid present at any time depends on the size of the purine nucleotide pool, which is derived from de novo purine synthesis, catabolism of tissue nucleic acids, and increased turnover of preformed purines. Uric acid is poorly soluble and must be excreted continuously to avoid toxic accumulation in the body. Baseline serum uric acid is established by the balancing of activity between secretory and absorptive urate transporters in both kidney and intestine. Urate secretion and absorption are mediated by separate, opposing groups of transporters. The majority of the genes involved in the variation in uric acid blood level encode urate transporters or associated regulatory proteins.

Thus the fraction of uric acid excreted by the kidney is the result of a complex interplay between secretion and reabsorption by specific and nonspecific uric acid transporters in the proximal tubule, and this sets the level of uric acid in the plasma. Because renal tubule excretion is greater in children than in adults, serum uric acid levels are a less reliable indicator of uric acid production in children than in adults, and therefore measurement of the level in urine may be required to determine excessive production. Clearance of a smaller portion of uric acid is through the gastrointestinal (GI) tract (biliary and intestinal secretion). Because of poor solubility of uric acid under normal circumstances,
uric acid is near the maximal tolerable limits, and small alterations in production or solubility or changes in secretion may lead to hyperuricemia and can result in precipitation monosodium urate crystals in extremities (e.g., fingers or toes), which defines clinical gout. In renal insufficiency, urate excretion is increased by residual nephrons and the GI tract. Increased production of uric acid is found in malignancy, Reye syndrome, Down syndrome, psoriasis, sickle cell anemia, cyanotic congenital heart disease, pancreatic enzyme replacement, glycogen storage disease (types I, III, IV, and V), hereditary fructose intolerance, and acyl-coenzyme A dehydrogenase deficiency.

The metabolism of both purines and pyrimidines can be divided into biosynthetic, salvage, and catabolic pathways. The first, the de novo pathway, involves a multistep biosynthesis of phosphorylated ring structures from precursors such as CO₂, glycine, and glutamine. Purine and pyrimidine nucleotides are produced from ribose-5-phosphate or carbamyl phosphate, respectively. The second, a single-step salvage pathway, recovers purine bases and pyrimidine nucleosides derived from either dietary intake or the catabolic pathway (Figs. 108.2 and 108.3). In the de novo pathway, the nucleosides guanosine, adenosine, cytidine, uridine, and thymidine are formed by the addition of ribose-1-phosphate to the purine bases guanine or adenine and to the pyrimidine bases cytosine, uracil, and thymine, respectively. The phosphorylation of these nucleosides produces monophosphate, diphosphate, and triphosphate nucleotides, as well as the deoxy-nucleotides that are utilized for DNA formation. Under usual circumstances, the salvage pathway predominates over the biosynthetic pathway because nucleotide salvage saves energy for cells. Only a small fraction of the nucleotides turned over by the body each day are degraded and excreted. Synthesis of nucleotides is most active in tissues with high rates of cellular turnover, such as gut epithelium, skin, and bone marrow. The third pathway is catabolism. The end product of the catabolic pathway of the purines in humans is uric acid, whereas catabolism of pyrimidines produces citric acid cycle intermediates.
Inborn errors in the synthesis of purine nucleotides comprise the
phosphoribosylpyrophosphate synthetase spectrum of disorders, including deficiency and superactivity, adenylosuccinate lyase deficiency, and 5-amino-4-imizolecarboxamide (AICA) riboside deficiency (AICA-ribosiduria). Disorders resulting from abnormalities in purine catabolism comprise muscle adenosine monophosphate (AMP) deaminase deficiency, adenosine deaminase deficiency, purine nucleoside phosphorylase deficiency, and xanthine oxidoreductase deficiency. Disorders resulting from the purine salvage pathway include hypoxanthine-guanine phosphoribosyltransferase (HPRT) deficiency and adenine phosphoribosyltransferase (APRT) deficiency.

Hereditary orotic aciduria (uridine monophosphate synthase deficiency) is an inborn error of pyrimidine synthesis that leads to an excessive excretion of orotic acid in urine. Dihydrorotate dehydrogenase deficiency (Miller syndrome), also a disorder of de novo pyrimidine synthesis, paradoxically may lead to orotic aciduria. Other pyrimidine disorders lead to abnormalities in pyrimidine catabolism, including dihydropyrimidine dehydrogenase (DPD) deficiency, dihydropyrimidinase (DPH) deficiency, β-ureidopropionase deficiency, pyrimidine 5′-nucleotidase deficiency, and thymidine phosphorylase deficiency. A disorder resulting from the pyrimidine salvage is thymidine kinase-2 deficiency.

Gout

Gout presents with hyperuricemia, uric acid nephrolithiasis, and acute inflammatory arthritis. Gouty arthritis is caused by monosodium urate crystal deposits that result in inflammation in joints and surrounding tissues. The presentation is most commonly monoarticular, typically in the metatarsophalangeal joint of the big toe. Tophi, deposits of monosodium urate crystals, may occur over points of insertion of tendons at the elbows, knees, and feet or over the helix of the ears. Primary gout usually occurs in middle-aged males and results mainly from decreased renal excretion of uric acid, or purine overconsumption, or high intake of alcohol or fructose, or a combination of these factors. Gout occurs in any condition that leads to reduced clearance of uric acid: during therapy for malignancy or with dehydration, lactic acidosis, ketoacidosis, starvation, diuretic therapy, and renal failure. Excessive purine, alcohol, or fructose ingestion may increase uric acid levels. The biochemical etiology of gout is unknown for most patients, and it is considered to have a basis in genetic polymorphisms, predominantly in uric acid transporters. Purine overproduction
is a rare cause of primary gout and is associated with several genetic disorders discussed later. **Secondary gout** is either the result of another disorder with rapid tissue breakdown or cellular turnover, leading to increased production or decreased excretion of uric acid, or the result of some types of drug treatment; for example, diuretics cause plasma volume reduction and can precipitate a gouty attack.

Gout resulting from **endogenous purine overproduction** is associated with hereditary disorders of 3 different enzymes that result in hyperuricemia. These include the HPRT deficiency spectrum (ranging from severe deficiency or Lesch-Nyhan syndrome to partial HPRT deficiency), 2 forms of superactivity of PP-ribose-P synthetase, and glycogen storage disease type I (glucose-6-phosphatase deficiency). In the first 2 disorders, the basis of hyperuricemia is purine nucleotide and uric acid overproduction, whereas in the 3rd disorder it is both excessive uric acid production and diminished renal excretion of urate. Glycogen storage disease types III, V, and VII are associated with exercise-induced hyperuricemia, the consequence of rapid ATP utilization and failure to regenerate it effectively during exercise (see Chapter 105.1).

**Juvenile gout** results from purine underexcretion. The earlier terminology *juvenile hyperuricemic nephropathy* has been replaced by the newer term (autosomal dominant) **tubulointerstitial kidney disease** (ADTKD). The term **ADTKD-UMOD** (*uromodulin-associated kidney disease*) is used for medullary cystic kidney disease type 2 and maps to chromosome 16p11.2. It results from uromodulin mutations. Other genes classified as forms of familial juvenile hyperuricemic nephropathy include those for renin and hepatic nuclear factor-1β. Unlike the 3 inherited purine disorders that are X-linked and the recessively inherited glycogen storage disease, these are autosomal dominant conditions. Familial juvenile hyperuricemic nephropathy is associated with a reduced fractional excretion of uric acid. Although it typically presents from puberty up to the 3rd decade, it has been reported in early childhood. It is characterized by early onset, hyperuricemia, gout, familial renal disease, and low urate clearance relative to glomerular filtration rate. It occurs in both males and females and is frequently associated with a rapid decline in renal function that may lead to death unless diagnosed and treated early. Once familial juvenile hyperuricemic nephropathy is recognized, presymptomatic detection is of critical importance to identify asymptomatic family members with hyperuricemia and to begin treatment, when indicated, to prevent nephropathy.
Genetics

Familial juvenile hyperuricemic nephropathy-2 (HNFJ2; 613092) is caused by mutation in the renin gene (REN; 179820) on chromosome 1q32. HNFJ3 (614227) has been mapped to chromosome 2p22.1-p21. ADTKD involves mutations of the mucin (MUC1) gene. The mutation of uromodulin has been traced to chromosome 16.

Treatment

Treatment of hyperuricemia involves the combination of allopurinol or febuxostat (xanthine oxidase inhibitors) to decrease uric acid production, probenecid to increase uric acid clearance in those with normal renal function, and increased fluid intake to reduce the concentration of uric acid. A low-purine diet, weight reduction, and reduced alcohol and fructose intake (fructose both reduces urate clearance and accelerates ATP breakdown to uric acid) are recommended.

Abnormalities in Purine Salvage

Hypoxanthine-Guanine Phosphoribosyltransferase (HPRT) Deficiency

Lesch-Nyhan disease (LND) is a rare X-linked disorder of purine metabolism that results from HPRT deficiency. This enzyme is normally present in each cell in the body, but its highest concentration is in the brain, especially in the basal ganglia. Clinical manifestations include hyperuricemia, intellectual disability, dystonic movement disorder that may be accompanied by choreoathetosis and spasticity, dysarthric speech, and compulsive self-biting, usually beginning with the eruption of teeth.

There is a spectrum of severity for the clinical presentations. HPRT levels are related to the extent of motor symptoms, to the presence or absence of self-injury, and possibly to the level of cognitive function. Purine overproduction is present. The majority of individuals with classic LND have low or undetectable levels of the HPRT enzyme. Partial deficiency in HPRT (Kelley-Seegmiller syndrome) with >1.5–2.0% enzyme is associated with purine overproduction.
and variable neurologic dysfunction (neurologic HPRT deficiency). HPRT deficiency with activity levels >8% of normal still shows purine (and uric acid) overproduction but apparently normal cerebral functioning (HPRT-related hyperuricemia), although cognitive deficits may occur. Qualitatively similar cognitive deficit profiles have been reported in both LND and variant cases. Variants produced scores intermediate between those of patients with LND and normal controls on almost every neuropsychological measure tested.

**Genetics**

The *HPRT* gene has been localized to the long arm of the X chromosome (q26-q27). The complete amino acid sequence for HPRT is known and is encoded by the *HPRT1* gene (approximately 44 kb; 9 exons). The disorder appears in males; occurrence in females is extremely rare and ascribed to nonrandom inactivation of the normal X chromosome. Absence of HPRT activity results in a failure to salvage hypoxanthine, which is degraded to uric acid. Failure to consume phosphoribosylpyrophosphate in the salvage reaction results in an increase in this metabolite, which drives de novo purine synthesis, leading to the overproduction of uric acid. Excessive uric acid production manifests as gout, necessitating specific drug treatment (allopurinol). Because of the enzyme deficiency, hypoxanthine accumulates in the cerebrospinal fluid (CSF), but uric acid does not; uric acid is not produced in the brain and does not cross the blood-brain barrier. The behavior disorder is not caused by hyperuricemia or excess hypoxanthine because patients with partial HPRT deficiency, the variants with hyperuricemia, do not self-injure, and infants with isolated hyperuricemia from birth do not develop self-injurious behavior.

The prevalence of the classic LND has been estimated at 1 in 100,000 to 1 in 380,000 persons based on the number of known cases in the United States. The incidence of partial variants is not known. Those with the classic syndrome rarely survive the 3rd decade because of renal or respiratory compromise. The life span may be normal for patients with partial HPRT deficiency without severe renal involvement.

**Pathology**

No specific brain abnormality is documented after detailed histopathology and electron microscopy of affected brain regions. MRI has documented reductions in the volume of basal ganglia nuclei. Abnormalities in neurotransmitter
metabolism have been identified in 3 autopsied cases. All 3 patients had very low HPRT levels (<1% in striatal tissue and 1–2% of control in thalamus cortex). There was a functional loss of 65–90% of the nigrostriatal and mesolimbic dopamine terminals, although the cells of origin in the substantia nigra did not show dopamine reduction. The brain regions primarily involved were the caudate nucleus, putamen, and nucleus accumbens. It is proposed that the neurochemical changes may be linked to functional abnormalities, possibly resulting from a diminution of arborization or branching of dendrites rather than cell loss. A neurotransmitter abnormality is demonstrated by changes in CSF neurotransmitters and their metabolites and is confirmed by positron emission tomography (PET) scans of dopamine function. In vivo reductions in the presynaptic dopamine transporter have been documented in the caudate and putamen of 6 individuals.

The mechanism whereby HPRT leads to the neurologic and behavioral symptoms is unknown. However, both hypoxanthine and guanine metabolism are affected, and GTP and adenosine have substantial effects on neural tissues. The functional link between purine nucleotides and the dopamine system is through salvage of guanine by HPRT to form GTP; this is essential for GTP cyclohydrolase activity, the first step in the synthesis of pterins and dopamine. In a controlled study that sought correlations between HPRT and GPRT and behavior, GPRT was more highly correlated than HPRT on 13 of 14 measures of the clinical phenotype; these included severity of dystonia, cognitive impairment, and behavioral abnormalities. These findings suggest that loss of guanine recycling might be more closely linked to the LND/LNV phenotype than loss of hypoxanthine recycling. Moreover, patients with inherited GTP cyclohydrolase deficiency show clinical features in common with LND.

Dopamine reduction in brain is documented in HPRT-deficient strains of mutant mice. Dopamine binding to its receptor results in either an activation (D1 receptor) or an inhibition (D2 receptor) of adenylcyclase. Both receptor effects are mediated by G proteins (GTP-binding proteins) dependent on guanine diphosphate in the guanine diphosphate/GTP exchange for cellular activation. Dopamine and adenosine systems are also linked through the role of adenosine as a neuroprotective agent in preventing neurotoxicity. Adenosine derives from AMP, which depends on hypoxanthine salvage in the brain by HPRT. Adenosine agonists mimic the biochemical and behavioral actions of dopamine antagonists, whereas adenosine receptor antagonists act as functional dopamine agonists. LND can thus be seen as arising ultimately from nucleotide depletion.
specifically in the brain, which relies on the HPRT salvage pathway, leading to dopamine and adenosine depletions.

**Clinical Manifestations**

At birth, infants with LND have no apparent neurologic dysfunction. After several months, developmental delay and neurologic signs become apparent. Before age 4 mo, hypotonic, recurrent vomiting, and difficulty with secretions may be noted. By 8-12 mo, extrapyramidal signs appear, primarily dystonic movements. In some patients, spasticity may become apparent at this time; in others it becomes apparent later in life.

Cognitive function is usually reported to be in the mild to moderate range of intellectual disability, although some individuals test in the low-normal range. Because test scores may be influenced by difficulty in testing caused by movement disorder and dysarthric speech, overall intelligence may be underestimated.

The age of onset of self-injury may be as early as 1 yr and occasionally as late as the teens. Self-injury occurs, although all sensory modalities, including pain, are intact. The **self-injurious behavior** (SIB) usually begins with self-biting, although other SIB patterns emerge with time. Most characteristically, the fingers, mouth, and buccal mucosa are mutilated. Self-biting is intense and causes tissue damage and may result in the amputation of fingers and substantial loss of tissue around the lips. Extraction of primary teeth may be required. The biting pattern can be asymmetric, with preferential mutilation of the left or right side of the body. The type of behavior is different from that seen in other intellectual disability syndromes involving self-injury. Self-hitting and head-banging are the most common initial presentations in other syndromes. The intensity of SIB generally requires that the patient be restrained. When restraints are removed, the patient with LND may appear terrified, and stereotypically place a finger in the mouth. The patient may ask for restraints to prevent elbow movement; when the restraints are placed, or replaced, he may appear relaxed and cheerful. Dysarthric speech may cause interpersonal communication problems; however, the higher-functioning children can express themselves fully and participate in verbal therapy.

The self-mutilation presents as a compulsive behavior that the child tries to control but frequently is unable to resist. Older individuals may enlist the help of others and notify them when they are comfortable enough to have restraints removed. In some cases the behavior may lead to deliberate self-harm. The LND
patient may also show compulsive aggression and inflict injury to others through pinching, grabbing, or hitting or by using verbal forms of aggression. Afterward he may apologize, stating that this behavior was out of his control. Other maladaptive behaviors include head- or limb-banging, eye-poking, and psychogenic vomiting.

**Diagnosis**

The presence of *dystonia* along with self-mutilation of the mouth and fingers suggests LND. With partial HPRT deficiency, recognition is linked to either hyperuricemia alone or hyperuricemia and a dystonic movement disorder. Serum levels of uric acid that exceed 4-5 mg uric acid/dL and a urine uric acid:creatinine ratio of ≥3-4 : 1 are highly suggestive of HPRT deficiency, particularly when associated with neurologic symptoms. The definitive diagnosis requires an analysis of the HPRT enzyme. This is assayed in an erythrocyte lysate. Individuals with classic LND have near 0% enzyme activity, and those with partial variants show values between 1.5% and 60%. The intact cell HPRT assay in skin fibroblasts offers a good correlation between enzyme activity and severity of disease. Molecular techniques are used for gene sequencing and identification of carriers.

Differential diagnosis includes other causes of infantile hypotonia and dystonia. Children with LND are often initially *incorrectly* diagnosed as having athetoid cerebral palsy. When a diagnosis of cerebral palsy is suspected in an infant with a normal prenatal, perinatal, and postnatal course, LND should be considered. Partial HPRT deficiency may be associated with acute renal failure in infancy; therefore clinical awareness of partial HPRT deficiency is of particular importance. The simplest test to exclude LND or partial deficiency is the urinary uric acid:creatinine ratio.

An understanding of the molecular disorder has led to effective drug treatment for uric acid accumulation and arthritic tophi, renal stones, and neuropathy. However, reduction in uric acid alone does not influence the neurologic and behavioral aspects of LND. Despite treatment from birth for uric acid elevation, behavioral and neurologic symptoms are unaffected. The most significant complications of LND are renal failure and self-mutilation.

**Treatment**

Medical management of LND focuses on prevention of renal failure by
pharmacologic treatment of hyperuricemia, with high fluid intake along with alkalization and allopurinol (or more often febuxostat). A low-purine diet and reduced fructose intake are desirable.

*Allopurinol* treatment must be monitored because urinary oxypurine excretion with all overproduction disorders is sensitive to allopurinol, resulting in an increased urine concentration of xanthine, which is extremely insoluble. Self-mutilation is reduced through behavior management and the use of restraints and/or removal of teeth. Pharmacologic approaches to decrease anxiety and spasticity with medication have mixed results. Drug therapy focuses on symptomatic management of anticipatory anxiety, mood stabilization, and reduction of self-injurious behavior. Although there is no standard drug treatment, diazepam may be helpful for anxiety symptoms, risperidone for aggressive behavior, and carbamazepine or gabapentin for mood stabilization. Each of these medications may reduce SIB by helping to reduce anxiety and stabilize mood. *S*-adenosylmethionine (*SAMe*), which is thought to act by countering nucleotide depletion in the brain, has been reported specifically to reduce the rate of self-injury in some cases. Animal studies have suggested that D1-dopamine receptor antagonists such as ecopipam may suppress SIB. Despite limited data, the drug appears to reduce SIB in most patients, suggesting further study to establish an appropriate dosing regimen and assess toxicity.

Several patients have received *bone marrow transplantation* (BMT), based on the hypothesis that the central nervous system (CNS) damage is produced by a circulating toxin. There is no evidence that BMT is a beneficial treatment approach; it remains an experimental and potentially dangerous therapy. Two patients received partial exchange transfusions every 2 mo for 3-4 yr. Erythrocyte HPRT activity was 10–70% of normal during this period, but no reduction of neurologic or behavioral symptoms was apparent. Successful preimplantation genetic diagnosis and in vitro fertilization for LND has been reported with the birth of an unaffected male infant.

Both the motivation for self-injury and its biologic basis must be addressed in treatment programs. However, behavioral techniques alone, using operant conditioning approaches, have not proved to be an adequate general treatment. Although *behavioral procedures* have had some selective success in reducing self-injury, difficulty with generalization outside the experimental setting limits this approach, and patients under stress may revert to their previous SIB. Behavioral approaches may also focus on reducing SIB through treatment of phobic anxiety associated with being unrestrained. The most common techniques
are systematic desensitization, extinction, and differential reinforcement of other (competing) behavior. Stress management has been recommended to assist patients to develop more effective coping mechanisms. Individuals with LND do not respond to contingent electric shock or similar aversive behavioral measures. An increase in self-injury may be observed when aversive methods are used.

Restraint (day and night) and dental procedures are common means to prevent self-injury. The time in restraints is linked to the age of onset of self-injury. Children with LND can participate in making decisions regarding restraints and the type of restraints. The time in restraints may potentially be reduced with systematic behavior treatment programs. Many patients have teeth extracted to prevent self-injury. Others use a protective mouth guard designed by a dentist. Most parents suggest that stress reduction and awareness of the patient's needs are the most effective in reducing self-injury. Positive behavioral techniques of reinforcing appropriate behavior are rated effective by almost half the families.

Deep brain stimulation to the anteroventral internal globus pallidus is a procedure that has successfully treated self-injury and lessened dystonia in several case reports.

**Adenine Phosphoribosyltransferase Deficiency (Dihydroxyadeninuria)**

APRT, a purine salvage enzyme, catalyzes the synthesis of AMP from adenine and 5-phosphoribosyl-1-pyrophosphate (PP-ribose-P). The absence of this enzyme results in the cellular accumulation of adenine and it being oxidized as an alternative substrate by xanthine dehydrogenase to form 2,8-dihydroxyadenine, which is extremely insoluble. APRT deficiency is present from birth, becoming apparent as early as 5 mo and as late as the 7th decade.

**Genetics**

The disorder is an autosomal recessive trait with considerable clinical heterogeneity. The APRT gene is located on chromosome 16q (16q24.3) and encompasses 2.8 kb of genomic DNA.

**Clinical Manifestations**

These include urinary calculus formation with crystalluria, urinary tract
infections, hematuria, renal colic, dysuria, and acute renal failure. Brownish spots on the infant's diaper or yellow-brown crystals in the urine suggest the diagnosis. The 2,8-dihydroxyadenine is cleared efficiently by the kidneys and so does not accumulate in plasma, but precipitates readily in the renal lumen.

**Laboratory Findings**

Urinary levels of adenine, 8-hydroxyadenine, and 2,8-dihydroxyadenine are elevated, whereas plasma uric acid is normal. The deficiency may be complete (type I) or partial (type II); the partial deficiency is reported in Japan. The diagnosis is made based on the level of residual enzyme in erythrocyte lysates. The renal calculi, composed of 2,8-dihydroxyadenine, are radiolucent, soft, and easily crushed. These stones are not distinguishable from uric acid stones by routine tests but require high-performance liquid chromatography (HPLC), ultraviolet (UV) light, infrared light, mass spectrometry, x-ray crystallography, or capillary electrophoresis for diagnosis, particularly to distinguish from stones in HPRT deficiency.

**Treatment**

Treatment includes high fluid intake, dietary purine restriction, and allopurinol, which inhibits the conversion of adenine to its metabolites and prevents further stone formation. Alkalization of the urine is to be avoided, because unlike that of uric acid, the solubility of 2,8-dihydroxyadenine does not increase up to pH 9. **Shock wave lithotripsy** has been reported to be successful. The **prognosis** depends on renal function at diagnosis. Early treatment is critical in the prevention of stones because severe renal insufficiency may accompany late recognition.

**Disorders Linked to Purine Nucleotide Synthesis**

**Phosphoribosylpyrophosphate Synthetase Superactivity and Deficiency**

Phosphoribosylpyrophosphate (PRPP) is a substrate involved in the synthesis of essentially all nucleotides and important in the regulation of the de novo
pathways of purine and pyrimidine nucleotide synthesis. The synthetase enzyme (PRPS) produces PRPP from ribose-5-phosphate and ATP (see Figs. 108.1 and 108.2). PRPP is the first intermediary compound in the de novo synthesis of purine nucleotides that lead to the formation of inosine monophosphate, then to ATP and GTP.

Genetic disorders of this enzyme affect only the PRPS-1 isoform; PRPS-2 mutations have not been described. PRPS-1 disorders are all X-linked and are divided into “superactivity,” which occurs as 2 phenotypes (infantile or early childhood onset, and a milder form with late-juvenile or early-adult onset), and “deficiency,” which is a spectrum disorder that is distinguished clinically according to severity as 3 disorders: Arts syndrome, Charcot-Marie-Tooth disease X-linked-5, and X-linked deafness-2.

Superactivity of the enzyme results in an increased generation of PRPP in dividing cells. Because PRPP aminotransferase, the first enzyme of the purine de novo pathway, is not physiologically saturated by PRPP, the synthesis of purine nucleotides increases, and consequently the production of uric acid is increased. PRPP synthetase superactivity is one of the few hereditary disorders in which the activity of an enzyme is enhanced. The infantile or early childhood form of PRPS-1 superactivity has severe neurologic consequences accompanied by uric acid overproduction, whereas individuals with the late-juvenile or early-adult presentation are neurologically normal but still have uric acid overproduction.

Deficiency of PRPS-1 produces depleted purine nucleotide synthesis in tissues dependent on PRPS-1, which includes brain as well as other neural tissues and lung.

**Genetics**

Three distinct complementary DNAs for PRPS have been cloned and sequenced. Two forms, PRPS-1 and PRPS-2, are X-linked to Xq22-q24 and Xp22.2-p.22.3 (escapes X inactivation), respectively, and are widely expressed. The 3rd locus maps to human chromosome 7 and appears to be transcribed only in the testes. PRPS-1 defects are thus inherited as X-linked traits and present with varying degrees of severity. The late-onset form of superactivity arises from increased transcription of normal messenger RNA; the cause of this has not been discovered. The early-onset form of superactivity arises from mutations affecting allosteric regulation of the protein that controls feedback inhibition by inorganic phosphate and dinucleotides. At the same time, these mutations destabilize the protein, so that in slow or nonreplicating cells, such as neurons
and red blood cells (RBCs), the enzyme becomes inactive. In contrast, the
deficiency phenotypes of PRPS-1 are produced by mutations directly affecting
enzyme function, usually in the substrate binding site. Even though the defect is
X-linked, it should be considered in a child or young adult of either sex with
hyperuricemia and/or hyperuricosuria and normal HPRT activity in lysed RBCs.

Clinical Manifestations
Affected hemizygous males with early-onset superactivity show signs of uric
acid overproduction that are apparent in infancy or early childhood, as well as
psychomotor delay and sensorineural deafness. Hypotonia, ataxia, and autistic-
like behavior have been described. Heterozygous female carriers may also
develop gout and hearing impairment. The late-onset type is found in males who
show only hyperuricemia and hyperuricosuria, but no neurologic signs. The
mildest form of PRPS-1 deficiency manifests as progressive postlingual hearing
loss in X-linked deafness-2 (DFN2). More severe mutations constitute the
Charcot-Marie-Tooth disease X-linked-5 phenotype, which includes
peripheral neuropathy, hearing impairment, and optic atrophy. The most severe
PRPS-1 mutations occur in patients with Arts syndrome, who also have central
neuropathy and an impaired immune system. Females appear to be unaffected,
but hemizygous males have usually not survived beyond the 1st decade,
typically succumbing to lung disease. SA Me therapy has prolonged survival,
although the neurologic deficits, including the deafness, do not appear to be
responsive.

A mechanism for the neurologic symptoms is not yet known, but it can be
hypothesized that nucleotide depletion is present in neural tissues, including the
brain. Abnormalities of hearing and vision are typical of PRPS-1 deficiency,
where the absence of this enzyme presumably compromises these highly energy-
dependent neural functions. The high transcript level of PRPS-1 in lung and
bone marrow also suggests that its absence may be causal for the recurrent lung
infections that characterize Arts syndrome.

Laboratory Findings
For PRPS-1 “superactivity” (both juvenile and adult presentations), serum uric
acid may be grossly raised and the urinary excretion of uric acid increased. For
PRPS “deficiency,” uric acid is normal, not low, probably because PRPS-2
provides the major uric acid–forming activity in liver and other major organs.
Diagnosis requires that PRPS-1 activity be measured in erythrocytes and cultured fibroblasts. The adult superactivity disorder must be differentiated from partial HPRT deficiency involving the salvage pathway, which also presents with mild or absent neurologic traits accompanied by hyperuricemia.

**Treatment**

Treatment of PRPS deficiency, specifically Arts syndrome, has involved mainly experimental therapy with SAMe, as a dietary supplement to correct the depletion of purines. Dietary purines are usually not absorbed into the body but are degraded to uric acid by the gut. SAMe supplementation (beginning at 20 mg/kg/day orally) has been effective in greatly reducing the acute hospitalization episodes of 2 brothers with Arts syndrome, over a period of 10 yr. Treatment of PRPS superactivity is aimed at controlling the hyperuricemia with allopurinol, which inhibits xanthine oxidase, the last enzyme of the purine catabolic pathway. Uric acid production is reduced and is replaced by hypoxanthine, which is more soluble, and xanthine. The initial dose of allopurinol is 10-20 mg/kg/24 hr in children and is adjusted to maintain normal uric acid levels in plasma. The risk of xanthine stone formation is similar to that described for LND. A low-purine diet (free of organ meats, dried beans, and sardines), high fluid intake, and alkalinization of the urine to establish a urinary pH of 6.0-6.5 are necessary. These measures control the hyperuricemia and urate nephropathy but do not affect the neurologic symptoms. There is no known treatment for the neurologic complications.

**Adenylosuccinase Lyase Deficiency (Succinylpurinuria)**

Adenylosuccinase lyase deficiency is an inherited deficiency of de novo purine synthesis in humans. Adenylosuccinase lyase is an enzyme that catalyzes 2 pathways in de novo synthesis and purine nucleotide recycling. These are the conversion of succinylaminoimidazole carboxamide ribotide (SAICAr) into aminimidazole carboxamide ribotide (AICAR) in the de novo synthesis of purine nucleotides and the conversion of adenylosuccinate (S-AMP) into AMP, the 2nd step in the conversion of inosine monophosphate (IMP) into AMP, in the purine nucleotide cycle. Adenylosuccinase lyase deficiency results in the accumulation in urine, CSF, and to a smaller extent in plasma, of SAICAr and
succinyladenosine (S-Ado), the dephosphorylated derivatives of SAICAr and S-AMP, respectively.

**Genetics**

Succinylpurinuria is an autosomal recessive disorder; the gene has been mapped to chromosome 22q13.1-q13.2, and approximately 50 gene mutations have been identified. Laboratory investigations show grossly raised succinylpurines in urine and CSF, which are normally undetectable.

**Clinical Manifestations**

The fatal neonatal form presents with lethal encephalopathy. Clinical manifestations include varying degrees of psychomotor retardation, generally accompanied by a seizure disorder and autistic-like behaviors (poor eye contact and repetitive behaviors). Neonatal seizures and a severe infantile epileptic encephalopathy are often the first manifestations of this disorder. Others demonstrate moderate to severe intellectual disability, sometimes associated with growth retardation and muscle hypotonia. One female tested in the mild range of intellectual disability. The form of adenylosuccinase lyase deficiency with profound intellectual disability has been designated type I and the variant case with mild intellectual disability type II. Other patients have an intermediate clinical symptom pattern with moderately delayed psychomotor development, seizures, stereotypies, and agitation.

**Pathology**

CT and MRI of the brain may show hypotrophy or hypoplasia of the cerebellum, particularly the vermis. It is proposed that rather than being caused by purine nucleotide depletion, the symptoms are from the neurotoxic effects of accumulating succinylpurines. The S-Ado: SAICAr ratio has been linked to phenotype severity, suggesting that SAICAr is the more toxic compound and that S-Ado might be neuroprotective.

The laboratory diagnosis is based on the presence in urine and CSF of SAICAr and S-Ado, both normally undetectable.

**Treatment**

No successful treatment has been demonstrated for adenylosuccinase lyase deficiency. SAMe supplementation therapy was tested for 6 mo for an infant
diagnosed in the early postnatal period, but no amelioration of symptoms was noted, providing further evidence that the disorder arises from nucleotide toxicity rather than depletion. Prenatal diagnosis has been reported. Systematic screening is suggested in infants and children with unexplained psychomotor retardation or seizure disorder.

**Aminoimidazole Carboxamide Ribotide (AICAR) Transformylase/Inosine Monophosphate (IMP) Cyclohydrolase Deficiency**

AICA riboside is the dephosphorylated product of AICAR, also termed ZMP. Along with its di- and triphosphates, ZMP accumulates in RBCs and fibrocytes in inherited deficiency of the bifunctional enzyme AICAR transformylase/IMP cyclohydrolase (*ATIC*), which catalyzes the conversion of AICAR to formyl-AICAR.

**Genetics**

This inborn error of purine biosynthesis is caused by a mutation of the *ATIC* gene effecting AICAR transformylase activity. In a single reported case, AICAR transformylase was profoundly deficient, whereas the IMP cyclohydrolase level was 40% of normal.

**Clinical Features**

The disorder is described in a female infant with profound intellectual disability, epilepsy, dysmorphic features (prominent forehead and metopic suture, brachycephaly, wide mouth with thin upper lip, low-set ears, and prominent clitoris because of fused labia minora), and congenital blindness.

**Laboratory Findings**

Urinary screening with the Bratton-Marshall test to detect AICA resulted in the identification of this disorder. The transformylase was found to be deficient in fibroblasts, confirming diagnosis of ATIC deficiency.

**Treatment**

No successful treatment is described.
Disorders Resulting From Abnormalities in Purine Catabolism

Myoadenylate Deaminase Deficiency (Muscle Adenosine Monophosphate Deaminase Deficiency)

Myoadenylate deaminase is a muscle-specific isoenzyme of AMP deaminase that is active in skeletal muscle. During exercise, the deamination of AMP leads to increased levels of IMP and ammonia in proportion to the work performed by the muscle. Two forms of myoadenylate deaminase deficiency are known: an inherited (primary) form that may be asymptomatic or associated with cramps or myalgia with exercise, and a secondary form that may be associated with other neuromuscular or rheumatologic disorders.

Clinical Manifestations

Clinical manifestations are typically isolated muscle weakness, fatigue, myalgias following moderate to vigorous exercise, or cramps. Myalgia may be associated with an increased serum creatine kinase level and detectable electromyelographic abnormalities. Muscle wasting or histologic changes on biopsy are absent. The age of onset may be as early 8 mo, with approximately 25% of cases recognized between 2 and 12 yr. The enzyme defect has been identified in asymptomatic family members. Secondary forms of muscle AMP deaminase deficiency have been identified in Werdnig-Hoffmann disease, Kugelberg-Welander syndrome, polyneuropathies, and amyotrophic lateral sclerosis (see Chapter 630.2). The metabolic disorder involves the purine nucleotide cycle. As shown in Fig. 108.2, the enzymes involved in this cycle are AMP deaminase, S-AMP synthetase, and S-AMP lyase. It is proposed that muscle dysfunction in AMP deaminase deficiency results from impaired energy production during muscle contraction. It is unclear how individuals may carry the deficit and be asymptomatic. In addition to muscle dysfunction, a mutation of liver AMP deaminase has been proposed as a cause of primary gout, leading to overproduction of uric acid.

Genetics
The inherited form of the disorder is an autosomal recessive trait. *AMPD1*, the gene responsible for encoding muscle AMP deaminase, is located on the short arm of chromosome 1 (1p13-21). Population studies reveal that a mutant allele is found at high frequency in white populations, but alternative splicing of the gene can result in removal of the mutation and normal enzyme function. As a result, the disorder is usually screened by performing the forearm ischemic exercise test. The elevation of venous plasma ammonia following exercise that is seen in unaffected individuals is absent in AMP deaminase deficiency.

**Laboratory Findings**

The final diagnosis is made by histochemical or biochemical assays of a muscle biopsy. The primary form is distinguished by the finding of enzyme levels <2% with little or no immunoprecipitable enzyme. Affected individuals are advised to exercise with caution to prevent rhabdomyolysis and myoglobinuria.

**Treatment**

Although there are no documented fully effective treatments for myoadenylate deaminase deficiency, it has been proposed that enhancing the rate of replenishment of the ATP pool might be beneficial. Using this rationale, treatment with ribose (2-60 g/24 hr orally in divided doses) or xylitol, which is converted to ribose, has been reported to improve endurance and muscle strength in some patients, but is ineffective in others. Genetic approaches may be feasible in the future for inherited cases, whereas treatment of the underlying condition is essential in secondary cases.

**Adenosine Deaminase Deficiency**

See Chapter 152.1.

**Purine Nucleoside Phosphorylase Deficiency**

See Chapter 152.2.

**Xanthine Oxidoreductase Deficiency (Hereditary Xanthinuria/Molybdenum Cofactor Deficiency)**
Xanthine oxidoreductase (XOR) is the catalytic enzyme in the final step of the purine catabolic pathway and oxidizes hypoxanthine to xanthine and xanthine to uric acid. Because XOR exists in 2 forms, xanthine dehydrogenase and xanthine oxidase, the deficiency is also referred to as xanthine dehydrogenase/xanthine oxidase deficiency. Xanthine, the immediate precursor of uric acid, is less soluble than uric acid in urine, and deficiency of the enzyme results in xanthinuria. XOR deficiency may occur in isolated form (xanthinuria type 1), in a combined form involving XOR and aldehyde oxidase deficiencies (xanthinuria type II), or multiple deficiencies of XOR, aldehyde oxidase, and sulfite oxidase (molybdenum cofactor deficiency). All 3 forms result in an almost total replacement of uric acid by hypoxanthine and xanthine in urine, while plasma uric acid is very low or undetectable.

Patients with the isolated form can be asymptomatic or can have mild symptoms; renal stones, often not visible on radiography, are a risk for renal damage and may appear at any age, when patients may present with loin pain or renal insufficiency. For type II xanthinuria the clinical presentation is similar to type I, but patients also have aldehyde oxidase deficiency, which has no known clinical attributes. Molybdenum cofactor deficiency arises from inherited deficiency of molybdenum cofactor synthase, which affects all 3 molybdoenzymes; as with isolated sulfite oxidase deficiency, it usually presents with neonatal feeding problems, neonatal seizures, increased or decreased muscle tone, ocular lens dislocation, severe intellectual disability, and death in early childhood. Milder cases have presented with lens dislocation only.

**Genetics**

The inheritance of all 3 types of xanthinuria is complex and autosomal recessive. Type I results from mutations in the human XDH gene located on chromosome 2p22. Type II xanthinuria arises from mutations in the molybdenum cofactor sulfurase gene located on chromosome 18q12.2; this enzyme completes the synthesis of the molybdenum cofactor, which is essential for the activity of both XOR and aldehyde oxidase. Type III xanthinuria (XOR, aldehyde oxidase, and sulfite oxidase deficiencies) can arise from functional mutations in any of 3 genes: MOCS1 (encoding 2 enzymes for synthesis of the precursor via a bicistronic transcript), MOCS2 (encoding molybdopterin synthase), or GPHN (encoding gephyrin), located at 6p21.2, 5q11.2, and 14q23.3, respectively.

**Laboratory Findings**
Diagnosis is made initially by measuring plasma and/or urinary concentrations of uric acid. Plasma uric acid is very low or absent (<1 mg/dL). Urinary uric acid is reduced, being replaced by xanthine and hypoxanthine. Type II patients can be distinguished by the absence in urine of methyl-2-pyridone-carboxamide, the product of nicotinamide (niacin) breakdown by aldehyde oxidase. Alternately, type II patients can be distinguished from type I by their inability to oxidize a test dose of allopurinol to oxypurinol via aldehyde oxidase. Molybdenum cofactor deficiency is distinguished by an additional excessive urinary excretion of sulfite and other sulfur-containing metabolites such as sulfocysteine.

Enzyme assay of XOR is not usually offered because it requires jejunal or liver biopsy, because these are the only human tissues that contain appreciable amounts of the enzyme. Sulfite oxidase and the molybdenum cofactor synthase can be measured in liver and fibroblasts. Molecular genetic analysis can be used to confirm diagnosis by searching for functional mutations among the 3 groups of genes.

**Treatment**

Although isolated deficiency is generally benign, treatment with a diet of low purines and low fructose (which reduces ATP breakdown to xanthine) with increased fluid intake is recommended. Allopurinol is not recommended. The prognosis for molybdenum cofactor deficiency has previously been very poor, but trials of cyclic pyranopterin monophosphate are promising in patients with a defect in the *MOCS1* gene.

**Disorders of Pyrimidine Metabolism**

The pyrimidines are the building blocks of DNA and RNA and involved in the formation of active intermediates in carbohydrate and phospholipid metabolism (e.g., uridine diphosphate glucose, cytidine diphosphate choline), glucuronidation in detoxification processes (uridine diphosphate), and glycosylation of proteins and lipids.

The essential precursor for pyrimidine biosynthesis is carbamyl-phosphate, which is shared with the urea cycle. Consequently, proximal blockages of the urea cycle results in carbamyl-phosphate overflowing into the pyrimidine pathway. Pyrimidine synthesis differs from that of purines in that the single pyrimidine ring is first assembled to form orotic acid and then linked to ribose
phosphate to form the central pyrimidine nucleotide uridine monophosphate (UMP). The pyrimidine bases, uracil and thymine, are catabolized in 4 steps (see Fig. 108.3 ). Eight disorders of pyrimidine metabolism are reviewed. Purine catabolism has an easily measurable end-point in uric acid; however, there is no equivalent compound in pyrimidine catabolism. Disorders of de novo pyrimidine synthesis include hereditary orotic aciduria and dihydroorotate dehydrogenase deficiency (Miller syndrome ). Thymidine kinase deficiency is part of pyrimidine salvage, and the other disorders involve overactivity (in one syndrome) or defects in the pyrimidine degradation pathway. Pyrimidine disorders may present as anemia, neuropathologies, acrofacial dysostosis, or multisystem mitochondrial disorders. The first 3 steps of the degradation pathways for thymine and uracil, respectively, make use of the same enzymes (DPD, DPH, and UP). These 3 steps result in the conversion of uracil into β-alanine. There is increasing evidence that pyrimidines play an important role in the regulation of the nervous system. Reduced production of the neurotransmitter function of β-alanine is hypothesized to produce clinical symptoms. Clinically, pyrimidine disorders may be overlooked because they are rare and their symptoms are not highly specific; however, they should be considered as possible causes of anemia and neurologic disease and are a contraindication for treatment of cancer patients with certain pyrimidine analogs.

**Uridine Monophosphate Synthase Type 1 Deficiency (Hereditary Orotic Aciduria)**

Hereditary orotic aciduria is a disorder of pyrimidine synthesis associated with deficient activity of the last 2 steps of the de novo pyrimidine synthetic pathway: orotate phosphoribosyltransferase and orotidine-5′-monophosphate decarboxylase (ODC). The activities of these 2 steps reside in separate domains of a bifunctional protein, UMP synthase. This catalyzes the 2-step conversion of orotic acid to UMP via orotidine monophosphate. Hereditary orotic aciduria (UMP synthase deficiency) results in the excessive accumulation of orotic acid.

**Genetics**

UMP synthase deficiency is inherited as an autosomal recessive disorder, with both functional domains encoded on a single gene, UMPS, located on the long arm of chromosome 3 (3q13). Theoretically, random mutations in the gene
should have equal chances of producing either orotate phosphoribosyltransferase or ODC deficiency, but there has been only a single case of ODC deficiency reported. Genetic metabolic defects that involve 4 of the 6 enzymes associated with the urea cycle may also result in orotic aciduria, secondary to PPRP depletion resulting from a substantial increased flux through the pyrimidine synthesis pathway.

**Clinical Manifestations**

Patients with hereditary orotic aciduria (UMP synthase type 1 deficiency) have a macrocytic hypochromic megaloblastic anemia unresponsive to usual therapy (iron, folic acid, vitamin B₁₂) and may develop leukopenia. Onset is usually in 1st months of life. Untreated, this disorder can lead to intellectual disability, failure to thrive, cardiac disease, strabismus, crystalluria, and occasional ureteric obstruction. Renal function is generally normal. Heterozygotes may have mild orotic aciduria but are not otherwise affected. The clinical features are thought to be related to pyrimidine nucleotide depletion. Metabolites derived from several pharmacologic agents (e.g., 5-azauridine, allopurinol) can produce secondary orotic aciduria and orotidinuria by specifically inhibiting the ODC step of UMP synthase. Orotic aciduria may also occur in association with parenteral nutrition, essential amino acid deficiency, and Reye syndrome.

**Laboratory Findings**

The enzymatic defect may be demonstrated in liver, lymphoblasts, erythrocytes, leukocytes, and cultured skin fibroblasts. A carrier detection test is available, as is prenatal diagnosis.

**Treatment**

The administration of uridine in doses of 50-300 mg/kg/day has led to clinical improvement and reduction in orotic acid excretion in UMP synthase type 1 deficiency. Lifelong treatment is required. Uracil is ineffective because, unlike purines, pyrimidine salvage occurs at the nucleoside (uridine) level. The long-term prognosis in uncomplicated cases is good; however, congenital malformations and other associated features may adversely affect outcome.

**Dihydroorotate Dehydrogenase Deficiency**
(Miller Syndrome)

Miller syndrome was the first mendelian disorder whose molecular basis was identified by whole exome sequencing and shown to correlate with mutations in dihydroorotate dehydrogenase (*DHODH*). The enzyme DHODH is associated with the mitochondrial electron transport chain and is required for de novo pyrimidine synthesis, catalyzing the oxidation of DHO to orotic acid.

**Clinical Manifestations**

Miller syndrome is a recognizable *acrofacial dysostosis syndrome* with a combination of craniofacial and limb anomalies. It includes micrognathia, orofacial clefts, malar hypoplasia, aplasia of the medial lower-lid eyelashes, cleft lip/palate, coloboma of the lower eyelid, and cup-shaped ears, combined with postaxial limb deformities, hypoplasia of the limbs with or without ulnar and fibular hypoplasia, and supernumerary nipples. Many of these features are similar to *Treacher Collins syndrome* (see Chapter 337).

**Laboratory Findings**

Assays of disease-associated *DHODH* alleles predict affected individuals have a deficiency of de novo pyrimidine synthesis, but with significant residual function.

**Treatment**

Theoretically, dietary supplementation with orotic acid or uridine should bypass the metabolic block. However, because the main effects occur in utero, it is unlikely that the phenotypic abnormality could be corrected.

**Dihydropyrimidine Dehydrogenase Deficiency (Thymine-Uraciluria, Pyrimidinuria)**

DPD catalyzes the initial and rate-limiting step in the degradation of the pyrimidine bases uracil and thymine. DPD has been identified in most tissues, with the highest activity being in lymphocytes.

**Genetics**

DPD deficiency is an autosomal recessive disorder, with the *DPYD* gene
mapping to chromosome 1p22, with at least 32 polymorphisms detected. It is estimated that the frequency of heterozygosity may be as high as 3%.

**Clinical Manifestations**
Children may have seizure disorder, intellectual disability and motor delay. Less common features are growth retardation, microcephaly, autistic-like behavior, and ocular anomalies. Others may have milder neurologic symptoms and language disorder. Unaffected individuals have been reported, suggesting possible secondary gene effects. Most patients have an initial period of normal psychomotor development, followed by subsequent developmental delays. Symptoms may be linked to altered uracil, thymine, or β-alanine homeostasis. Because β-alanine is a structural analog of γ-aminobutyric acid and glycine, it has been proposed that it may affect inhibitory neurotransmission. DPD is the initial and rate-limiting enzyme in the inactivation of the antineoplastic drug 5-fluorouracil (5-FU), being responsible for 80% of its catabolism. Patients with partial DPD deficiency are at risk for developing a severe 5-FU–associated toxicity. In adult patients, neurotoxicity (headache, somnolence, visual illusions, memory impairment) linked to pyrimidinemia after 5-FU treatment for cancer is reported in previously healthy individuals.

**Laboratory Findings**
DPD deficiency is characterized by a variable phenotype and diagnosed by the gross accumulation of thymine and uracil in urine (thymine-uraciluria), plasma, and CSF. Uric acid levels have been reported to be normal. Prenatal diagnosis has been reported.

**Treatment**
There is no established treatment for this disorder, although patients with seizures do respond to anticonvulsant medications. *DPYD* genetic variants associated with partial or complete DPD activity and occurring with relatively high frequency in populations are potentially useful predictive markers of patient response to 5-FU chemotherapy.

**Dihydropyrimidinase Deficiency**
*(Dihydropyrimidinuria)*
DPH is the 2nd enzyme in the 3-step degradation pathway of uracil and thymine. DPH deficiency is characterized by increased urinary excretion of dihydouracil and dihydrothymine (dihydropyrimidinuria), as well as uracil and thymine. Similar to DPD deficiency, there is a variable clinical phenotype.

**Genetics**

This is an autosomal recessive disorder, with the *DPYS* gene mapped to chromosome 8q22. One study found no significant difference in residual activity between mutations observed in symptomatic and asymptomatic individuals, again similar to DPD deficiency. Population prevalence in a Japanese sample was 0.1%.

**Clinical Manifestations**

Clinical manifestations are similar to DPD deficiency, which is evidence that defects in these sequential steps produce a common disorder. Symptoms in 3 unrelated affected cases included seizures with dysmorphic features and developmental delay in 2 patients. However, 3 unrelated infants and 2 adult asymptomatic cases were identified in a screening program for pyrimidine degradation disorders in Japan and were asymptomatic despite the accumulation of pyrimidine degradation products in body fluids.

**Laboratory Findings**

Organic acid screening may identify increased amounts of uracil and thymine in urine. Oral loading tests with uracil, dihydouracil, thymine, and dihydrothymine have been used to detect carriers of DPH deficiency. In symptomatic cases, treatment with β-alanine has been attempted with equivocal results. A single case of increased sensitivity to 5-FU has been reported.

**Deficiency of β-Ureidopropionase (N-Carbamyl-β-Amino Aciduria)**

The pyrimidine bases uracil and thymine are degraded via the consecutive action of 3 enzymes to β-alanine and β-aminoisobutyric acid, respectively. The 3rd enzyme in the pathway is ureidopropionase (UP), and its deficiency leads to N-carbamyl-β-amino aciduria. 3-Ureidopropionic acid (3-UPA) acts as an endogenous neurotoxin through inhibition of mitochondrial energy metabolism,
resulting in the initiation of secondary, energy-dependent excitotoxic mechanisms.

**Genetics**

Fluorescence in situ hybridization (FISH) localized the human β-ureidopropionase gene, *UPB1*, to 22q11.2.

**Clinical Manifestations**

These include muscular hypotonia, dystonic movements, seizures, and severe developmental delay. Some individuals with UP deficiency and no neurologic problems have been reported.

**Laboratory Findings**

Neuropathology involves both gray and white matter. UP deficiency leads to pathologic accumulation of 3-UPA in body fluids. Urinary analysis in a reported case showed elevated levels of *N*-carbamyl-β-alanine and *N*-carbamyl-β-aminoisobutyric acid (ureidoisobutyric acid). The enzyme is expressed only in the liver, and no activity of β-ureidopropionase is detected in a liver biopsy.

**Treatment**

There is no known treatment for UP deficiency.

**Pyrimidine 5′-Nucleotidase Deficiency**

Erythrocyte maturation is accompanied by RNA degradation and the release of mononucleotides. Pyrimidine 5′-nucleotidase is the first degradative enzyme of the pyrimidine salvage cycle and catalyzes the hydrolysis of pyrimidine 5′-nucleotides to the corresponding nucleosides. Enzyme deficiency results in the accumulation of high levels of cytidine and uridine nucleotides in the erythrocytes, which in turn results in hemolysis. Deficiency of pyrimidine 5′-nucleotidase may be at least in part compensated in vivo by other nucleotidases or perhaps other nucleotide metabolic pathways.

**Genetics**

This is an autosomal recessive disorder involving the gene *NT5C3A* on chromosome 7 (7p15).
**Clinical Manifestations**

Affected patients with pyrimidine 5′-nucleotidase deficiency clinically present with a defect restricted to erythrocytes and characterized by nonspherocytic hemolytic anemia with basophilic stippling. Other characteristic features include splenomegaly, increased indirect bilirubin, and hemoglobinuria. **Lead** is a powerful inhibitor of pyrimidine 5′-nucleotidase, and assessment of lead levels should be included whenever hemolytic anemia, pyrimidine 5′-nucleotidase deficiency, and basophilic stippling are found together.

**Laboratory Findings**

Diagnosis requires assay of erythrocyte UMP hydrolysis to form uridine and inorganic phosphate. The enzyme defect should be suspected in patients with nonspherocytic hemolytic anemia with basophilic stippling. The anemia is usually moderate, and transfusions are rarely necessary.

**Treatment**

There is no specific treatment. Splenectomy has not proved to be effective. Lead-induced acquired pyrimidine 5′ nucleotidase deficiency is treatable, unlike the congenital deficiency.

**Overactive Cytosolic 5′-Nucleotidase (Pyrimidine Nucleotide Depletion)**

Pyrimidine nucleotide depletion and overactive cytosolic 5′-nucleotidase, may lead to a neurodevelopmental disorder. Four unrelated patients showed 6-10–fold elevation in the activity of pyrimidine 5′-nucleotidase in fibroblasts with both purine and pyrimidine substrates. Investigation in cultured fibroblasts derived from these patients showed normal incorporation of purine bases into nucleotides but decreased incorporation of uridine and orotic acid.

**Clinical Manifestations**

These include developmental delay, seizures, ataxia, recurrent infections, severe language deficit, hyperactivity, short attention span, and aggressive behavior appearing within the 1st few years of life. Affected patients show electroencephalogram abnormalities. Metabolic testing is normal except for persistent hypouricosuria. It is proposed that increased catabolic activity and
decreased pyrimidine salvage cause a deficiency of pyrimidine nucleotides.

**Treatment**

Treatment is with oral uridine based on compensating for the increased nucleotide catabolism. All reported patients treated with uridine showed improved speech and behavior, decreased seizure activity with discontinuation of seizure medications, and decreased infections.

**Thymidine Phosphorylase Deficiency (Mitochondrial Neurogastrointestinal Encephalomyopathy)**

Thymidine phosphorylase catalyzes the catabolism of thymidine to thymine. This enzyme is also known as platelet-derived endothelial cell growth factor because of its angiogenic properties, or gliostatin, indicating its inhibitory effects on glial cell proliferation. It has been implicated in mitochondrial nucleoside metabolism. Plasma thymidine level is increased more than 20-fold in patients compared to controls. Loss of function of thymidine phosphorylase causes mitochondrial neurogastrointestinal encephalomyopathy (MNGIE), which is inherited as a single autosomal recessive disorder, causing mitochondrial DNA depletion and instability. In MNGIE, loss of thymidine phosphorylase activity causes toxic accumulations of the nucleosides thymidine and deoxyuridine, which are phosphorylated to the corresponding nucleoside triphosphate in the mitochondrion, leading to mitochondrial deoxynucleoside triphosphate pool imbalances and aberrant mitochondrial DNA replication.

**Genetics**

The *TYMP* gene encoding thymidine phosphorylase has been identified as the *MNGIE* gene and is mapped to chromosome 22q13.32-qter, but the protein is imported into mitochondria.

**Clinical Manifestations**

Clinical manifestations of MNGIE usually begin in adolescence and young adulthood and include ptosis, progressive external ophthalmoparesis, GI dysmotility (pseudoobstruction) and malabsorption, cachexia, peripheral neuropathy, skeletal muscle myopathy, and leukoencephalopathy.
Laboratory Findings

Muscle biopsies typically reveal mitochondrial abnormalities. Screening is performed by detection of grossly raised thymidine and deoxyuridine in urine and plasma, which are normally absent. Confirmation of the diagnosis can be made by assay of thymidine phosphorylase activity in peripheral leukocytes. Molecular genetic analysis will show functional mutations in the *TYMP* gene. Increased thymidine and/or deoxyuridine nucleotides may cause mitochondrial nucleotide pool imbalance, resulting in mitochondrial DNA alterations, in particular DNA depletion.

Treatment

Supportive treatment is indicated. There is no established therapy for MNGIE; bone marrow transplantation has been performed on several patients, but no improvement in symptoms or disease progression has been reported. Allogeneic hematopoietic stem cell transplantation to restore thymidine phosphorylase activity and eliminate toxic metabolites is a potential therapy for MNGIE.

Thymidine Kinase 2 Deficiency

Thymidine kinase 2 (TK2) is a key enzyme for the pyrimidine salvage pathway to provide precursor nucleotide for mitochondrial DNA. TK2 deficiency causes tissue-specific depletion of mitochondrial DNA. TK2 normally phosphorylates thymidine and deoxycytidine.

Genetics

The TK2 gene is located on chromosome 16q 22; the deficiency is inherited in an autosomal recessive manner.

Clinical Manifestations

Affected individuals with TK2 deficiency have severe myopathy and depletion of muscular mitochondrial DNA in infancy.

Treatment

No specific treatment is available. Supportive treatment is indicated.

Hutchinson-Gilford progeria syndrome (HGPS), or progeria, is a rare, fatal, autosomal dominant segmental premature aging disease. With an estimated incidence of 1 in 4 million live births and prevalence of 1 in 20 million living individuals, there are an estimated total of 400 children living with progeria in 2018 worldwide. There is no gender, ethnic, or regional bias.

Progeria is caused by a single-base mutation in the *LMNA* gene, which results in the production of a mutant lamin A protein called *progerin*. Lamin A is an intermediate filament inner nuclear membrane protein found in most differentiated cells of the body. Without progerin-specific treatment, children with progeria develop premature progressive atherosclerosis and die of heart failure, usually between ages 5 and 20 yr. Progerin is found in increased concentration in skin and the vascular wall of normal older individuals compared to younger individuals, suggesting a role in normal aging.

**Clinical Manifestations**

Children develop the appearance of accelerated aging, but both clinical and biologic overlaps with aging are segmental, or partial. Physical appearance changes dramatically each year that they age (Fig. 109.1). The descriptions discussed next are roughly in order of clinical appearance.
Dermatologic Changes

Skin findings are often apparent as initial signs of progeria. These are variable in severity and include areas of discoloration, stippled pigmentation, tightened areas that can restrict movement, and areas of the trunk or legs where small (1-2 cm), soft, bulging skin is present. Although usually born with normal hair presence, cranial hair is lost within the first few years, leaving soft, downy, sparse immature hair on the scalp, no eyebrows, and scant eyelashes. Nail dystrophy occurs later in life.

Failure to Thrive

Children with progeria experience apparently normal fetal and early postnatal development. Between several months and 1 yr of age, abnormalities in growth and body composition are readily apparent. Severe failure to thrive ensues, heralding generalized lipoatrophy, with apparent wasting of limbs, circumoral
cyanosis, and prominent veins around the scalp, neck, and trunk. The mean weight percentile is usually normal at birth, but decreases to below the 3rd percentile despite adequate caloric intake for normal growth and normal resting energy expenditure. A review of 35 children showed an average weight increase of only 0.44 kg/yr, beginning at 24 mo of age and persisting through life. There is interpatient variation in weight gain, but the projected weight gain over time in individual patients is constant, linear, and very predictable; this sharply contrasts with the parabolic growth pattern for normal age- and gender-matched children. Children reach an average final height of approximately 1 meter and weight of approximately 15 kg. Head circumference is normal. The weight deficit is more pronounced than the height deficit and, associated with the loss of subcutaneous fat, results in the emaciated appearance characteristic of progeria. Clinical problems caused by the lack of subcutaneous fat include sensitivity to cold temperatures and foot discomfort caused by lack of fat cushioning. Overt diabetes is very unusual in progeria, but about 30–40% of children have insulin resistance.

Ocular Abnormalities

Ophthalmic signs and symptoms are caused in part by tightened skin and a paucity of subcutaneous fat around the eyes. Children often experience hyperopia and signs of ocular surface disease from nocturnal lagophthalmos and exposure keratopathy, which in turn may lead to corneal ulceration and scarring. Some degree of photophobia is common. Most patients have relatively good acuity; however, advanced ophthalmic disease can be associated with reduced acuity. Children with progeria should have an ophthalmic evaluation at diagnosis and at least yearly thereafter. Aggressive ocular surface lubrication is recommended, including the use of tape tarsorrhaphy at night.

Craniofacial and Dental Phenotypes

Children develop craniofacial disproportion, with micrognathia and retrognathia caused by mandibular hypoplasia. Typical oral and dental manifestations include hypodontia, delayed tooth eruption, severe dental crowding, ogival palatal arch, ankyloglossia, presence of median sagittal palatal fissure, and generalized gingival recession. Eruption may be delayed for many months, and primary teeth may persist for the duration of life. Secondary teeth are present but may or may
not erupt. They sometimes erupt on the lingual and palatal surfaces of the mandibular and maxillary alveolar ridges, rather than in place of the primary incisors. In some, but not all cases, extracting primary teeth promotes movement of secondary teeth into place.

**Bone and Cartilaginous Abnormalities**

Development of bone structure and bone density represents a unique skeletal dysplasia that is not based in malnutrition. Acroosteolysis of the distal phalanges, distal clavicular resorption, and thin, tapered ribs are early signs of progeria (as early as 3 mo of age). *Facial disproportion a narrowed nasal bridge and retrognathia makes intubation extremely difficult, and fiberoptic intubation is recommended.* A pyriform chest structure and small clavicles can lead to reducible glenohumeral joint instability. Growth of the spine and bony pelvis are normal. However, dysplastic growth of the femoral head and neck axis result in coxa valgus (i.e., straightening of the femoral head-neck axis >125 degrees) and coxa magna, where the diameter of the femoral head is disproportionately large for the acetabulum, resulting in hip instability. The resulting hip dysplasia can be progressive and may result in osteoarthritis, avascular necrosis, hip dislocation, and inability to bear weight. Other changes to the appendicular skeleton include flaring of the humeral and femoral metaphyses and constriction of the radial neck. Growth plate morphology is generally normal but can be variable within a single radiograph. The appearance of ossification centers used to define bone age is normal. Bone structure assessed by peripheral quantitative computed tomography (pQCT) of the radius demonstrates distinct and severe abnormalities in bone structural geometry, consistent with progeria representing a *skeletal dysplasia.* Areal bone mineral density (aBMD) z scores measured by dual-energy X-ray absorptiometry (DXA) adjusted for height-age, and true (volumetric) BMD assessed by pQCT are normal to mildly reduced, refuting the assumption that patients with progeria are osteoporotic. Fracture rates in progeria are normal and not associated with fragility fractures observed in other pediatric metabolic bone diseases, such as osteogenesis imperfecta.

Contractures in multiple joints (e.g., fingers, elbows, hips, knees, ankles) may be present at birth and may progress with age because of changes in the laxity of the surrounding soft tissue structures (joint capsule, ligament, skin). Along with irregularities in the congruency of articulating joint surfaces, these changes serve to limit joint motion and affect the pattern of gait. Physical therapy is
recommended routinely and throughout life to maximize joint function.

**Hearing**

Low-tone conductive hearing loss is pervasive in progeria and indicative of a stiff tympanic membrane and/or deficits in the middle ear bony and ligamentous structures. Overall, this does not affect ability to hear the usual spoken tones, but preferential classroom seating is recommended, with annual hearing examinations.

**Cardiovascular Disease**

Approximately 80% of progeria deaths are caused by heart failure, possibly precipitated by events such as superimposed respiratory infection or surgical intervention. Progeria is a primary vasculopathy characterized by pervasive accelerated vascular stiffening, followed by large- and small-vessel occlusive disease from atherosclerotic plaque formation, with valvular and cardiac insufficiency in later years. Hypertension, angina, cardiomegaly, metabolic syndrome, and congestive heart failure are common end-stage events.

A study of transthoracic echocardiography in treatment-naïve patients revealed diastolic left ventricular dysfunction associated with age-related decline in lateral and septal early (E’) diastolic tissue Doppler velocity z scores and an increase in the ratio of mitral inflow (E) to lateral and septal E’ velocity z scores. Other echocardiographic findings included left ventricular hypertrophy, left ventricular systolic dysfunction, and mitral or aortic valve disease. These tend to appear later in life. Routine carotid ultrasound for plaque monitoring, carotid-femoral pulse wave velocity (PWV$_{cf}$) measures for vascular stiffening, and echocardiography are recommended.

**Cerebrovascular Arteriopathy and Stroke**

Cerebral infarction may occur while the child exhibits a normal electrocardiogram. The earliest incidence of stroke occurred at age 0.4 yr. More often strokes occur in the later years. Over the life span, MRI evidence of infarction can be found in 60% of progeria patients, with half of these clinically silent. Both large- and small-vessel disease is found; collateral vessel formation is extensive. Carotid artery blockages are well documented, but infarction can
occur even in their absence. A propensity for strokes and an underlying stiff vasculature make maintaining adequate blood pressure through hydration (habitually drinking well) a priority in progeria patients; special care should be taken when considering maintenance of consistent blood pressure during general anesthesia, airplane trips, and hot weather. In addition, 15% of deaths in children with progeria occur from head injury or trauma, including subdural hematoma. This implies an underlying susceptibility to subdural hematoma.

**Sexual Development**

Females with progeria can develop Tanner Stage II secondary sexual characteristics, including signs of early breast development and sparse pubic hair. They do not achieve Tanner Stage III. Despite minimal to no physical signs of pubertal development and minimal body fat, over half of females experience spontaneous menarche at a median age of 14 yr. Those experiencing menarche vs nonmenstruating females have similar body mass indices, percentage body fat, and serum leptin levels, all of which are vastly below the healthy adolescent population. If bleeding becomes severe, the complete blood count may be decreased, and an oral contraceptive may be used to decrease bleeding severity. Secondary sexual characteristics in males have not been studied. There are no documented cases of reproductive capacity in females or males with progeria.

**Normally Functioning Systems**

Liver, kidney, thyroid, immune, gastrointestinal, and neurologic systems (other than stroke related) remain intact. Intellect is normal for age, possibly in part from downregulation of progerin expression in the brain by a brain-specific micro-RNA, miRNA-9.

**Laboratory Findings**

The most consistent laboratory findings are low serum leptin below detectable levels (>90%) and insulin resistance (60%). Platelet count is often moderately high. High-density lipoprotein (HDL) cholesterol and adiponectin concentrations decrease with increasing age to values significantly below normal. Otherwise, lipid panels, high-sensitivity C-reactive protein, blood chemistries, liver and kidney function tests, endocrine test, and coagulation tests are generally normal.
Molecular Pathogenesis

Mutations in the *LMNA* gene cause progeria. The normal *LMNA/C* gene encodes the proteins lamin A and C, of which only lamin A is associated with human diseases. The lamin proteins are the principal proteins of the nuclear lamina, a complex molecular interface located between the inner membrane of the nuclear envelope and chromatin. The integrity of the lamina is central to many cellular functions, creating and maintaining structural integrity of the nuclear scaffold, DNA replication, RNA transcription, organization of the nucleus, nuclear pore assembly, chromatin function, cell cycling, senescence, and apoptosis.

Progeria is almost always a sporadic autosomal dominant disease. There are 2 documented sibling occurrences, both presumably stemming from parental mosaicism, where 1 phenotypically normal parent has germline mosaicism. It is caused by the accelerated use of an alternative, internal splice site that results in the deletion of 150 base pairs in the 3’ portion of exon 11 of the *LMNA* gene. In about 90% of cases, this results from a single C to T transition at nucleotide 1824 that is silent (Gly608Gly) but optimizes an internal splice site within exon 11. The remaining 10% of cases possess 1 of several single-base mutations within the intron 11 splice donor site, thus reducing specificity for this site and altering the splicing balance in favor of the internal splice. Subsequent to all these mutations, translation followed by posttranslational processing of the altered mRNA produces progerin, a shortened abnormal lamin A protein with a 50–amino acid deletion near its C-terminal end. An understanding of the posttranslational processing pathway and how it is altered to create progerin has led to a number of treatment prospects for the disease (Fig. 109.2).
Both lamin A and progerin possess a methylated farnesyl side group attached during posttranslational processing. This is a lipophilic moiety that facilitates intercalation of proteins into the inner nuclear membrane, where most of the lamin and progerin functions are performed. For normal lamin A, loss of the methylated farnesyl anchor releases prelamin from the nuclear membrane, rendering it soluble for autophagic degradation. However, progerin retains its farnesyl moiety. It remains anchored to the membrane, binding other proteins, causing blebbing of the nucleus, disrupting mitosis, and altering gene expression. Progerin also retains a methyl moiety.
Disease in progeria is produced by a dominant negative mechanism; *the action of progerin*, not the diminution of lamin A, causes the disease phenotype. The severity of disease is determined in part by progerin levels, which are regulated by the particular mutation, tissue type, or other factors influencing use of the internal splice site.

**Diagnosis and Differential Diagnosis**

Overall, the constellation of small body habitus, bone, hair, subcutaneous fat, and skin changes results in the marked physical resemblance among patients with progeria (Fig. 109.3). For this reason, clinical diagnosis can be achieved or excluded with relative confidence even at young ages, even though there have been a few cases of low–progerin-expressing patients with extremely mild signs. Clinical suspicion should be followed by *LMNA* genetic sequence testing. The disorders that resemble progeria are those grouped as the senile-like syndromes and include Wiedmann-Rautenstrauch syndrome, Werner syndrome, Cockayne syndrome, Rothmund-Thomson syndrome, restrictive dermopathy, and Nestor-Guillermo progeria syndrome (Table 109.1). Patients often fall under none of these diagnoses and represent ultra-rare, unnamed progeroid laminopathies that carry either non–progerin-producing mutations in *LMNA* or the lamin-associated enzyme (*ZMPSTE24*), or progeroid syndromes without lamin-associated mutations.

**Treatment and Prognosis**

Children with progeria develop a severe premature form of atherosclerosis. Prior to death, cardiac decline with left-sided hypertrophy, valvular insufficiency, and pulmonary edema develop; neurovascular decline with transient ischemic attacks (TIAs), strokes, and occasionally seizures can result in significant morbidity. Death occurs generally between ages 5 and 20 yr, with a median life span of 14.5 yr, resulting from heart failure, sometimes with superimposed respiratory infection (approximately 80%); from head injury or trauma, including subdural hematoma (approximately 15%); and rarely from stroke (1–3%) or complications from anesthesia during surgery (1–3%).

*Growth hormone*, 0.05 mg/kg/day subcutaneously, has resulted in increased rate of weight gain and overall size, but still well below that seen in normal
children. Low-dose aspirin therapy is recommended at 2 mg/kg/day, as an extension of what is known about decreasing cardiovascular risk in the general at-risk adult population. It is not known whether growth hormone or low-dose aspirin has any effect on morbidity or mortality.

Several clinical treatment trials have been based on medications that target the posttranslational pathway of progerin (see Fig. 109.2). Inhibiting posttranslational progerin farnesylation is aimed at preventing this disease-causing protein from anchoring to the nuclear membrane, where it carries out much of its damage. A prospective single-arm clinical trial was conducted with the farnesyltransferase inhibitor lonafarnib (NCT00425607). Lonafarnib was well tolerated; the most common side effects were diarrhea, nausea, and loss of appetite, which generally improved with time. Subgroups of patients experienced increased rate of weight gain, decreased vascular stiffness measured by decreased PWV$_{cf}$ and carotid artery echodensity, improved left ventricular diastolic function, increased radial bone structural rigidity, improved sensorineural hearing, and early evidence of decreased headache, TIA, and stroke rates. Dermatologic, dental, joint contracture, insulin resistance, lipodystrophy, BMD, and joint contractures were unaffected by drug treatment. A lonafarnib extension study was initiated, which added 30 children to the study. Children treated with lonafarnib demonstrated an increase in estimated survival over untreated children with progeria.

A clinical trial that added pravastatin (FDA approved to lower cholesterol) and zoledronate (FDA approved for osteoporosis) to the lonafarnib regimen was similarly aimed at inhibiting progerin farnesylation (NCT00916747), but results showed no detected improvements in clinical status over lonafarnib monotherapy. An ongoing clinical trial adding everolimus (FDA-approved mTOR inhibitor) to the lonafarnib regimen is aimed at accelerating autophagy of progerin, thus theoretically reducing its accumulation and cellular damage (NCT02579044). Results of this study are forthcoming.

**Patient Resources**

The Progeria Research Foundation (www.progeriaresearch.org) maintains an international progeria patient registry, provides a diagnostics program and complete patient care manual, and coordinates clinical treatment trials. It funds preclinical and clinical research to define the molecular basis of the disorder and
to discover treatments and a cure. The Foundation website is an excellent source of current information on progeria for families of children with the disorder, their physicians, and interested scientists. Additional resources include the National Human Genome Research Institute (www.genome.gov/11007255/), National Center for Biotechnology Information Genereviews (www.ncbi.nlm.nih.gov/books/NBK1121/), and National Center for Advancing Translational Sciences (www.rarediseases.info.nih.gov/diseases/7467/progeria).

Bibliography

Porphyrias are metabolic diseases resulting from altered activities of specific enzymes of the heme biosynthetic pathway. These enzymes are most active in bone marrow and liver. **Erythropoietic porphyrias**, in which overproduction of heme pathway intermediates occurs primarily in bone marrow erythroid cells, usually present at birth or in early childhood with *cutaneous photosensitivity*, or in the case of congenital erythropoietic porphyria, even in utero as nonimmune hydrops. Erythropoietic protoporphyria is the most common porphyria in children and of most interest to pediatricians. Most porphyrias are *hepatic*, with overproduction and initial accumulation of porphyrin precursors or porphyrins in the liver. Activation of hepatic porphyrias is very rare during childhood, reflecting the distinct hepatic regulatory mechanisms for heme biosynthesis that are influenced by pubertal development. Homozygous forms of the hepatic porphyrias may manifest clinically before puberty. Children who are heterozygous for inherited hepatic porphyrias may present with nonspecific and unrelated symptoms, and parents often request advice about long-term prognosis and express concerns about drugs that may exacerbate these conditions.

The DNA sequences and chromosomal locations are established for the genes of the enzymes in this pathway, and multiple disease-related mutations have been found for each porphyria. However, benign variants identified by gene sequencing can be misleading. The inherited porphyrias display autosomal dominant, autosomal recessive, or X-linked inheritance. Although initial diagnosis of porphyria by biochemical methods remains essential, it is especially important to confirm the diagnosis by demonstrating a specific pathogenic gene mutation(s).
The Heme Biosynthetic Pathway

Heme is required for a variety of hemoproteins, such as hemoglobin, myoglobin, respiratory cytochromes, and cytochrome P450 enzymes (CYPs). It is believed that the 8 enzymes in the pathway for heme biosynthesis are active in all tissues. Hemoglobin synthesis in erythroid precursor cells accounts for approximately 85% of daily heme synthesis in humans. Hepatocytes account for most of the rest, primarily for synthesis of CYPs, which are especially abundant in the liver endoplasmic reticulum, and turn over more rapidly than many other hemoproteins, such as the mitochondrial respiratory cytochromes. Pathway intermediates are the porphyrin precursors δ-aminolevulinic acid (ALA, also known as 5-aminolevulinic acid) and porphobilinogen (PBG), as well as porphyrins (mostly in their reduced forms, known as porphyrinogens) (Fig. 110.1). These intermediates do not accumulate in significant amounts under normal conditions or have important physiologic functions.
Altered activity of each enzyme in the pathway has been associated with a specific type of porphyria (Table 110.1). The first enzyme, ALA synthase (ALAS), occurs in 2 forms. An erythroid specific form, ALAS2, is deficient in X-linked sideroblastic anemia, as a result of mutations of the ALAS2 gene on chromosome Xp11.2. Gain-of-function mutations of ALAS2 caused by deletions in the last exon cause X-linked protoporphyria (XLP), which is phenotypically identical to erythropoietic protoporphyria.

Regulation of heme synthesis differs in the 2 major heme-forming tissues. Liver heme biosynthesis is primary controlled by the ubiquitous form of ALAS (ALAS1). Synthesis of ALAS1 in liver is regulated by a “free” heme pool (see Fig. 110.1), which can be augmented by newly synthesized heme or by existing heme released from hemoproteins and destined for breakdown to biliverdin by heme oxygenase.

In the erythron, novel regulatory mechanisms allow for the production of the very large amounts of heme needed for hemoglobin synthesis. The response to stimuli for hemoglobin synthesis occurs during cell differentiation, leading to an increase in cell number. Also, unlike the liver, heme has a stimulatory role in hemoglobin formation, and the stimulation of heme synthesis in erythroid cells is accompanied by increases not only in ALAS2, but also by sequential induction of other heme biosynthetic enzymes. Separate erythroid-specific and nonerythroid or “housekeeping” transcripts are known for the first 4 enzymes in the pathway. The separate forms of ALAS are encoded by genes on different chromosomes, but for each of the other three, erythroid and nonerythroid transcripts are transcribed by alternative promoters in the same gene. Heme also regulates the rate of its synthesis in erythroid cells by controlling the transport of iron into reticulocytes.

Intermediates of the heme biosynthetic pathway are efficiently converted to heme and, normally, only small amounts of the intermediates are excreted. Some may undergo chemical modifications before excretion. Whereas the porphyrin precursors ALA and PBG are colorless, nonfluorescent, and largely excreted unchanged in urine, PBG may degrade to colored products such as the brownish pigment called porphobilin or spontaneously polymerize to uroporphyrins. Porphyrins are red in color and display bright-red fluorescence when exposed to long-wavelength ultraviolet (UV) light. Porphyrinogens are the reduced form of porphyrins, and are colorless and nonfluorescent, but are readily autoxidized to the corresponding porphyrins when they accumulate or are outside the cell. Only the type III isomers of uroporphyrinogen and coproporphyrinogen are converted to heme (see Fig. 110.1).

ALA and PBG are excreted in urine. Excretion of porphyrins and
porphyrinogens in urine or bile is determined by the number of carboxyl groups. Those with many carboxyl groups, such as *uroporphyrin* (octacarboxyl porphyrin) and *heptacarboxyl porphyrin*, are water soluble and readily excreted in urine. Those with fewer carboxyl groups, such as *protoporphyrin* (dicarboxyl porphyrin), are not water soluble and are excreted in bile and feces. *Coproporphyrin* (tetracarboxyl porphyrin) is excreted partly in urine and partly in bile. Because coproporphyrin I is more readily excreted in bile than coproporphyrin III, impaired hepatobiliary function may increase total urinary coproporphyrin excretion and the ratio of these isomers.

**Classification and Diagnosis of Porphyrias**

Two useful classification schemes reflect either the underlying pathophysiology or the clinical features of porphyrias (see Table 110.1). In hepatic porphyrias and erythropoietic porphyrias the source of excess production of porphyrin precursors and porphyrins is the liver and bone marrow, respectively. Acute porphyrias cause neurologic symptoms that are associated with increases of one or both of the porphyrin precursors, ALA and PBG. In the cutaneous porphyrias, photosensitivity results from transport of porphyrins in blood from the liver or bone marrow to the skin. Dual porphyria refers to the very rare cases of porphyria with deficiencies of 2 different heme pathway enzymes.

Porphyria cutanea tarda (PCT), acute intermittent porphyria (AIP), and erythropoietic protoporphyrnia (EPP) are the 3 most common porphyrias, in that order, considering all age-groups, and are very different in clinical presentation, precipitating factors, methods of diagnosis, and effective therapy (Table 110.2). Two less common acute porphyrias, hereditary coproporphyrinia (HCP) and variegate porphyria (VP), can also cause blistering photosensitivity (see Table 110.1). Congenital erythropoietic porphyria (CEP) causes more severe blistering lesions, often with secondary infection and mutilation. EPP and XLP have the same phenotype and are distinct from the other cutaneous porphyrias in causing nonblistering photosensitivity that occurs acutely after sun exposure. EPP is also the most common porphyria to become manifest before puberty.

### First-Line Laboratory Diagnostic Testing

A few sensitive and specific first-line laboratory tests should be obtained whenever symptoms or signs suggest the diagnosis of porphyria. If a first-line or screening test is significantly abnormal, more comprehensive testing should follow to establish the type of porphyria. Overuse of lab tests for screening can lead to unnecessary expense and even delay in diagnosis. In patients who present with a past diagnosis of porphyria, lab reports that were the basis for the original diagnosis must be reviewed, and if these were inadequate, further testing considered.

Acute porphyria should be suspected in patients with neurovisceral symptoms such as abdominal pain after puberty, when initial clinical evaluation does not suggest another cause. Urinary PBG and total porphyrins should be measured. Urinary PBG is virtually always increased during acute attacks of AIP, HCP, and VP and is not substantially increased in any other medical conditions. Therefore this measurement is both sensitive and specific. Results from spot (single void) urine specimens are highly informative because very substantial increases are expected during acute attacks of porphyria. A 24 hr collection can unnecessarily delay diagnosis. The same spot urine specimen should be saved for quantitative determination of PBG and total porphyrins (both expressed relative to creatinine) to confirm the qualitative PBG result. ALA is often measured as well, but is usually less elevated than PBG in AIP, HCP, and VP. In ALA dehydratase porphyria, urinary ALA and porphyrins, but not PBG, are greatly elevated. Urinary porphyrins may remain increased longer than porphyrin precursors in some cases of HCP and VP. Measurement of urinary porphyrins alone should be
avoided for screening, however, because they are often increased in many disorders other than porphyrias, such as liver diseases, and misdiagnoses of porphyria can result from minimal increases in urinary porphyrins that have no diagnostic significance.

**Blistering Cutaneous Porphyrias**

Blistering skin lesions caused by porphyria are virtually always accompanied by increases in total plasma and urinary porphyrins. Porphyrins in plasma in VP are mostly covalently linked to plasma proteins and readily detected by a diagnostic peak in a fluorescence scanning method. The normal range for plasma porphyrins is somewhat increased in patients with end-stage renal disease.

**Nonblistering Cutaneous Porphyria**

Measurement of total erythrocyte protoporphyrin and, if the total amount is elevated, fractionation of protoporphyrin into its metal-free and zinc-chelated forms, is essential for diagnosis of EPP and XLP. Unfortunately, this is not offered by some major commercial laboratories. Results of zinc protoporphyrin measurements are often recorded (even in the same report) as both protoporphyrin and free erythrocyte protoporphyrin, with each calculated differently, based on past practices for screening for lead poisoning (which only increases zinc protoporphyrin). Thus the obsolete term free protoporphyrin does not mean metal-free protoporphyrin, because it was defined as iron-free protoporphyrin, and dates from before it was known that (except in protoporphyrias) protoporphyrin in erythrocytes is mostly zinc chelated. This unnecessary confusion makes diagnosis and reliable exclusion of protoporphyrias difficult. Total plasma porphyrins are elevated in most but not all cases of protoporphyria, so a normal level should not be relied on to exclude protoporphyria when total erythrocyte protoporphyrin is elevated.

Increases in erythrocyte total and zinc-chelated protoporphyrin occur in many other conditions, including iron deficiency, lead poisoning, hemolysis, anemia of chronic disease, and other erythrocyte disorders. Therefore the diagnosis of EPP must be confirmed by showing a predominant increase in metal-free protoporphyrin. In XLP, both free and zinc protoporphyrin are elevated.

**Second-Line Testing**

More extensive testing is well justified when a first-line test is positive. For
example, a substantial increase in PBG may be caused by AIP, HCP, or VP, and these can be distinguished by measuring erythrocyte porphobilinogen deaminase, urinary porphyrins (using the same spot urine sample), fecal porphyrins, and plasma porphyrins. The various porphyrias that cause blistering skin lesions are differentiated by measuring porphyrins in urine, feces, and plasma. Confirmation at the gene level is important once the diagnosis is established by biochemical testing.

Testing for Subclinical Porphyria

It is often difficult to diagnose or rule out porphyria in patients who had suggestive symptoms months or years in the past, and in relatives of patients with acute porphyrias, because porphyrin precursors and porphyrins may be normal. More extensive testing and consultation with a specialist laboratory and physician may be needed. Before evaluating relatives, the diagnosis of porphyria should be firmly established in an index case, and the lab results reviewed to guide the choice of tests for the family members. The index case or another family member with confirmed porphyria should be retested if necessary. Identification of a disease-causing mutation in an index case greatly facilitates detection of additional gene carriers, because biochemical tests in latent carriers may be normal.

δ-Aminolevulinic Acid Dehydratase Deficient Porphyria

ALA dehydratase deficient porphyria (ADP) is sometimes termed Doss porphyria after the investigator who described the first cases. The term plumboporphyria emphasizes the similarity of this condition to lead poisoning, but incorrectly implies that it is caused by lead exposure.

Etiology

This porphyria results from a deficiency of ALA dehydratase (ALAD), which is inherited as an autosomal recessive trait. Only six cases have been confirmed by mutation analysis. The prevalence of heterozygous ALAD deficiency was estimated to be <1% in Germany and approximately 2% in Sweden.
Pathology and Pathogenesis

ALAD catalyzes the condensation of 2 molecules of ALA to form the pyrrole PBG (see Fig. 110.1). The enzyme is subject to inhibition by a number of exogenous and endogenous chemicals. ALAD is the principal lead-binding protein in erythrocytes, and lead can displace the zinc atoms of the enzyme. Inhibition of erythrocyte ALAD activity is a sensitive index of lead exposure.

Eleven abnormal ALAD alleles, most with point mutations, have been identified, some expressing partial activity, such that heme synthesis is partially preserved. The amount of residual enzyme activity may predict the phenotypic severity of this disease.

ADP is often classified as a hepatic porphyria, although the site of overproduction of ALA is not established. A patient with severe, early-onset disease underwent liver transplantation, without significant clinical or biochemical improvement, which might suggest that the excess intermediates did not originate in the liver. Excess urinary coproporphyrin III in ADP might originate from metabolism of ALA to porphyrinogens in a tissue other than the site of ALA overproduction. Administration of large doses of ALA to normal individuals also leads to substantial coproporphyrinuria. Increased erythrocyte protoporphyrin, as in all other homozygous porphyrias, may be explained by accumulation of earlier pathway intermediates in bone marrow erythroid cells during hemoglobin synthesis, followed by their transformation to protoporphyrin after hemoglobin synthesis is complete. Neurologic symptoms are attributed to neurotoxic effects of ALA, but this is unproven.

Clinical Manifestations

In most cases, symptoms resemble other acute porphyrias, including acute attacks of abdominal pain and peripheral neuropathy. Precipitating factors, such as exposure to harmful drugs, have not been evident in most cases. Four of the reported cases were adolescent males. A Swedish infant had more severe disease, with neurologic impairment and failure to thrive. A 63 yr old man in Belgium developed an acute motor polyneuropathy concurrently with a myeloproliferative disorder.

Laboratory Findings

Urinary ALA, coproporphyrin III, and erythrocyte zinc protoporphyrin are
substantially increased. Urinary PBG is normal or slightly increased. Erythrocyte ALAD activity is markedly reduced, and both parents have approximately half-normal activity of this enzyme and normal urinary ALA.

Diagnosis and Differential Diagnosis

The other 3 acute porphyrias are characterized by substantial increases in both ALA and PBG. In contrast, ALA but not PBG is substantially increased in ADP. A marked deficiency of erythrocyte ALAD and half-normal activity in the parents support the diagnosis. Other causes of ALAD deficiency, such as lead poisoning, must be excluded. Succinylacetone accumulates in hereditary tyrosinemia type 1 and is structurally similar to ALA, inhibits ALAD, and can cause increased urinary excretion of ALA and clinical manifestations that resemble acute porphyria. Idiopathic acquired ALAD deficiency has been reported. Unlike lead poisoning, the deficient ALAD activity in ADP is not restored by the in vitro addition of sulphhydryl reagents such as dithiothreitol. Even if no other cause of ALAD deficiency is found, it is essential to confirm the diagnosis of ADP by molecular studies.

Treatment

Treatment experience with ADP is limited but is similar to other acute porphyrias. Glucose seems to have minimal effectiveness but may be tried for mild symptoms. Hemin therapy was apparently effective for acute attacks in male adolescents, and weekly infusions prevented attacks in 2 of these patients. Hemin was not effective either biochemically or clinically in the Swedish child with severe disease, and it produced a biochemical response but no clinical improvement in the Belgian man with a late-onset form, who had a peripheral neuropathy but no acute attacks. Hemin is also effective in treating porphyria-like symptoms associated with hereditary tyrosinemia and can significantly reduce urinary ALA and coproporphyrin in lead poisoning. Avoidance of drugs that are harmful in other acute porphyrias is advisable. Liver transplantation was not effective in the child with severe disease.

Prognosis

The outlook is generally good in typical ADP cases, although recurrent attacks
may occur. The course was unfavorable in the Swedish child with more severe disease and is uncertain in adults with late-onset disease associated with myeloproliferative disorders.

Prevention and Genetic Counseling

Heterozygous parents should be aware that subsequent children are at risk for ADP, as in any autosomal recessive disorder. Prenatal diagnosis is possible but has not been reported.

Acute Intermittent Porphyria

AIP is also termed pyrroloporphyria, Swedish porphyria, and intermittent acute porphyria and is the most common type of acute porphyria in most countries.

Etiology

AIP results from the deficient activity of the housekeeping form of porphobilinogen deaminase (PBGD). This enzyme is also known as hydroxymethylbilane (HMB) synthase (the prior term, uroporphyrinogen I synthase, is obsolete). PBGD catalyzes the deamination and head-to-tail condensation of 4 PBG molecules to form the linear tetrapyrole, HMB (also known as preuroporphyrinogen; see Fig. 110.1). A unique dipyrromethane cofactor binds the pyrrole intermediates at the catalytic site until 6 pyrroles (including the dipyrrole cofactor) are assembled in a linear fashion, after which the tetrapyrrole HMB is released. The apo-deaminase generates the dipyrrole cofactor to form the holodeaminase, and this occurs more readily from HMB than from PBG. Indeed, high concentrations of PBG may inhibit formation of the holodeaminase. The product HMB can cyclize nonenzymatically to form nonphysiologic uroporphyrinogen I, but in the presence of the next enzyme in the pathway is more rapidly cyclized to form uroporphyrinogen III.

Erythroid and housekeeping forms of the enzyme are encoded by a single gene on human chromosome 11 (11q24.1 → q24.2), which contains 15 exons. The 2 isoenzymes are both monomeric proteins and differ only slightly in molecular weight (approximately 40 and 42 kDa), and result from alternative splicing of 2 distinct messenger RNA (mRNA) transcripts arising from 2 promoters. The housekeeping promoter functions in all cell types,
erythroid cells.

The pattern of inheritance of AIP is autosomal dominant, with very rare homozygous cases that present in childhood. More than 400 \textit{PBGD} mutations, including missense, nonsense, and splicing mutations, and insertions and deletions have been identified in AIP and in many population groups, including blacks. Most mutations are found in only one or a few families. Because of founder effects, however, some are more common in certain geographic areas, such as northern Sweden (W198X), Holland (R116W), Argentina (G116R), Nova Scotia (R173W), and Switzerland (W283X). De novo mutations may be found in approximately 3% of cases. The nature of the \textit{PBGD} mutation does not account for the severity of the clinical presentation, which varies greatly within families. \textbf{Chester porphyria} was initially described as a variant form of acute porphyria in a large English family but was found to be caused by a \textit{PBGD} mutation.

Most mutations lead to approximately half-normal activity of the housekeeping and erythroid isozymes and half-normal amounts of their respective enzyme proteins in all tissues of heterozygotes. In approximately 5% of unrelated AIP patients, the housekeeping isozyme is deficient, but the erythroid-specific isozyme is normal. Mutations causing this variant are usually found within exon 1 or its 5’ splice donor site or initiation of translation codon.

\section*{Pathology and Pathogenesis}

Induction of the rate-limiting hepatic enzyme ALAS1 is thought to underlie acute exacerbations of this and the other acute porphyrias. AIP remains latent (or asymptomatic) in the great majority of those who are heterozygous carriers of \textit{PBGD} mutations, and this is almost always the case before puberty. In those with no history of acute symptoms, porphyrin precursor excretion is usually normal, suggesting that half-normal hepatic PBGD activity is sufficient unless hepatic ALAS1 activity is increased. Patients can also be asymptomatic with elevated levels of porphyrin precursors and are classified as \textit{asymptomatic high excretors}. These patients may have a remote history of symptoms. Many factors that lead to clinical expression of AIP, including certain drugs and steroid hormones, have the capacity to induce hepatic ALAS1 and CYPs. When hepatic heme synthesis is increased, half-normal PBGD activity may become limiting, and ALA, PBG, and other heme pathway intermediates may accumulate. In addition, heme synthesis becomes impaired, and heme-mediated repression of
hepatic ALAS1 is less effective. It is not proved, however, that hepatic PBGD remains constant at approximately 50% of normal activity during exacerbations and remission of AIP, as in erythrocytes. An early report suggested that the enzyme activity is considerably less than half-normal in the liver during an acute attack. Hepatic PBGD activity might be reduced further once AIP becomes activated if, as suggested, excess PBG interferes with assembly of the dipyrrromethane cofactor for this enzyme. It also seems likely that currently unknown genetic factors play a contributing role in, for example, patients who continue to have attacks even when known precipitants are avoided.

AIP is almost always latent before puberty and becomes active mostly in adult women, which suggests that endocrine factors, and especially adult levels of female steroid hormones, are important for clinical expression. Premenstrual attacks are probably the result of endogenous progesterone. Acute porphyrias are sometimes exacerbated by exogenous steroids, including oral contraceptive preparations containing progestins. Surprisingly, pregnancy is usually well tolerated, suggesting that beneficial metabolic changes may ameliorate the effects of high levels of progesterone.

**Drugs** that are unsafe in acute porphyrias (Table 110.3) include those having the capacity to induce hepatic ALAS1, which is closely associated with induction of CYPs. Some chemicals (e.g., griseofulvin) can increase heme turnover by promoting the destruction of specific CYPs to form an inhibitor (e.g., N-methyl protoporphyrin) of ferrochelatase (FECH, the final enzyme in the pathway). Sulfonamide antibiotics are harmful but apparently not inducers of hepatic heme synthesis. Ethanol and other alcohols are inducers of ALAS1 and some CYPs.

* Porphyria has been listed as a contraindication, warning, precaution, or adverse effect in U.S. labeling for these drugs. Estrogens are also listed as harmful in porphyria but have been implicated as harmful in acute porphyrias, mostly based only on experience with estrogen-progestin combinations. Although estrogens can exacerbate porphyria cutanea tarda, there is little evidence they are harmful in the acute porphyrias.

† Porphyria has been listed as a precaution in U.S. labeling for this drug. However, this drug is regarded as safe by other sources.

‡ These drugs have been classified as probably safe by some sources, but this is controversial, and they should be avoided.

This partial listing does not include all available information about drug safety in acute porphyrias. Other sources should be consulted for drugs not listed here.

ACEIs, Angiotensin-converting enzyme inhibitors; CCBs, calcium channel blockers.

**Nutritional factors**, principally reduced intake of calories and carbohydrates, as may occur with illness or attempts to lose weight, can increase porphyrin precursor excretion and induce attacks of porphyria. Increased carbohydrate intake may ameliorate attacks. Hepatic ALAS1 is modulated by the peroxisome proliferator-activated receptor-γ coactivator-1α, which is an important link between nutritional status and exacerbations of acute porphyria.

Other factors have been implicated. Chemicals in cigarette smoke, such as polycyclic aromatic hydrocarbons, can induce hepatic CYPs and heme synthesis.
A survey of AIP patients found an association between smoking and repeated porphyric attacks. Attacks may result from metabolic stress and impaired nutrition associated with major illness, infection, or surgery. Clinical observations suggest an additive effect of multiple predisposing factors, including drugs, endogenous hormones, nutritional factors, and smoking, are common.

**Neurologic Mechanisms**

The mechanism of neural damage in acute porphyrias is poorly understood. The most favored hypothesis at present is that 1 or more heme precursors, or perhaps a derivative, are neurotoxic. Increased ALA in AIP, HCP, VP, ADP, plumbism, and hereditary tyrosinemia type 1, which have similar neurologic manifestations, suggests that this substance or a derivative may be neuropathic. Porphyrins derived from ALA after its uptake into cells may have toxic potential. ALA can also interact with γ-aminobutyric acid (GABA) receptors. Severe AIP greatly improves after allogeneic liver transplantation. This experience and the demonstration that recipients of AIP livers develop porphyria support the hypothesis that heme precursors from the liver cause the neurologic manifestations.

**Epidemiology**

AIP occurs in all races and is the most common acute porphyria, with an estimated prevalence in most countries of 5 in 100,000. In Sweden, prevalence was estimated to be 7.7 in 100,000, including latent cases with normal porphyrin precursors. A much higher prevalence of 60-100 in 100,000 in northern Sweden is the result of a founder effect. The combined prevalence of AIP and VP in Finland is approximately 3.4 in 100,000. A survey of chronic psychiatric patients in the United States using an erythrocyte PBGD determination found a high prevalence (210 in 100,000) of PBGD deficiency, but a study in Mexico found a similar prevalence in psychiatric patients and controls. Population screening by erythrocyte PBGD activity or DNA analysis revealed a prevalence of 200 heterozygotes per 100,000 people in Finland, and 1 in approximately 1,675 (60 in 100,000) in France. Studies using exomic/genomic databases show that the estimated frequency of pathogenic mutations in the *HMBS* gene is 0.00056 (56 in 100,000) suggesting that the penetrance of this disorder may be as low as 1%. 

and that carriers of \textit{PBGD} mutations that can cause AIP are much more common than previously believed.

**Clinical Manifestations**

Neurovisceral manifestations of acute porphyrias may appear any time after puberty, but rarely before (Table 110.4). Symptomatic childhood cases have been reported, but most were not adequately documented biochemically and confirmed by genetic testing. Abdominal pain is the most common presenting symptom in such cases, but seizures are common and may precede the diagnosis of AIP. Other manifestations reported in children include peripheral neuropathy, myalgias, hypertension, irritability, lethargy, and behavioral abnormalities. A population-based study in Sweden indicated that symptoms suggestive of porphyria may occur in heterozygotes during childhood, even, in contrast to adults, when urinary porphyria precursors are not elevated. This study did not compare the frequency of such nonspecific symptoms in a control group of children. Very rare cases of homozygous AIP present differently, with severe neurologic manifestations early in childhood.

</table>
Acute attacks in adults are characterized by a constellation of nonspecific symptoms, which may become severe and life threatening. Abdominal pain occurs in 85–95% of AIP patients; is usually severe, steady, and poorly localized, but is sometimes cramping; and accompanied by signs of ileus, including abdominal distention and decreased bowel sounds. Nausea, vomiting, and constipation are common, but increased bowel sounds and diarrhea may occur. Bladder dysfunction may cause hesitancy and dysuria. Tachycardia, the most common physical sign, occurs in up to 80% of attacks. This is often accompanied by hypertension, restlessness, coarse or fine tremors, and excess sweating, which are attributed to sympathetic overactivity and increased catecholamines. Other common manifestations include mental symptoms; pain in the extremities, head, neck, or chest; muscle weakness; and sensory loss. Because all these manifestations are neurologic rather than inflammatory, there is little or no abdominal tenderness, fever, or leukocytosis.

Porphyric neuropathy is primarily motor and appears to result from axonal degeneration rather than demyelinization. Sensory involvement is indicated by pain in the extremities, which may be described as muscle or bone pain, and by numbness, paresthesias, and dysesthesias. Paresis may occur early in an attack but is more often a late manifestation in an attack that is not recognized and adequately treated. Rarely, severe neuropathy develops when there is little or no abdominal pain. Motor weakness most commonly begins in the proximal muscles of the upper extremities and then progresses to the lower extremities and the periphery. It is usually symmetric, but occasionally asymmetric or focal. Initially, tendon reflexes may be little affected or hyperactive and become decreased or absent. Cranial nerves, most often X and VII, may be affected, and blindness from involvement of the optic nerves or occipital lobes has been reported. More common central nervous system (CNS) manifestations include seizures, anxiety, insomnia, depression, disorientation, hallucinations, and paranoia. Seizures may result from hyponatremia, porphyria itself, or an
unrelated cause. Chronic depression and other mental symptoms occur in some patients, but attribution to porphyria is often difficult.

**Hyponatremia** is common during acute attacks. Inappropriate antidiuretic hormone (ADH) secretion is often the most likely mechanism, but salt depletion from excess renal sodium loss, gastrointestinal (GI) loss, and poor intake have been suggested as causes of hyponatremia in some patients. Unexplained reductions in total blood and red blood cell volumes are sometimes found and increased ADH secretion might then be an appropriate physiologic response. Other electrolyte abnormalities may include hypomagnesemia and hypercalcemia.

The attack usually resolves within several days, unless treatment is delayed. Abdominal pain may resolve within a few hours and paresis within a few days. Even severe motor neuropathy can improve over months or several years, but may leave some residual weakness. Progression of neuropathy to respiratory paralysis and death seldom occurs with appropriate treatment and removal of harmful drugs. Sudden death may result from cardiac arrhythmia.

**Laboratory Findings**

Levels of ALA and PBG are substantially increased during acute attacks. These levels may decrease after an attack but usually remain increased unless the disease becomes asymptomatic for a prolonged period.

Porphyryins are also markedly increased, which accounts for reddish urine in AIP. These are predominantly uroporphyrins, which can form nonenzymatically from PBG. Because the increased urinary porphyrins in AIP are predominantly isomer III, however, their formation is likely to be largely enzymatic, which might occur if excess ALA produced in the liver enters cells in other tissues and is then converted to porphyrins by the heme biosynthetic pathway. Porphobilin, a degradation product of PBG, and dipyrrylmethenes appear to account for brownish urinary discoloration. Total fecal porphyrins and plasma porphyrins are normal or slightly increased in AIP. Erythrocyte protoporphyrin may be somewhat increased in patients with manifest AIP.

Erythrocyte PBGD activity is approximately half-normal in most patients with AIP. The normal range is wide and overlaps with the range for AIP heterozygotes. Some *PBGD* gene mutations cause the enzyme to be deficient only in nonerythroid tissues. PBGD activity is also highly dependent on erythrocyte age, and an increase in erythropoiesis from concurrent illness in an
AIP patient may raise the activity into the normal range. Thus, PBGD activity alone is insufficient to make the diagnosis of AIP.

**Diagnosis and Differential Diagnosis**

An increased urinary PBG level establishes that a patient has 1 of the 3 most common acute porphyrias (see Table 110.2). Measuring PBG in serum is preferred when there is coexistent severe renal disease but is less sensitive when renal function is normal. Measurement of urinary ALA is less sensitive than PBG and also less specific, but will detect ADP, the 4th type of acute porphyria. Erythrocyte PBGD activity is decreased in most AIP patients and helps confirm the diagnosis in a patient with high PBG. A normal enzyme activity in erythrocytes does not exclude AIP.

Knowledge of the PBGD mutation in a family enables reliable identification of other gene carriers. Prenatal diagnosis can be performed by amniocentesis or chorionic villus sampling (CVP) in a fetus with a known PBGD mutation in the family. Prenatal diagnosis is typically not performed due to the low penetrance of the disorder and favorable prognosis with treatment.

**Complications**

AIP and other acute porphyrias are typically associated with mild abnormalities in liver function tests; some patients develop chronic liver disease. The risk of hepatocellular carcinoma is also increased, perhaps 60-70–fold after age 50, even in asymptomatic individuals who have increased porphyrins or porphyrin precursors. Few patients who developed this neoplasm had increases in serum α-fetoprotein. Patients with acute porphyrias, especially >50 yr old, should be screened at least yearly by ultrasound or an alternative imaging method.

The risk of chronic hypertension and impaired renal function is increased in these patients, most often with evidence of interstitial nephritis. A nephrotoxic effect of ALA may contribute. This may progress to severe renal failure and require renal transplantation.

Patients with recurrent attacks may develop chronic neuropathic pain, although this has not been well characterized. Referral to a neurologist is recommended for any patient with ongoing or residual neurologic symptoms. In addition, depression and anxiety are common in these patients.
Treatment

Hemin

Intravenous (IV) hemin is the treatment of choice for most acute attacks of porphyria. There is a favorable biochemical and clinical response to early treatment with hemin, but less rapid clinical improvement if treatment is delayed. It is no longer recommended that therapy with hemin for a severe attack be started only after an unsuccessful trial of IV glucose for several days. Mild attacks without severe manifestations, such as paresis, seizures, hyponatremia, or pain requiring opioids, may be treated with IV glucose. After IV administration, hemin binds to hemopexin and albumin in plasma and is taken up primarily in hepatocytes, where it augments the regulatory heme pool in hepatocytes, represses the synthesis of hepatic ALAS1, and dramatically reduces porphyrin precursor overproduction.

Hemin* is available for IV administration in the United States as lyophilized hematin (Panhematin, Recordati). Degradation products begin to form as soon as the lyophilized product is reconstituted with sterile water, and these are responsible for phlebitis at the site of infusion and a transient anticoagulant effect. Loss of venous access due to phlebitis is common after repeated administration. Stabilization of lyophilized hematin by reconstitution with 30% human albumin can prevent these adverse effects; this is recommended especially if a peripheral vein is used for the infusion. Uncommon side effects of hemin include fever, aching, malaise, hemolysis, anaphylaxis, and circulatory collapse. Heme arginate, a more stable hemin preparation, is available in Europe and South Africa.

Hemin treatment should be instituted only after a diagnosis of acute porphyria has been initially confirmed by a marked increase in urinary PBG. When prior documentation of the diagnosis is available for review, it is not essential to confirm an increase in PBG with every recurrent attack, if other causes of the symptoms are excluded clinically. The standard regimen of hemin for treatment of acute porphyrnic attacks is 3-4 mg/kg/day for 4 days. Lower doses have less effect on porphyrin precursor excretion and probably less clinical benefit.

General and Supportive Measures

Drugs that may exacerbate porphyrias (see Table 110.3 ) should be discontinued whenever possible, and other precipitating factors identified. Hospitalization is warranted, except for mild attacks; for treatment of severe pain, nausea, and
vomiting; for administration of hemin and fluids; and for monitoring vital capacity, nutritional status, neurologic function, and electrolytes. Pain usually requires an opioid; there is low risk for addiction after recovery from the acute attack. Ondansetron or a phenothiazine such as chlorpromazine is needed for nausea, vomiting, anxiety, and restlessness. Low doses of short-acting benzodiazepines can be given for restlessness or insomnia. β-Adrenergic blocking agents may be useful during acute attacks to control tachycardia and hypertension but may be hazardous in patients with hypovolemia and incipient cardiac failure.

**Carbohydrate Loading**

The effects of carbohydrates on repressing hepatic ALAS1 and reducing porphyrin precursor excretion are weak compared to those of hemin. Therefore, carbohydrate loading is seldom beneficial except in mild attacks. Glucose polymer solutions by mouth are sometimes tolerated. At least 300 g of IV glucose, usually given as a 10% solution, has been recommended for adults hospitalized with attacks of porphyria. Amounts up to 500 g daily may be more effective, but large volumes may favor development of hyponatremia.

**Other Therapies**

Liver transplantation was effective in several patients with severe AIP. A group from the United Kingdom reported their experience with liver transplantation in 10 AIP patients with significantly impaired quality of life and recurrent attacks refractory to medical management. Patients had a complete biochemical and symptomatic resolution after transplantation; 2 patients succumbed to multiorgan failure. Liver transplantation was also successful in a U.S. patient with AIP and intractable symptoms who became unresponsive to hemin therapy; liver transplantation normalized porphyrin precursor excretion, and symptoms resolved. However, liver transplantation is a high-risk procedure and should be considered only as a last resort. Hepatocyte-targeted RNA interference (RNAi) therapy is being developed to reverse directly the extremely elevated hepatic ALAS1 mRNA in this disease. Preliminary results from clinical trials are promising.

**Seizures and Other Complications**

Seizures caused by hyponatremia or other electrolyte imbalances may not
require prolonged treatment with anticonvulsant drugs, most of which have at least some potential for exacerbating acute porphyrias. Bromides, gabapentin, and probably vigabatrin are safe. Clonazepam may be less harmful than phenytoin or barbiturates. Control of hypertension is important and may help prevent chronic renal impairment, which can progress and require renal transplantation.

**Safe and Unsafe Drugs**

Patients often do well with avoidance of harmful drugs. Table 110.3 lists some drugs known or strongly suspected to be harmful or safe in the acute porphyrias. More extensive listings are available from the European Porphyria Network (www.porphyria-europe.com) and American Porphyria Foundation (www.porphyriafoundation.com), but some listings are controversial. Information regarding safety is lacking for many drugs, especially for those recently introduced.

Exogenous progestins, usually in combination with estrogens, can induce attacks of porphyria. Estrogens are seldom reported to be harmful when given alone. Synthetic steroids with an ethynyl substituent can cause a mechanism-based destruction of hepatic CYPs and should probably be avoided in patients with acute porphyria. Danazol is especially contraindicated.

**Other Situations**

Major surgery can be carried out safely in patients with acute porphyria, especially if barbiturates are avoided. Halothane has been recommended as an inhalation agent and propofol and midazolam as IV induction agents. Pregnancy is usually well tolerated, which is surprising, because levels of progesterone, a potent inducer of hepatic ALAS1, are considerably increased during pregnancy. Some women do experience continuing attacks during pregnancy. This has sometimes been attributed to reduced caloric intake or metoclopramide, a drug sometimes used to treat hyperemesis gravidarum and considered harmful in acute porphyrias.

Diabetes mellitus and other endocrine conditions are not known to precipitate attacks of porphyria. In fact, the onset of diabetes mellitus and resulting high circulating glucose levels may decrease the frequency of attacks and lower porphyrin precursor levels in AIP.
Prognosis

The outlook for patients with acute porphyrias has improved greatly in the past several decades. In Finland, for example, 74% of patients with AIP or VP reported that they led normal lives, and <30% had recurrent attacks during several years of follow-up. In those presenting with acute symptoms, recurrent attacks were most likely within the next 1-3 yr. Moreover, only 6% of gene carriers who had never had attacks developed symptoms. The improved outlook may result from earlier detection, better treatment of acute attacks, and replacement of harmful drugs such as barbiturates and sulfonamides with safer drugs. However, some patients continue to have recurrent attacks, chronic pain, and other symptoms, even after avoiding known exacerbating factors.

Prevention

For prevention of attacks, it is important to identify multiple inciting factors and remove as many as possible. Drugs for concurrent medical conditions should be reviewed. Because dietary factors are often unapparent, consultation with a dietitian may be useful. A well-balanced diet that is somewhat high in carbohydrate (60–70% of total calories) and sufficient to maintain weight is recommended. There is little evidence that additional dietary carbohydrate helps further in preventing attacks, and it may lead to weight gain. Patients who wish to lose excess weight should do so gradually and when they are clinically stable. Rapid weight loss after bariatric surgery may exacerbate acute porphyrias. Iron deficiency, which can be detected by a low serum ferritin level, should be corrected.

*Gonadotropin-releasing hormone* (GnRH) analogs, which reversibly suppress ovulation, can be dramatically effective for preventing frequently recurring luteal phase attacks, but baseline and continuing gynecologic evaluation and bone mineral density measurements are important; transdermal estrogen or a bisphosphonate may be added to prevent bone loss. Hemin administered once or twice weekly can prevent frequent, noncyclic attacks of porphyria in some patients. Alternatively, single-dose hemin can be administered “on demand” at an outpatient infusion center to abort an attack and prevent hospitalization, if a patient can recognize early “prodromal” symptoms. Inpatient management is warranted, however, if advanced manifestations such as vomiting, paresis, or other neuropsychiatric symptoms have developed.
Genetic Counseling

A mutation identified in the index case can be sought in the child. Counseling should emphasize that the great majority of those who inherit a \textit{PBGD} mutation never develop symptoms, and the prognosis of those who do is favorable. Therefore a normal, healthy life is expected, especially with avoidance of harmful drugs and other factors and prompt recognition and treatment of symptoms should they occur. Given the favorable outlook for most mutation carriers, even during pregnancy, having children is not precluded, and prenatal diagnosis of acute porphyrias is less important than it is for many other inherited diseases.

Congenital Erythropoietic Porphyria

Also termed \textit{Günther disease}, this rare disease usually presents with photosensitivity shortly after birth or in utero as nonimmune hydrops.

Etiology

CEP is an autosomal recessive disease caused by a marked deficiency of uroporphyrinogen III synthase (UROS). Many \textit{UROS} mutations have been identified among CEP families. Later-onset disease in adults is likely to be associated with myeloproliferative disorders and expansion of a clone of erythroblasts that carry a \textit{UROS} mutation.

Pathology and Pathogenesis

UROS, which is extremely deficient in CEP, catalyzes inversion of pyrrole ring D of HMB and rapid cyclization of the linear tetrapyrrole to form uroporphyrinogen III. This enzyme is also termed \textit{uroporphyrinogen III cosynthase}. The human enzyme is a monomer. The gene for the enzyme is found on chromosome 10q25.3→q26.3 and contains 10 exons. Erythroid and housekeeping transcripts are generated by alternative promoters but encode the same enzyme.

In CEP, HMB accumulates in erythroid cells during hemoglobin synthesis and cyclizes nonenzymatically to form uroporphyrinogen I, which is auto-oxidized to uroporphyrin I. Some of the uroporphyrinogen I that accumulates is metabolized
to coproporphyrinogen I, which accumulates because it is not a substrate for coproporphyrinogen oxidase. Thus, both uroporphyrin I and coproporphyrin I accumulate in the bone marrow and are then found in circulating erythrocytes, plasma, urine, and feces.

A variety of UROS mutations have been identified in CEP, including missense and nonsense mutations, large and small deletions and insertions, splicing defects, and intronic branch point mutations. At least 4 mutations have been identified in the erythroid-specific promoter. Many patients inherited a different mutation from each parent, and most mutations have been detected in only one or a few families. An exception is a common mutation, C73R, which is at a mutational hot spot and was found in approximately 33% of alleles. One child with CEP had a GATA1 mutation, with no URO S mutation. The CEP phenotype may be modulated by gain of function ALAS2 mutations, which were first identified as causing XLP.

Genotype–phenotype correlations have been based on the in vitro expression of various CEP mutations and the severity of associated phenotypic manifestations. The C73R allele, which is associated with a severe phenotype in homozygotes or in patients heteroallelic for C73R and another mutation expressing little residual activity, resulted in <1% of normal enzyme activity. Patients with the C73R allele and heteroallelic for other mutations expressing more residual activity have milder disease.

Hemolysis is a common feature of CEP. Excess porphyrins in circulating erythrocytes cause cell damage, perhaps by a phototoxic mechanism, leading to both intravascular hemolysis and increased splenic clearance of erythrocytes. Also important is ineffective erythropoiesis, with intramedullary destruction of porphyrin-laden erythroid cells and breakdown of heme. Expansion of the bone marrow as a result of erythroid hyperplasia may contribute, along with vitamin D deficiency, to bone loss. Nutrient deficiencies sometimes cause erythroid hypoplasia. Despite the marked deficiency of UROS, heme production in the bone marrow is increased because of hemolysis and a compensatory increase in hemoglobin production. This occurs, however, at the expense of marked accumulation of HMB, which is converted to porphyrinogens and porphyrins.

**Clinical Manifestations**

In severe cases, CEP can cause fetal loss or may be recognized in utero as causing intrauterine hemolytic anemia and nonimmune hydrops fetalis. CEP
may be associated with neonatal hyperbilirubinemia, and phototherapy may unintentionally induce severe photosensitivity and scarring.

The most characteristic presentation is reddish urine or pink staining of diapers by urine or meconium shortly after birth (Fig. 110.2). With sun exposure, severe blistering lesions appear on exposed areas of skin on the face and hands and have been termed *hydroa estivale* because they are more severe with greater sunlight exposure during summer (Fig. 110.3). Vesicles and bullae, as well as friability, hypertrichosis, scarring, thickening, and areas of hypopigmentation and hyperpigmentation are very similar to those seen in PCT but usually much more severe. Infection and scarring sometimes cause loss of facial features and fingers and damage to the cornea, ears, and nails. Porphyrins are deposited in dentin and bone in utero. Reddish brown teeth in normal light, an appearance termed *erythrodontia*, display reddish fluorescence under long-wave UV light (Fig. 110.4). Unaffected children born to a mother with CEP may have erythrodontia. Hemolysis and splenomegaly are common in CEP. Bone marrow compensation may be adequate, especially in milder cases. Patients with severe phenotypes, however, are often transfusion dependent. Splenomegaly may contribute to the anemia and cause leukopenia and thrombocytopenia, which may be complicated by significant bleeding. Neuropathic symptoms are absent, and there is no sensitivity to drugs, hormones, or carbohydrate restriction. The liver may be damaged by iron overload or viral hepatitis acquired from blood transfusions.
FIG. 110.2  Congenital erythropoietic porphyria (CEP). The diaper of a baby with CEP demonstrates the red color of urine. (From Paller AS, Macini AJ: Hurwitz clinical pediatric dermatology, ed 3, Philadelphia, 2006, Elsevier Saunders, p 517.)

Milder cases of CEP with onset of symptoms in adult life and without erythrodontia may mimic PCT. These late-onset cases are likely to be associated with myeloproliferative disorders and expansion of a clone of cells carrying a UROS mutation.

**Laboratory Findings**

Urinary porphyrin excretion and circulating porphyrin levels in CEP are much higher than in almost all other porphyrias. Urinary porphyrin excretion can be as high as 50-100 mg daily and consists mostly of uroporphyrin I and coproporphyrin I. ALA and PBG are normal. Fecal porphyrins are greatly increased, with a predominance of coproporphyrin I.

Marked increases in erythrocyte porphyrins in CEP also consist mostly of uroporphyrin I and coproporphyrin I. These porphyrins are also increased in bone marrow, spleen, plasma, and to a lesser extent, liver. The porphyrin pattern in erythrocytes is influenced by rates of erythropoiesis and erythroid maturation. A predominance of protoporphyrin has been noted in some CEP patients, and in 1 such patient, uroporphyrin and coproporphyrin increased when erythropoiesis was stimulated by blood removal.

**Diagnosis and Differential Diagnosis**

The diagnosis of CEP should be documented by full characterization of porphyrin patterns and identification of the underlying mutations. In later-onset
cases, an underlying myeloproliferative disorder and a *UROS* somatic mutation should be suspected and studied in detail.

The clinical picture in hepatoerythropoietic porphyria (HEP) may be very similar, but the porphyrin patterns in urine and feces in HEP resemble PCT. A predominant increase in erythrocyte protoporphyrin is unusual in CEP but is characteristic of HEP as well as rare homozygous cases of AIP, HCP, and VP. EPP and XLP are also distinguished by normal urinary porphyrins and by increases in erythrocyte metal-free protoporphyrin, whereas the increased protoporphyrin in other conditions is mostly complexed with zinc.

CEP should be suspected as a cause of nonimmune hydrops or hemolytic anemia in utero. With recognition of the disease at this stage, intrauterine transfusion can be considered, avoiding severe, scarring photosensitivity from phototherapy for hyperbilirubinemia after birth. Prenatal diagnosis is feasible by finding red-brown discoloration and increased porphyrins in amniotic fluid and measuring porphyrins in fetal erythrocytes and plasma. *UROS* activity can be measured in cultured amniotic fluid cells, or *UROS* mutations identified in chorionic villi or cultured amniotic cells.

**Treatment**

Protection from sunlight exposure, minimizing skin trauma, and prompt treatment of any cutaneous infections are essential in managing CEP. Sunscreen lotions and beta-carotene are sometimes beneficial. Transfusions to achieve a level of hemoglobin sufficient to suppress erythropoiesis significantly can be quite effective in reducing porphyrin levels and photosensitivity. Concurrent deferoxamine to reduce iron overload and hydroxyurea to suppress erythropoiesis further may provide additional benefit. Splenectomy reduces hemolysis and transfusion requirements in some patients. Oral charcoal may increase fecal loss of porphyrins but may contribute little in more severe cases. IV hemin may be somewhat effective but has not been extensively studied and seems unlikely to provide long-term benefit.

The most effective treatment is marrow stem cell transplantation in early childhood, which has greatly reduced porphyrin levels and photosensitivity and increased long-term survival.

**Prognosis**
The outlook is favorable in milder cases and in patients with more severe disease, especially after successful bone marrow or stem cell transplantation. Otherwise, prognosis relates to adherence to sunlight avoidance.

**Prevention and Genetic Counseling**

Genetic counseling is important for affected families because CEP can be recognized before birth, and a severe phenotype can often be predicted by identifying the nature of the *UROS* mutations.

**Porphyria Cutanea Tarda**

Porphyria cutanea tarda is the most common and readily treated human porphyria (see Table 110.2 ). It occurs in mid or late adult life and is rare in children. Previous terms include *symptomatic porphyria, PCT symptomatica,* and *idiosyncratic porphyria.* The underlying cause is a liver-specific, acquired deficiency of uroporphyrinogen decarboxylase (*UROD*) with contributions by several types of genetic and acquired susceptibility factors, including heterozygous *UROD* mutations in familial PCT. HEP, the homozygous form of familial PCT, usually has a more severe presentation in childhood, resembling CEP clinically.

**Etiology**

PCT is caused by a reduction of hepatic *UROD* activity to ≤20% of normal activity. An inhibitor of hepatic *UROD* has been characterized as a *uroporphomethene,* which is derived from partial oxidation of the enzyme substrate uroporphyrinogen. CYPs, such as CYP1A2, as well as iron, are involved in its formation (Fig. 110.5 ). Although enzyme activity is inhibited, the amount of hepatic enzyme protein measured immunochemically remains at its genetically determined level.
UROD catalyzes the decarboxylation of the 4 acetic acid side chains of uroporphyrinogen (an octacarboxyl porphyrinogen) to form coproporphyrinogen (a tetracarboxyl porphyrinogen). The enzyme reaction occurs in a sequential, clockwise fashion, with the intermediate formation of hepta-, hexa-, and pentacarboxyl porphyrinogens. Uroporphyrinogen III, as compared with other uroporphyrinogen isomers, is the preferred substrate. Human UROD is a dimer with the 2 active site clefts juxtaposed. The UROD gene is on chromosome 1p34 and contains 10 exons, with only 1 promoter. Therefore the gene is transcribed as a single mRNA in all tissues.

The majority of PCT patients (80%) have no UROD mutations and have sporadic (type 1) disease. Some are heterozygous for UROD mutations and have familial (type 2) PCT. Described mutations include missense, nonsense, and splice-site mutations; several small and large deletions; and small insertions, with only a few identified in more than 1 family. A few of these mutations may be located near the active site cleft, but most appear to involve regions with important structural roles. Being heterozygous for a UROD mutation is insufficient to cause PCT. Individuals with type 2 PCT are born with 50% of normal UROD activity, and later in life other susceptibility factors (as in type 1) lead to production of the uroporphormethene inhibitor and further reduction on hepatic UROD activity to <20% of normal. Because penetrance of the genetic trait is low, many patients with familial PCT have no family history of the disease.
Induction of hepatic ALAS1 is not a prominent feature in PCT, although alcohol may increase this enzyme slightly. Iron and estrogens are not potent inducers of ALAS1, and drugs that are potent inducers of ALAS1 and CYPs are much less frequently implicated in PCT than in acute porphyrias.

Blistering skin lesions result from porphyrins that are released from the liver. Sunlight exposure leads to generation of reactive oxygen species (ROS) in the skin, complement activation, and lysosomal damage.

**Epidemiology**

Differences in prevalence probably relate to geographic variations in susceptibility factors such as hepatitis C and ethanol use. The yearly incidence in the United Kingdom was estimated at 2-5 in 1 million in the general population, and the prevalence in the United States and Czechoslovakia was estimated at 1 in 25,000 and 1 in 5,000 in the general population, respectively. The disease was reported to be prevalent in the Bantus of South Africa in association with iron overload. PCT is more common in males, possibly because of greater alcohol intake, and in women it is usually associated with estrogen use.

A massive outbreak of PCT occurred in eastern Turkey in the 1950s. Wheat intended for planting and treated with hexachlorobenzene as a fungicide was consumed by many at a time of food shortage. Cases and small outbreaks of PCT after exposure to other chemicals including di- and trichlorophenols and 2,3,7,8-tetrachlorodibenzo-p -dioxin (TCDD, dioxin) have been reported. The manifestations improved in most cases when the exposure was stopped. There are reported cases of delayed onset many years after chemical exposure.

**Pathology and Pathogenesis**

Porphyria cutanea tarda is classified into 3 clinically similar types. Generation of a UROD inhibitor in the liver plays an important role in all 3 types. The 80% of patients with type 1 (sporadic) PCT have no UROD mutations, and UROD activity is normal in nonhepatic tissues such as erythrocytes. In type 2 (familial) PCT, a heterozygous UROD mutation results in a partial (approximately 50%) deficiency of UROD in all tissues from birth, and the disease becomes active in some heterozygotes after further reduction of hepatic UROD activity to ≤20% of normal. HEP results from inheritance of a UROD mutation from each parent and typically causes severe photosensitivity resembling CEP starting in early
childhood. Some compound heterozygotes have developed symptoms in childhood more typical of PCT. **Type 3** is rare and describes PCT without a UROD mutation occurring in more than 1 family member. Another genetic basis, such as HFE mutations, may be identified in type 3.

CYPs, especially CYP1A2, can catalyze the oxidation of uroporphyrinogen to uroporphyrin. This uroporphyrinogen oxidase activity is enhanced by iron and leads to formation of a UROD inhibitor (see Fig. 110.5). CYP1a2 seems essential for development of uroporphyrinuria in rodents, because experimental uroporphyrinuria does not develop in CYP1a2 knockout mice.

**Susceptibility Factors**

The following factors are implicated in the development of PCT, and these occur in various combinations in individual patients.

**Iron**

A normal or increased amount of iron in the liver is essential for developing PCT, and treatment by phlebotomy to reduce hepatic iron leads to remission. Serum ferritin levels are usually in the upper part of the normal range or moderately increased, and liver histology commonly shows increased iron staining. Prevalence of the C282Y mutation of the HFE gene, which is the major cause of hemochromatosis in people of northern European ancestry, is increased in both type 1 and type 2 PCT, and approximately 10% of patients are C282Y homozygotes. In southern Europe the H63D mutation is more prevalent. PCT may develop in patients with secondary iron overload. Reduced hepatic expression of the hormone hepcidin occurs in hemochromatosis and also in PCT, regardless of HFE genotype, which may explain hepatic siderosis in this condition.

**Hepatitis C**

Hepatitis C virus (HCV) infection is highly prevalent in PCT in most geographic locations; in the United States, for example, HCV is present in 56–74% of cases, which is similar to rates in southern Europe. Prevalence of hepatitis C in PCT is lower in northern Europe (<20%). Steatosis and oxidative stress in HCV infection may favor iron-mediated generation of ROS and a UROD inhibitor. Dysregulation of hepcidin occurs in hepatitis C and may lead to increased iron absorption.
Human Immunodeficiency Virus

Many reports suggest that HIV infection can contribute to the development of PCT, although less frequently than HCV.

Ethanol

The long-recognized association between alcohol and PCT may be explained by the generation of ROS, which may cause oxidative damage, mitochondrial injury, depletion of reduced glutathione and other antioxidant defenses, increased production of endotoxin, and activation of Kupffer cells. Also, alcohol may contribute to iron overload by impairing hepcidin production.

Smoking and Cytochrome P450 Enzymes

Smoking has not been extensively studied as a susceptibility factor but is often associated with alcohol use in PCT. It may act to induce hepatic CYPs and oxidative stress. Hepatic CYPs are thought to be important in oxidizing uroporphyrinogen and generating a UROD inhibitor (see Fig. 110.5). Genetic polymorphisms of CYP1A2 and CYP1A1 have been implicated in human PCT. The frequency of an inducible CYP1A2 genotype was more common in PCT patients than in controls in several studies.

Antioxidant Status

Ascorbic acid deficiency contributes to uroporphyrina in laboratory models and perhaps in human PCT. In one series, plasma ascorbate levels were substantially reduced in 84% of patients with PCT. Low levels of serum carotenoids were also described, further suggesting that oxidant stress in hepatocytes is important in PCT.

Estrogens

Use of estrogen-containing oral contraceptives (OCs) or postmenopausal estrogen replacement therapy is frequently associated with PCT (type 1 or 2) in women. PCT sometimes occurs during pregnancy, although it is not clear whether the risk is increased.

Clinical Manifestations
**Cutaneous Manifestations**

PCT is readily recognized by blistering and crusted skin lesions on the backs of the hands, which are the most sun-exposed areas of the body, and somewhat less often on the forearms, face, ears, neck, legs, and feet (Fig. 110.6). The fluid-filled vesicles usually rupture and become crusted or denuded areas, heal slowly, and are subject to infection. The skin on the backs of the hands is characteristically friable, and minor trauma may cause blisters or denudation of skin. Small white plaques, termed *milia*, may precede or follow vesicle formation. Facial hypertrichosis and hyperpigmentation are also common. Severe scarring and thickening of sun-exposed skin may resemble scleroderma. Skin biopsy findings include subepidermal blistering and deposition of periodic acid–Schiff-(PAS)–positive material around blood vessels and fine fibrillar material at the dermoepithelial junction, which may be related to excessive skin fragility. IgG, other immunoglobulins, and complement are also deposited at the dermoepithelial junction and around dermal blood vessels. The skin lesions and histologic changes are not specific for PCT. The same findings occur in VP and HCP and resemble those of CEP and HEP, but are usually less severe. PCT usually develops in mid or late adult life. Onset in early adult life may be seen in those with *UROD* or *HFE* mutations. Childhood onset is rare and may be associated with cancer chemotherapy and *UROD* mutations.

*FIG. 110.6  Porphyria cutanea tarda (PCT). A, Right hand of a patient with PCT, revealing numerous erosions and erythematous patches. B, Close-up of right hand. (From Horner*
Liver Abnormalities

PCT is almost always associated with nonspecific liver abnormalities, especially increased serum transaminases and γ-glutamyltranspeptidase, even in the absence of heavy alcohol intake or hepatitis C. Most histologic findings, such as necrosis, inflammation, increased iron, and increased fat, are nonspecific. Specific findings include red fluorescence of liver tissue, and fluorescent, birefringent, needle-like inclusions presumably consisting of porphyrins. Electron microscopy shows these inclusions are in lysosomes, and paracrystalline inclusions are found in mitochondria. Distorted lobular architecture and cirrhosis are more common with long-standing disease.

The risk of developing hepatocellular carcinoma is increased, with reported incidences ranging from 4–47% in PCT. These tumors seldom contain large amounts of porphyrins.

Other Features and Associations

Mild or moderate erythrocytosis in some adult patients is not well understood, but chronic lung disease from smoking may contribute. An earlier onset of symptoms may be noted in patients with genetic predisposing factors, such as an inherited partial deficiency of UROD or the C282Y/C282Y HFE genotype. Iron overload secondary to conditions such as myelofibrosis and end-stage renal disease (ESRD) may be associated with PCT. The disease can be especially severe in patients with ESRD because the lack of urinary excretion leads to much higher concentrations of porphyrins in plasma, and the excess porphyrins are poorly dialyzable. PCT occurs more frequently in patients with systemic lupus erythematosus and other immunologic disorders than would be expected by chance.

Laboratory Findings

Porphyrins accumulate in the liver mostly as the oxidized porphyrins rather than porphyrinogens in PCT, as indicated by the immediate red fluorescence observed in liver tissue. This develops over weeks or months before porphyrins appear in plasma and are transported to the skin, causing photosensitivity. In contrast to
the acute hepatic porphyrias, only a very small increase in synthesis of heme pathway intermediates and little or no increase in hepatic ALAS1 are required to account for the excess porphyrins excreted in PCT.

Hepatic UROD deficiency leads to a complex pattern of excess porphyrins, which initially accumulate as porphyrinogens and then undergo nonenzymatic oxidation to the corresponding porphyrins (uro-, hepta-, hexa-, and pentacarboxyl porphyrins, and isocoproporphyrins). Uroporphyrin and heptacarboxyl porphyrin predominate in urine, with lesser amounts of coproporphyrin and penta- and hexacarboxyl porphyrin. A normally minor pathway is accentuated by UROD deficiency, whereby pentacarboxyl porphyrinogen is oxidized by coproporphyrinogen oxidase (CPOX; the next enzyme in the pathway), forming isocoproporphyrinogen, an atypical tetracarboxyl porphyrinogen. Relative to normal values, urinary porphyrins are increased to a greater extent than fecal porphyrins. However, the total amount of porphyrins excreted in feces in PCT exceeds that in urine, and total excretion of type III isomers (including isocoproporphyrins, which are mostly derived from the type III series) exceeds that of type I isomers. Perhaps because uroporphyrinogen III is the preferred substrate for UROD, more uroporphyrinogen I than III accumulates and is excreted as uroporphyrin I in PCT. Hepta- and hexacarboxyl porphyrin are mostly isomer III; and pentacarboxyl porphyrin and coproporphyrin are approximately equal mixtures of isomers I and III.

### Diagnosis and Differential Diagnosis

Plasma porphyrins are always increased in clinically manifest PCT, and a total plasma porphyrin determination is useful for screening. A normal value rules out PCT and other porphyrias that produce blistering skin lesions. If increased, it is useful to determine the plasma fluorescence emission maximum at neutral pH, because a maximum near 619 nm is characteristic of PCT (as well as CEP and HCP) and importantly, excludes VP, which has a distinctly different fluorescence maximum. Increased urinary or plasma porphyrins, with a predominance of uroporphyrin and heptacarboxyl porphyrin, is confirmatory. Urine porphyrins are less useful for initial screening because nonspecific increases, especially of coproporphyrin, occur in liver disease and other medical conditions. Urinary ALA may be increased slightly, and PBG is normal. Mild cases of CEP can mimic PCT clinically, and this possibility is ruled out by finding normal or only
mildly increased levels of erythrocyte porphyrins.

Familial (type 2) can be distinguished from sporadic (type 1) PCT by finding decreased erythrocyte UROD activity (in type 2), or more reliably by finding a disease-related UROD mutation. Type 3 is distinguished from type 1 only by occurrence of PCT in a relative. Biochemical findings in HEP are similar to those in PCT, but with an additional marked increase in erythrocyte zinc protoporphyrin.

**Pseudoporphyria** (also known as pseudo-PCT) presents with skin lesions that closely resemble PCT, but without significant increases in plasma porphyrins. A photosensitizing agent such as a nonsteroidal antiinflammatory drug (NSAID) is sometimes implicated. Both PCT and pseudoporphyria may occur in patients with ESRD.

**Complications**

Cutaneous blisters may rupture and become infected, sometimes leading to cellulitis. In more-severe disease in patients with ESRD, repeated infections can be mutilating, as in CEP. **Pseudoscleroderma**, with scarring, contraction, and calcification of skin and subcutaneous tissue, is a rare complication. Other complications include advanced liver disease and hepatocellular carcinoma.

**Treatment**

Two specific and effective forms of treatment, phlebotomy and low-dose hydroxychloroquine, are available. Susceptibility factors should be removed when possible. The diagnosis of PCT must be firmly established because conditions that produce identical cutaneous lesions do not respond to these treatments. Treatment can usually be started after demonstrating an increase in plasma total porphyrins and excluding VP by analysis of the fluorescence spectrum at neutral pH, while urine and fecal studies are still pending. Use of alcohol, estrogens (in women), and smoking should be stopped and patients tested for HCV, HIV, and HFE mutations. Susceptibility factors and degree of iron overload, as assessed by the serum ferritin concentration, can influence the choice of treatment.

**Phlebotomy** is considered standard therapy and is effective in both children and adults with PCT because it reduces hepatic iron content. Treatment is guided by plasma (or serum) ferritin and porphyrin levels. Hemoglobin or hematocrit
levels should be followed to prevent symptomatic anemia. For adults, a unit of blood (450 mL) is removed at about 2 wk intervals until a target serum ferritin near the lower limit of normal (15 ng/mL) is achieved. A total of 6-8 phlebotomies is often sufficient in adults. After this, plasma porphyrin concentrations continue to fall from pretreatment levels (generally 10-25 µg/dL) to below the upper limit of normal (1 µg/dL), usually after several more weeks. This is followed by gradual clearing of skin lesions, sometimes including pseudoscleroderma. Liver function abnormalities may improve, and hepatic siderosis, needle-like inclusions, and red fluorescence of liver tissue will disappear. Although remission usually persists even if ferritin levels later return to normal, it is advisable to follow porphyrin levels and reinstitute phlebotomies if porphyrins begin to increase. Infusions of deferoxamine, an iron chelator, may be used when phlebotomy is contraindicated.

An alternative when phlebotomy is contraindicated or poorly tolerated is a low-dose regimen of hydroxychloroquine (or chloroquine). Normal doses of these 4-aminoquinoline antimalarials in PCT increase plasma and urinary porphyrin levels and increase photosensitivity, reflecting an outpouring of porphyrins from the liver. This is accompanied by acute hepatocellular damage, with fever, malaise, nausea, and increased serum transaminases, but is followed by complete remission of the porphyria. These adverse consequences of normal doses are largely avoided by a low-dose regimen (for adults, hydroxychloroquine 100 mg or chloroquine 125 mg, i.e., half a normal tablet, twice weekly), which can be continued until plasma or urine porphyrins are normalized. In young children, half the adult dose is recommended. There is at least some risk of retinopathy, which may be lower with hydroxychloroquine. The mechanism of action of 4-aminoquinolines in PCT is not known but is quite specific, because these drugs are not useful in other porphyrias. Recent studies indicate that low-dose hydroxychloroquine is as safe and effective as phlebotomy in adults with PCT.

In patients with PCT and hepatitis C, PCT should be treated first because this condition is more symptomatic and can be treated more quickly and effectively. Treatment of PCT by phlebotomy may not be possible once interferon-ribavirin treatment is complicated by anemia. Moreover, treatment of hepatitis C may be more effective after iron reduction. Whether direct-acting antiviral agents should be used initially for treating both hepatitis C and PCT is under investigation.

PCT in patients with ESRD is often more severe and difficult to treat. However, erythropoietin administration can correct anemia, mobilize iron, and
support phlebotomy in many cases. Improvement after renal transplantation may be partly from resumption of endogenous erythropoietic production.

Liver imaging and a serum α-fetoprotein determination may be advisable in all PCT patients, perhaps at 6-12 mo intervals, for early detection of hepatocellular carcinoma. Finding low-erythrocyte UROD activity or a UROD mutation identifies those with an underlying genetic predisposition, which does not alter treatment but is useful for genetic counseling.

**Prognosis**

Porphyria cutanea tarda is the most readily treated form of porphyria, and complete remission is expected with treatment either by phlebotomy or low-dose hydroxychloroquine. There is little information on rates of recurrence and long-term outlook. Risk for hepatocellular carcinoma is increased, and some susceptibility factors such as hepatitis C can lead to complications even after PCT is in remission.

**Prevention and Genetic Counseling**

A heritable UROD mutation can usually be detected or excluded by measuring erythrocyte UROD activity, although DNA studies are more sensitive. Relatives of patients with UROD mutations have an increased risk for developing PCT and may have increased motivation to avoid adverse behaviors such as ethanol and tobacco use and exposures to HCV and HIV (although such counseling would be given to anyone). The finding of HFE mutations, and especially C282Y, should prompt screening of relatives, some of whom may be C282Y homozygotes and warrant lifelong monitoring of serum ferritin.

**Hepatoerythropoietic Porphyria**

HEP is the homozygous form of familial (type 2) PCT; it resembles CEP clinically. Excess porphyrins originate mostly from liver, with a pattern consistent with severe UROD deficiency. This rare disorder has no particular racial predominance.

**Etiology**
HEP is an autosomal recessive disorder, and most patients have inherited a different mutation from unrelated parents. In contrast to most mutations in familial PCT, most causing HEP are associated with expression of some residual enzyme activity. At least 1 genotype is associated with the predominant excretion of pentacarboxyl porphyrin.

Pathology and Pathogenesis
Excess porphyrins originate primarily from the liver in HEP, although the substantial increase in erythrocyte zinc protoporphyrin indicates that the heme biosynthetic pathway is also impaired in bone marrow erythroid cells. Apparently, porphyrinogens accumulate in the marrow while hemoglobin synthesis is most active and are metabolized to protoporphyrin after hemoglobin synthesis is complete. The cutaneous lesions are a result of photoactivation of porphyrins in skin, as in other cutaneous porphyrias.

Clinical Manifestations
As in CEP, this disease usually presents with blistering skin lesions, hypertrichosis, scarring, and red urine in infancy or childhood. Sclerodermoid skin changes are sometimes prominent. Unusually mild cases have been described. Concurrent conditions that affect liver function can alter disease severity; the disease manifested because of hepatitis A in a 2 yr old child and then improved with recovery of liver function.

Laboratory Findings
Biochemical findings resemble those in PCT, with accumulation and excretion of uroporphyrin, heptacarboxyl porphyrin, and isocoproporphyrin. In addition, erythrocyte zinc protoporphyrin is substantially increased.

Diagnosis and Differential Diagnosis
HEP is distinguished from CEP by increases in both uroporphyrin and heptacarboxyl porphyrin, and isocoproporphyrins. In CEP, the excess erythrocyte porphyrins are predominantly uroporphyrin I and coproporphyrin I rather than protoporphyrin. Blistering skin lesions are unusual in EPP, the excess erythrocyte protoporphyrin in that disease is metal free and not complexed with
zinc, and urinary porphyrins are normal.

**Treatment and Prognosis**

Avoiding sunlight exposure is most important in managing HEP, as in CEP. Oral charcoal was helpful in a severe case associated with dyserythropoiesis. Phlebotomy has shown little or no benefit. The outlook depends on the severity of the enzyme deficiency and may be favorable if sunlight can be avoided.

**Prevention and Genetic Counseling**

As part of genetic counseling in affected families, it is feasible to diagnose HEP in utero, either by analysis of porphyrins in amniotic fluid or DNA studies.

**Hereditary Coproporphyria**

This autosomal dominant hepatic porphyria is caused by a deficiency of coproporphyrinogen oxidase (CPOX). The disease presents with acute attacks, as in AIP. Cutaneous photosensitivity may occur, but much less often than in VP. Rare homozygous cases present in childhood.

**Etiology**

A partial (50%) deficiency in CPOX activity has been found in all cells studied from patients with HCP. A much more profound deficiency is found in homozygous cases. Human CPOX is a homodimer composed of 39 kDa subunits and contains no metals or prosthetic groups. The enzyme requires molecular oxygen and is localized in the mitochondrial intermembrane space. A single active site on the enzyme catalyzes the oxidative decarboxylation of 2 of the 4 propionic acid groups of coproporphyrinogen III to form the 2 vinyl groups at positions 2 and 4, on rings A and B, respectively, of protoporphyrinogen IX. Most of the intermediate tricarboxyl porphyrinogen, termed harderoporphyrinogen, is not released before undergoing the 2nd decarboxylation to protoporphyrinogen IX. Coproporphyrinogen I is not a substrate for this enzyme.

The human CPOX gene contains 7 exons and is located on chromosome 3q12.1. A single promoter contains elements for both housekeeping and
erythroid-specific expression. A variety of CPOX mutations have been described in HCP, with a predominance of missense mutations and no genotype-phenotype correlations. **Harderoporphyria**, an autosomal recessive biochemical variant form of HCP, is caused by CPOX mutations that impair substrate binding, leading to premature release of harderoporphyrinogen.

**Epidemiology**

HCP is less common than AIP and VP, but its prevalence has not been carefully estimated. There is no obvious racial predominance. Homozygous HCP is rare and presents during childhood. Harderoporphyria, a biochemically distinguishable variant of HCP, has been recognized in heteroallelic and homoallelic forms.

**Pathology and Pathogenesis**

Increased ALA and PBG during acute attacks of HCP may be explained by induction of ALAS1 and by the normally relatively low activity of PBGD in the liver. Hepatic ALAS1 is increased during acute attacks but is normal when the disease is latent and porphyrin precursor excretion is normal. Because coproporphyrinogen III concentration in the liver is probably less than the $K_m$ for CPOX, the reaction rate is likely to be determined in part by substrate concentration. The substrate coproporphyrinogen appears to be lost more readily from the liver cell than, for example, uroporphyrinogen, especially when heme synthesis is stimulated. Coproporphyrin and coproporphyrinogen are both transported into bile and excreted in urine, and do not appear to accumulate in the liver in HCP.

**Clinical Manifestations**

Symptoms are identical to those of AIP except that attacks are generally milder, and cutaneous lesions that resemble those in PCT develop occasionally. Severe motor neuropathy and respiratory paralysis can occur. As in other acute porphyrias, HCP is almost always latent before puberty, and symptoms are most common in adult women. Attacks are precipitated by the same factors that cause attacks in AIP, including fasting, OCs, and hormone increases during the luteal phase of the menstrual cycle. Concomitant liver diseases may increase porphyrin
retention and photosensitivity. The risk of hepatocellular carcinoma is increased, as in other acute porphyrias.

The clinical features of homozygous HCP or harderoporphyria begin in early childhood and include jaundice, hemolytic anemia, hepatosplenomegaly, and skin photosensitivity. These symptoms are generally quite distinct from those seen in heterozygotes. Hematologic features are particularly characteristic in harderoporphyria.

Laboratory Findings

The porphyrin precursors ALA and PBG are increased during acute attacks in HCP but may decrease more rapidly than in AIP. Marked increases in coproporphyrin III in urine and feces are more persistent in HCP. In homozygous cases, porphyrin excretion may be more increased and is accompanied by substantial increases in erythrocyte zinc protoporphyrin. Harderoporphyria is characterized by a marked increase in fecal excretion of harderoporphyrin (tricarboxyl porphyrin) as well as coproporphyrin. Plasma porphyrins are usually normal or only slightly increased.

Diagnosis and Differential Diagnosis

The diagnosis of HCP is readily established in patients with clinically manifest disease, although urinary ALA, PBG, and uroporphyrin may revert to normal more quickly than in AIP. Urinary coproporphyrin III is increased. Urinary porphyrins, especially coproporphyrin, can be increased in many medical conditions (e.g., liver disease), and small increases that are not diagnostically significant may lead to an incorrect diagnosis of HCP. Fecal porphyrins are mostly coproporphyrin (isomer III) in HCP, whereas in VP, coproporphyrin III and protoporphyrin are often increased approximately equally. Plasma porphyrins are usually normal in HCP and increased in VP.

The ratio of fecal coproporphyrin III to coproporphyrin I is especially sensitive for detecting latent heterozygotes (especially adults). Assays for CPOX, a mitochondrial enzyme, require cells such as lymphocytes and are not widely available. Identification of a CPOX mutation in an index case greatly facilitates screening family members.

Treatment and Prognosis
Acute attacks of HCP are treated as in AIP, which includes IV hemin and identifying and avoiding precipitating factors. Cholestyramine may be of some value for photosensitivity occurring with liver dysfunction. Phlebotomy and chloroquine are not effective. GnRH hormone analogs can be effective for prevention of cyclic attacks. The prognosis is generally better than in AIP.

Prevention and genetic counseling are the same as in other acute porphyrias.

**Variegate Porphyria**

This hepatic porphyria is caused by a deficiency of protoporphyrinogen oxidase (PPOX), which is inherited as an autosomal dominant trait. The disorder is termed **variegate** because it can present with neurologic or cutaneous manifestations, or both. Other terms have included *porphyria variegata, protocoproporphyria,* and *South African genetic porphyria.* Rare cases of homozygous VP are symptomatic in childhood.

**Etiology**

PPOX is approximately half normal in all cells studied in patients with VP. The enzyme is more markedly deficient in rare cases of homozygous VP, with approximately half-normal enzyme activity in parents.

Human PPOX is a homodimer that contains flavin adenine dinucleotide and is localized to the cytosolic side of the inner mitochondrial membrane. Membrane-binding domains may be docked onto human FECH, the next enzyme in the pathway, which is embedded in the opposite side of the membrane. PPOX catalyzes the oxidation of protoporphyrinogen IX to protoporphyrin IX by the removal of 6 hydrogen atoms. The enzyme requires molecular oxygen. The substrate is readily oxidized nonenzymatically to protoporphyrin under aerobic conditions, or if exported into the cytosol. PPOX is highly specific for protoporphyrinogen IX and is inhibited by tetrapyrroles such as heme, biliverdin, and bilirubin and by certain herbicides that cause protoporphyrin to accumulate and induce phototoxicity in plants. Inhibition by bilirubin may account for decreased PPOX activity in Gilbert disease.

The human *PPOX* gene on chromosome 1q22-q23 consists of 1 noncoding and 12 coding exons. A single PPOX transcript is produced in a variety of tissues, but putative transcriptional element binding sequences may allow for erythroid-specific expression. Many *PPOX* mutations have been reported in VP.
families. A missense mutation, R59W, is prevalent in South Africa. No convincing genotype-phenotype correlations have been identified. Mutations in homozygous cases of VP are more likely to encode enzyme proteins with residual activity.

Epidemiology

VP is less common than AIP in most countries. The R59W mutation is highly prevalent in South African whites (3 in 1,000 in this population). This example of “genetic drift” or founder effect has been traced to a man or his wife who emigrated from Holland to South Africa in 1688. In Finland, prevalence is 1.3 in 100,000 people and is about as common as AIP.

Pathology and Pathogenesis

Acute attacks develop in a minority (approximately 25%) of heterozygotes for PPOX deficiency and are often attributable to drugs, steroids, and nutritional factors that play a role in other acute porphyrias. Protoporphyrinogen IX accumulates and undergoes autoxidation to protoporphyrin IX. Coproporphyrinogen III accumulates, perhaps as the result of a close functional association between PPOX in the inner mitochondrial membrane and CPOX in the intermembrane space. Liver porphyrin content is not increased. The increased porphyrin content in plasma consists of porphyrin-peptide conjugates, which may be formed from protoporphyrinogen. Increased ALA and PBG during acute attacks may be explained, as in HCP, by induction of ALAS1 by exacerbating factors, and by the normally relatively low activity of PBGD in liver. Furthermore, PBGD is inhibited by protoporphyrinogen, the substrate for PPOX.

Clinical Manifestations

Symptoms develop in some heterozygotes after puberty. Neurovisceral symptoms occurring as acute attacks are identical to AIP but are generally milder and less often fatal. Drugs, steroids, and nutritional alterations such as fasting, which are harmful in AIP, can also induce attacks of VP. Attacks occur equally in males and females, at least in South Africa. Cutaneous fragility, vesicles, bullae, hyperpigmentation, and hypertrichosis of sun-exposed areas are much
more common than in HCP. They are likely to occur apart from and to be longer lasting than the neurovisceral symptoms. OCs can precipitate cutaneous manifestations. Acute attacks have become less common, and skin manifestations are more frequently the initial presentation; this may result from earlier diagnosis and counseling. The risk of hepatocellular carcinoma is increased.

Symptoms of homozygous VP begin in infancy or childhood. These children generally have severe photosensitivity, neurologic symptoms, seizures, developmental disturbances, and sometimes growth retardation, but they do not have acute attacks.

**Laboratory Findings**

Urinary ALA, PBG, and uroporphyrin are increased during acute attacks, but often less so than in AIP, and may be normal or only slightly increased during remission. Plasma porphyrins, urinary coproporphyrin III, and fecal coproporphyrin III and protoporphyrin are more persistently increased between attacks. Erythrocyte zinc protoporphyrin levels are greatly increased in homozygous VP and may be modestly increased in heterozygous cases.

**Diagnosis and Differential Diagnosis**

VP is readily distinguished biochemically from AIP and HCP, which also present with acute attacks and increases in PBG. Plasma porphyrin analysis is especially useful because the plasma porphyrins in VP are tightly protein bound, resulting in a characteristic fluorescence emission spectrum at neutral pH. Fecal porphyrins are increased, with approximately equal amounts of coproporphyrin III and protoporphyrin. Fluorometric detection of plasma porphyrins is more sensitive than stool porphyrin analysis in asymptomatic VP. PPOX assays using cells that contain mitochondria, such as lymphocytes, are sensitive for identifying asymptomatic carriers but are not widely available. Knowing the PPOX mutation in an index case enables the identification of relatives who carry the same mutation.

**Treatment**

Acute attacks are treated as in AIP. Hemin is beneficial for acute attacks but not
for cutaneous symptoms. Light protection is important in patients with skin manifestations, using long-sleeved clothing, gloves, a broad-brimmed hat, and opaque sunscreen preparations. Exposure to short-wavelength UV light, which does not excite porphyrins, may increase skin pigmentation and provide some protection. Phlebotomy and chloroquine are not effective. Surprisingly, oral activated charcoal was reported to increase porphyrin levels and worsen skin manifestations.

**Prognosis and Prevention**

The outlook of patients with VP has improved, which may be attributed to improved treatment, earlier diagnosis, and detection of latent cases. Cyclic acute attacks in women can be prevented with a GnRH analog, as in AIP. A diagnosis of VP or any other acute porphyria should not lead to difficulty obtaining insurance, because the prognosis is usually good once the diagnosis is established.

Genetic counseling is the same as in other acute porphyrias.

**Erythropoietic Protoporphyria and X-Linked Protoporphyria**

These forms of protoporphyria are genetically distinct but have essentially the same phenotype. In EPP, an autosomal recessive disorder, protoporphyrin accumulates as the result of a marked deficiency of FECH, the last enzyme in the heme biosynthetic pathway, because of FECH mutations. EPP is sometimes termed *erythrohepatic protoporphyria*, although the liver does not contribute substantially to production of excess protoporphyrin in uncomplicated cases. XLP is the most recently described porphyria, in which gain-of-function *ALAS2* mutations leads to overproduction of ALA in the marrow, where it is metabolized to excess amounts of protoporphyrin.

**Etiology**

Ferrochelatase (FECH), the enzyme that is deficient in EPP, catalyzes the final step in heme synthesis, which is insertion of ferrous iron ($\text{Fe}^{2+}$) into protoporphyrin IX (see Fig. 110.1). The enzyme is also termed *heme synthetase*.
or *protoheme ferrolyase*. The human enzyme is a dimer, and each homodimer contains a [2Fe-2S] cluster, which may have a role in bridging homodimers. FECH is found in the mitochondrial inner membrane, where its active site faces the mitochondrial matrix. It may be associated with complex I of the mitochondrial electron transport chain, and the ferrous iron substrate may be produced on nicotinamide adenine dinucleotide oxidation. FECH is specific for the reduced form of iron but can utilize other metals, such as Zn$^{2+}$ and Co$^{2+}$, and other dicarboxyl porphyrins. Accumulation of free protoporphyrin rather than zinc protoporphyrin in EPP indicates that formation of the latter is dependent on FECH activity in vivo.

The human *FECH* gene is located on chromosome 18q21.3, has a single promoter sequence, and contains 11 exons. Two mRNAs of 1.6 and 2.5 kb were described, which may be explained by the use of 2 alternative polyadenylation signals. The larger transcript is more abundant in murine erythroid cells, suggesting erythroid-specific regulation of FECH. A variety of *FECH* mutations have been reported in EPP, including missense, nonsense, and splicing mutations; small and large deletions; and an insertion.

The inheritance of 2 alleles associated with reduced FECH activity is required for disease expression. This is consistent with FECH activities as low as 15–25% of normal in EPP patients. In most patients, a pathogenic mutation on 1 *FECH* allele is combined with a common variant affecting the other allele. This common variant *FECH* allele (IVS3-48T>C) produces less-than-normal amounts of enzyme because it expresses an aberrantly spliced mRNA that is degraded by a nonsense-mediated RNA decay mechanism. The IVS3-48T > C *FECH* variant by itself does not cause disease, even when homozygous. In a few families, 2 severe *FECH* mutations have been found, without the IVS3-48T>C allele.

EPP with autosomal recessive inheritance occurs naturally in cattle and in mouse models.

XLP is associated with gain-of-function deletions in the last exon of *ALAS2*. These lesions delete the last 10-20 amino acids of the ALAS2 polypeptide and apparently make the enzyme more stable. Metal-free protoporphyrin predominates in erythrocytes in these cases, but because FECH activity is normal, the proportion of zinc protoporphyrin is greater than in classic EPP. XLP accounts for approximately 2% of cases with the EPP phenotype in Europe and approximately 10% of cases in North America.

EPP is sometimes associated with myelodysplastic syndromes and expansion of a clone of hematopoietic cells with deletion of 1 *FECH* allele or with other
FECH mutations. In such cases there is late onset of the disease.

Epidemiology

EPP is the most common porphyria to cause symptoms in children but is often not diagnosed until adult life. Overall it is the 3rd most common porphyria, although its prevalence is not precisely known (see Table 110.2). It is described mostly in white people but occurs in other races. The IVS3-48T>C splice variant is common in whites and Japanese but rare in Africans, which explains lower disease prevalence in populations of African origin.

Pathology and Pathogenesis

FECH is deficient in all tissues in EPP, but bone marrow reticulocytes are thought to be the primary source of the excess protoporphyrin, some of which enters plasma and circulates to the skin. Circulating erythrocytes are no longer synthesizing heme and hemoglobin, but they contain excess free protoporphyrin, which also contributes. In XLP caused by terminal deletions in exon 11 of ALAS2, all intermediates of the heme pathway are overproduced and ultimately accumulate in bone marrow erythroblasts as protoporphyrin. FECH is not deficient in XLP, so this enzyme chelates some of the excess protoporphyrin with zinc. An aberrantly spliced mitoferrin transcript, which limits iron transport into mitochondria, has also been described in XLP. The liver functions as an excretory organ rather than a major source for excess protoporphyrin. FECH deficiency in the skin and liver may be important, however, because tissue transplantation studies in mice suggest that skin photosensitivity and liver damage occur only when FECH is deficient in these tissues.

Patients with EPP and XLP are maximally sensitive to light in the 400 nm range, which corresponds to the so-called Soret band, the narrow peak absorption maximum that is characteristic for protoporphyrin and other porphyrins. Having absorbed light, porphyrins enter an excited energy state and release energy as fluorescence, singlet oxygen, and other ROS. Resulting tissue damage is accompanied by lipid peroxidation, oxidation of amino acids, cross linking of proteins in cell membranes, and damage to capillary endothelial cells. Such damage may be mediated by photoactivation of the complement system and release of histamine, kinins, and chemotactic factors. Repeated acute damage leads to thickening of the vessel walls and perivascular deposits from
accumulation of serum components. Deposition of amorphous material containing immunoglobulin, complement components, glycoproteins, acid glycosaminoglycans, and lipids occurs around blood vessels in the upper dermis. There is little evidence for impaired erythropoiesis or hemolysis in EPP. However, mild anemia with microcytosis, hypochromia, and reticulocytosis is common. Iron accumulation in erythroblasts and ring sideroblasts has been noted in bone marrow in some patients. Decreased transferrin saturation and low or low-normal serum ferritin suggest iron deficiency. Iron status should be carefully evaluated in EPP patients, keeping in mind that iron deficiency may lead to further increases in protoporphyrin and increase the risk for cholestasis. Poor response to oral iron supplements is described in EPP and is unexplained. Some patients report increased photosensitivity when given iron supplements, but whether this is from transient increases in porphyrins when iron deficiency is corrected and erythropoiesis increases is not known. Case reports suggest that iron supplementation decreases protoporphyrin and improves anemia, especially in patients with XLP.

Liver damage develops in a small proportion of EPP and XLP patients and is attributed to excess protoporphyrin, which is insoluble in water and excreted only by hepatic uptake, and biliary excretion is cholestatic. Some may be reabsorbed by the intestine and undergo enterohepatic circulation. With cholestasis the excess protoporphyrin that accumulates in the liver can form crystalline structures in hepatocytes and impair mitochondrial function.

**Clinical Manifestations**

Symptoms of cutaneous photosensitivity begin in childhood and consist of acute pain and itching often occurring within minutes of sunlight exposure and followed by redness and swelling with continued exposure (Fig. 110.7). Petechiae and purpuric lesions may be seen, but blisters are rare. Swelling may resemble angioneurotic edema and *solar urticaria*. Symptoms are usually worse in the spring and summer. Chronic changes may include lichenification, leathery pseudovesicles, labial grooving, and nail changes, but changes in pigmentation and pronounced scarring are unusual. Although physical findings in EPP and XLP may not be impressive, the symptoms significantly impair quality of life to a greater extent than in PCT or VP. An association between EPP caused by mutations affecting both FECH alleles and seasonal palmar keratoderma is unexplained. Neuropathy develops only in some patients with severe hepatic
decompensation. XLP males have a more severe phenotype with higher protoporphyrin levels than most EPP patients. XLP females have a variable clinical presentation—some with no symptoms or mild symptoms and others with severe symptoms similar to XLP males. This variability in females is likely the result of random X-chromosome inactivation.

Unless hepatic or other complications develop, protoporphyrin levels and symptoms of photosensitivity remain remarkably stable for many years in most patients. Factors that exacerbate hepatic porphyrias play little or no role in EPP or XLP. Erythrocyte protoporphyrin levels may decrease and sunlight tolerance may improve during pregnancy, which is unexplained.

**Laboratory Findings**

Protoporphyrin is substantially increased in circulating erythrocytes in EPP and consists almost entirely of free protoporphyrin. In XLP, both zinc protoporphyrin and free protoporphyrin are increased, although the latter still predominates. Protoporphyrin is also increased in bone marrow, plasma, bile, and feces. Other porphyrins and porphyrin precursors are normal in uncomplicated EPP and XLP.
Diagnosis and Differential Diagnosis

A diagnosis of EPP is confirmed biochemically by finding a substantially elevated concentration of total erythrocyte protoporphyrin, which is predominantly (at least 85%) metal free and not complexed with zinc. In XLP, both free and zinc-complexed protoporphyrins are elevated. Erythrocyte total protoporphyrin levels are on average higher in XLP and more variable between individuals with EPP, possible reflecting differences in severity of the many reported FECH mutations. Erythrocyte zinc protoporphyrin concentration is increased with little increase in metal-free protoporphyrin in homozygous porphyrias (except CEP), iron deficiency, lead poisoning, anemia of chronic disease, hemolytic conditions, and many other erythrocytic disorders. Measurement of FECH activity requires cells containing mitochondria and is not widely available.

Plasma total porphyrin concentration is often less increased in EPP than in other cutaneous porphyrias and may be normal. Great care must be taken to avoid light exposure during sample processing, because plasma porphyrins in EPP are particularly subject to photodegradation. Urinary porphyrin precursors and porphyrins are not increased.

DNA studies are strongly recommended for confirming FECH or ALAS2 mutations and for genetic counseling.

Life-threatening protoporphyrhic hepatopathy is characterized by greater increases in erythrocyte and plasma protoporphyrin levels, increased photosensitivity and either chronically abnormal liver function tests or rapidly progressive hepatic failure. Presumably this is heralded by increases above the patient's baseline erythrocyte and plasma porphyrin levels, but this has not been documented, because most such patients have not had adequate baseline determinations of porphyrin values. Increases in urinary porphyrins, especially coproporphyrin, in this setting are attributable to liver dysfunction.

Complications

There is an increased risk of biliary stones, which contain protoporphyrin and are sometimes symptomatic, requiring cholecystectomy. Protoporphyrinic hepatopathy occurs in <5% of protoporphyria patients, including children, and may be chronic or progress rapidly to death from liver failure. This liver disease is sometimes the major presenting feature of EPP. In XLP, liver disease may be
more frequent, and in one report of 8 families, 17% of patients had overt liver dysfunction. Protoporphyric hepatopathy can cause acute upper abdominal pain suggesting biliary obstruction, and unnecessary laparotomy to exclude this possibility can be detrimental. Concurrent conditions that impair liver function, such as viral hepatitis, alcohol- or drug-induced liver disease, or OCs may contribute. Whether iron deficiency may contribute is unclear. Liver histology shows marked deposition of protoporphyrin as inclusions in liver cells and bile canaliculi. Patients with protoporphyreric liver failure most often have FECH “null mutations” and the IVS3–48T>C hypoexpression allele, but some may have 2 severe mutant FECH alleles or XLP caused by ALAS2 exon 11 deletions. The bone marrow is probably the major source of protoporphyrin, even in EPP patients with hepatic failure.

**Treatment**

Exposure to sunlight should be avoided, which is aided by wearing closely woven clothing. A systematic review of treatment options, including beta-carotene, oral cysteine, and vitamin C, showed no proven efficacy of these treatments. One report suggested that high doses of cimetidine were effective in reducing symptoms in 3 children with EPP, but no objective clinical evidence of efficacy was presented.

Measures to darken the skin may also be helpful. This may be accomplished by narrow-band UV-B phototherapy. Double-blind, placebo-controlled studies in the United States and Europe of *afamelanotide*, a synthetic analog of melanocyte-stimulating hormone, showed an increase in pain-free sun exposure and improved quality of life in patients with protoporphyria. This drug is approved for adult use in Europe and is pending U.S. Food and Drug Administration (FDA) approval, and studies in children are anticipated.

Drugs or hormone preparations that impair hepatic excretory function should be avoided, particularly in patients with liver dysfunction, and iron deficiency should be corrected if present, especially in XLP. Vitamin D supplementation and hepatitis A and B vaccination are recommended.

Treatment of protoporphyrionic hepatopathy must be individualized, and results are unpredictable. Ursodeoxycholic acid may be of some value in early stages. Cholestyramine or activated charcoal may interrupt the enterohepatic circulation of protoporphyrin, promote its fecal excretion, and reduce liver protoporphyrin content. Spontaneous resolution may occur, especially if another reversible cause
of liver dysfunction, such as viral hepatitis or alcohol abuse, is contributing. In patients with severe hepatic decompensation, combined treatment with plasmapheresis, transfusion to correct anemia and suppress erythropoiesis, IV hemin to suppress erythroid and possibly hepatic protoporphyrin production, ursodeoxycholic acid, vitamin E, and cholestyramine may be beneficial and bridge patients to liver transplantation.

Motor neuropathy resembling that seen in acute porphyrias sometimes develops in protoporphyria patients with liver disease before or after transfusion or liver transplantation and is sometimes reversible. Artificial lights, such as operating room lights during liver transplantation or other surgery, may cause severe photosensitivity, with extensive burns of the skin and peritoneum and damage to circulating erythrocytes.

Although liver disease may recur in the transplanted liver as a result of continued bone marrow production of excess protoporphyrin, outcomes are comparable to transplantation for other types of liver disease. Bone marrow transplantation should also be considered after liver transplantation if a suitable donor is available.

Prognosis
Typical EPP patients have lifelong photosensitivity but can otherwise expect normal longevity. Protoporphyric liver disease is often life-threatening; however, the incidence is low.

Prevention and Genetic Counseling
Symptoms can be prevented by avoiding sunlight. Avoiding agents that may cause liver damage may help prevent liver complications. Opinions vary on the value of iron replacement, and this is currently under study.

DNA studies to identify FECH mutations, the common IVS3–48T>C FECH hypoexpression allele, or ALAS2 exon 11 deletions are important for genetic counseling. When EPP is caused by a severe FECH mutation and the common IVS3–48T>C FECH allele, DNA studies in the spouse to determine the presence, or more likely the absence, of the hypoexpression allele can predict whether offspring are at risk for EPP. EPP may improve during pregnancy.
**Dual Porphyria**

An unusual pattern of porphyrin precursors and porphyrins may suggest mutations of 2 heme pathway enzymes, as documented in 2 patients. One presented with acute porphyria and had heterozygous mutations of both *CPOX* and *ALAD*. The other had symptoms of AIP and PCT and was reported to have both *HMBS* and *UROD* mutations. In other reported cases, 1 or both enzyme deficiencies were based on enzyme measurements.

**Porphyria Resulting From Tumors**

Very rarely, hepatocellular tumors contain and presumably produce excess porphyrins, but such cases have not been studied carefully. Hepatocellular carcinomas complicating PCT and acute hepatic porphyrias usually are not described as containing large amounts of porphyrins. Erythropoietic porphyrias can develop late in life from clonal expansion of erythroid cells containing a specific enzyme deficiency in patients who have developed myelodysplastic or myeloproliferative syndromes.

* Hemin is the generic name for all heme preparations used for intravenous administration. Hemin is also a chemical term that refers to the oxidized (ferric) form of heme (iron protoporphyrin IX) and is usually isolated as hemin chloride. In alkaline solution, the chloride is replaced by the hydroxyl ion, forming hydroxyheme, or hematin.
CHAPTER 111

Hypoglycemia

Mark A. Sperling

Glucose has a central role in fuel economy and is a source of energy storage in the form of glycogen, fat, and protein (see Chapter 105). As an immediate source of energy, glucose provides 38 mol of adenosine triphosphate (ATP) per mole of glucose oxidized. Glucose is essential for energy metabolism in the brain, where it is usually the preferred substrate and where its utilization accounts for nearly all the brain's oxygen consumption. Cerebral transport of glucose is a GLUT-1, carrier-mediated, facilitated diffusion process that is dependent on blood glucose concentration and not regulated by insulin. Therefore, low concentrations of blood glucose result in cerebral glucopenia. Deficiency of brain glucose transporters can result in seizures because of low cerebral and cerebrospinal fluid (CSF) glucose concentrations (hypoglycorrhachia) despite normal blood glucose levels. To maintain the blood glucose concentration and prevent it from falling precipitously to levels that impair brain function, an elaborate regulatory system has evolved.

The defense against hypoglycemia includes the autonomic nervous system and hormones that act in concert to enhance glucose production through enzymatic modulation of glycogenolysis and gluconeogenesis, while simultaneously limiting peripheral glucose utilization, which conserves glucose for cerebral metabolism. Hypoglycemia represents a defect in one or several of the complex interactions that normally integrate glucose homeostasis during feeding and fasting. This process is particularly important for neonates, in whom there is an abrupt transition from intrauterine life, characterized by dependence on transplacental glucose supply, to extrauterine life, characterized ultimately by the autonomous ability to maintain euglycemia. Because prematurity or placental insufficiency may limit tissue nutrient deposits, and genetic abnormalities in enzymes or hormones may become evident in the neonate, hypoglycemia is
common in the neonatal period.

Definition

In neonates, there is not always an obvious correlation between blood glucose concentration and the classic clinical manifestations of hypoglycemia. The absence of symptoms does not indicate that glucose concentration is normal and has not fallen to less than some optimal level for maintaining brain metabolism. There is evidence that hypoxemia and ischemia may potentiate the role of hypoglycemia in causing permanent brain sequelae. Consequently, the lower limit of accepted normality of the blood glucose level in newborn infants with associated illness that already impairs cerebral metabolism has not been determined (see Chapter 127). Because of concern for possible neurologic, intellectual, or psychologic sequelae in later life, most authorities recommend that any value of blood glucose <55 mg/dL in neonates be viewed with suspicion, investigated, and vigorously treated if there are symptoms or it persists or recurs after a meal. This is particularly applicable after the initial 2-3 hr of life, when glucose normally has reached its nadir; subsequently, blood glucose levels begin to rise and achieve values of 55-65 mg/dL or higher after 12-24 hr. By day 3 of life in normal full-term newborns, blood glucose averages approximately 65 mg/dL (range 65-100). Therefore, in otherwise normal, full-term infants after day 3 of life and in older infants and children, a whole blood glucose concentration <55 mg/dL (10–15% higher for serum or plasma) represents hypoglycemia, because counter-regulatory mechanisms are activated at these glucose concentrations. In older children an idealized definition of hypoglycemia is based on “Whipple's Triad”; a plasma glucose concentration less than 60 mg/dL, together with concurrent CNS- or catecholamine-based symptoms, and resolution of symptoms when glucose concentration is restored to normal by treatment with glucose.

Significance and Sequelae

Most of the endogenous hepatic glucose production in infants and young children, which occurs several hours after feeding and during fasting, can be accounted for by brain metabolism.

Because the brain grows most rapidly in the 1st yr of life, and the larger
proportion of glucose turnover is used for brain metabolism, sustained or repetitive hypoglycemia in infants and children can retard brain development and function. *Transient isolated and asymptomatic hypoglycemia of short duration does not appear to be associated with these severe sequelae.* In the rapidly growing brain, glucose may also be a source of membrane lipids and, together with protein synthesis, can provide structural proteins and myelination important for normal brain maturation. Under conditions of severe and sustained hypoglycemia, these cerebral structural substrates may become degraded to energy-usable intermediates such as lactate, pyruvate, amino acids, and ketoacids, which can support brain metabolism at the expense of brain growth. The capacity of the newborn brain to take up and oxidize ketone bodies is about 5-fold greater than that of the adult brain. However, the capacity of the liver to produce ketone bodies is limited in the immediate newborn period, especially in the presence of hyperinsulinism, which acutely inhibits hepatic glucose output, lipolysis, and ketogenesis, thereby depriving the brain of any alternate fuel sources. Although the brain may metabolize ketones, these alternate fuels cannot completely replace glucose as an essential central nervous system (CNS) fuel. The deprivation of the brain's major energy source during hypoglycemia and particularly the limited availability of alternate fuel sources during hyperinsulinism have predictable adverse consequences on brain metabolism and growth: decreased brain oxygen consumption and increased breakdown of endogenous structural components, with destruction of functional membrane integrity.

The major long-term sequelae of severe, prolonged hypoglycemia are cognitive impairment, recurrent seizure activity, cerebral palsy, and autonomic dysregulation. Subtle effects on personality are also possible but have not been clearly defined. Permanent neurologic sequelae are present in 25–50% of patients <6 mo old with severe recurrent symptomatic hypoglycemia. These sequelae may be reflected in pathologic changes characterized by reduced myelination in cerebral white matter and atrophy of the cerebral cortex, reflected in enlargement of the sulci and thinning of the gyri of the brain. These sequelae also are more likely when alternative fuel sources are limited, as occurs with hyperinsulinism, when the episodes of hypoglycemia are repetitive or prolonged, or when they are compounded by hypoxia. There is no precise knowledge relating the duration or severity of hypoglycemia to subsequent neurologic development of children in a predictable manner. Although less common, hypoglycemia in older children may also produce long-term neurologic defects
through neuronal death mediated, in part, by cerebral excitotoxins released during hypoglycemia.

**Substrate, Enzyme, and Hormonal Integration of Glucose Homeostasis In the Newborn**

Under nonstressed conditions, fetal glucose is derived entirely from the mother through placental transfer. Therefore, fetal glucose concentration usually reflects, but is slightly lower than, maternal glucose levels. Catecholamine release, which occurs with fetal stress such as hypoxia, mobilizes fetal glucose and free fatty acids (FFAs) through β-adrenergic mechanisms, reflecting β-adrenergic activity in fetal liver and adipose tissue. Catecholamines may also inhibit fetal insulin and stimulate glucagon release.

The acute interruption of maternal glucose transfer to the fetus at delivery imposes an immediate need to mobilize endogenous glucose. Three related events facilitate this transition: changes in hormones, changes in their receptors, and changes in key enzyme activity. There is a 3-5-fold abrupt increase in glucagon concentration within minutes to hours of birth. The insulin level usually falls initially and remains in the basal range for several days, without demonstrating the usual brisk response to physiologic stimuli such as glucose. A dramatic surge in spontaneous catecholamine secretion is also characteristic. Epinephrine can also augment growth hormone (GH) secretion by α-adrenergic mechanisms; GH levels are markedly elevated at birth. In addition, cortisol levels are higher in the immediate newborn period in infants born vaginally than by cesarean birth, in part reflecting the stress of labor on fetal cortisol secretion. Acting in concert, these hormonal changes at birth mobilize glucose by glycogenolysis and gluconeogenesis, activate lipolysis, and promote ketogenesis. As a result of these processes, plasma glucose concentration stabilizes after a transient decrease immediately after birth; liver glycogen stores become rapidly depleted within hours of birth; and gluconeogenesis from alanine, a major gluconeogenic amino acid, can account for approximately 10% of glucose turnover in the human newborn infant by several hours of age. FFA concentrations also increase sharply in concert with the surges in glucagon and epinephrine, followed later by rises in ketone bodies. Glucose is thus partially
spared for brain utilization while FFAs and ketones provide alternative fuel sources for muscle as well as essential gluconeogenic factors such as acetyl-coenzyme A (CoA) and the reduced form of nicotinamide adenine dinucleotide from hepatic fatty acid oxidation, which is required to drive gluconeogenesis.

In the early postnatal period, responses of the endocrine pancreas favor glucagon secretion so that blood glucose concentration can be maintained. These adaptive changes in hormone secretion are paralleled by similarly striking adaptive changes in hormone receptors. Key enzymes involved in glucose production also change dramatically in the perinatal period. Thus, there is a rapid fall in glycogen synthase activity and a sharp rise in phosphorylase activity after delivery. Similarly, the activity of the rate-limiting enzyme for gluconeogenesis, phosphoenolpyruvate carboxykinase, rises dramatically after birth, activated in part by the surge in glucagon and the fall in insulin. This framework can explain several causes of neonatal hypoglycemia based on inappropriate changes in hormone secretion and unavailability of adequate reserves of substrates in the form of hepatic glycogen, muscle as a source of amino acids for gluconeogenesis, and lipid stores for the release of fatty acids. In addition, appropriate activities of key enzymes governing glucose homeostasis are required (see Fig. 105.1).

**In Older Infants and Children**

Hypoglycemia in older infants and children is analogous to that of adults, in whom glucose homeostasis is maintained by glycogenolysis in the immediate postfeeding period and by gluconeogenesis several hours after meals. The liver of a 10 kg child contains 20-25 g of glycogen, which is sufficient to meet normal glucose requirements of 4-6 mg/kg/min for only 6-12 hr. Beyond this period, hepatic gluconeogenesis must be activated. Both glycogenolysis and gluconeogenesis depend on the metabolic pathway summarized in Fig. 105.1. Defects in glycogenolysis or gluconeogenesis may not be manifested in infants until the frequent feeding at 3-4 hr intervals ceases and infants sleep through the night, a situation usually present by 3-6 mo of age. The source of gluconeogenic precursors is derived primarily from muscle protein. The muscle bulk of infants and small children is substantially smaller relative to body mass than that of adults, whereas glucose requirements per unit of body mass are greater in children. Therefore the ability to compensate for glucose deprivation by gluconeogenesis is more limited in infants and young children, as is the ability to
withstand fasting for prolonged periods. The ability of muscle to generate alanine, the principal gluconeogenic amino acid, may also be limited. Thus, in normal young children, the blood glucose level falls after 24 hr of fasting, insulin concentrations fall appropriately to levels of <5 µU/mL, lipolysis and ketogenesis are activated, and ketones may appear in the urine.

The switch from glycogen synthesis during and immediately after meals to glycogen breakdown and later gluconeogenesis is governed by hormones, with insulin of central importance. After a meal, plasma insulin concentrations increase to peak levels of 5-10–fold greater than their normal baseline concentration of approximately 5-10 µU/mL, which serves to lower the blood glucose concentration through the activation of glycogen synthesis, enhancement of peripheral glucose uptake, and inhibition of glucose production. In addition, lipogenesis is stimulated, whereas lipolysis and ketogenesis are curtailed. During fasting, plasma insulin concentrations fall to ≤5 µU/mL, and together with the rise of counter-regulatory hormones, this fall in insulin results in activation of gluconeogenic pathways (see Fig. 105.1 ). Fasting glucose concentrations are maintained through the activation of glycogenolysis and gluconeogenesis, inhibition of glycogen synthesis, and activation of lipolysis and ketogenesis. It should be emphasized that a plasma insulin concentration of >5 µU/mL, in association with a blood glucose concentration of ≤55 mg/dL (2.8-3.0 mM), is abnormal, indicating a state of excessive insulin action, termed hyperinsulinism, caused by failure of the mechanisms that normally result in suppression of insulin secretion during fasting or hypoglycemia.

The hypoglycemic effects of insulin are opposed by the actions of several hormones whose concentration in plasma increases as blood glucose falls. These counter-regulatory hormones—glucagon, growth hormone, cortisol, and epinephrine—act synergistically and in concert to increase blood glucose concentrations by activating glycogenolytic enzymes (glucagon, epinephrine); inducing gluconeogenic enzymes (glucagon, cortisol); inhibiting glucose uptake by muscle (epinephrine, growth hormone, cortisol); mobilizing amino acids from muscle for gluconeogenesis (cortisol); activating lipolysis and thereby providing glycerol for gluconeogenesis and fatty acids for ketogenesis (epinephrine, cortisol, GH, glucagon); and inhibiting insulin release and promoting GH and glucagon secretion (epinephrine).

Congenital or acquired deficiency of any one of these hormones is uncommon but will result in hypoglycemia, which occurs when endogenous glucose production cannot be mobilized to meet energy needs in the postabsorptive state,
that is, 4-6 hr in the newborn and 8-12 hr after meals or during fasting in an infant or child. Concurrent deficiency of several hormones (hypopituitarism-ACTH-cortisol deficiency combined with GH deficiency) may result in hypoglycemia that is more severe or appears earlier during fasting than that seen with isolated hormone deficiencies. Most of the causes of hypoglycemia in neonates, infants, and children reflect inappropriate adaptation to fasting as a result of (1) excess insulin action, (2) inadequate counter-regulatory hormone response primarily of cortisol and GH, (3) enzymatic defects in the mechanisms for glycogen storage and release, or (4) defects in gluconeogenesis.

Clinical Manifestations

See Chapter 127.

Clinical features of hypoglycemia generally fall into 2 categories: (1) symptoms associated with the activation of the autonomic nervous system and epinephrine release, usually seen with a rapid decline in blood glucose concentration and (2) symptoms caused by decreased cerebral glucose utilization (cerebral glucopenia), usually associated with a slow decline in blood glucose level or prolonged hypoglycemia (Table 111.1). Although these classic symptoms occur in older children, the symptoms of hypoglycemia in newborns and infants may be subtler and include cyanosis, apnea, hypothermia, hypotonia, poor feeding, lethargy, and seizures, all reflecting the deprivation of glucose for normal brain activity. Some of these symptoms may be so mild that they are missed. Occasionally, hypoglycemia may be asymptomatic in the immediate newborn period. Newborns with hyperinsulinism are often large for gestational age (LGA), mimicking the features of the infant born to a mother with poorly controlled diabetes. Older infants with hyperinsulinism may eat excessively because of chronic hypoglycemia and become obese. In childhood, hypoglycemia may present as behavior problems, inattention, ravenous appetite, or seizures. It may be misdiagnosed as epilepsy, inebriation, personality disorders, headache, hysteria, and developmental delay. A blood glucose determination should always be performed in sick neonates, who should be vigorously treated if concentrations are <55 mg/dL. At any age, hypoglycemia should be considered a cause of an initial episode of convulsions or a sudden deterioration in psychobehavioral functioning or level of consciousness.

Table 111.1
Manifestations of Hypoglycemia in Childhood

Features Associated With Activation of Autonomic Nervous System and Epinephrine Release*

- Anxiety †
- Perspiration †
- Palpitation (tachycardia) †
- Pallor ‡
- Tremulousness ‡
- Weakness
- Hunger
- Nausea
- Emesis

Features Associated With Cerebral Glucopenia

- Headache †
- Mental confusion †
- Visual disturbances (↓ acuity, diplopia) †
- Organic personality changes †
- Inability to concentrate †
- Dysarthria
- Staring
- Paresthesias
- Dizziness
- Amnesia
- Ataxia, incoordination
- Refusal to feed ‡
- Somnolence, lethargy ‡
- Seizures ‡
- Coma
- Stroke, hemiplegia, aphasia
- Decerebrate or decorticate posture
Some of these features will be attenuated if the patient is receiving β-adrenergic blocking agents.

† Common.
‡ Most common manifestations in the newborn.

Many neonates have asymptomatic (chemical) hypoglycemia. The incidence of symptomatic hypoglycemia is highest in small-for-gestational-age (SGA) infants (Fig. 111.1). The exact incidence of symptomatic hypoglycemia has been difficult to establish because many of the symptoms in neonates occur together with other conditions, such as infections, especially sepsis and meningitis; CNS anomalies, hemorrhage, or edema; hypocalcemia and hypomagnesemia; asphyxia; drug withdrawal; apnea of prematurity; congenital heart disease; or polycythemia.

The onset of symptoms in neonates varies from a few hours to a week after birth. In approximate order of frequency, symptoms include jitteriness or tremors, apathy, episodes of cyanosis, seizures, intermittent apneic spells or

![Incidence of hypoglycemia by birthweight, gestational age, and intrauterine growth. (From Lubchenco LO, Bard H: Incidence of hypoglycemia in newborn infants classified by birthweight and gestational age, Pediatrics 47:831–838, 1971.)](image-url)
tachypnea, weak or high-pitched cry, limppness or lethargy, difficulty feeding (latching on), and eye rolling. Episodes of sweating, sudden pallor, hypothermia, and cardiac arrest and failure may also occur. Frequently, a clustering of episodic symptoms may be noted. Because these clinical manifestations may result from various causes, it is critical to measure serum glucose levels and determine whether symptoms disappear with the administration of sufficient glucose to raise the blood glucose to normal levels; if they do not, other diagnoses must be considered.

**Classification of Hypoglycemia in Infants and Children**

Classification is based on knowledge of the control of glucose homeostasis in infants and children ([Table 111.2](#)).

Hyperinsulinism

- Recessive $K_{ATP}$ channel HI
- Recessive HADH (hydroxyl acyl-CoA dehydrogenase) mutation HI
- Recessive UCP2 (mitochondrial uncoupling protein 2) mutation HI
- Focal $K_{ATP}$ channel HI
- Dominant $K_{ATP}$ channel HI
- Atypical congenital hyperinsulinemia (no mutations in $ABCC8$ or $KCN11$ genes)
- Dominant glucokinase HI
- Dominant glutamate dehydrogenase HI (hyperinsulinism-hyperammonemia syndrome)
- Dominant mutations in HNF-4A and HNF-1A (hepatocyte nuclear factors 4α and 1α) HI with monogenic diabetes of youth later in life
- Dominant mutation in SLC16A1 (the pyruvate transporter)—exercise-induced hypoglycemia
- Activating mutations in the calcium channel CACNA1D (permit calcium influx and thus unregulated insulin secretion)
- Acquired or familial islet adenoma associated with mutations in $MEN1$ gene
- Beckwith-Wiedemann syndrome
- Kabuki syndrome
- Insulin administration (Munchausen syndrome by proxy)
- Oral sulfonylurea drugs
- Congenital disorders of glycosylation

Counter-Regulatory Hormone Deficiency

- Panhypopituitarism
- Isolated growth hormone deficiency
- Adrenocorticotropic hormone deficiency
- Addison disease (including congenital adrenal hypoplasia, adrenal leukodystrophy, triple A syndrome, ACTH receptor deficiency, and autoimmune disease complex)
- Epinephrine deficiency
Glycogenolysis and Gluconeogenesis Disorders

- Glucose-6-phosphatase deficiency (GSD Ia)
- Glucose-6-phosphate translocase deficiency (GSD Ib)
- Amylo-1,6-glucosidase (debranching enzyme) deficiency (GSD III)
- Liver phosphorylase deficiency (GSD VI)
- Phosphorylase kinase deficiency (GSD IX)
- Glycogen synthetase deficiency (GSD 0)
- Fructose-1,6-diphosphatase deficiency
- Pyruvate carboxylase deficiency
- Galactosemia
- Hereditary fructose intolerance

Lipolysis Disorders

Fatty Acid Oxidation Disorders

- Carnitine transporter deficiency (primary carnitine deficiency)
- Carnitine palmitoyltransferase-1 deficiency
- Carnitine translocase deficiency
- Carnitine palmitoyltransferase-2 deficiency
- Secondary carnitine deficiencies
  - Very-long-, long-, medium-, short-chain acyl-CoA dehydrogenase deficiency

Other Etiologies

Substrate-Limited Causes

- Ketotic hypoglycemia
- Poisoning—drugs
- Salicylates
- Alcohol
- Oral hypoglycemic agents
- Insulin
- Propranolol
- Pentamidine
- Quinine
Disopyramide
Ackee fruit (unripe)—hypoglycin
Litchi – associated toxin (toxic hypoglycemic syndrome).
Vacor (rat poison)
Trimethoprim-sulfamethoxazole (with renal failure)
L-Asparaginase and other antileukemic drugs

Liver Disease

Reye syndrome
Hepatitis
Cirrhosis
Hepatoma

Amino Acid and Organic Acid Disorders

Maple syrup urine disease
Propionic acidemia
Methylmalonic acidemia
Tyrosinosis
Glutaric aciduria
3-Hydroxy-3-methylglutaric aciduria

Systemic Disorders

Sepsis
Carcinoma/sarcoma (secreting—insulin-like growth factor II)
Heart failure
Malnutrition
Malabsorption
Antiinsulin receptor antibodies
Antiinsulin antibodies
Neonatal hyperviscosity
Renal failure
Diarrhea
Burns
Shock
Chiari malformation
Postsurgical complication
Pseudohypoglycemia (leukocytosis, polycythemia)
Excessive insulin therapy of insulin-dependent diabetes mellitus
Factitious disorder
Nissen fundoplication (dumping syndrome)
Falciparum malaria

GSD, Glycogen storage disease; HI, hyperinsulinemia; $\text{K}_{\text{ATP}}$, regulated potassium channel.

**Neonatal, Transient, Small-for-Gestational-Age, and Premature Infants**

The estimated incidence of symptomatic hypoglycemia in newborns is 1-3 in 1,000 live births. This incidence is increased several fold in certain high-risk neonatal groups (see Table 111.2 and Fig. 111.1). Premature and SGA infants are vulnerable to the development of hypoglycemia. The factors responsible for the high frequency of hypoglycemia in this group, as well as in other groups outlined in Table 111.2, are related to the inadequate stores of liver glycogen, muscle protein, and body fat needed to sustain the substrates required to meet energy needs. These infants are small by virtue of prematurity or impaired placental transfer of nutrients. Their enzyme systems for gluconeogenesis may not be fully developed. Transient hyperinsulinism responsive to diazoxide has also been reported as contributing to hypoglycemia in asphyxiated, SGA, and premature newborn infants. This form of hyperinsulinism, associated with perinatal asphyxia, intrauterine growth restriction, maternal toxemia, and other perinatal stressors, is probably the most common cause of hyperinsulinemic hypoglycemia in neonates and may be quite severe. In most patients the condition resolves quickly, but it may persist to 7 mo of life or longer.

In contrast to deficiency of substrates or enzymes, the hormonal system appears to be functioning normally at birth in most low-risk neonates. Despite hypoglycemia, plasma concentrations of alanine, lactate, and pyruvate are higher, implying their diminished rate of utilization as substrates for gluconeogenesis. Infusion of alanine elicits further glucagon secretion but causes
no significant rise in glucose. During the initial 24 hr of life, plasma concentrations of acetoacetate and β-hydroxybutyrate are lower in SGA infants than in full-term infants, implying diminished lipid stores, diminished fatty acid mobilization, impaired ketogenesis, or a combination of these conditions. Diminished lipid stores most likely occur because fat (triglyceride) feeding of newborns results in elevated plasma levels of glucose, ketones such as β-hydroxybutyrate, and FFAs. For infants with perinatal asphyxia and SGA newborns who have transient hyperinsulinism, the combination of hypoglycemia together with diminished concentrations of β-hydroxybutyrate and FFAs are the diagnostic hallmarks of hyperinsulinism.

The role of FFAs and their oxidation in stimulating neonatal gluconeogenesis is essential. The provision of FFAs as triglyceride feedings from formula or human milk together with gluconeogenic precursors may prevent the hypoglycemia that usually ensues after neonatal fasting. For these and other reasons, milk feedings are introduced early (at birth or within 2-4 hr) after delivery. In the hospital setting, when feeding is precluded by virtue of respiratory distress or other illness, or when feedings alone cannot maintain blood glucose concentrations at levels >55 mg/dL, intravenous (IV) glucose at a rate that supplies 4-8 mg/kg/min should be started. Infants with transient neonatal hypoglycemia can usually maintain the blood glucose level spontaneously after 2-3 days of life, but some require longer periods of support. In these latter infants, insulin values >5 µU/mL at the time of hypoglycemia should be treated with diazoxide.

**Infants Born to Diabetic Mothers**

See Chapter 127.1.

Of the transient hyperinsulinemic states, infants born to diabetic mothers are the most common. Gestational diabetes affects approximately 2% of pregnant women, and 1 in 1,000 pregnant women have insulin-dependent diabetes. At birth, infants born to these mothers may be large and plethoric, and their body stores of glycogen, protein, and fat are replete.

Hypoglycemia in infants of diabetic mothers is mostly related to hyperinsulinemia and partly related to diminished glucagon secretion. Hypertrophy and hyperplasia of the islets is present, as is a brisk, biphasic, and typically mature insulin response to glucose; this brisk insulin response is absent in normal infants. Infants born to diabetic mothers also have a subnormal surge
in plasma glucagon immediately after birth, subnormal glucagon secretion in response to stimuli, and initially, excessive sympathetic activity that may lead to adrenomedullary exhaustion, as reflected by decreased urinary excretion of epinephrine. The normal plasma hormonal pattern of low insulin, high glucagon, and high catecholamines is reversed to a pattern of high insulin, low glucagon, and low epinephrine. As a consequence of this abnormal hormonal profile, endogenous glucose production is significantly inhibited compared with that in normal infants, thus predisposing them to hypoglycemia.

 Mothers whose diabetes has been well controlled during pregnancy, labor, and delivery generally have infants near normal size who are less likely to develop neonatal hypoglycemia and other complications formerly considered typical of such infants. In supplying exogenous glucose to these hypoglycemic infants, it is important to avoid hyperglycemia that evokes a prompt exuberant insulin release, which may result in rebound hypoglycemia. When needed, glucose should be provided at continuous infusion rates of 4-8 mg/kg/min, but the appropriate dose for each patient must be individually adjusted. During labor and delivery, maternal hyperglycemia should be avoided because it results in fetal hyperglycemia, which predisposes to hypoglycemia when the glucose supply is interrupted at birth. Hypoglycemia persisting beyond day 3 after birth or initially occurring after 1 wk of life requires an evaluation for the causes listed in Table 111.2.

 Infants born with erythroblastosis fetalis may also have hyperinsulinemia and share many physical features, such as large body size, with infants born to diabetic mothers. The cause of the hyperinsulinemia in infants with erythroblastosis is not clear.

**Persistent or Recurrent Hypoglycemia in Infants and Children**

**Hyperinsulinism**

Most children with hyperinsulinism that causes hypoglycemia present in the neonatal period or later in infancy. Hyperinsulinism is the most common cause of persistent hypoglycemia in early infancy. Infants who have hyperinsulinism may be macrosomic at birth, reflecting the anabolic effects of insulin in utero. There is no history or biochemical evidence of maternal diabetes. The onset of symptoms is from birth to 18 mo of age, but occasionally it only becomes
evident in older children.

Insulin concentrations are inappropriately elevated at the time of documented hypoglycemia; with nonhyperinsulinemic hypoglycemia, plasma insulin concentrations should be <5 µU/mL. In affected infants, plasma insulin concentrations at the time of hypoglycemia are usually >5 µU/mL. Some authorities set more stringent criteria, arguing that any value of insulin >2 µU/mL with hypoglycemia is abnormal. The insulin (µU/mL):glucose (mg/dL) ratio is typically >0.4; plasma insulin-like growth factor binding protein-1 (IGFBP-1), β-hydroxybutyrate, and FFA levels are low with hyperinsulinism. Rare instances of activating mutations in the insulin receptor signaling pathway have been reported where the clinical and biochemical features are similar to states of excessive insulin secretion, yet insulin concentrations are low to the point of being undetectable. Therefore, the preferred term is hyperinsulinism, to describe a state of increased insulin action. Macrosomic infants may present with hypoglycemia from the 1st days of life. Infants with lesser degrees of hyperinsulinism may manifest hypoglycemia only after the 1st few wk to mo, when the frequency of feedings has been decreased to permit the infant to sleep through the night, and hyperinsulinism prevents the mobilization of endogenous glucose. Increasing appetite and demands for feeding, wilting spells, jitteriness, and frank seizures are the most common presenting features.

Additional clues include the rapid development of fasting hypoglycemia within 4-8 hr of food deprivation, compared with other causes of hypoglycemia (Tables 111.3 and 111.4); the need for high rates of exogenous glucose infusion to prevent hypoglycemia, often at rates >10-15 mg/kg/min; the absence of ketonemia or acidosis; and elevated C-peptide or proinsulin levels at the time of hypoglycemia. The latter insulin-related products are absent in factitious hypoglycemia from exogenous administration of insulin as a form of child abuse (see Chapter 16.2). Hypoglycemia is invariably provoked by withholding feedings for several hours, permitting simultaneous measurement of glucose, insulin, ketones, and FFAs in the same sample at the time of clinically manifested hypoglycemia. This is termed the critical sample. The glycemic response to glucagon at the time of hypoglycemia reveals a brisk increment in glucose concentration of at least 40 mg/dL, which implies that glucose mobilization has been restrained by insulin but that glycogenolytic mechanisms are intact (Tables 111.5 to 111.7).

- Cortisol
Growth hormone
Thyroxine, thyroid-stimulating hormone
Insulin-like growth factor binding protein-1 †

* Glucagon 0.5 mg with maximum of 1 mg IV or IM.
† Measure once only before or after glucagon administration. Rise in glucose of ≥40 mg/dL after glucagon given at the time of hypoglycemia strongly suggests a hyperinsulinemic state with adequate hepatic glycogen stores and intact glycogenolytic enzymes. If ammonia is elevated to 100-200 µM, consider activating mutation of glutamate dehydrogenase.

Diagnosis of Acute Hypoglycemia in Infants and Children
Acute Symptoms Present

1. Obtain blood sample before and 30 min after glucagon administration.
2. Obtain urine as soon as possible. Examine for ketones; if not present and hypoglycemia confirmed, suspect hyperinsulinemia or fatty acid oxidation defect; if present, suspect ketotic, hormone deficiency, inborn error of glycogen metabolism, or defective gluconeogenesis.
3. Measure glucose in the original blood sample. If hypoglycemia is confirmed, proceed with substrate-hormone measurement as in Table 111.5.
4. If glycemic increment after glucagon exceeds 40 mg/dL above basal, suspect hyperinsulinemia.
5. If insulin level at time of confirmed hypoglycemia is >5 µU/mL, suspect endogenous hyperinsulinemia; if >100 µU/mL, suspect factitious hyperinsulinemia (exogenous insulin injection). Admit to hospital for supervised fast.
6. If cortisol is <10 µg/dL or growth hormone is <5 ng/mL, or both, suspect adrenal insufficiency or pituitary disease, or both. Admit to hospital for hormonal testing and neuroimaging.

History Suggestive: Acute Symptoms Not Present

1. Careful history for relation of symptoms to time and type of food intake, considering age of patient. Exclude possibility of alcohol or drug ingestion. Assess possibility of insulin injection, salt craving, growth velocity, or intracranial pathology.
2. Careful examination for hepatomegaly (glycogen storage disease; defect in gluconeogenesis); pigmentation (adrenal failure); stature and neurologic status (pituitary disease).
3. Admit to hospital for provocative testing:
   a. 24 hr fast under careful observation; when symptoms provoked, proceed with steps 1-4 as when acute symptoms present.
   b. Pituitary-adrenal function using arginine-insulin stimulation test if indicated.
4. Consider molecular diagnostic test before liver biopsy for histologic and enzyme determinations.
The measurement of serum IGFBP-1 concentration may help diagnose hyperinsulinism. The secretion of IGFBP-1 is acutely inhibited by insulin action; IGFBP-1 concentrations are low during hyperinsulinism-induced hypoglycemia. In patients with spontaneous or fasting-induced hypoglycemia with a low insulin level (ketotic hypoglycemia, normal fasting), IGFBP-1 concentrations are significantly higher.

The differential diagnosis of endogenous hyperinsulinism includes diffuse β-cell hyperplasia or focal β-cell microadenoma. The distinction between these 2 major entities is important because the diffuse hyperplasia, if unresponsive to medical therapy, requires near-total pancreatectomy, despite which hypoglycemia may persist or diabetes mellitus may ensue later. Some, but not all, affected infants may respond to sirolimus. By contrast, focal adenomas diagnosed preoperatively or intraoperatively permit localized curative resection with subsequent normal glucose metabolism. Approximately 50% of the autosomal recessive or sporadic forms of neonatal/infantile hyperinsulinism are caused by focal microadenomas, which may be distinguished from the diffuse form by the pattern of insulin response to selective insulin secretagogues infused into an arterial branch supplying the pancreas, with sampling by the hepatic vein. However, these invasive and technically difficult procedures have been largely abandoned in favor of positron emission tomography (PET) using 18-fluoro-L-dopa. This technique can distinguish the diffuse form (uniform fluorescence throughout the pancreas) from the focal form (focal uptake of 18-fluoro-L-dopa and localized fluorescence) with an extremely high degree of reliability, success, specificity, and sensitivity (see Fig. 111.3).

Insulin-secreting macroadenomas are rare in childhood and may be diagnosed preoperatively by CT or MRI. The plasma levels of insulin alone, however, cannot distinguish the aforementioned entities. The diffuse or microadenomatous forms of islet cell hyperplasia represent a variety of genetic defects responsible for abnormalities in the endocrine pancreas, characterized by autonomous insulin secretion that is not appropriately reduced when blood glucose declines spontaneously or in response to provocative maneuvers such as fasting (see Tables 111.4, 111.7, and 111.8). Clinical, biochemical, and molecular genetic approaches permit classification of congenital hyperinsulinism, formerly termed nesidioblastosis, into distinct entities.
Persistent hyperinsulinemic hypoglycemia of infancy (PHHI) may be inherited or sporadic, is severe, and is caused by mutations that affect the regulation of the potassium channel intimately involved in insulin secretion by the pancreatic β cell (Fig. 111.2). Normally, glucose entry into the β cell is enabled by the non–insulin-responsive glucose transporter GLUT-2. On entry, glucose is phosphorylated to glucose-6-phosphate by the enzyme glucokinase, enabling glucose metabolism to generate ATP. The rise in the molar ratio of ATP relative to adenosine diphosphate (ADP) closes the ATP-sensitive potassium channel in the cell membrane (K$_{ATP}$ channel). This channel is composed of 2 subunits, the K$_{IR}$ 6.2 channel, part of the family of inward-rectifier potassium channels, and a regulatory component in intimate association with K$_{IR}$ 6.2 known as the sulfonylurea receptor (SUR1). Together, K$_{IR}$ 6.2 and SUR1 constitute the potassium-sensitive ATP channel K$_{ATP}$. Normally, the K$_{ATP}$ is open, but with the rise in ATP and closure of the channel, potassium accumulates intracellularly, causing depolarization of the membrane, opening of voltage-gated calcium channels, influx of calcium into the cytoplasm, and secretion of insulin by exocytosis. The genes for both SUR1 and K$_{IR}$ 6.2 are located close together on the short arm of chromosome 11, the site of the insulin gene.

**FIG. 111.2** Schematic of the pancreatic cell with some important steps in insulin secretion. The membrane-spanning, adenosine triphosphate (ATP)–sensitive potassium
channel ($K_{ATP}$) consists of 2 subunits: the sulfonylurea receptor (SUR) and the inward rectifying K channel ($K_{ir}$ 6.2). In the resting state, the ratio of ATP to adenosine diphosphate (ADP) maintains $K_{ATP}$ in an open state, permitting efflux of intracellular $K^+$. When blood glucose concentration rises, its entry into the β cell is facilitated by the Glut-2 glucose transporter, a process not regulated by insulin. Within the β cell, glucose is converted to glucose-6-phosphate by the enzyme glucokinase and then undergoes metabolism to generate energy. The resultant increase in ATP relative to ADP closes $K_{ATP}$, preventing efflux of $K^+$, and the rise of intracellular $K^+$ depolarizes the cell membrane and opens a calcium ($Ca^{2+}$) channel. The intracellular rise in $Ca^{2+}$ triggers insulin secretion by exocytosis. Sulfonylureas trigger insulin secretion by reacting with their receptor (SUR) to close $K_{ATP}$; diazoxide inhibits this process, whereas somatostatin, or its analog octreotide, inhibits insulin secretion by interfering with calcium influx. Genetic mutations in SUR1 or $K_{ir}$ 6.2 that prevent $K_{ATP}$ from being open tonically maintain inappropriate insulin secretion and are responsible for autosomal recessive forms of persistent hyperinsulinemic hypoglycemia of infancy (PHHI). One form of autosomal dominant PHHI is caused by an activating mutation in glucokinase. The amino acid leucine also triggers insulin secretion by closure of $K_{ATP}$. Metabolism of leucine is facilitated by the enzyme glutamate dehydrogenase (GDH), and overactivity of this enzyme in the pancreas leads to hyperinsulinemia with hypoglycemia, associated with hyperammonemia from overactivity of GDH in the liver. Mutations in the pyruvate channel SLC16A1 can cause ectopic expression in the β cell and permit pyruvate, accumulated during exercise, to induce insulin secretion and thus exercise-induced hypoglycemia. Mutations in the mitochondrial uncoupling protein 2 (UCP2) and hydroxyl acyl-CoA dehydrogenase (HADH) are associated with hyperinsulinism (HI) by mechanisms yet to be defined. Mutations in the transcription factors hepatocyte nuclear factors (HNF) 4α and 1α can be associated with neonatal macrosomia and HI, but progress to monogenic diabetes of youth (MODY) later in life. Activating mutations in the calcium channel CACNA1D permit calcium influx and hence unregulated insulin secretion at membrane voltages which normally exclude calcium flux. √, Stimulation; GTP, guanosine triphosphate; X, inhibition.

**Inactivating** mutations in the gene for SUR1 or, less often, $K_{ir}$ 6.2 prevent the potassium channel from opening; it remains variably closed with constant depolarization and therefore constant inward flux of calcium. Thus, insulin secretion is continuous and not governed by the glucose concentration. A milder autosomal dominant form of these defects is also reported. Similarly, an **activating** mutation in the gene for glucokinase or for glutamate dehydrogenase enzyme activity increases substrate metabolism and results in closure of the potassium channel through overproduction of ATP, which causes hyperinsulinism. Genetic defects in fatty acid metabolism, in the insulin transcription factors HNF-4α and HNF-1α, and in the uncoupling protein UCP-2 of the mitochondrial gene complex also have been involved in hyperinsulinemic hypoglycemia. Most recently, an activating mutation in the calcium channel has been reported to permit flux of calcium into the β cell, resulting in excessive, dysregulated insulin secretion and hypoglycemia that responds to diazoxide. **Inactivating** mutations of the glucokinase gene or **activating** mutations of the ATP-regulated potassium channel, which prevent or limit closure of the channel, are responsible for inadequate insulin secretion and form the basis of some forms of maturity-onset diabetes of youth and neonatal diabetes mellitus (see Chapter
The familial forms of PHHI are more common in certain populations, notably Arabic and Ashkenazi Jewish communities, where it may reach an incidence of approximately 1 in 2,500, compared with the sporadic rates in the general population of 1 in 50,000. These **autosomal recessive forms** of PHHI typically present in the immediate newborn period as macrosomic newborns with a weight frequently >4.0 kg and severe recurrent or persistent hypoglycemia manifesting in the initial hours or days of life. Glucose infusions as high as 15-20 mg/kg/min and frequent feedings fail to maintain euglycemia. **Diazoxide**, which acts by opening $K_{ATP}$ channels, fails to control hypoglycemia adequately. Somatostatin (**octreotide**), which also opens $K_{ATP}$ channels and inhibits calcium flux, may be partially effective in 50% of patients (see Fig. 111.2). Calcium channel-blocking agents have had inconsistent effects. When affected patients are unresponsive to these measures, **pancreatectomy** is strongly recommended to avoid the long-term neurologic sequelae of hypoglycemia. If surgery is undertaken, preoperative CT or MRI rarely reveals an isolated adenoma, which would then permit local resection. Intraoperative ultrasonography may identify a small impalpable adenoma, permitting local resection. Adenomas often present in late infancy or early childhood.

Distinguishing between **focal** and **diffuse** cases of **persistent hyperinsulinism** has been attempted in several ways. Preoperatively, transhepatic portal vein catheterization and selective pancreatic venous sampling to measure insulin may localize a focal lesion from the step-up in insulin concentration at a specific site. Selective catheterization of arterial branches supplying the pancreas, followed by infusion of a secretagogue such as calcium and portal vein sampling for insulin concentration (arterial stimulation–venous sampling) may localize a lesion. Both approaches are highly invasive, restricted to specialized centers, and not uniformly successful in distinguishing the focal from the diffuse forms. Thus these techniques are not recommended and have largely been abandoned. Fluorine 18 ($^{18}$F)–labeled $l$-dopa combined with PET scanning is a highly promising means to distinguish the focal from the diffuse lesions of hyperinsulinism unresponsive to medical management (Fig. 111.3). The gold standard remains intraoperative **histologic** characterization. Diffuse hyperinsulinism is characterized by large β cells with abnormally large nuclei, whereas focal adenomatous lesions display small and normal β-cell nuclei. Although **SUR1** mutations are present in both types, the focal lesions arise by a random loss of a maternally imprinted growth-inhibitory gene on maternal
chromosome 11p, in association with paternal transmission of a mutated SUR1 or KIR 6.2 paternal chromosome 11p, expressing the insulin-like growth factor 2 (IGF2) gene. Thus the focal form represents a double hit–loss of maternal repressor and transmission of a paternal mutation that contains a growth-promoting gene. This is similar to what occurs in children with the hyperinsulinemic hypoglycemia seen in Beckwith-Wiedemann syndrome, as discussed later.

Local excision of the focal adenomatous islet cell hyperplasia results in a cure with little or no recurrence. For the diffuse form, near-total resection of 85–90% of the pancreas is recommended. The near-total pancreatectomy required for the diffuse hyperplastic lesions, however, is often associated with persistent hypoglycemia or later development of hyperglycemia or frank, insulin-dependent diabetes mellitus.

Further resection of the remaining pancreas may occasionally be necessary if hypoglycemia recurs and cannot be controlled by medical measures, such as the use of octreotide or diazoxide.
Experienced pediatric surgeons in medical centers equipped to provide the necessary preoperative and postoperative care, diagnostic evaluation, and management should perform surgery. In some patients who have been managed medically, hyperinsulinism and hypoglycemia regress over months. If hypoglycemia first manifests between 3 and 6 mo of age or later, a therapeutic trial using medical approaches with diazoxide, octreotide, and frequent feedings can be attempted for up to 2-4 wk. Failure to maintain euglycemia without undesirable side effects from the drugs may prompt the need for surgery. Some success in suppressing insulin release and correcting hypoglycemia in patients with PHHI has been reported with the use of the long-acting somatostatin analog octreotide. Most cases of neonatal PHHI are sporadic; familial forms permit genetic counseling on the basis of anticipated autosomal recessive inheritance. A 2nd form of familial PHHI suggests autosomal dominant inheritance. The clinical features tend to be less severe, and onset of hypoglycemia is most likely, but not exclusively, to occur beyond the immediate newborn period and usually beyond the period of weaning, at an average age at onset of 1 yr. At birth, macrosomia is rarely observed, and response to diazoxide is almost uniform. The initial presentation may be delayed and rarely may occur as late as 30 yr, unless provoked by fasting. The genetic basis for this autosomal dominant form has not been delineated; it is not always linked to KIR 6.2/SUR1. The activating mutation in glucokinase is transmitted in an autosomal dominant manner. If a family history is present, genetic counseling for a 50% recurrence rate can be given for future offspring.

A 3rd form of persistent PHHI is associated with mild and asymptomatic hyperammonemia, usually as a sporadic occurrence, although dominant inheritance occurs. Presentation is more like the autosomal dominant form than the autosomal recessive form. Diet and diazoxide control symptoms, but pancreatectomy may be necessary in some patients. The association of hyperinsulinism and hyperammonemia is caused by an inherited or de novo gain-of-function mutation in the enzyme glutamate dehydrogenase. The resulting increase in glutamate oxidation in the pancreatic β cell raises the ATP concentration and thus the ATP/ADP ratio, which closes K_{ATP}, leading to membrane depolarization, calcium influx, and insulin secretion (see Fig. 111.2). In the liver the excessive oxidation of glutamate to β-ketoglutarate may generate ammonia and divert glutamate from being processed to N-acetylglutamate, an essential cofactor for removal of ammonia through the urea cycle by activation of the enzyme carbamoyl phosphate synthetase. The hyperammonemia is mild,
with concentrations of 100-200 µM/L, and produces no CNS symptoms or consequences, as seen in other hyperammonemic states. Leucine, a potent amino acid for stimulating insulin secretion and implicated in **leucine-sensitive hypoglycemia**, acts by allosterically stimulating glutamate dehydrogenase. Thus, leucine-sensitive hypoglycemia may be a form of the hyperinsulinemia-hyperammonemia syndrome or a potentiation of mild disorders of the $K_{\text{ATP}}$ channel; it need not always be associated with a modest increase in serum ammonia.

Hypoglycemia associated with hyperinsulinemia is also seen in approximately 50% of patients with **Beckwith-Wiedemann syndrome** (see Chapter 576). This syndrome is caused by an imprinting disorder (see Chapter 98.8) and characterized by omphalocele, gigantism, macroglossia, microcephaly, and visceromegaly (Fig. 111.4). Distinctive lateral earlobe fissures and facial nevus flammeus are present; hemihypertrophy occurs in many of these infants. Diffuse islet cell hyperplasia occurs in infants with hypoglycemia. The diagnostic and therapeutic approaches are the same as those discussed previously, although microcephaly and slowing of brain development may occur independent of hypoglycemia. Patients with Beckwith-Wiedemann syndrome may acquire tumors, including Wilms tumor, hepatoblastoma, adrenal carcinoma, gonadoblastoma, and rhabdomyosarcoma. This overgrowth syndrome is caused by mutations in the chromosome 11p15.5 region close to the genes for insulin, $SUR1$, $K_{IR}$ 6.2, and $IGF2$. Duplications in this region and genetic imprinting from a defective or absent copy of the maternally derived gene are involved in the variable features and patterns of transmission. Hypoglycemia may resolve in weeks to months of medical therapy. Pancreatic resection may rarely be needed.
Kabuki syndrome, caused by mutations in a methyltransferase or demethylase, is the 2nd most common syndromic form of hyperinsulinemic hypoglycemia of infancy (HHI) after Beckwith-Wiedemann Syndrome. Neonatal hypoglycemia with congenital hyperinsulinism occurs in about 70% of children with this syndrome; most are diazoxide responsive. Congenital hyperinsulinemia also is reported to occur in Turner syndrome. Activating mutations in AKT2 and in PI3-kinase of the insulin signaling cascade have been reported in association with hypoketotic hypoglycemia and other metabolic features indicative of excessive insulin action, but insulin concentrations are subnormal as a result of negative feedback from the activated insulin receptor signal.

HHI is reported as a manifestation of 1 form of congenital disorder of glycosylation. Disorders of protein glycosylation usually present with neurologic symptoms but may also include liver dysfunction with hepatomegaly,
intractable diarrhea, protein-losing enteropathy, and hypoglycemia (see Chapter 105.6). These disorders are often underdiagnosed. One entity associated with HHI is caused by phosphomannose isomerase deficiency, and clinical improvement followed supplemental treatment with oral mannose, 0.17 g/kg 6 times per day.

After the 1st 12 mo of life, hyperinsulinemic states are uncommon until islet cell adenomas reappear as a cause after the patient is several years of age. Hyperinsulinemia as a result of islet cell adenoma should be considered in any child ≥5 yr who presents with hypoglycemia. Islet cell adenomas do not “light up” during scanning with 18 F-labeled L-dopa. An islet cell adenoma in a child should arouse suspicion of the possibility of multiple endocrine neoplasia type I (Wermer syndrome), which involves mutations in the menin gene and may be associated with hyperparathyroidism and pituitary tumors. Tables 111.7 and 111.8 outline the diagnostic approach. In a newborn, fasting for only 6-8 hr (1 missed meal in a 3-4 hr feeding schedule) may be sufficient to provoke hypoglycemia, and this maneuver should be performed to exclude persistent forms of hypoglycemia before discharge from a neonatal unit. In older infants and children, fasting for up to 24-36 hr usually provokes hypoglycemia; coexisting hyperinsulinemia confirms the diagnosis, provided that factitious administration of insulin by the parents is excluded. Occasionally, provocative tests may be required. Exogenously administered insulin can be distinguished from endogenous insulin by simultaneous measurement of C-peptide concentration. If C-peptide levels are elevated, endogenous insulin secretion is responsible for the hypoglycemia; if C-peptide levels are low but insulin values are high, exogenous insulin has been administered, perhaps as a form of child abuse (see Chapter 16.2). Islet cell adenomas at this age are treated by surgical excision. Antibodies to insulin or the insulin receptor (insulin mimetic action) are also rarely associated with hypoglycemia. Some tumors produce IGFs, thereby provoking hypoglycemia by interacting with the insulin receptor. The astute clinician must also consider the possibility of deliberate or accidental ingestion of drugs such as a sulfonylurea or related compound that stimulates insulin secretion. In such cases, both insulin and C-peptide concentrations in blood will be elevated. Inadvertent substitution of an insulin secretagogue by a dispensing error should be considered in those taking medications who suddenly develop documented hypoglycemia.

1 Glucose-6-phosphatase deficiency.
2 Hepatomegaly may not be present in the newborn.

Details of each condition are discussed in the text.

0 absence of ketonuria or hepatomegaly; + mildly detected ketonuria or hepatomegaly; ++ moderately increased; +++ markedly increased; 0, Absence; ↑ or ↓ indicates, respectively, small increase or decrease; ↑↑ or ↓↓ indicates, respectively, large increase or decrease.

A rare form of hyperinsulinemic hypoglycemia has been reported after exercise. Whereas glucose and insulin remain unchanged in most people after moderate, short-term exercise, rare patients manifest severe hypoglycemia with hyperinsulinemia 15-50 min after the same standardized exercise. This form of exercise-induced hyperinsulinism is caused by abnormal responsiveness of β-cell insulin release to pyruvate generated during exercise. The gene responsible
for this syndrome, *SLC16A1*, regulates a transporter (MCT1R) that controls the entry of pyruvate into cells. Dominant mutations in *SLC16A1* that increase the ectopic expression of MCTR1 in pancreatic β cells permit excessive entry of pyruvate into β cells and act to increase insulin secretion, with resultant hypoglycemia during exercise.

Hypoglycemia with so-called nesidioblastosis has also rarely been reported after *bariatric surgery* for obesity. The mechanism for this form of hyperinsulinemic hypoglycemia remains to be defined.

Infants and children with *Nissen fundoplication*, a relatively common procedure used to ameliorate gastroesophageal reflux, frequently have an associated “dumping” syndrome with hypoglycemia. Characteristic features include significant hyperglycemia of 200 mg/dL and up to 500 mg/dL 30 min postprandially, and severe hypoglycemia (average 32 mg/dL in one series) 1.5-3.0 hr later. The early hyperglycemia phase is associated with brisk and excessive insulin release that causes the rebound hypoglycemia. A role for exaggerated GLP1 secretion has been proposed and glucagon responses have been reported to be inappropriately low in some cases. However, the physiologic mechanisms are not always clearly understood, and attempted treatments not always effective; *acarbose*, an inhibitor of glucose absorption, was reported to be successful in one small series.

**Endocrine Deficiencies**

Hypoglycemia associated with endocrine deficiency is usually caused by adrenal cortisol insufficiency with or without associated growth hormone deficiency (see *Chapters 573* and *593*). In *panhypopituitarism*, isolated adrenocorticotropic hormone (ACTH) or GH deficiency, or combined ACTH and GH deficiency, the incidence of hypoglycemia is as high as 20%. In the newborn period, hypoglycemia may be the presenting feature of hypopituitarism; in males, a microphallus may provide a clue to a coexisting deficiency of gonadotropin. Newborns with hypopituitarism often have a form of hepatitis associated with *cholestatic jaundice* and hypoglycemia. The combination of hypoglycemia and cholestatic jaundice requires exclusion of hypopituitarism as a cause, as the jaundice resolves with replacement treatment of GH, cortisol, and thyroid as required. This constellation is often associated with the syndrome of *septooptic dysplasia*. When adrenal disease is severe, as in congenital adrenal hyperplasia caused by enzyme defects in cortisol synthesis, adrenal hemorrhage, or
congenital adrenal hypoplasia, serum electrolyte disturbances with hyponatremia and hyperkalemia or disordered genital development may provide diagnostic clues (see Chapter 576). In older children, failure of growth should suggest GH deficiency. Hyperpigmentation, weakness, or salt craving may provide the clue to primary adrenal insufficiency (Addison disease), characterized by greatly increased ACTH levels or adrenal unresponsiveness to exogenous ACTH caused by a defect in the adrenal receptor for ACTH, congenital adrenal hypoplasia, adrenoleukodystrophy, or the Allgrove triple A syndrome. The frequent association of Addison disease in childhood with hypoparathyroidism (hypocalcemia), chronic mucocutaneous candidiasis, and other endocrinopathies that constitute the autoimmune polyendocrinopathy syndrome type 1 should be considered. Adrenoleukodystrophy and congenital adrenal hypoplasia are sex-linked conditions and should be considered in the differential diagnosis of primary Addison disease in male children (see Chapter 104.2).

Hypoglycemia in cortisol-GH deficiency may be caused by decreased gluconeogenic enzymes with cortisol deficiency, increased glucose utilization because of a lack of the antagonistic effects of GH on insulin action, or failure to supply endogenous gluconeogenic substrate in the form of alanine and lactate with compensatory breakdown of fat and generation of ketones. Deficiency of these hormones results in reduced gluconeogenic substrate, which resembles the syndrome of ketotic hypoglycemia. Investigation of a child with hypoglycemia therefore requires exclusion of ACTH-cortisol or GH deficiency and, if diagnosed, its appropriate replacement with cortisol or GH.

Epinephrine deficiency could theoretically be responsible for hypoglycemia. Urinary excretion of epinephrine has been decreased in some patients with spontaneous or insulin-induced hypoglycemia in whom absence of pallor and tachycardia were also noted. This suggests that failure of catecholamine release, as the result of a defect anywhere along the hypothalamic-autonomic-adrenomedullary axis, might be responsible for the hypoglycemia. This possibility has been challenged, however, because of the rarity of hypoglycemia in patients with bilateral adrenalectomy, provided that they receive adequate glucocorticoid replacement, and because diminished epinephrine excretion is found in normal patients with repeated insulin-induced hypoglycemia. Many of the patients described as having hypoglycemia with failure of epinephrine excretion fit the criteria for ketotic hypoglycemia (see next). Also, repetitive hypoglycemia leads to diminished cortisol plus epinephrine responses, as seen most often in insulin-treated diabetes mellitus and the syndrome of
hypoglycemia unawareness, associated with autonomic failure.

Glucagon deficiency in infants or children may theoretically be associated with hypoglycemia but has never been documented.

**Substrate-Limited Etiologies**

**Ketotic Hypoglycemia**

Idiopathic ketotic hypoglycemia is the most common form of *childhood* hypoglycemia. This condition usually presents between ages 18 mo and 5 yr and remits spontaneously by 8-9 yr. Hypoglycemic episodes typically occur during periods of intercurrent illness when food intake is limited. The classic history is of a child who eats poorly or completely avoids the evening meal, is difficult to arouse from sleep the following morning and thus eats poorly again, and may have a seizure or may be comatose by mid-morning. Another common presentation occurs when parents sleep late, and the affected child is unable to eat breakfast, thus prolonging the overnight fast.

At the time of documented hypoglycemia, there is associated marked ketonuria and ketonemia; plasma insulin concentrations are appropriately low, ≤5 µU/mL, thus excluding hyperinsulinemia. A ketogenic-provocative diet, formerly a diagnostic test, is no longer used to establish the diagnosis because fasting alone provokes a hypoglycemic episode with ketonemia and ketonuria within 12-18 hr in susceptible individuals. Normal children of similar age can withstand fasting without hypoglycemia developing during the same period, although even normal children may acquire these features by 36 hr of fasting.

Children with ketotic hypoglycemia have plasma alanine concentrations that are markedly reduced in the basal state after an overnight fast and decline even further with prolonged fasting. **Alanine**, produced in muscle, is a major gluconeogenic precursor. Alanine is the only amino acid that is significantly lower in these children, and infusions of alanine (250 mg/kg) produce a rapid rise in plasma glucose without causing significant changes in blood lactate or pyruvate levels, indicating that the entire gluconeogenic pathway from the level of pyruvate is intact, but that there is a deficiency of substrate. Glycogenolytic pathways are also intact because glucagon induces a normal glycemic response in affected children in the fed state. The levels of hormones that counter hypoglycemia are appropriately elevated, and insulin is appropriately low.

The etiology of ketotic hypoglycemia may be a defect in any of the complex steps involved in protein catabolism, oxidative deamination of amino acids,
transamination, alanine synthesis, or alanine efflux from muscle. Children with ketotic hypoglycemia are frequently smaller than age-matched controls and often have a history of transient neonatal hypoglycemia. Any decrease in muscle mass may compromise the supply of gluconeogenic substrate at a time when glucose demands per unit of body weight are already relatively high, thus predisposing the patient to the rapid development of hypoglycemia, with ketosis representing the attempt to switch to an alternative fuel supply. Children with ketotic hypoglycemia may represent the low end of the spectrum of children's capacity to tolerate fasting. Similar relative intolerance to fasting is present in normal children, who cannot maintain blood glucose after 30-36 hr of fasting, compared with the adult's capacity for prolonged fasting. Although the defect may be present at birth, it may not be evident until the child is stressed by more prolonged periods of calorie restriction. Moreover, the spontaneous remission observed in children at age 8-9 yr might be explained by the increase in muscle bulk with its resultant increase in supply of endogenous substrate and the relative decrease in glucose requirement per unit of body mass with increasing age.

In anticipation of spontaneous resolution of this syndrome, treatment of ketotic hypoglycemia consists of frequent feedings of a high-protein, high-carbohydrate diet. During intercurrent illnesses, parents should be taught to test the child's urine for the presence of ketones, the appearance of which precedes hypoglycemia by several hours. In the presence of ketonuria, liquids of high carbohydrate content should be offered to the child. If these cannot be tolerated, the child should be treated with IV glucose administration in a hospital.

**Branched-Chain Ketonuria (Maple Syrup Urine Disease)**

See Chapter 103.6.

The hypoglycemic episodes were once attributed to high levels of leucine, but evidence indicates that interference with the production of alanine and its availability as a gluconeogenic substrate during calorie deprivation is responsible for hypoglycemia.

**Glycogen Storage Disease**

See Chapter 105.1.

**Glucose-6-Phosphatase Deficiency (Type I Glycogen Storage Disease)**
Affected children usually display a remarkable tolerance to their chronic hypoglycemia; blood glucose values in the range of 20-50 mg/dL are not associated with the classic symptoms of hypoglycemia, possibly reflecting the adaptation of the CNS to ketone bodies and lactate as alternative fuels. Hepatomegaly and poor growth are consistent physical features. Hypoglycemia is associated with acidosis (HCO$_3^-$ < 18 mEq/L) and increased β-hydroxybutyrate and lactate; hyperuricemia also is frequently seen. Management is discussed in detail in Chapter 105.1.

**Amylo-1,6-Glucosidase Deficiency (Debrancher Enzyme Deficiency; Type III Glycogen Storage Disease)**

See Chapter 105.1.

**Liver Phosphorylase Deficiency (Type VI Glycogen Storage Disease)**

Low hepatic phosphorylase activity may result from a defect in any of the steps of activation; a variety of defects have been described. Hepatomegaly, excessive deposition of glycogen in liver, growth retardation, and occasional symptomatic hypoglycemia occur. A diet high in protein and reduced in carbohydrate usually prevents hypoglycemia.

**Glycogen Synthetase Deficiency**

The inability to synthesize glycogen is rare. Hypoglycemia and hyperketonemia occur after fasting because glycogen reserves are greatly decreased or absent. After feeding, however, hyperglycemia with glucosuria may occur because of the inability to assimilate some of the glucose load into glycogen. During fasting hypoglycemia, levels of the counter-regulatory hormones, including catecholamines, are appropriately elevated or normal, and insulin levels are appropriately low. The liver is not enlarged. Protein-rich feedings at frequent intervals result in dramatic clinical improvement, including growth velocity. Glycogen synthetase deficiency mimics the syndrome of ketotic hypoglycemia and should be considered in the differential diagnosis of that syndrome.

**Disorders of Gluconeogenesis**

**Fructose-1,6-Diphosphatase Deficiency**
A deficiency of this enzyme results in a block of gluconeogenesis from all possible precursors below the level of fructose-1,6-diphosphate. Infusion of these gluconeogenic precursors results in lactic acidosis without a rise in glucose; acute hypoglycemia may be provoked by inhibition of glycogenolysis. Glycogenolysis remains intact, and glucagon elicits a normal glycemic response in the fed, but not in the fasted, state. Accordingly, affected individuals have hypoglycemia only during caloric deprivation, as in fasting, or during intercurrent illness. As long as glycogen stores remain normal, hypoglycemia does not develop. In affected families, there may be a history of siblings with known hepatomegaly who died in infancy with unexplained metabolic acidosis.

**Defects in Fatty Acid Oxidation**

See Chapter 104.1.

The important role of fatty acid oxidation in maintaining gluconeogenesis is underscored by examples of congenital or drug-induced defects in fatty acid metabolism that may be associated with fasting hypoglycemia. Various congenital enzymatic deficiencies cause defective carnitine or fatty acid metabolism. A severe and relatively common form of fasting hypoglycemia with hepatomegaly, cardiomyopathy, and hypotonia occurs with long- and medium-chain fatty acid CoA dehydrogenase deficiency. Plasma carnitine levels are low, ketones are not present, but dicarboxylic aciduria is present in urine. Clinically, patients with acyl-CoA dehydrogenase deficiency present with a Reye-like syndrome (see Chapter 388), recurrent episodes of severe fasting hypoglycemic coma, and cardiorespiratory arrest (sudden infant death syndrome–like events). Severe hypoglycemia and metabolic acidosis without ketosis also occur in patients with multiple acyl-CoA dehydrogenase disorders. Hypotonia, seizures, and acid odor are other clinical clues. Survival depends on whether the defects are severe or mild; diagnosis is established from studies of enzyme activity in liver biopsy tissue or in cultured fibroblasts from affected patients. Tandem mass spectrometry can be employed for blood samples, even those on filter paper, for screening of congenital inborn errors. Molecular diagnosis also is available for most entities. The frequency of acyl-CoA dehydrogenase deficiency is at least 1 in 10,000-15,000 births. Avoidance of fasting and supplementation with carnitine may be lifesaving in these patients, who generally present in infancy.

Interference with fatty acid metabolism also underlies the fasting
hypoglycemia associated with Jamaican vomiting sickness, with atractyloside, and with the drug valproate. In Jamaican vomiting sickness the unripe ackee fruit contains a water-soluble toxin, hypoglycin, which produces vomiting, CNS depression, and severe hypoglycemia. The hypoglycemic activity of hypoglycin derives from its inhibition of gluconeogenesis secondary to its interference with the acyl-CoA and carnitine metabolism essential for the oxidation of long-chain fatty acids. The disease is almost totally confined to Jamaica, where ackee forms a staple of the diet for the poor population. The ripe ackee fruit no longer contains this toxin.

Atractyloside is a reagent that inhibits oxidative phosphorylation in mitochondria by preventing the translocation of adenine nucleotides, such as ATP, across the mitochondrial membrane. Atractyloside is a perhydrophenanthrenic glycoside derived from Atractylis gummifera. This plant is found in the Mediterranean basin; ingestion of this “thistle” is associated with hypoglycemia and a syndrome similar to Jamaican vomiting sickness. A similar illness noted in India, the acute toxic encephalopathy-hypoglycemic syndrome, may be caused by litchi consumption. Litchi contains hypoglycin A and/or methylenecyclopropylglycine, which may inhibit fatty acid oxidation or gluconeogenesis.

The anticonvulsant drug valproate is associated with side effects, predominantly in young infants, which include a Reye-like syndrome, low serum carnitine levels, and the potential for fasting hypoglycemia.

In all these conditions, hypoglycemia is not associated with ketonemia and ketonuria.

Acute Alcohol Intoxication

The liver metabolizes alcohol as a preferred fuel, and generation of reducing equivalents during the oxidation of ethanol alters the reduced form of nicotinamide adenine dinucleotide:nicotinamide adenine dinucleotide ratio, which is essential for certain gluconeogenic steps. As a result, gluconeogenesis is impaired and hypoglycemia may ensue if glycogen stores are depleted by starvation or by preexisting abnormalities in glycogen metabolism. In toddlers who have been unfed for some time, even the consumption of small quantities of alcohol can precipitate these events. The hypoglycemia promptly responds to IV glucose, which should always be considered in a child who presents initially with coma or seizure, after taking a blood sample to determine glucose concentration. The possibility that child ingested alcoholic drinks must also be
considered if there was a preceding evening party. A careful history allows the diagnosis to be made and may avoid needless and expensive hospitalization and investigation.

**Salicylate Intoxication**

See Chapter 77.

Both hyperglycemia and hypoglycemia occur in children with salicylate intoxication. Accelerated utilization of glucose, resulting from augmentation of insulin secretion by salicylates, and possible interference with gluconeogenesis may contribute to hypoglycemia. Infants are more susceptible than older children. Monitoring of blood glucose levels with appropriate glucose infusion in the event of hypoglycemia should form part of the therapeutic approach to salicylate intoxication in childhood. Ketosis may occur.

**Phosphoenolpyruvate Carboxykinase Deficiency**

Deficiency of the rate-limiting gluconeogenic enzyme phosphoenolpyruvate carboxykinase is associated with severe fasting hypoglycemia and variable onset after birth. Hypoglycemia may occur within 24 hr after birth, and defective gluconeogenesis from alanine can be documented in vivo. Liver, kidney, and myocardium demonstrate fatty infiltration, and atrophy of the optic nerve and visual cortex may occur. Hypoglycemia may be profound. Lactate and pyruvate levels in plasma have been normal, but a mild metabolic acidosis may be present. The fatty infiltration of various organs is caused by increased formation of acetyl-CoA, which becomes available for fatty acid synthesis. Diagnosis of this rare entity can be made with certainty only through appropriate enzymatic determinations in liver biopsy material or molecular diagnosis. Avoidance of periods of fasting through frequent feedings rich in carbohydrate should be helpful because glycogen synthesis and breakdown are intact.

**Pyruvate Carboxylase Deficiency**

See Chapter 105.4.

**Other Enzyme Defects**

**Galactosemia (Galactose-1-Phosphate Uridyl Transferase Deficiency)**
See Chapter 105.2.

**Fructose Intolerance (Fructose-1-Phosphate Aldolase Deficiency)**

See Chapter 105.3.

Acute hypoglycemia is caused by fructose-1-phosphate aldolase deficiency, which inhibits glycogenolysis via the phosphorylase system and of gluconeogenesis at the level of fructose-1,6-diphosphate aldolase. Affected individuals usually learn spontaneously to eliminate fructose from their diet.

**Defects in Glucose Transporters**

**GLUT-1 Deficiency**

Rarely, infants with a seizure disorder are found to have low CSF glucose concentrations despite normal plasma glucose. Lactate concentrations in CSF are low, suggesting decreased glycolysis rather than bacterial infection, which causes low CSF glucose with high lactate. The erythrocyte glucose transporter (GLUT-1) is defective, suggesting a similar defect in the brain glucose transporter responsible for the clinical features. A ketogenic diet reduces the severity of seizures by supplying an alternate source of brain fuel that bypassed the defect in glucose transport.

**GLUT-2 Deficiency**

Children with hepatomegaly, galactose intolerance, and renal tubular dysfunction (Fanconi-Bickel syndrome) have a deficiency of GLUT-2 of plasma membranes. In addition to liver and kidney tubules, GLUT-2 is also expressed in pancreatic β cells. Thus the clinical manifestations reflect impaired glucose release from liver and defective tubular reabsorption of glucose plus phosphaturia and aminoaciduria.

**Systemic Disorders**

Several systemic disorders are associated with hypoglycemia in infants and children. Neonatal sepsis is often associated with hypoglycemia, possibly as a result of diminished caloric intake with impaired gluconeogenesis. Similar mechanisms may apply to the hypoglycemia found in severely malnourished
infants or those with severe malabsorption. Hyperviscosity with a central hematocrit >65% is associated with hypoglycemia in at least 10–15% of affected infants. Falciparum malaria is associated with hyperinsulinemia and hypoglycemia. Heart and renal failure are also associated with hypoglycemia, but the mechanism is obscure.

**Diagnosis and Differential Diagnosis**

Table 111.8 and Fig. 111.5 list the pertinent clinical and biochemical findings in the common childhood disorders associated with hypoglycemia. A careful and detailed history is essential in every suspected or documented case of hypoglycemia (see Table 111.7). Specific points to note include age at onset, temporal relation to meals or caloric deprivation, and a family history of prior infants known to have had hypoglycemia or of unexplained infant deaths.

![Algorithm for diagnosis of hypoglycemia based on fasting fuel responses.](image)

In the 1st week of life, most infants have the transient form of neonatal hypoglycemia either as a result of prematurity/intrauterine growth restriction or by virtue of being born to diabetic mothers. The absence of a history of maternal diabetes, but the presence of macrosomia and the characteristic large plethoric appearance of an infant of a diabetic mother, should arouse the possibility of hyperinsulinemic hypoglycemia of infancy, probably resulting from a $K_{ATP}$ channel defect that is familial (autosomal recessive) or sporadic. Decreased β-
hydroxybutyrate, low FFAs, and plasma insulin concentration >5 μU/mL or C-peptide >0.5 ng/mL in the presence of documented hypoglycemia confirm this diagnosis. The presence of hepatomegaly should arouse suspicion of an enzyme deficiency such as glucose-6-phosphatase in glycogen storage disease (GSD) I or other GSDs; if a non–glucose-reducing sugar is present in the urine (e.g., Clinitest positive but Clinistix negative), galactosemia is most likely. In males, the presence of a microphallus suggests the possibility of hypopituitarism, which also may be associated with cholestatic jaundice in both sexes; evidence of a midline facial defect such as cleft palate also suggests possible hypopituitarism as the cause of hypoglycemia from deficiency in GH and/or cortisol. A high index of suspicion and awareness of hypoglycemia as the cause for unusual behavior of any sick newborn should prompt a bedside glucose determination. However, because glucose meters have an accuracy of only ±20%, any blood glucose value <60 mg/dL must be confirmed by a formal laboratory measurement that is performed without delay on a blood sample preserved in a tube that prevents glycolysis, which can cause spurious low values.

After the newborn period, clues to the cause of persistent or recurrent hypoglycemia may be obtained through a careful history, physical examination, and initial laboratory findings. The temporal relation of the hypoglycemia to food intake may suggest that the defect is one of gluconeogenesis, if symptoms occur 6 hr or more after meals. If hypoglycemia occurs shortly after meals, hyperinsulinism should be suspected and confirmed or excluded via measurement of β-hydroxybutyrate, insulin, C-peptide, and FFAs in a sample in which blood glucose is <55 mg/dL. The autosomal dominant forms of hyperinsulinemic hypoglycemia need to be considered, with measurement of glucose, insulin, and ammonia and careful history for other affected family members of any age. Measurement of IGFBP-1 may be useful; it is low in states of hyperinsulinism and high in other forms of hypoglycemia. The presence of hepatomegaly suggests one of the enzyme deficiencies in glycogen breakdown or in gluconeogenesis, as outlined in Table 111.8. The absence of ketonemia or ketonuria at the initial presentation strongly suggests hyperinsulinism or a defect in fatty acid oxidation. In most other causes of hypoglycemia, with the exception of galactosemia and fructose intolerance, ketonemia and ketonuria are present at the time of fasting hypoglycemia. During hypoglycemia, serum should be obtained for determination of substrates, especially glucose, β-hydroxybutyrate, lactate, and FFAs, as well as hormones, especially insulin, C-peptide, cortisol, ACTH, and GH, followed by repeated measurement of glucose after an
intramuscular or IV injection of glucagon, as outlined in Table 111.7. Table 111.8 summarizes the interpretation of the findings. Hypoglycemia with ketonuria in children between ages 18 mo and 5 yr is most likely to be ketotic hypoglycemia, especially if hepatomegaly is absent. The ingestion of a toxin, including alcohol or salicylate, can usually be excluded rapidly by the history. Inadvertent or deliberate drug ingestion and errors in dispensing medicines should also be considered. Factitious disorder (Munchausen) by proxy should be considered when parents or other caregivers have access to insulin or insulin secretagogues—high insulin concentrations in the sample with low concentrations of C-peptide confirm exogenous insulin administration.

Deliberate or accidental ingestion of drugs that stimulate endogenous insulin secretion will result in both high insulin and C-peptide concentrations and may require specialized laboratory methods that identify the offending substance.

When the history is suggestive, but acute symptoms are not present, a 24 hr supervised fast can usually provoke hypoglycemia and resolve the question of hyperinsulinism or other conditions (see Table 111.8). Such a fast rarely needs to be extended to 36 hr, and only in older children. Such a fast is contraindicated if a fatty acid oxidation defect is suspected; other approaches such as mass tandem spectrometry or molecular diagnosis, or both, should be considered. Because adrenal insufficiency may mimic ketotic hypoglycemia, plasma cortisol and ACTH levels should be determined at the time of documented hypoglycemia; increased buccal or skin pigmentation may provide the clue to primary adrenal insufficiency with elevated ACTH (melanocyte-stimulating hormone) activity. Short stature or a decrease in the growth rate may provide the clue to pituitary insufficiency involving GH as well as ACTH. Definitive tests of pituitary-adrenal function, such as the arginine-insulin stimulation test for GH, IGF-1, IGFBP-1, and cortisol release, may be necessary.

In the presence of hepatomegaly and hypoglycemia, a presumptive diagnosis of the enzyme defect can often be made through the clinical manifestations, presence of hyperlipidemia, acidosis, hyperuricemia, response to glucagon in the fed and fasted states, and response to infusion of various appropriate precursors (see Table 111.7). Table 111.8 summarizes these clinical findings and investigative approaches. Definitive diagnosis of the GSD may require molecular diagnosis (see Chapter 105.1). Occasional patients with all the manifestations of GSD are found to have normal enzyme activity. These definitive studies require special expertise available only in certain institutions.
Treatment

The prevention of hypoglycemia and its resultant effects on CNS development are critically important in the newborn period. For neonates with hyperinsulinism not associated with maternal diabetes, subtotal or focal pancreatectomy may be needed, unless hypoglycemia can be readily controlled with long-term diazoxide, with somatostatin analogs (e.g., octreotide), or with sirolimus. Other novel approaches for treating hyperinsulinemic hypoglycemia are being investigated.

Treatment of acute symptomatic neonatal or infant hypoglycemia includes IV administration of 2 mL/kg of 10% dextrose in water (D10W), followed by a continuous infusion of glucose at 6-8 mg/kg/min, adjusting the rate to maintain blood glucose levels in the normal range. If hypoglycemic seizures are present, some recommend a 4 mL/kg bolus of D10W.

Treatment of asymptomatic hypoglycemia in at-risk infants usually includes enteral feedings rather than parenteral glucose. If symptoms develop or the hypoglycemia persists despite enteral feedings, IV glucose is indicated. Dextrose gel (40% at 400 mg/kg) administered into the mouth may be an alternative to enteral feedings if breast milk or if formula is not available.

The management of persistent neonatal or infantile hypoglycemia includes increasing the rate of IV glucose infusion to 10-15 mg/kg/min or more, if needed. This may require a central venous or umbilical venous catheter to administer a hypertonic 15–25% glucose solution. If hyperinsulinism is present, it should be medically managed initially with diazoxide and then somatostatin analogs. If hypoglycemia is unresponsive to IV glucose plus diazoxide (maximal doses up to 15 mg/kg/day) and somatostatin analogs, partial or near-total pancreatectomy should be considered. Such surgery should be performed in centers with the requisite facilities and trained staff experienced in the procedures. If possible, surgery should be preceded by 18F-L-DOPA scanning to localize a lesion which can then provide guidance to the surgeon for curative resection before the operation is undertaken.

Oral diazoxide, 5-15 mg/kg/24 hr in divided doses twice daily, may reverse hyperinsulinemic hypoglycemia but may also produce hirsutism, edema, nausea, hyperuricemia, electrolyte disturbances, advanced bone age, IgG deficiency, and rarely, hypertension with prolonged use. The long-acting somatostatin analog octreotide may be helpful in controlling hyperinsulinism causing hypoglycemia in patients with islet cell disorders, including genetic mutations in K_{ATP} channel.
and islet cell adenoma. In neonates and young infants, glucagon given by continuous IV infusion at 5 µg/kg/hr, together with octreotide, 20-50 µg/kg/day subcutaneously every 6-12 hr, may maintain blood glucose, but generally these agents are used as a temporizing measure before partial or more complete pancreatectomy. Potential but unusual complications of octreotide include poor growth because of impaired GH release, pain at the injection site, vomiting, diarrhea, and hepatic dysfunction (hepatitis, cholelithiasis), and necrotizing enterocolitis; tachyphylaxis to the drug's effects is more common. Octreotide may be particularly useful for the treatment of refractory hypoglycemia despite subtotal pancreatectomy.

Total pancreatectomy is not optimal therapy because of the risks of surgery, permanent diabetes mellitus, and exocrine pancreatic insufficiency. Continued prolonged medical therapy without pancreatic resection, if hypoglycemia is controllable, is worthwhile because over time some children have a spontaneous resolution of the hyperinsulinism-induced hypoglycemia. This should be balanced against the risk of hypoglycemia-induced CNS injury and the toxicity of drugs.

**Prognosis**

The prognosis is good in asymptomatic neonates with hypoglycemia of short duration. Hypoglycemia recurs in 10–15% of infants after adequate treatment. Recurrence is more common if IV fluids are extravasated or discontinued too rapidly before oral feedings are well tolerated. Children who had transient neonatal hypoglycemia have an increased incidence of ketotic hypoglycemia later in life.

The prognosis for normal intellectual function must be guarded because prolonged, recurrent, and severe symptomatic hypoglycemia is associated with neurologic sequelae. Symptomatic infants with hypoglycemia, particularly low-birthweight infants, those with persistent hyperinsulinemic hypoglycemia, and severely hypoglycemic infants born to poorly controlled diabetic mothers, have a poorer prognosis for subsequent normal intellectual development than asymptomatic infants.

Infant Mortality

The infant mortality rate is a metric used by public health agencies, policymakers, and governments to gauge the overall quality of pediatric and population health among a given population residing within geographically defined boundaries. The rate is stated as the number of infant deaths per 1,000 live births. Specific definitions support each variable. In the United States, an infant death is defined as mortality taking place from the time after delivery at any gestational age, up to the 1st birthday. No age correction is made to account for a premature birth. Each infant death is assigned to a geographic entity (e.g., county, state, country) on the basis of the mother’s home address at the time of death. The definition of a live birth is typically based on the complete expulsion of the productions of conception from the uterus and 1 of 3 criteria: detection of cardiac activity (by auscultation or palpation of the umbilical cord stump), definite movement generated by voluntary muscle contraction, or any respiratory effort. It is important to note that this definition does not incorporate any gestational age cutoff.

The risk of mortality and major morbidity is particularly high around the time of birth (Fig. 112.1). Therefore, within the spectrum of infant mortality, certain subcategories are used in maternal and child health practice to focus on specific periods of high risk. The perinatal period is typically defined as the time from the 28th wk of pregnancy through the 7th postpartum day. The neonatal period spans the 1st 28 days of life and can be further subdivided into early neonatal (1st 7 days) and late neonatal (days 8-28) (Fig. 112.2). The primary causes of mortality shift as infancy progresses: during the perinatal and neonatal periods, preterm birth (Fig. 112.3) and congenital malformations predominate,
whereas **unsafe sleep practices** accounts for the majority of deaths during the remainder of infancy. In developing countries with limited resources, preterm birth remains a concern, but other causes, such as infection, birth asphyxia, and complications of labor and delivery, add an additional burden (see **Fig. 112.2**).
FIG. 112.2  A, Cause of death distribution for the neonatal period, and by the early (<7 days) and late (7–28 days) neonatal periods, for 194 countries in 2012. B, Variation in cause-specific neonatal mortality rates (NMRs) by level of NMR in 2012, showing risk difference by cause of death compared with the lowest mortality group (NMR <5). Data from Child Health Epidemiology Reference Group and World Health Organization (WHO) estimates for 194 countries for 2012. Estimates are based on multicause statistical models. In 2012, an additional estimated 196,000 deaths occurred in the postneonatal period from neonatal conditions (preterm birth, intrapartum related) and an estimated further 309,000 from term, small for gestational age. (From Lawn JE, Blencowe H, Oza S, et al: Every
Rankings and Trends

Over the past century, infant mortality rates have declined in the United States and across most of the world. However, rates continue to differ worldwide (Fig. 112.4). In general, the highest rates are observed in low-resource, developing countries. However, the United States remains an anomaly among nations in the developed world. Table 112.1 shows infant mortality rates from a representative sample of developed countries. The rates are adjusted to exclude deaths before 24 wk gestation to account for potential variation in definitions of live births that might occur at the threshold of viability, to ensure comparability. Beginning in
the 1980s, U.S. rates began to consistently exceed other developed nations; in 2015, U.S. infant mortality rates were >2-fold higher than in many developed countries. A wide range of infant mortality rates is also observed, with the highest rates in the Southeast United States and lower rates in the Upper Midwest, the Northeast, and the West Coast.

Data from the National Center for Health Statistics: *Natl Vital Stat Rep* 63(5):1, 2014 (Fig 1).
[https://www.cdc.gov/nchs/data/nvsr/nvsr63/nvsr63_05.pdf](https://www.cdc.gov/nchs/data/nvsr/nvsr63/nvsr63_05.pdf).

**Major Causes of Infant Death**

In the United States and Europe, most infant deaths fall into 1 of 3 major categories of causation: preterm birth, congenital malformations, and sleep related (e.g., SIDS). Infections, trauma, birth asphyxia, and injuries account for the remainder. The pattern differs in the developing world, where infections and asphyxia predominate. When considered based on the classification of infant cause of death by the *International Classification of Diseases, Tenth Revision*, congenital malformations are the leading cause, followed by disorders related to prematurity and low birthweight. Nonetheless, preterm birth rather than congenital malformations accounts for the majority of infant deaths in the United States, when deaths from unique complications of prematurity are included.

The U.S. preterm birth rate is substantially higher than in other developed countries and best explains elevated U.S. infant mortality rates. Worldwide, preterm birth rates display a tight concordance with infant mortality rates, providing further evidence for the importance of this linkage (Fig. 112.5). In the era of modern neonatal intensive care, most preterm birth deaths occur among the earliest gestational ages (<28 wk), and within the 1st few days of life, because of profound respiratory immaturity and insufficiency. The remaining preterm birth deaths result from morbidities associated with prematurity. Late preterm birth (35-36 wk gestation) is not a significant contributor to infant mortality.
International variation in live-birth registration practices may explain the elevated U.S. infant mortality. Although these technical explanations deserve further investigation, they should not be used to justify high U.S. infant mortality. In the United States, where live-birth registration practices are consistent, substantial variation in infant mortality and preterm birth rates implies systemic rather than technical explanations.

**Racial Disparity and Infant Mortality**

There is a significant disparity between infant mortality rates among U.S.-born white and black (African American) infants. This difference persists, even when socioeconomic status (SES) and educational levels are considered. The disparity is restricted to blacks; Hispanic populations in the United States tend to have infant mortality rates in line with the white population. Understanding this *Hispanic paradox* may provide insight into mechanisms driving the African American disparity. Interestingly, South Asian (Indian) populations in the United States may also have elevated infant mortality driven by low birthweight. Preterm birth and low birthweight are the key drivers of the black infant mortality disparity. Black preterm births rates are twice that of other U.S. racial and ethnic groups (Fig. 112.6), a gap that has persisted for decades. This is
especially true for preterm birth rates at very low gestational ages, <28 wk, where mortality risks are high, even with the availability of modern neonatal intensive care units (NICUs). Racial disparities of mortality are not present among those receiving NICU care. Mechanistic explanations for the racial disparity remain elusive. Theories based on concepts of lifetime stress from experiences of racism or adverse life events are compelling (Chapter 2.1) However, studies focusing on stress and pregnancy outcomes fail to demonstrate clear mechanistic links.

**FIG. 112.6** The gap between black and white preterm birth rates in the United States has persisted for >3 decades. NH, Non-Hispanic; AIAN, American Indian/Alaskan Native; API, Asian/Pacific Islander. (Data from the National Center for Health Statistics.)

**Congenital Malformations**

Infant deaths from congenital malformations are the 2nd leading cause of infant death after premature birth. Many disorders reside in this category, with **congenital heart disease** the leading etiology. From a public health perspective, specific interventions can reduce the potential for certain congenital malformations, most notably periconceptional folic acid intake and appropriate vaccination programs to prevent diseases such as rubella during pregnancy. However, the mechanism of most congenital malformations remains poorly understood and therefore not yet amenable to population-based prevention strategies. In contrast to preterm birth, there is no discernible racial disparity for mortality caused by congenital malformations in the United States.
Sleep-Related Deaths (SUID, SIDS)

**Sudden unexpected infant death (SUID)** is a sudden and unexpected death during infancy. Following a thorough investigation of the death, SUID may be explained through mechanisms such as cosleeping and suffocation, or airway obstruction caused by soft objects or excessive bedding. **Sudden infant death syndrome (SIDS)** is a subcategory of SUID assigned to SUIDS that cannot be explained after a thorough investigation, including postmortem examination (see *Chapter 402*). SIDS represents a small fraction of all sleep-related deaths. With the advent of effective public health messaging, rates of sleep-related deaths in the United States have declined. However, a wide variation of rates is still observed across different geographic jurisdictions. SUID rates also display a racial disparity. The leading cause of infant death beyond the neonatal period is **unsafe infant sleep practices**.

Infant Mortality Reduction

Reduction of U.S. infant mortality is a challenging but attainable goal. Decreasing the preterm birth rate, especially extreme prematurity before 28 wk gestation, is an imperative. Improving our understanding of the biologic factors that control gestational duration and initiation of labor and delivery is key. Studies of intramuscular (but not vaginal) progesterone treatment during pregnancy for women known to be at elevated risk for a preterm birth have proved promising. However, the mechanism of action is not well understood, and the public health impact appears limited except perhaps for women with a previous preterm birth. Improving our understanding of how social determinants of health and health behavior influence birth outcomes is also important. **Smoking** during pregnancy is known to drive low birthweight, preterm birth, and elevated mortality. Improving interventions to eliminate smoking during pregnancy should reduce infant mortality. Understanding mechanistic links between the biology of parturition and the social and behavioral determinants of health is imperative.

Preterm Birth

Preterm birth is defined as a live birth occurring before the 37th wk of gestation. Comparison of preterm births between countries or other jurisdictions can be
compromised by methods used to calculate gestational age. Three approaches are currently in use: last menstrual period (LMP), obstetric estimate (OE), and a combined estimate. The last defers to the LMP unless the value is missing from the vital record information or is extremely inconsistent with the recorded birth weight. In this circumstance (0.4% of record in 2013) the combined method uses the OE value. From a public health perspective, the OE offers superior validity. Since 2014 reports by federal agencies and stakeholder organizations (e.g., March of Dimes) use the OE to state preterm birth rates. The OE is typically a 1–2% lower preterm birth rate than the LMP or combined method. In 2016 the national preterm birth rate based on OE was 9.84%, compared to an 11.40% rate using the combined method.

The mortality and morbidity challenges encountered by a newborn delivered at 36 wk differ in severity from delivery at 25 wk. Subcategories of preterm birth corresponding to late (35-36 wk), moderate (32-34 wk), and early (<32 wk) acknowledge important differences in morbidity and mortality risk. From an infant mortality perspective, an additional subcategory of the early preterm population, extreme preterm births (<28 wk) has substantial importance, because >50% of all infant deaths occur in this population.

In addition to socioeconomic and racial factors, genetic variables may be associated with pregnancy duration and risk for preterm birth. Variants in EBF1, EEFSEC, AGTR2, WNT4, ADCY5, and RAP2C are reported to be associated with pregnancy length, whereas variants in EBF1, EEFSEC, and AGTR2 loci are associated with preterm birth. In addition, 7 unrelated free RNA transcripts in maternal blood cells have been found to predict preterm delivery. These results are preliminary but may add specific targets for prevention of prematurity.

The Late Preterm Neonate

There is an important appreciation for the significance of late preterm delivery. Often these infants seem similar to their term counterparts, but epidemiologic data demonstrate that they are at significantly higher risk for apneic episodes, disorders of thermoregulation (e.g., hypothermia), hypoglycemia, respiratory distress, feeding difficulties, dehydration, and suspected sepsis. They are more likely to require NICU admission and experience an extended hospital stay. Late preterm neonates also appear to have a higher risk for longer-term neurologic problems, such as attention-deficit disorders and learning disabilities.

Late preterm deliveries may result from complications of pregnancy (e.g.,
chorioamnionitis, premature rupture of membranes) or maternal conditions (e.g., preeclampsia). Many are caused by elective delivery through induction of labor or scheduled cesarean birth during the late preterm period. As appreciation grew for an elevated morbidity and mortality risk in late preterm infants, a movement to eliminate elective deliveries before 39 wk gained national traction. The Ohio Perinatal Quality Collaborative initiated a statewide quality improvement initiative to eliminate elective deliveries before 39 wk of gestation through establishment of a multihospital learning network. Their work led to a material and sustained reduction of elective deliveries, with attendant reductions in neonatal morbidity and hospital length of stay.

The Moderate and Early Preterm Neonate

As gestational age at delivery declines, morbidity and mortality risks increase. With modern neonatal intensive care, the potential for survival at a given gestational age has improved. With that, the threshold gestational age for offering comprehensive neonatal intensive care has correspondingly declined. However, assigning a specific gestational age for threshold of viability remains a challenging problem. Current published data suggest minimal life-sustaining impact for neonatal intensive care offered before 22-23 wk gestation. However, covariables such as birthweight and perhaps exposure to antenatal steroids must be considered. Neonates born at extremely early gestational ages are at very high risk for morbidities carrying lifelong consequences. Major morbidities of prematurity contribute to infant mortality after the early neonatal period (e.g., BPD, IVH, NEC, PDA). All are more common in extremely premature infants, and when present, each can prolong NICU length of stay or may be listed as an immediate cause of death. Therefore, multidisciplinary decision-making with direct family participation is essential.

Preterm neonates at moderate and early gestational ages are at elevated risk for all the complications of late prematurity. Additional categories of morbidity that are absent or extremely rare in the late preterm and term populations also become much more common at earlier gestational ages (Table 112.2). These include adverse neurodevelopmental sequelae such as cerebral palsy, periventricular leukomalacia, intraventricular hemorrhage, hydrocephalus, visual impairment, and hearing impairment. Problems affecting other major organ systems include bronchopulmonary dysplasia, necrotizing enterocolitis, and patent ductus arteriosus. Early preterm infants are at the highest risk for these
complications, which also tend to be more severe.

BPD, Bronchopulmonary dysplasia; CPAP, continuous positive airway pressure; HIE, hypoxia-ischemic encephalopathy; IVH, intraventricular hemorrhage; NEC, necrotizing colitis; PDA, patent ductus arteriosus.

**Intraventricular hemorrhage** (IVH) occurs when the very fragile capillaries of the periventricular white matter and choroid plexus rupture. The typical pathophysiology is accumulation of blood in the lateral ventricles, which can lead to obstruction of cerebrospinal fluid circulation and ultimately hydrocephalus.
Bronchopulmonary dysplasia (BPD) is a complication of respiratory distress syndrome and prematurity leading to reactive airway disease, alveolar insufficiency, and in severe cases, pulmonary hypertension and death. BPD remains the most common morbidity of prematurity among NICU survivors. The most powerful predictor of BPD is gestational age: as gestational age decreases, the risk of BPD increases. Oxygen exposure and treatment with positive pressure ventilation also increase the risk of developing BPD at any gestational age.

Necrotizing enterocolitis (NEC) is a devastating inflammatory process that can occur anywhere in the lower gastrointestinal tract, most often at the distal ilium and ascending colon. In approximately 40% of patients, surgical exploration and resection of necrotic bowel is required, increasing potential for failure to thrive, malabsorption, and short bowel syndrome. Those at the lowest gestational ages are at the highest risk. Interestingly, preterm infants at the earliest gestational ages tend to develop NEC later in their hospital course than moderate or late preterm infants, suggesting a developmental window of susceptibility.

Patent ductus arteriosus (PDA) is a common finding in preterm neonates born before 28 wk. The ductus arteriosus must be patent during intrauterine life to sustain fetal circulation. Under normal physiologic conditions, the ductus undergoes functional closure within a few minutes of parturition. However, under conditions of marginal oxygenation and ventilation, ductal closure in preterm infants may be delayed. If ductal patency persists, it can promote pulmonary overcirculation, complicating the management of respiratory disease.

Low Birthweight, Intrauterine Growth Restriction, and Small for Gestational Age

Low birthweight (LBW) is classified as any live birth <2,500 g. The very-low-birthweight (VLBW) subcategory corresponds to <1,500 g. In general, LBW and VLBW infants are also preterm, although other intrauterine conditions discussed below also contribute. Intrauterine growth restriction (IUGR) refers to deficiency of fetal growth and an abnormal fetal growth trajectory. Etiologies of IUGR include certain congenital infections (e.g., rubella, cytomegalovirus), placental insufficiency, environmental factors (e.g., maternal smoking), and certain congenital conditions (e.g., aneuploidy). In contrast, small-for-gestational-age (SGA) neonates are constitutionally normal, without known genetic abnormalities or pathologic conditions. SGA and IUGR may occur at any
gestational age. Birthweight and gestational age combine to predict mortality and morbidity risk at any gestational age. Healthcare providers can use an online mortality calculator developed by the National Institute of Child Health and Human Development (NICHD) Neonatal Research Network that incorporates gestational age and birthweight to assist with prenatal counseling for families anticipating a preterm delivery.

Bibliography

See also Chapter 21.

Although the neonatal period is a highly vulnerable time as infants complete the many physiologic adjustments required for extrauterine existence, this transition is uneventful for most full-term infants. Management of the newborn should focus on parental anticipatory guidance and early detection of conditions or complications that carry risk of morbidity or even death.

113.1

History in Neonatal Pediatrics

Assessment of the newborn should begin with a review of the maternal and family history, the pregnancy, and the delivery. Details of this history should include the following information, which will guide further evaluation and management in the newborn period:

- Demographic and social data (socioeconomic status, age, race, prenatal care utilization, substance use). Newborns whose mothers are young (<18 yr
old) or who have concerns regarding housing, food insecurity, or access to healthcare may warrant evaluation by a social worker or case manager. Newborns exposed in utero to substances such as alcohol, cocaine, nicotine, caffeine, and opioids should be evaluated for associated symptoms (see Chapter 126).

◆ Maternal medical conditions (cardiopulmonary disorders, infectious diseases, genetic disorders, anemia, diabetes mellitus, current medications). Newborns of diabetic mothers warrant screening within the 1st 24 hr of life for severe hypoglycemia (see Chapter 127.1).

◆ Past medical illnesses in the mother and family, including previous siblings with a history of jaundice (see Chapter 123.3).

◆ Previous maternal reproductive problems: stillbirth, prematurity, blood group sensitization (see Chapter 124).

◆ Events occurring in the present pregnancy (prenatal laboratory and imaging results, preterm labor, fetal assessments, vaginal bleeding, acute illness, duration of rupture of membranes). Such information may prompt additional newborn testing, such as rapid plasma reagin (RPR) testing in the case of a positive maternal syphilis screen, or renal ultrasound imaging if fetal pyelectasis was detected prenatally.
Description of the labor (duration, fetal presentation, fetal distress, fever) and delivery (cesarean section, anesthesia or sedation, use of forceps, Apgar scores, need for resuscitation). This information, combined with clinical assessment of the newborn, will determine risk for clinical deterioration and need for further monitoring and intervention.

113.2 Physical Examination of the Newborn Infant

Neera K. Goyal

Many physical and behavioral characteristics of a normal newborn infant are described in Chapter 21. The initial examination of a newborn infant should be performed as soon as possible after delivery. Temperature, pulse, respiratory rate, color, signs of respiratory distress, tone, activity, and level of consciousness of infants should be monitored frequently until stabilization. For high-risk deliveries, this examination should take place in the delivery room and should focus on congenital anomalies, maturation and growth, and pathophysiologic problems that may interfere with normal cardiopulmonary and metabolic adaptation to extrauterine life. Congenital anomalies of varying degrees of severity may be present in 3–5% of infants. After a stable delivery room course, a second and more detailed examination should be performed within 24 hr of birth.

If an infant remains in the hospital longer than 48 hr, repeat assessments should be performed throughout the hospital stay including a discharge
examination within 24 hr of discharge. For a healthy infant, the mother should be present during this examination; even minor, seemingly insignificant anatomic variations may worry the parents and should be explained. The explanation must be careful and skillful so that otherwise unworried parents are not unduly alarmed. Infants should not be discharged from the hospital without a final examination because certain abnormalities, particularly cyanosis and heart murmurs, often appear or disappear in the immediate neonatal period; in addition, evidence of disease that has just been acquired may be noted. The pulse (normal: 120-160 beats/min), respiratory rate (normal: 30-60 breaths/min), temperature, weight, length, head circumference, and dimensions of any visible or palpable structural abnormality should be assessed. Blood pressure is determined if a neonate appears ill or has a heart murmur. Pulse oximetry should be performed to screen for critical congenital heart disease and is part of the routine screening for newborn infants.

Examining a newborn requires patience, gentleness, and procedural flexibility. Thus, if the infant is quiet and relaxed at the beginning of the examination, palpation of the abdomen or auscultation of the heart should be performed first, before other, more intrusive manipulations are attempted.

General Appearance

Physical activity may be decreased by the effects of illness or drugs; an infant may be either lying with the extremities motionless, to conserve energy for the effort of difficult breathing, or vigorously crying, with accompanying activity of the arms and legs. Both active and passive muscle tone and any unusual posture should be noted. Coarse, tremulous movements with ankle or jaw myoclonus are more common and less significant in newborn infants than at any other age. Such movements tend to occur when an infant is active, whereas convulsive twitching usually occurs in a quiet state. Edema may produce a superficial appearance of good nutrition. Pitting after applied pressure may or may not be noted, but the skin of the fingers and toes lacks the normal fine wrinkles when filled with fluid. Edema of the eyelids commonly results from irritation caused by the administration of silver nitrate. Generalized edema may occur with prematurity, hypoproteinemia secondary to severe erythroblastosis fetalis, nonimmune hydrops, congenital nephrosis, Hurler syndrome, and from unknown causes. Localized edema suggests a congenital malformation of the lymphatic system; when confined to one or more extremities of a female infant, it may be
the initial sign of Turner syndrome (see Chapters 98 and 604).

**Skin**

Vasomotor instability and peripheral circulatory sluggishness are revealed by deep redness or purple lividity in a crying infant, whose color may darken profoundly with closure of the glottis preceding a vigorous cry, and by harmless cyanosis (acrocyanosis) of the hands and feet, especially when they are cool. Mottling, another example of general circulatory instability, may be associated with serious illness or related to a transient fluctuation in skin temperature. An extraordinary division of the body from the forehead to the pubis into red and pale halves is known as harlequin color change, a transient and harmless condition. Significant cyanosis may be masked by the pallor of circulatory failure or anemia; alternatively, the relatively high hemoglobin content of the 1st few days and the thin skin may combine to produce an appearance of cyanosis at a higher partial pressure of arterial oxygen (Pao\textsubscript{2}) than in older children. Localized cyanosis is differentiated from ecchymosis by the momentary blanching pallor (with cyanosis) that occurs after pressure. The same maneuver also helps in demonstrating icterus. Pallor may be caused by anemia, asphyxia, shock, or edema. Early recognition of anemia may lead to a diagnosis of fetomaternal blood transfusion, erythroblastosis fetalis, subcapsular hematoma of the liver or spleen, subdural hemorrhage, or fetal-maternal or twin-twin transfusion. Without being anemic, postmature infants tend to have paler and thicker skin than term or premature infants. The ruddy appearance of plethora is seen with polycythemia.

The vernix and common transitory macular capillary hemangiomas of the eyelids and neck are described in Chapter 669. Cavernous hemangiomas are deeper, blue masses that, if large, may trap platelets and produce disseminated intravascular coagulation or interfere with local organ function. Scattered petechiae may be seen on the presenting part (usually the scalp or face) after a difficult delivery. Slate-blue, well-demarcated areas of pigmentation called mongolian spots are seen over the buttocks, back, and sometimes other parts of the body in more than 50% of black, Native American, and Asian infants, and occasionally in white infants. These benign patches have no known anthropologic significance despite their name; they tend to disappear within the 1st year. The vernix, skin, and especially the cord may be stained brownish
yellow if the amniotic fluid has been colored by the passage of meconium during or before birth.

The skin of premature infants is thin and delicate and tends to be deep red; in extremely premature infants, the skin appears almost gelatinous and translucent. Fine, soft, immature hair called lanugo frequently covers the scalp and brow and may also cover the face of premature infants. Lanugo has usually been lost or replaced by vellus hair in term infants. Tufts of hair over the lumbosacral spine suggest an underlying abnormality, such as occult spina bifida, a sinus tract, or a tumor. The nails are rudimentary in very premature infants, but they may protrude beyond the fingertips in infants born past term. Postterm infants may have a peeling, parchment-like skin (Fig. 113.1), a severe degree of which may mimic ichthyosis congenita (see Chapter 677).

![Fig. 113.1](image)

**FIG. 113.1** Infant with intrauterine growth restriction as a result of placental insufficiency. Note the long, thin appearance with peeling, parchment-like dry skin, alert expression, meconium staining of the skin, and long nails. (From Clifford S: Advances in pediatrics, vol 9, Chicago, 1962, Year Book.)

In many neonates, small, white papules on an erythematous base develop 1-3 days after birth. This benign rash, erythema toxicum, persists for as long as 1 wk, contains eosinophils, and is usually distributed on the face, trunk, and extremities (see Chapter 666). Pustular melanosis, a benign lesion seen predominantly in black neonates, contains neutrophils and is present at birth as a vesiculopustular eruption around the chin, neck, back, extremities, and palms or soles; it lasts 2-3 days. Both lesions need to be distinguished from more dangerous vesicular eruptions such as herpes simplex (see Chapter 279) and
staphylococcal disease of the skin (Chapter 208.1).

Amniotic bands may disrupt the skin, extremities (amputation, ring constriction, syndactyly), face (clefts), or trunk (abdominal or thoracic wall defects). Their cause is uncertain but may be related to amniotic membrane rupture or vascular compromise with fibrous band formation. Excessive skin fragility and extensibility with joint hypermobility suggest Ehlers-Danlos syndrome (see Chapter 679), Marfan syndrome (Chapter 722), congenital contractural arachnodactyly, and other disorders of collagen synthesis.

Skull

The skull may be molded, particularly if the infant is the first-born and if the head has been engaged in the pelvic canal for a considerable time. Caput succedaneum, caused by scalp pressure from the uterus, cervix, or pelvis, appears as a circular boggy area of edema with indistinct borders and often with overlying ecchymosis. A cephalohematoma presents as a well-circumscribed fluid-filled mass that does not cross suture lines. Unlike caput succedaneum, cephalohematoma is often not present at delivery but develops over the 1st few hr of life. Both cephalohematoma and caput succedaneum must be distinguished from a subgaleal hemorrhage, which is not restricted by the boundaries of the sutures and therefore is larger and more diffuse. Subgaleal hemorrhage requires prompt recognition because extensive bleeding may result in hypovolemic shock, with estimated mortality up to 20%. The head circumference of all newborns should be plotted on a growth chart to identify an excessively small head (microcephaly) or excessively large head (megalencephaly). The diagnostic differential for microcephaly is broad and includes underlying genetic disorders, congenital infection, and intrauterine drug exposure (see Chapter 609). Megalencephaly can suggest hydrocephaly, storage disease, achondroplasia, cerebral gigantism, neurocutaneous syndromes, or inborn errors of metabolism, or it may be familial. The suture lines and the size and fullness of the anterior and posterior fontanels should be determined digitally by palpation. The parietal bones tend to override the occipital and frontal bones. Premature fusion of sutures (cranial synostosis) is identified as a hard nonmovable ridge over the suture and an abnormally shaped skull. Great variation in the size of the fontanels exists at birth; if small, the anterior fontanel usually tends to enlarge during the 1st few mo after birth. The persistence of excessively large anterior (normal: 20 ±10 mm) and posterior fontanels has been associated with several
disorders (Table 113.1). Persistently small fontanels suggest microcephaly, craniosynostosis, congenital hyperthyroidism, or wormian bones; presence of a 3rd fontanel suggests trisomy 21 but is seen in preterm infants. Soft areas (craniotabes) are occasionally found in the parietal bones at the vertex near the sagittal suture; they are more common in preterm infants and in infants who have been exposed to uterine compression. Although such soft areas are usually insignificant, their possible pathologic cause should be investigated if they persist. Soft areas in the occipital region suggest the irregular calcification and wormian bone formation associated with osteogenesis imperfecta, cleidocranial dysostosis, lacunar skull, cretinism, and occasionally Down syndrome.

</tbody>
</table>

Atrophic or alopecic scalp areas may represent **aplasia cutis congenita**, which may be sporadic, or autosomal dominant, or associated with trisomy 13, chromosome 4 deletion, or Johanson-Blizzard syndrome. **Deformational plagiocephaly** may be the result of in utero positioning forces on the skull and manifests as an asymmetric skull and face with ear malalignment (see Chapter 610). It is associated with torticollis and vertex positioning. Depression of the skull (indentation, fracture, Ping-Pong ball deformity) is usually of prenatal onset and a result of prolonged focal pressure by the maternal pelvic bone.

**Face**
The general appearance of the face should be noted with regard to **dysmorphic features**, such as epicanthal folds, widely or narrowly spaced eyes, microphthalmos, asymmetry, long philtrum, and low-set ears, which are often associated with congenital syndromes. The face may be asymmetric as a result of a 7th nerve palsy, hypoplasia of the depressor muscle at the angle of the mouth, or an abnormal fetal posture (see Chapter 128); when the jaw has been held against a shoulder or an extremity during the intrauterine period, the mandible may deviate strikingly from the midline. Symmetric facial palsy suggests absence or hypoplasia of the 7th nerve nucleus (**Möbius syndrome**).

**Eyes**

The eyes often open spontaneously if the infant is held up and tipped gently forward and backward. This maneuver, a result of labyrinthine and neck reflexes, is more successful for inspecting the eyes than is forcing the lids apart. Conjunctival and retinal hemorrhages are usually benign. Retinal hemorrhages are more common with vacuum- or forceps-assisted deliveries than spontaneous vaginal delivery and least common after cesarean section. They are usually bilateral, intraretinal, and in the posterior pole. They resolve in most infants by 2 wk of age (85%) and in all infants by 4 wk. **Pupillary reflexes** are present after 28-30 wk of gestation. The iris should be inspected for colobomas and heterochromia. A cornea >1 cm in diameter in a term infant (with photophobia and tearing) or corneal clouding suggests congenital glaucoma and requires prompt ophthalmologic consultation. The presence of bilateral red reflexes suggests the absence of cataracts and intraocular pathology (see Chapter 637). **Leukokoria** (white pupillary reflex) suggests cataracts, tumor, chorioretinitis, retinopathy of prematurity, or a persistent hyperplastic primary vitreous and warrants an immediate ophthalmologic consultation (see Chapter 640).

**Ears**

Deformities of the pinnae are occasionally seen. Unilateral or bilateral preauricular skin tags occur frequently; if pedunculated, they can be tightly ligated at the base, resulting in dry gangrene and sloughing. The tympanic membrane, easily seen otoscopically through the short and straight external auditory canal, normally appears dull gray.
Nose

The nose may be slightly obstructed by mucus accumulated in the narrow nostrils. The nares should be symmetric and patent. Dislocation of the nasal cartilage from the vomerian groove results in asymmetric nares. Anatomic obstruction of the nasal passages secondary to unilateral or bilateral choanal atresia results in respiratory distress.

Mouth

A normal mouth may rarely have precocious dentition, with natal (present at birth) or neonatal (eruption after birth) teeth in the lower incisor position or aberrantly placed; these teeth are shed before the deciduous ones erupt (see Chapter 333). Alternatively, such teeth occur in Ellis–van Creveld, Hallermann-Streiff, and other syndromes. Extraction is not usually indicated. Premature eruption of deciduous teeth is even more unusual. The soft and hard palate should be inspected and palpated for a complete or submucosal cleft, and the contour noted if the arch is excessively high or the uvula is bifid. On the hard palate on either side of the raphe, there may be temporary accumulations of epithelial cells called Epstein pearls. Retention cysts of similar appearance may also be seen on the gums. Both disappear spontaneously, usually within a few weeks of birth. Clusters of small, white or yellow follicles or ulcers on erythematous bases may be found on the anterior tonsillar pillars, most frequently on the 2nd or 3rd day of life. Of unknown cause, they clear without treatment in 2-4 days.

Neonates do not have active salivation. The tongue appears relatively large; the frenulum may be short, but its shortness (tongue-tie or ankyloglossia) is rarely a reason for cutting it. If there are problems with feedings (breast or bottle) and the frenulum is short, frenulectomy (frenotomy) may be indicated. Frenotomy may reduce maternal nipple pain and improve breastfeeding scores more rapidly than no treatment, but over time, neonates not treated with frenotomy also have successful feeding. The sublingual mucous membrane occasionally forms a prominent fold. The cheeks have fullness on both the buccal and the external aspects as a result of the accumulation of fat in the sucking pads. These pads, as well as the labial tubercle on the upper lip (sucking callus), disappear when suckling ceases. A marble-sized buccal mass is usually caused by benign idiopathic fat necrosis.
The throat of a newborn infant is difficult to see because of the low arch of the palate; it should be clearly viewed because posterior palatal or uvular clefs are easy to miss. The tonsils are small.

**Neck**

The neck appears relatively short. Abnormalities are not common but include goiter, cystic hygroma, branchial cleft cysts, teratoma, hemangioma, and lesions of the sternocleidomastoid muscle that are presumably traumatic or caused by a fixed positioning in utero that produces either a hematoma or fibrosis, respectively. Congenital *torticollis* causes the head to turn toward and the face to turn away from the affected side (see Chapter 700.1). Plagiocephaly, facial asymmetry, and hemihypoplasia may develop if it is untreated (see Chapter 610). Redundant skin or webbing in a female infant suggests intrauterine lymphedema and Turner syndrome (see Chapters 98 and 604). Both clavicles should be palpated for fractures.

**Chest**

Breast hypertrophy is common, and milk may be present (but should not be expressed). Asymmetry, erythema, induration, and tenderness suggest mastitis or a breast abscess. Supernumerary nipples, inverted nipples, or widely spaced nipples with a shield-shaped chest may be seen; the last finding suggests Turner syndrome.

**Lungs**

Much can be learned by observing breathing. Normal variations in rate and rhythm are characteristic and fluctuate according to the infant's physical activity, the state of wakefulness, or the presence of crying. Because fluctuations are rapid, the *respiratory rate* should be counted for a full minute with the infant in the resting state, preferably asleep. Under these circumstances, the usual rate for normal term infants is 30-60 breaths/min; in premature infants the rate is higher and fluctuates more widely. A rate consistently >60 breaths/min during periods of regular breathing that persists for >1 hr after birth is an indication to rule out pulmonary, cardiac, or metabolic disease (acidosis) etiologies. Preterm infants
may breathe with a Cheyne-Stokes rhythm, known as **periodic respiration**, or with complete irregularity. Irregular gasping, sometimes accompanied by spasmodic movements of the mouth and chin, strongly indicates serious impairment of the respiratory centers.

The breathing of newborn infants at rest is almost entirely **diaphragmatic**, so during inspiration, the soft front of the thorax is usually drawn inward while the abdomen protrudes. If the baby is quiet, relaxed, and with good color, this “paradoxical movement” does not necessarily signify insufficient ventilation. On the other hand, labored respiration with retractions is important evidence of respiratory distress syndrome, pneumonia, anomalies, or mechanical disturbance of the lungs. A weak, persistent or intermittent groaning, whining cry, or **grunting** during expiration can signify potentially serious cardiopulmonary disease or sepsis and warrants immediate attention. When benign, the grunting resolves 30-60 min after birth. Flaring of the alae nasi and retraction of the intercostal muscles and sternum are common signs of pulmonary pathology.

Normally, the breath sounds are **bronchovesicular**. Suspicion of pulmonary pathology because of diminished breath sounds, rhonchi, retractions, or cyanosis should always be verified with a chest radiograph.

**Heart**

Normal variation in the size and shape of the chest makes it difficult to estimate the size of the heart. The location of the heart should be determined to detect **dextrocardia**. The pulse is usually 110-140 beats/min at rest but may vary normally from 90 beats/min in relaxed sleep to 180 beats/min during activity. The still higher rate of supraventricular tachycardia (>220 beats/min) may be determined better with a cardiac monitor or electrocardiogram (ECG) than by auscultation. Preterm infants usually have a higher resting heart rate, up to about 160 beats/min, but may have a sudden onset of sinus bradycardia secondary to apnea. On both admission to and discharge from the nursery, the infant's pulses should be palpated in the upper and lower extremities to detect **coarctation of the aorta**. Transitory murmurs usually represent a closing ductus arteriosus. Although congenital heart disease (CHD) may not initially produce a murmur, a substantial portion of infants in whom persistent murmurs are detected during routine neonatal examination have underlying malformation. Routine screening for critical CHD using pulse oximetry is performed between 24 and 48 hr of life, which overall yields a sensitivity approaching 80% and specificity >99%. Pulse
oximetry screening with $\text{So}_2$ of $\geq 95\%$ in the right hand or either foot and $<3\%$ difference between the right hand and foot is considered a normal screening test. Those with $\text{So}_2 < 95\%$ should be referred for evaluation and possible echocardiogram (see Chapter 452). Blood pressure (BP) measurements are indicated in the evaluation of ill-appearing infants and those in whom CHD is suspected. The oscillometric method is the easiest and most accurate noninvasive method available. Mean BP values vary by gestational age, however for all neonates, BP is expected to rise in the 1st 72 hr after birth (Fig. 113.2).

![Nomogram for mean blood pressure (BP) in neonates with gestational ages of 23-43 wk. Derived from continuous arterial BP measurements obtained from 103 infants admitted to the neonatal intensive care unit. The graph shows the predicted mean BP of neonates of different gestational ages during the 1st 72 hr of life. Each line represents the lower limit of the 80% confidence interval (2-tail) of the mean BP for each gestational age-group; 90% of infants for each gestational age-group will be expected to have a mean BP value equal to or above the value indicated by the corresponding line, the lower limit of the confidence interval. (From Nuntnarumit P, Yang W, Bada-Ellzey SB: Blood pressure measurements in the newborn, ClinPerinatol 26:976–996, 1999.)](image)

**Abdomen**

The liver is usually palpable, sometimes as much as 2 cm below the rib margin. Less often, the tip of the spleen may be felt. The approximate size and location of each kidney can usually be determined on deep palpation. At no other period of life does the amount of air in the gastrointestinal tract vary so much, nor is it usually so great under normal circumstances. The intestinal tract is gasless at
birth. Gas is swallowed soon after birth, and gas should normally be present in the rectum on radiograph by 24 hr of age. The abdominal wall is normally weak (especially in premature infants), and diastasis recti and umbilical hernias are common, particularly among black infants.

Unusual masses should be investigated immediately with ultrasonography. Renal pathology is the cause of most neonatal abdominal masses. Cystic abdominal masses include hydronephrosis, multicystic-dysplastic kidneys, adrenal hemorrhage, hydrometrocolpos, intestinal duplication, and choledochal, ovarian, omental, or pancreatic cysts. Solid masses include neuroblastoma, congenital mesoblastic nephroma, hepatoblastoma, and teratoma. A solid flank mass may be caused by renal vein thrombosis, which becomes clinically apparent with hematuria, hypertension, and thrombocytopenia. Renal vein thrombosis in infants is associated with polycythemia, dehydration, maternal diabetes, asphyxia, sepsis, nephrosis, and hypercoagulable states such as antithrombin III and protein C deficiency.

Abdominal distention at birth or shortly afterward suggests either obstruction or perforation of the gastrointestinal tract, often as a result of meconium ileus; later distention suggests lower bowel obstruction, sepsis, or peritonitis. A scaphoid abdomen in a newborn suggests diaphragmatic hernia. Abdominal wall defects produce an omphalocele when they occur through the umbilicus and gastroschisis when they occur lateral to the midline (see Chapter 125 ). Omphalocleses are associated with other anomalies and syndromes, such as Beckwith-Wiedemann, conjoined twins, trisomy 18, meningomyelocele, and imperforate anus. Omphalitis is an acute local inflammation of the periumbilical tissue that may extend to the abdominal wall, the peritoneum, the umbilical vein or portal vessels, or the liver and may result in later portal hypertension. The umbilical cord should have 2 arteries and 1 vein. A single umbilical artery is associated with an increased risk for an occult renal anomaly.

**Genitals**

The genitals and mammary glands normally respond to transplacentally acquired maternal hormones to produce enlargement and secretion of the breasts in both sexes and prominence of the genitals in females, often with considerable nonpurulent discharge. These transitory manifestations require no intervention.

An imperforate hymen or other causes of vaginal obstruction may result in hydrometrocolpos and a lower abdominal mass. A normal scrotum at term is
relatively large; its size may be increased by the trauma of breech delivery or by a transitory hydrocele, which is distinguished from a hernia by palpation and transillumination. The testes should be in the scrotum or should be palpable in the canals in term infants. Black male infants usually have dark pigmentation of the scrotum before the rest of the skin assumes its permanent color. The scrotum may be ecchymotic from breech presentation or a retroperitoneal hemorrhage; it may contain meconium particles associated with meconium peritonitis.

The prepuce or foreskin of a newborn infant is normally tight and adherent to the penile glans at birth and cannot be retracted. The foreskin should separate naturally over several months. Severe hypospadias or epispadias should always suggest either that abnormal sex chromosomes are present (see Chapter 98) or that the infant is actually a masculinized female with an enlarged clitoris, because this finding may be the first evidence of adrenogenital syndrome (see Chapter 594). Erection of the penis is common and has no significance. Urine is usually passed during or immediately after birth; a period without voiding may normally follow. Most neonates void by 12 hr, and approximately 95% of preterm and term infants void within 24 hr.

**Anus**

Some passage of meconium usually occurs within the 1st 12 hr after birth; 99% of term infants and 95% of premature infants pass meconium within 48 hr of birth. Physical examination is usually sufficient for diagnosis of imperforate anus, if the anal opening is absent or incorrectly located. However, if there is a fistula to the skin, urethra or vagina, a newborn can pass meconium; in such cases, unless a careful exam is done, imperforate anus may not be suspected. Abdominal radiographs are used to confirm distal obstruction and to determine how low the rectum is. In females with imperforate anus, careful examination of the vestibule must be made to ensure separate openings of the urethra and vagina. All newborns with anorectal malformations warrant evaluation for possible associated cardiac, renal and spine anomalies.

The dimple or irregularity in skin fold often normally present in the sacrococcygeal midline may be mistaken for an actual or potential neurocutaneous sinus.

**Extremities**
During examination of the extremities, the effects of fetal posture (see Chapter 692) should be noted so that their cause and usual transitory nature can be explained to the mother. Such explanations are particularly important after breech presentations. A fracture or nerve injury associated with delivery can be detected more frequently by observation of the extremities in spontaneous or stimulated activity than by any other means. The hands and feet should be examined for polydactyly, syndactyly, and abnormal dermatoglyphic patterns such as a simian crease.

The hips of all infants should be examined with specific maneuvers to rule out congenital dislocation (see Chapter 698.1).

**Neurologic Examination**

See Chapter 21.

In utero neuromuscular diseases associated with limited fetal motion produce a constellation of signs and symptoms that are independent of the specific disease. Severe positional deformations and contractures produce arthrogryposis. Other manifestations of fetal neuromuscular disease include breech presentation, polyhydramnios, failure to breathe at birth, pulmonary hypoplasia, dislocated hips, undescended testes, thin ribs, and clubfoot. Many congenital disorders manifest as hypotonia, hypertonia, or seizures.

**Bibliography**

The initial steps of management for all newborns after delivery are to provide warmth, drying, and tactile stimulation, while simultaneously evaluating respiratory effort, heart rate, and color. Full-term, vigorous infants may initially be placed on the mother's abdomen after delivery, during which time delayed clamping of the umbilical cord (30-60 sec) is recommended to improve transitional circulation and increase neonatal red blood cell (RBC) volume. Clearing the mouth of secretions with gentle suction with a bulb syringe or soft catheter is indicated if there is an excessive (copious) amount of fluid in the mouth or nares. In resource-poor countries, gentle wiping of the face, nose, and mouth with a soft cloth may be equally effective as a bulb syringe. Spontaneously breathing neonates without distress require no assisted method to clear their airway.

The Apgar score is a practical method of systematically evaluating infants immediately after birth and is assessed at 1 and 5 min of life (Table 113.2). Most healthy infants who appear to be in satisfactory condition may remain in skin-to-skin contact with their mothers for immediate bonding and nursing. However, infants who fail to initiate or sustain respiratory effort after stimulation, those with a heart rate <100 beats/min, and those with persistent central cyanosis should be placed under warmers for prompt resuscitation and monitoring (see Chapter 121). Apgar scores should not be used to determine need for resuscitation or to guide steps of resuscitation. However, changes in Apgar scores at sequential time points after birth can reflect how well the infant is responding to resuscitation. If the 5 min score remains <7, additional scores should be assigned every 5 min for up to 20 min. In addition to fetal distress, a number of factors, including prematurity and drugs given to the mother during labor, can result in low Apgar scores (Table 113.3).

* At 60 sec after complete birth of the infant (disregarding the cord and placenta), the 5 objective signs listed here are evaluated, and each is given a score of 0, 1, or 2. A total score of 10 indicates an infant in the best possible condition. An infant with a score of 0-3 requires immediate resuscitation.

* Regardless of the etiology, a low Apgar score because of fetal asphyxia, immaturity, central nervous system depression, or airway obstruction identifies an infant needing immediate resuscitation.

† No fetal acidosis or hypoxia; low Apgar score.
Maintenance of Body Heat

Newborn infants are at risk for heat loss and hypothermia for several reasons. Relative to body weight, the body surface area (BSA) of a newborn infant is approximately 3 times that of an adult. Generation of body heat depends in large part on body weight, but heat loss depends on BSA. In low-birthweight and preterm infants, the insulating layer of subcutaneous fat is thin. The estimated rate of heat loss in a newborn is approximately 4 times that of an adult. Under the usual delivery room conditions (20-25°C [68-77°F]), an infant's skin temperature falls approximately 0.3°C (0.54°F)/min, and deep body temperature decreases approximately 0.1°C (0.18°F)/min during the period immediately after delivery; these rates generally result in a cumulative loss of 2-3°C (3.6-5.4°F) in deep body temperature (corresponding to a heat loss of approximately 200 kcal/kg). The heat loss occurs by 4 mechanisms: convection of heat energy to the cooler surrounding air, conduction of heat to the colder materials touching the infant, heat radiation from the infant to other nearby cooler objects, and evaporation from skin and lungs.

Metabolic acidosis, hypoxemia, hypoglycemia, and increased renal excretion of water and solutes may develop in term infants exposed to cold after birth because of their effort to compensate for heat loss. Heat production is augmented by increasing the metabolic rate and oxygen consumption in part by releasing norepinephrine, which results in nonshivering thermogenesis through oxidation of fat, particularly brown fat. In addition, muscular activity may increase. Hypoglycemic or hypoxic infants cannot increase their oxygen consumption when exposed to a cold environment, and their central temperature decreases. After labor and vaginal delivery, many newborn infants have mild to moderate metabolic acidosis, for which they may compensate by hyperventilating, a response that is more difficult for infants with central nervous system (CNS) depression (asphyxia, drugs) and infants exposed to cold stress in the delivery room. Therefore, to reduce heat loss, it is desirable to ensure that infants are dried and either wrapped in blankets or placed with the mother or under radiant warmers. Skin-to-skin contact with the mother is the optimal method of maintaining temperature in the stable newborn. Because carrying out resuscitative measures on a covered infant or one enclosed in an incubator is
difficult, a radiant heat source should be used to warm the baby during resuscitation.

**Antiseptic Skin and Cord Care**

Nursery personnel should use alcohol-based solutions or chlorhexidine or iodophor-containing antiseptic soaps for routine handwashing before caring for each infant. Rigid enforcement of hand-to-elbow washing for 2 min in the initial wash and 15-30 sec in subsequent washes is essential for staff and visitors entering the nursery. Careful removal of the amniotic fluid and blood from the skin shortly after birth may reduce the risk of infection with bloodborne agents. For the infant's first bath, the entire skin and cord should be cleansed with warm water or a mild nonmedicated soap solution and rinsed with water to reduce the incidence of skin and periumbilical colonization with pathogenic bacteria and subsequent infectious complications. Based on World Health Organization (WHO) recommendations, this should be delayed until 24 hr of life to allow full transition to extraterine life with emphasis on maternal–infant bonding and early breastfeeding. To avoid heat loss, the infant should then be dried and wrapped in clean blankets.

*Staphylococcus aureus* remains the most frequent pathogenic bacteria to colonize the umbilical cord, although other common pathogens include group A and group B streptococci and gram-negative bacilli. Pathogenic bacteria may derive from the mother's birth canal or various bacterial sources, including the nonsterile hands of personnel attending the delivery. Topical chlorhexidine to the umbilical cord is recommended for infants born outside of birthing centers or hospital settings, and for those born in low-resource communities with high neonatal mortality rates. However, in high-resource countries the incidence of omphalitis is very low and the severity is mild, so **dry cord care** is recommended without the application of topical substances such as alcohol or chlorhexidine. Dry cord care involves leaving the umbilical cord exposed to air or loosely covered, cleaning it with soap and water if it becomes soiled. Colonization and infection of newborns from potentially pathogenic organisms can also be reduced through continuous rooming-in with their mother, which creates an environment conducive for colonization from less pathogenic bacteria acquired from the mother's flora.

**Vernix** is spontaneously shed within 2-3 days, much of it adhering to the clothing, which should be completely changed daily. The diaper should be
checked before and after feeding and when the baby cries; it should be changed when wet or soiled. The perineal area can be cleaned with baby wipes or with mild soap and warm water. Meconium or feces should be cleansed from the buttocks with sterile cotton moistened with sterile water. The foreskin of a male infant should not be retracted.

### Newborn Prophylaxis and Screening

Newborn assessment and vital sign monitoring may vary by hospital but generally decreases in frequency after the 1st 1-2 hr after birth. For well-appearing newborns, a reasonable interval between assessments is 4 hr during the 1st 2-3 days of life and 8 hr thereafter. The infant's temperature should be taken by axillary measurement, with a normal range of 36.5-37.4°C (97.7-99.3°F). Weighing at birth and daily thereafter is sufficient.

The eyes of all infants, including those of cesarean birth, must be protected against gonococcal ophthalmia neonatorum by application of a 1 cm ribbon of erythromycin (0.5%) or tetracycline (1.0%) sterile ophthalmic ointments in each lower conjunctival sac. This procedure may be delayed during the initial short-alert period after birth to promote bonding, but once applied, drops should not be rinsed out (see Chapters 219 and 253.3 ). A 1% silver nitrate solution is an acceptable alternative but leads to a transient chemical conjunctivitis in 10–20% of cases.

Although hemorrhage in newborn infants can be a result of factors other than vitamin K deficiency, an intramuscular (IM) injection of 0.5-1 mg of water-soluble vitamin K₁ (phytonadione) should be given to all infants shortly after birth to prevent hemorrhagic disease of the newborn (see Chapter 124.4 ). Oral vitamin K is *not* as effective as the parenteral dosage.

Hepatitis B immunization before discharge from the nursery is recommended for newborns with weight >2 kg, irrespective of maternal hepatitis status.

Neonatal screening is available for various genetic, metabolic, hematologic, and endocrine disorders. All states in the United States have adopted the recommendations of the *Advisory Committee on Heritable Disorders in Newborns and Children*, although the specific tests performed vary by state based in part to disease prevalence, detection rates, and costs (see Chapter 102 ). The most commonly identified disorders (and their rates) include hypothyroidism (52/100,000 births), cystic fibrosis (30/100,000),
hemoglobinopathies (26/100,000), medium-chain acyl–coenzyme A dehydrogenase deficiency (6/100,000), galactosemia (5/100,000), phenylketonuria (5/100,000), and adrenal hyperplasia (5/100,000). To be effective in the timely identification and prompt management of treatable diseases, screening programs must include not only high-quality laboratory tests but also follow-up of infants with abnormal test results; education, counseling, and psychologic support for families; and prompt referral of the identified neonate for accurate diagnosis and appropriate treatment.

**Hearing impairment**, a serious morbidity that affects speech and language development, may be severe in 2/1,000 births and overall affects 5/1,000 births. Universal screening of infants is recommended to ensure early detection of hearing loss and appropriate, timely intervention. Parents of infants who fail screening should be counseled on the importance of screening results, reinforcing the need for prompt audiologic confirmation and emphasizing the potential for normal language development with prompt intervention.

Universal screening with pulse oximetry provides early detection of ductal dependent cyanotic congenital heart disease (see Chapter 452).

Universal screening for hyperbilirubinemia should include risk assessment in all infants with measurement of serum or transcutaneous bilirubin levels before hospital discharge (see Chapter 123.4, Kernicterus).

Universal screening for congenital hip dysplasia with physical examination with the **Ortolani test** (sensation of the dislocated hip reducing) and **Barlow test** (unstable hip dislocating from the acetabulum) is recommended, but routine hip ultrasound is not indicated.

Screening for hypoglycemia is risk based and should be performed in infants who are small for gestational age, large for gestational age, born to mothers who have diabetes, preterm, or symptomatic (see Chapter 127.1).

For infants with suspected maternal chorioamnionitis, current clinical guidelines recommend laboratory screening for sepsis, including a blood culture, and at least 48 hr of broad-spectrum antibiotic therapy. However, evidence suggests a low incidence of sepsis among well-appearing, term neonates, and that frequent, reliable observation to detect early signs of sepsis, with or without laboratory studies, may be appropriate. (see Chapter 129).

**Table 113.4** lists minimum criteria to be met before newborn discharge. A shortened hospital stay (<48 hr after delivery) may be reasonable for healthy, term newborns but is not always appropriate. Early discharge requires careful ambulatory follow-up at home (by a visiting nurse) or in the office within 48 hr.
of discharge.

### 113.4

**Circumcision**

*Neera K. Goyal*
Male circumcision consists of the surgical removal of some, or all, of the foreskin from the penis, and is one of the most common procedures performed worldwide. Circumcision performed during the newborn period has considerably lower complication rates than when performed later in life. The procedure should only be performed in healthy newborns whose condition is stable. Those providing circumcision should be adequately trained in both sterile techniques and effective pain management to reduce risk of complications. The surgery includes dilation of the preputial orifice to visualize the glans, freeing the preputial epithelium from the epithelium of the glans, placement of the circumcision device (Gomco clamp, Plastibell, or Mogen clamp) to enhance hemostasis, and removal of foreskin. For pain management, topical 4% lidocaine (i.e., LMX4 cream), a dorsal penile nerve block, and a subcutaneous ring block are all effective options. Topical anesthetic creams may cause a higher incidence of skin irritation in low-birthweight infants; therefore penile nerve block techniques should be chosen for this group. Usually, the dorsal penile nerve block consists of injections of 0.4 mL of 1% lidocaine without epinephrine on both sides of the base of the penis. The subcutaneous circumferential ring block involves 0.8 mL of 1% lidocaine without epinephrine injected at the base or midshaft of the penis and may provide the most effective analgesia compared with other techniques. Nonpharmacologic techniques, such as positioning on a padded environment and use of sucrose pacifiers, are useful adjuncts to improve infant comfort during the procedure but are insufficient as sole therapies to prevent procedural and postprocedural pain.

Contraindications to this procedure include critically ill infants, those with blood dyscrasias, individuals who have a family history of bleeding disorders, and those who have congenital abnormalities (e.g., hypospadias), congenital chordee, or deficient shaft skin (e.g., penoscrotal fusion, congenital buried penis). In addition, it should be confirmed before the procedure that the newborn received IM vitamin K in accordance with standard practice of newborn care. Premature infants may undergo circumcision before discharge.

Preventive health benefits of elective circumcision for male newborns include significant reductions in the risk of urinary tract infection in the 1st year of life, heterosexual acquisition of HIV and transmission of other sexually transmitted infections (human papillomavirus, herpes simplex virus type 2, and syphilis), and penile cancer. Acute complications from circumcision in the United States and other high-resource countries are rare, including bleeding (0.08–0.18%), infection (0.06%), and penile injury (0.04%). More catastrophic injuries,
including glans or penile amputation, are extremely rare and published as case reports only. Later complications can include excessive residual skin (incomplete circumcision), excessive skin removal, adhesions (natural and vascularized skin bridges), meatal stenosis, phimosis, and epithelial inclusion cysts.

Current evidence indicates while health benefits outweigh the risks of male circumcision, health benefits are not great enough to recommend routine circumcision for all male newborns. Therefore, physicians who counsel families about this decision should explain the potential benefits and risks, in a nonbiased manner, and ensure that parents understand that circumcision is an elective procedure. Ultimately, parents should decide whether circumcision is in the best interests of their male child, weighing the medical information in context of their own religious, ethical, and cultural beliefs and practices.

Regardless of whether or not the newborn is circumcised, parents should be instructed in the care of the penis at discharge from the newborn hospital stay. The circumcised penis should be washed gently each day with soap and water. As part of normal healing, the glans may appear raw or yellowish for 7-10 days. Gauze with petroleum jelly can be used to cover the area and should be changed with each urine and stool until the glans heals.

**Bibliography**

113.5

**Parent–Infant Bonding**

*Neera K. Goyal*

See also Chapter 21.

Normal infant development depends partly on a series of affectionate responses exchanged between a mother and her newborn infant that binds them psychologically and physiologically. This bonding is facilitated and reinforced by the emotional support of a loving family. The attachment process may be important in enabling some mothers to provide loving care during the neonatal period and subsequently during childhood. The power of this attachment is so great that it enables the mother and the father to make unusual sacrifices necessary for the day-to-day care of the infant, care night after night, giving feedings 24 hr a day, attending to crying, and so on. The sacrifices continue for many years as parents dedicate much of their lives to their children.

Parent–infant bonding is initiated before birth with the planning and confirmation of the pregnancy. Subsequently, there is a growing awareness of the baby as an individual, starting usually with the remarkably powerful event of
quickening or sensation of fetal movements. After delivery and during the ensuing weeks, sensory (visual, auditory, olfactory) and physical contact between the mother and baby triggers various mutually rewarding and pleasurable interactions, such as the mother touching the infant's extremities and face with her fingertips and encompassing and gently massaging the infant's trunk with her hands. Touching an infant's cheek elicits responsive turning toward the mother's face or toward the breast with nuzzling and licking of the nipple, a powerful stimulus for prolactin secretion. An infant's initial quiet alert state provides the opportunity for eye-to-eye contact, which is particularly important in stimulating the loving and possessive feelings of many parents for their babies. An infant's crying elicits the maternal response of touching the infant and speaking in a soft, soothing, higher-toned voice.

Initial contact between the mother and infant should take place in the delivery room, and opportunities for extended intimate contact and breastfeeding should be provided within the 1st hours after birth. Delayed or abnormal maternal–infant bonding, as occurs because of prematurity, infant or maternal illness, birth defects, or family stress, may harm infant development and maternal caretaking ability. Hospital routines should be designed to encourage parent–infant contact. Rooming-in arrangements, care by parents, and family-centered care increase the opportunities for better parent–infant interaction.

**Rooming-in and Breastfeeding**

See Chapter 56 for full discussions of breastfeeding and formula feeding.

Ample evidence indicates that there are infant and maternal benefits to breastfeeding. One important hospital practice to encourage successful breastfeeding is rooming-in of newborns with their mothers. Therefore, it should be encouraged that term, healthy infants remain continuously in the mother's room whenever possible. To reduce the risk of sudden infant death syndrome, infants should be placed to sleep supine in a bassinet, preferably of clear plastic to allow for easy visibility and care. All professional care should be given to the infant in the bassinet, including the physical examination, clothing changes, temperature taking, skin cleansing, and other procedures that, if performed elsewhere, would establish a common contact point and possibly provide a channel for cross-infection. The clothing and bedding should be minimal, only enough needed for an infant's comfort; the room temperature should be kept at approximately 22-26°C (72-78°F).
Additional practices that encourage successful breastfeeding include antepartum education and encouragement, immediate postpartum mother–infant contact with suckling, demand feeding, inclusion of maternal partners in breastfeeding education, and support from experienced women. Nursing at first for least 5 min at each breast is reasonable, allows a baby to obtain most of the available breast contents, and provides effective stimulation for increasing the milk supply. Nursing episodes should then be extended according to the comfort and desire of the mother and infant. A confident and relaxed mother, supported by an encouraging home and hospital environment, is likely to nurse well. The **Baby-Friendly Hospital Initiative**, a global effort sponsored by WHO and the UN Children's Fund to promote breastfeeding, recommends 10 steps to successful breastfeeding (Table 113.5). When instituted together as a complete bundle, these practices can improve multiple outcomes, including breastfeeding initiation, duration of exclusive breastfeeding, and duration of overall breastfeeding. In the United States, however, the vast majority of newborns are still not delivered in Baby-Friendly hospitals that have implemented all 10 steps. Educating mothers during pregnancy and showing mothers how to breastfeed are the most widely implemented strategies, while establishment of written breastfeeding policies, restriction of formula access, and establishment of breastfeeding support groups after discharge are among the most challenging to implement.

Drugs and Breastfeeding

Ideally, drugs of any type should be avoided in breastfeeding women, unless prescribed for specific medical conditions. Many mothers are advised to discontinue breastfeeding or avoid taking essential medications due to fears of adverse infant effects. However, such an approach may be inappropriate in many cases, as only a small proportion of medications are contraindicated when breastfeeding. When weighing risks and benefits, healthcare providers should consider the following factors in discussion with the family: maternal need for the medication, potential effects on lactation, extent of excretion into human milk, extent of oral absorption by the breastfeeding infant, potential adverse infant effects, proportion of feedings comprised of breast milk, and age of the infant. Although previous editions of this text sought to list medications potentially used during lactation and to describe their potential for infant harm, revisions to this text can no longer keep pace with rapidly changing information available via the internet, published studies, and new drug approvals. For up-to-date information on drug levels in human milk and infant serum, possible adverse effects on infant health and lactation, and recommendations for possible medication alternatives, providers should refer to LactMed (http://toxnet.nlm.nih.gov).

Among US women of childbearing age, illicit drug use and legal substance use or abuse is common, with >5% of pregnant women reporting active illicit drugs, >9% alcohol use, and >15% cigarette use. Multiple drug use is also common. For mothers desiring to breastfeed with a history of current or past illegal drug abuse or legal drug use or abuse, healthcare providers must carefully and thoughtfully weigh the documented benefits of human milk and breastfeeding against the risks associated with the substance that the infant may be exposed to during lactation. Most illicit drugs are found in human milk with varying degrees of oral bioavailability, and breastfeeding is generally contraindicated (Table 113.6). However, mothers with substance use disorders should be encouraged to breastfeed under the following circumstances: established engagement in substance abuse treatment (e.g., methadone or buprenorphine maintenance therapy) that includes counseling and social support; abstinence from drug use for 90 days before delivery, with maternal urine toxicology testing at delivery negative other than prescribed substances, ability to maintain sobriety demonstrated in an outpatient setting, and engagement and compliance with care.

**Contraindications to Breastfeeding**
Medical contraindications to breastfeeding in the United States include infants with galactosemia, maple syrup urine disease, and phenylketonuria. Maternal conditions that contraindicate breastfeeding include infection with human T-cell lymphotropic virus types 1 and 2, active tuberculosis (until appropriately treated ≥2 wk and not considered contagious), herpesvirus infection on breast, use of or dependence on certain illicit drugs, and maternal treatment with some radioactive compounds (Table 113.7). Because clean water and affordable replacement feeding are available in the United States, it is recommended that HIV-infected mothers not breastfeed their infants regardless of maternal viral load and antiretroviral therapy. However, in resource-limited countries where diarrhea and pneumonia are significant causes of infant and child mortality, breastfeeding may not be contraindicated for HIV-positive mothers receiving antiretroviral therapy. Donor human milk, particularly that purchased online, may be contaminated with potential pathogens. Contamination is much less of a concern with pasteurized human milk obtained from a milk bank.

CHAPTER 114

High-Risk Pregnancies

Kristen R. Suhrie, Sammy M. Tabbah

The care of high-risk pregnancies should be coordinated with an experienced maternal-fetal medicine specialist.

In general, high-risk pregnancies are those that increase the likelihood of maternal complications, miscarriage, fetal death, preterm delivery, intrauterine growth restriction (IUGR), poor cardiopulmonary or metabolic transitioning at birth, fetal or neonatal disease, congenital malformations, or intellectual impairment and other handicaps (Table 114.1). There is no accepted comprehensive definition of what constitutes a high-risk pregnancy, therefore, specific epidemiologic data regarding the incidence/prevalence cannot be reliably reported. Some factors, such as ingestion of a teratogenic drug in the first trimester, are causally related to the risk, while others, such as polyhydramnios, are associations that alert a physician to determine the etiology and avoid the inherent risks associated with excessive amniotic fluid. Although assessing antepartum risk is important in reducing perinatal mortality and morbidity, some pregnancies become high risk only during labor and delivery; therefore careful monitoring is critical throughout the intrapartum course.

</table>

Identifying high-risk pregnancies is important not only because it is the first
step toward prevention but also because critical steps may often be taken to reduce the risks to the fetus or neonate if the physician is alerted to the specific condition early in pregnancy.

**Genetic Factors**

The occurrence of chromosomal abnormalities, congenital anomalies, inborn errors of metabolism, cognitive delay, or any familial disease in blood relatives increases the risk of the same condition in the infant. Because many parents recognize only obvious clinical manifestations of genetically determined diseases, specific inquiry should be made about any disease affecting one or more blood relatives. A high index of suspicion should be maintained to the possibility of autosomal recessive disorders in offspring of couples who are closely related (i.e., consanguinity).

**Maternal Factors**

The lowest neonatal mortality rate occurs in infants of mothers who receive adequate prenatal care and who are 20-30 yr of age. Pregnancies in both teenagers and women older than 40, particularly primiparous women, are at increased risk for IUGR, fetal distress, preeclampsia, and stillbirth. Advanced maternal age increases the risk of both chromosomal and nonchromosomal fetal malformations (Fig. 114.1).
Maternal illness (Table 114.2), multiple pregnancies (particularly those involving monochorionic twins), infections (Table 114.3), and certain drugs (see Chapter 115.4) increase the risk for the fetus. The use of assisted reproductive technology (e.g., ovulation induction, in vitro fertilization, intracytoplasmic sperm injection) increases the risk of prematurity, perinatal mortality, infant morbidity, low and very-low birthweight, imprinting disorders, and cerebral palsy. These risks are largely because of the increase in multiple gestations with such technology and the association with prematurity. The risks for birth defects are also increased with assisted reproductive technology, in part because of epigenetic effects on gene expression.

**Preterm birth** is common in high-risk pregnancies (see Chapter 117). Factors associated with prematurity (see Table 114.1) include multiple gestations as well as biologic markers such as cervical shortening, genital
infection, presence of fetal fibronectin in cervicovaginal secretions, serum α-fetoprotein (AFP), and premature rupture of membranes (PROM). PROM occurs in 3% of all pregnancies in the United States and is a leading identifiable cause of prematurity.

The presence of polyhydramnios or oligohydramnios indicates high-risk pregnancies. Amniotic fluid volume is variable throughout pregnancy and progressively increases from 10 to 30 wk of gestation. On average, volume is typically <10 mL at 8 wk and increases to 630 and 770 mL at 22 and 28 wk, respectively. After 30 wk, the rate of increase slows and the volume remains fairly constant until 36-38 wk gestation. This is followed by a progressive decline, with an average volume of 515 mL at 41 wk of gestation. Polyhydramnios complicates 1–3%, and oligohydramnios 1–5%, of pregnancies; although the true incidence of amniotic fluid disorders is confounded by the lack of a uniform approach to diagnosis. The ultrasound (US) criteria for these diagnoses are based on either the amniotic fluid index (AFI) or a deepest vertical pocket (DVP). The AFI is determined by measuring the vertical dimension of amniotic fluid pockets in 4 quadrants and reporting the sum of these values. An index >24 cm suggests polyhydramnios, whereas an index <5 cm suggests oligohydramnios. The DVP method reports the deepest pocket of fluid identified with a value of 2-8 cm is considered normal.

Polyhydramnios is associated with preterm labor, abruptio placentae, maternal diabetes, multiple congenital anomalies, aneuploidy, and fetal neuromuscular dysfunction or obstruction of the gastrointestinal tract that interferes with reabsorption of the amniotic fluid that is normally swallowed by the fetus (Table 114.4). Increased fetal urination, as with congenital nephrotic syndrome, or edema formation, such as hydrops fetalis, is also associated with excessive amniotic fluid volume. US demonstrates the increased amniotic fluid surrounding the fetus and detects associated fetal anomalies, hydrops, pleural effusions, and ascites. Idiopathic polyhydramnios is the most common cause, affecting approximately 40% of patients. About 25% of these cases will demonstrate an abnormality in the postnatal period. Otherwise, approximately 33% of prenatally detected cases have an associated anomaly, and 25% are associated with maternal diabetes. Severe and symptomatic polyhydramnios may be managed by serial reduction amniocenteses. Treatment is indicated for acute maternal respiratory discomfort and threatened preterm labor, or to provide time for the administration of corticosteroids to enhance fetal lung maturity.

**Oligohydramnios** is associated with congenital anomalies; IUGR; severe
renal, bladder, or urethral anomalies; and drugs that interfere with fetal urination (see Table 114.4). Oligohydramnios becomes most evident after 16-20 wk of gestation, when fetal urination is the major source of amniotic fluid. PROM is a common cause of oligohydramnios and must be ruled out if present, especially if a normal-sized bladder and kidneys are seen on fetal US. Oligohydramnios causes fetal compression abnormalities such as fetal distress/stillbirth from umbilical cord compression, clubfoot, spadelike hands, and a flattened nasal bridge. The most serious complication of chronic oligohydramnios is pulmonary hypoplasia, especially if present during the canalicular stage of fetal lung development, which occurs between 16 and 24 wk of gestation. The risk of umbilical cord compression during labor and delivery is increased in pregnancies complicated by oligohydramnios and may be alleviated by saline amniinfusion via a transcervical intrauterine pressure catheter, which has been demonstrated to reduce the need for cesarean section and improve Apgar scores.

A pregnancy should be considered high risk when the uterus is inappropriately large or small. A uterus large for the estimated stage of gestation suggests the presence of multiple fetuses, polyhydramnios, or an excessively large infant. An inappropriately small uterus suggests oligohydramnios or poor fetal growth.

**Mode of delivery** is influenced by a complex interplay between maternal-fetal factors. Spontaneous vaginal delivery is always preferred when not otherwise contraindicated. Operative vaginal delivery with vacuum or forceps is a safe alternative to cesarean delivery in appropriately selected patients. The absolute rate of significant newborn injury from these procedures is low, with rates ranging from 1 in 650-850 for intracranial hemorrhage and 1 in 220-385 for neurologic complications. With some of these injuries, the *indication* for operative vaginal delivery is more likely to be associated with the injury than the procedure itself, and could not have been prevented with a cesarean birth.

**Cesarean delivery** is indicated for a wide variety of circumstances. Cesarean-born infants present problems that are often related to the unfavorable obstetric circumstance that necessitated the operation. In normal term pregnancies without indication of fetal distress, cesarean delivery carries a greater neonatal risk than delivery through the birth canal. Even when accounting for gestational age, any malformations, birthweight, and multiple gestations, infants born ≥34 wk of gestation via elective cesarean section have 2 times the mortality rate of babies born following a planned vaginal birth, even if cesarean delivery was ultimately required. They also are 1.4 times as likely to require neonatal intensive care unit (NICU) admission and 1.8 times as likely to require breathing support for >30
min after birth. Cesarean-born infants are also at increased risk for persistent pulmonary hypertension of the newborn. An elective cesarean birth should be delayed until ≥39 wk of gestation, assuming there is no indication for delivery earlier.

Obstetric anesthesia is a vital component of care on the labor and delivery unit. The most common form of anesthesia in this patient population is regional (i.e., epidural or spinal). From the fetal/neonatal standpoint, the most significant complication encountered with this procedure is acute maternal hypotension, which can significantly impair uteroplacental perfusion. Fetal heart rate (FHR) abnormalities are common in this circumstance and, rarely, require emergent cesarean delivery if not amenable to standard in utero resuscitative efforts. Opioid analgesia is sometimes used in women who are not candidates for regional anesthesia. This form of pain relief is best avoided as delivery approaches, to minimize risk of neonatal depression. To this end, when opioid use is necessary, it is best to prescribe regimens that have a very short half-life. It is essential that the pediatric team is present at the birth in women receiving opioid analgesia. Furthermore, the pediatricians must be alerted to the specific type of opioid used, because all these drugs cross the placenta and have varying neonatal pharmacokinetics. Some of the common regimens used and their respective neonatal half-life are listed in the referenced American College of Obstetricians and Gynecologists (ACOG) practice bulletin on obstetric anesthesia.

The major emphasis in fetal medicine involves (1) assessment of fetal growth and maturity, (2) evaluation of fetal well-being or distress, (3) assessment of the effects of maternal disease on the fetus, (4) evaluation of the effects of drugs administered to the mother on the fetus, and (5) identification and when possible treatment of fetal disease or anomalies.

One of the most important tools used to access fetal well-being is ultrasonography (ultrasound, US); it is both safe and reasonably accurate. Indications for antenatal US include estimation of gestational age (unknown dates, discrepancy between uterine size and dates, or suspected growth restriction), assessment of amniotic fluid volume, estimation of fetal weight and growth, determination of the location of the placenta and the number and position of fetuses, and identification of congenital anomalies. Fetal MRI is a more advanced imaging method that is thought to be safe to the fetus and neonate and is used for more advanced diagnostic and therapeutic planning (Fig. 115.1).
**Fetal Growth and Maturity**

Kristen R. Suhrrie, Sammy M. Tabbah

Fetal growth can be assessed by US as early as 6-8 wk of gestation by measurement of the crown-rump length. Accurate determination of gestational age can be achieved through the 1st half of pregnancy; however, first-trimester assessment by crown-rump length measurement is the most effective method of pregnancy dating. In the second trimester and beyond, a combination of biometric measures (i.e., biparietal diameter, head and abdominal circumference, femoral diaphysis length) is used for gestational age and growth assessment (**Fig. 115.2**). If a single US examination is performed, the most information can be obtained with a scan at 18-20 wk, when both gestational age and fetal anatomy...
can be evaluated. Serial scans assessing fetal growth are performed when risk factors for **fetal growth restriction (FGR)** are present. Two patterns of FGR have been identified: *symmetric* FGR, typically present early in pregnancy, and *asymmetric* FGR, typically occurring later in gestation. The most widely accepted definition of FGR in the United States is an **estimated fetal weight (EFW)** of less than the 10th percentile (Fig. 115.3). Some aspects of human fetal growth and development are summarized in Chapter 20.

**FIG. 115.2** Fetal measurements: 3rd, 10th, 50th, 90th, and 97th smoothed centile curves. A, Fetal head circumference; B, fetal biparietal diameter; C, fetal occipitofrontal diameter; D, fetal abdominal circumference; and E, fetal femur length measured by ultrasound (US) according to gestational age. (From Papageorghiou AT, Ohyma EO, Altman DG, et al: International standards for fetal growth based on serial US measurements: the Fetal Growth Longitudinal Study of the INTERGROWTH-21st Project, Lancet 384:869–878, 2014, Fig 3.)
Fetal maturity and dating are usually assessed by last menstrual period (LMP), assisted reproductive technology (ART)–derived gestational age, or US assessments. Dating by LMP assumes an accurate recall of the 1st day of LMP, a menstrual cycle that lasted 28 days, and ovulation occurring on the 14th day of the cycle, which would place the estimated delivery date (EDD) 280 days after LMP. Inaccuracies with any of these parameters can lead to an incorrectly assigned gestational age if the LMP is used for dating. Dating by ART is the most accurate method for assigning gestational age with EDD occurring 266 days after conception (when egg is fertilized by sperm). When US is used for dating, the most accurate assessment of gestational age is by first-trimester ($\leq 13\frac{1}{2}$ wk) US measurement of crown-rump length, which is accurate to within 5-7 days. In contrast, US dating in the second trimester is accurate to 10-14 days, and third trimester is only accurate to 21-30 days. Dating of a pregnancy is critical to determine when delivery should occur, if growth is appropriate during the pregnancy, and when testing and interventions should be offered. The earliest assessment of pregnancy dating should be used throughout the pregnancy unless methodologies used later in pregnancy are significantly different.

Romero R, Deter R. Should serial fetal biometry be used in all
Fetal Distress

Kristen R. Suhrie, Sammy M. Tabbah

Fetal compromise may occur during the antepartum or intrapartum period. It may be asymptomatic in the antenatal period but is often suspected by maternal perception of decreased fetal movement. **Antepartum fetal surveillance** is warranted for women at increased risk for fetal death, including those with a history of stillbirth, intrauterine growth restriction (IUGR), oligohydramnios or polyhydramnios, multiple gestation, rhesus sensitization, hypertensive disorders, diabetes mellitus or other chronic maternal disease, decreased fetal movement, preterm labor, preterm rupture of membranes (PROM), and postterm pregnancy. The predominant cause of antepartum fetal distress is uteroplacental insufficiency, which may manifest clinically as IUGR, fetal hypoxia, increased vascular resistance in fetal blood vessels (Figs. 115.4 and 115.5), and, when severe, mixed respiratory and metabolic (lactic) acidosis. The goal of antepartum fetal surveillance is to identify the fetus at risk of stillbirth such that appropriate interventions (i.e., delivery vs optimization of underlying maternal medical condition) can be implemented to allow for a healthy live-born infant. **Table 115.1** lists methods for assessing fetal well-being.
FIG. 115.4 Normal doppler velocity in sequential studies of fetal umbilical artery flow velocity waveforms from one normal pregnancy. Note the systolic peak flow with lower but constant heart flow during diastole. The systolic/diastolic ratio can be determined and, in normal pregnancies, is <3 after the 30th wk of gestation. The numbers indicate the weeks of gestation. (From Trudinger B: Doppler US assessment of blood flow. In Creasy RK, Resnik R, editors: Maternal-fetal medicine: principles and practice, ed 5, Philadelphia, 2004, Saunders.)
FIG. 115.5  Abnormal umbilical artery Doppler in which the diastolic component shows flow in a reverse direction. This finding occurs in severe intrauterine hypoxia and intrauterine growth restriction. (From Trudinger C: Doppler US assessment of blood flow. In Creasy RK, Resnik R, editors: Maternal-fetal medicine: principles and practice, ed 5, Philadelphia, 2004, Saunders.)

The most common noninvasive tests are the nonstress test (NST) and the biophysical profile (BPP). The NST monitors the presence of fetal heart rate (FHR) accelerations that follow fetal movement. A reactive (normal) NST result demonstrates 2 FHR accelerations of at least 15 beats/min above the baseline FHR lasting 15 sec during 20 min of monitoring. A nonreactive NST result suggests possible fetal compromise and requires further assessment with a BPP. Although the NST has a low false-negative rate, it does have a high false-positive rate, which is often remedied by the BPP. The full BPP assesses fetal breathing, body movement, tone, NST, and amniotic fluid volume. It effectively combines acute and chronic indicators of fetal well-being, which improves the predictive value of abnormal testing (Table 115.2 ). A score of 2 or 0 is given for each observation. A total score of 8-10 is reassuring; a score of 6 is equivocal, and retesting should be done in 12-24 hr; and a score of 4 or less warrants immediate evaluation and possible delivery. The BPP has good negative predictive value. The modified BPP consists of the combination of an US estimate of amniotic fluid volume (the amniotic fluid index) and the NST. When results of both are normal, fetal compromise is very unlikely. Signs of progressive compromise seen on Doppler US include reduced, absent, or reversed diastolic waveform velocity in the fetal aorta or umbilical artery (see Fig. 115.5 and Table 115.1 ). The umbilical vein and ductus venosus waveforms are also used to assess the degree of fetal compromise. Fetuses at highest risk of stillbirth often have combinations of abnormalities, such as growth restriction, oligohydramnios, reversed diastolic Doppler umbilical artery blood flow velocity, and a low BPP.

* Modification of the criteria for reduced amniotic fluid from <1 cm to <2 cm would seem reasonable. Ultrasound is used for biophysical assessment of the fetus.

Fetal compromise during labor may be detected by monitoring the FHR, uterine pressure, and fetal scalp blood pH (Fig. 115.6 ). **Continuous fetal heart rate monitoring** detects abnormal cardiac patterns by instruments that compute the beat-to-beat FHR from a fetal electrocardiographic signal. Signals are derived either from an electrode attached to the fetal presenting part, from an ultrasonic transducer placed on the maternal abdominal wall to detect continuous ultrasonic waves reflected from the contractions of the fetal heart, or from a phonotransducer placed on the mother’s abdomen. Uterine contractions are recorded from an intrauterine pressure catheter or from an external tocotransducer applied to the maternal abdominal wall overlying the uterus. FHR patterns show various characteristics, some of which suggest fetal compromise. The baseline FHR is determined over 10 min devoid of accelerations or decelerations. Over the course of pregnancy, the normal baseline FHR gradually decreases from approximately 155 beats/min in early pregnancy to 135 beats/min at term. The normal range throughout pregnancy is 110-160 beats/min. **Tachycardia** (>160 beats/min) is associated with early fetal hypoxia, maternal fever, maternal hyperthyroidism, maternal β-sympathomimetic drug or atropine
therapy, fetal anemia, infection, and some fetal arrhythmias. Arrhythmias do not generally occur with congenital heart disease and may resolve spontaneously at birth. **Fetal bradycardia** (<110 beats/min) may be normal (e.g., 105-110 beats/min) but may occur with fetal hypoxia, placental transfer of local anesthetic agents and β-adrenergic blocking agents, and occasionally, heart block with or without congenital heart disease.

![Patterns of periodic fetal heart rate (FHR) deceleration.](image)

**FIG. 115.6** Patterns of periodic fetal heart rate (FHR) deceleration. The tracing in A shows early deceleration occurring during the peak of uterine contractions as a result of pressure on the fetal head. B, Late deceleration caused by uteroplacental insufficiency. C, Variable deceleration as a result of umbilical cord compression. Arrows denote the time relationship between the onset of FHR changes and uterine contractions. (From Hon EH: An atlas of fetal heart rate patterns, New Haven, CT, 1968, Harty Press.)

Normally, the baseline FHR is variable as a result of opposing forces from the fetal sympathetic and parasympathetic nervous systems. **Variability** is classified as follows: **absence of variability**, if an amplitude change is undetectable;
minimal variability, if amplitude range is ≤5 beats/min; moderate variability, if amplitude range is 6-25 beats/min; and marked variability, if amplitude range is >25 beats/min. Variability may be decreased or lost with fetal hypoxemia or the placental transfer of drugs such as atropine, diazepam, promethazine, magnesium sulfate, and most sedative and narcotic agents. Prematurity, the sleep state, and fetal tachycardia may also diminish beat-to-beat variability.

Accelerations or decelerations of the FHR in response to or independent of uterine contractions may also be monitored (see Fig. 115.6 ). An acceleration is an abrupt increase in FHR of ≥15 beats/min in ≥15 sec. The presence of accelerations or moderate variability reliably predicts the absence of fetal metabolic acidemia. However, their absence does not reliably predict fetal acidemia or hypoxemia. Early decelerations are a physiologic vagal response to uterine contractions, with resultant fetal head compression, and represent a repetitive pattern of gradual decrease and return of the FHR that is coincidental with the uterine contraction (Table 115.3 ). Variable decelerations are associated with umbilical cord compression and are characterized by a V or U shaped pattern, are abrupt in onset and resolution, and may occur with or without uterine contractions.

</table>
The decrease in FHR is ≥15 beats/min, lasting ≥15 sec, and <2 min in duration. When variable decelerations are associated with uterine contractions, their onset, depth, and duration commonly vary with successive uterine contractions.

Late decelerations are associated with fetal hypoxemia and are characterized by onset after a uterine contraction is well established and persists into the interval following resolution of the contraction. The late deceleration pattern is usually associated with maternal hypotension or excessive uterine activity, but it may be a response to any maternal, placental, umbilical cord, or fetal factor that limits effective oxygenation of the fetus. The significance of late decelerations varies according to the underlying clinical context. They are most likely to be associated with true fetal hypoxemia/acidemia when they are recurrent and occur in conjunction with decreased or absent variability. Late decelerations represent a compensatory, chemoreceptor-mediated response to fetal hypoxemia. The transient decrease in FHR serves to increase ventricular preload during the peak of hypoxemia (i.e., at the crest of a uterine contraction). If fetal acidemia progresses, late decelerations may become less pronounced or absent, indicating severe hypoxic depression of myocardial function. Prompt delivery is indicated if late decelerations are unresponsive to oxygen supplementation, hydration, discontinuation of labor stimulation, and position changes. Approximately 10–15% of term fetuses have terminal (just before delivery) FHR decelerations that are usually benign if they last <10 min before delivery.

A 3-tier system has been developed by a panel of experts for interpretation of FHR tracings (Table 115.4). Category I tracings are normal and are strongly predictive of normal fetal acid-base status at the time of the observation. Category II tracings are not predictive of abnormal fetal status, but there is insufficient evidence to categorize them as category I or III; therefore further evaluation, surveillance, and reevaluation are indicated. Category III tracings are abnormal and predictive of abnormal fetal acid-base status at the time of observation. Category III tracings require prompt evaluation and efforts to resolve expeditiously the abnormal FHR as previously discussed for late decelerations.

**Table 115.4**

**Three-Tier Fetal Heart Rate (FHR) Interpretation System**
CATEGORY I
Category I FHR tracings include all the following:
• Baseline rate: 110-160 beats/min
• Baseline FHR variability: moderate
• Late or variable decel erations: absent
• Early decelerations: present or absent
• Accelerations: present or absent

CATEGORY II
Category II FHR tracings include all FHR tracings not categorized as category I or category III. Category II tracings may represent an appreciable fraction of those encountered in clinical care. Examples of category II FHR tracings include any of the following:

Baseline Rate
• Bradycardia not accompanied by absence of baseline variability
• Tachycardia

Baseline FHR Variability
• Minimal baseline variability
• Absence of baseline variability not accompanied by recurrent decelerations
• Marked baseline variability

Accelerations
• Absence of induced accelerations after fetal stimulation

Periodic or Episodic Decelerations
• Recurrent variable decelerations accompanied by minimal or moderate baseline variability
• Prolonged deceleration, ≥2 min but <10 min
• Recurrent late decelerations with moderate baseline variability
• Variable decelerations with other characteristics, such as slow return to baseline, “overshoots,” and “shoulders”

CATEGORY III
Category III FHR tracings include either:
• Absence of baseline FHR variability
  or
• Any of the following:
  • Recurrent late decelerations
  • Recurrent variable decelerations
  • Bradycardia
  • Sinusoidal pattern

Umbilical cord blood samples obtained at delivery are useful to document fetal acid-base status. Although the exact cord blood pH value that defines significant fetal acidemia is unknown, an umbilical artery pH <7.0 has been associated with greater need for resuscitation and a higher incidence of respiratory, gastrointestinal, cardiovascular, and neurologic complications. Nonetheless, in many cases, even when a low pH is detected, newborn infants are neurologically normal.

**Maternal Disease and the Fetus**
Infectious Diseases

See Table 114.3 in Chapter 114 for a list of common maternal infectious diseases that impact the fetus and newborn.

Almost any maternal infection with severe systemic manifestations may result in miscarriage, stillbirth, or premature labor. Whether these results are a consequence of infection of the fetus or are secondary to maternal illness is not always clear. Another important factor to consider when dealing with infectious diseases in pregnancy is the timing of infection. In general, infections that occur earlier in the pregnancy (first or second trimester) are more likely to result in miscarriage or problems with organogenesis, such as the neuromigrational abnormalities seen in newborns with congenital CMV infections.

Cytomegalovirus (CMV) is the most common congenital infection, affecting 0.2–2.2% of all neonates (see Chapter 282 ). Perinatal transmission can occur at any time during the pregnancy; however, the most devastating sequelae occur with first-trimester infection. After a primary infection, 12–18% of neonates will have signs and symptoms at birth, and as many as 25% can develop long-term complications. The most common complication is congenital hearing loss. Severely affected infants have an associated 30% mortality, and 65–80% of survivors develop severe neurologic morbidity. A mother with a history of CMV may experience reactivation of the disease or may be infected with a different strain of the virus and transmit the infection to the fetus. Currently, there are no well-studied or validated antenatal therapies targeted toward decreasing disease severity or preventing congenital infection in the setting of primary maternal CMV infection. Preliminary data from some studies have demonstrated promise with drugs such as valganciclovir and CMV-specific hyperimmune globulin, but confirmatory data are lacking. For this reason, the American College of Obstetricians and Gynecologists (ACOG) does not recommend antenatal therapy for congenital CMV infection outside of an established research protocol.

Noninfectious Diseases (see Table 114.2 )
Maternal diabetes increases the risk for neonatal hypoglycemia, hypocalcemia, respiratory distress syndrome and other respiratory problems, feeding difficulties, polycythemia, macrosomia, growth restriction, myocardial dysfunction, jaundice, and congenital malformations (see Chapter 127.1). There is an increased risk of uteroplacental insufficiency, polyhydramnios, and fetal demise in poorly controlled diabetic mothers. Preeclampsia-eclampsia, chronic hypertension, and chronic renal disease can result in IUGR, prematurity, and fetal death, all probably caused by diminished uteroplacental perfusion.

Uncontrolled maternal hypothyroidism or hyperthyroidism is responsible for relative infertility, spontaneous abortion, premature labor, and fetal death. Hypothyroidism in pregnant women (even if mild or asymptomatic) can adversely affect neurodevelopment of the child, especially if the newborn is found to have congenital hypothyroidism.
