Wiley Encyclopedia of Chemical Biology (WECB) is the only major reference resource devoted to the cross-disciplinary field of chemical biology. WECB is a first port of call for academic researchers and advanced students looking for timely and authoritative review-type information in this field. The articles in WECB, contributed by world-class authors, are designed to

- illuminate the crucial role of chemistry and chemical techniques in the life sciences
- support the information needs of researchers in the field of chemical biology
- provide relevant and readily accessible information to upper-level students and to scientists in adjacent disciplines

WECB is an evolving online database of information, combining the most useful features of traditional reference works and review journals in a compelling format designed to exploit the full potential of the online medium. Extensive linking to the primary literature and to other online resources further enhances the value of the encyclopedia as a gateway to the broader scientific literature.

The editorial approach and structure of WECB will assure the longevity of its content. Through a systematic program of updates, the encyclopedia will be allowed to grow and evolve as the field itself grows and evolves, ensuring that it will remain an authoritative resource for chemical biology research and education for many years to come.

We have assembled the following distinguished Advisory Board to assist in the compilation of this work:

Tadhg Begley (Chair), Professor of Chemistry and Chemical Biology, Cornell University
Barbara Baird, Professor of Chemistry and Chemical Biology, Cornell University
Carl Batt, Professor of Food Science, Director of Ludwig Institute for Cancer Research Partnership, Cornell University
Hagan Bayley, Professor of Chemical Biology, University of Oxford
Carolyn Bertozzi, Professor of Chemistry, University of California, Berkeley
Timothy Bugg, Professor of Chemistry, University of Warwick
David Cane, Professor of Chemistry and Biochemistry, Brown University
Richard Cerione, Professor of Chemistry and Chemical Biology, Cornell University
Benjamin Cravatt, Professor of Chemistry and Cell Biology, The Scripps Research Institute
Steve Ealick, Professor of Chemistry and Chemical Biology, Cornell University
Jed Fisher, Professor of Chemistry and Biochemistry, University of Notre Dame
Sidney Hecht, Professor of Chemistry, University of Virginia
Robert Hertzberg, Vice President, Screening & Compound Profiling, GlaxoSmithKline Pharmaceuticals
Linda Hsieh-Wilson, Professor of Chemistry, California Institute of Technology
Tom Muir, Professor of Chemistry, Rockefeller University
Matt Pretender, Professor of Chemistry, University of Gigapedia
Lawrence Que, Jr., Professor of Chemistry, University of Minnesota
Kevan Shokat, Professor of Cellular and Molecular Pharmacology, University of California, San Francisco
Jeffrey Skolnick, Director Center for the Study of Systems Biology, Georgia Institute of Technology
William Smith, Professor of Biological Chemistry, University of Michigan
Dotsevi Sogah, Professor of Chemistry and Chemicaliology, Cornell University
Joanne Stubbe, Professor of Biochemistry, Massachusetts Institute of Technology
# Contents: Articles by Topic

## 1 Applications of Chemical Biology

### 1.1 Biomaterials
- Biocompatibility of Materials Used in Medical Devices, Methods For Evaluating
- Controlled Drug Delivery: Pharmacokinetic Considerations, Methods and Systems

### 1.2 Biotechnology
- Directed Evolution, Novel and Improved Enzymes through

### 1.3 Chemical Biology of Disease
- Anxiety Disorders: Macromolecular Pathways and Interactions
- Chronic Obstructive Pulmonary Disease (COPD), Inflammatory Mechanisms of
- Depression, Chemical Mechanisms of
- Hemozoin: A Paradigm for Biominerals in Disease
- Hypoxic Response and Associated Diseases
- Lysosomal Disorders
- Metabolic Diseases, Biological Mechanisms of
- Mitochondrial Medicine, Biochemical Evaluation of Mitochondrial Function
- Protein Misfolding and Disease, Chemical Biology of
- Protein Trafficking Diseases, Small Molecule Approaches to
- Saliva in Health and Disease, Chemical Biology of
- Schizophrenia, Biological Mechanisms of
- Systems Approach to Studying Disease

### 1.4 Pharmacology and Drug Discovery
- ADME Properties of Drugs
- Allergy and Asthma, Small Molecules to Target
- Lead Optimization in Drug Discovery
- Metals in Medicine, Imaging Agents
- Natural Products as Anticancer Agents
- Pharmaceutical Industry, Biocatalysts and Chemo catalysts
- Plant-Derived Natural Products Research, Recent Progress in Drug Discovery Based on
- Platinum Anticancer Drugs, Chemical Biology of
- Programmed Cell Death as a Therapeutic Approach
- RNA Interference to Treat Human Diseases, Applications of
- Transcription-Based Therapeutics

## 2 Biomolecules within the Cell

### 2.1 Glycans (Carbohydrates)
- Chemistry of Neoglycoproteins
- Glycan Biosynthesis in Mammals
- Glycosphingolipids, Chemistry of
- Starch Biosynthesis In Plants

### 2.2 Lipids
- Chemistry of Lipid Domains
- Essential Fatty Acids, Physiologic and Clinical Significance of
- Lipid Bilayers, Properties of
- Lipids, Chemical Diversity of
- Lipids, Organization and Aggregation of
- Lipids, Phase Transitions of

### 2.3 Natural Products
- Alkaloid Biosynthesis
- Chlorophylls and Carotenoids, Chemistry of

Medical devices are used for a variety of functions in humans. This review elaborates on the types of tests used to evaluate biocompatibility of the interactions between man-made medical devices and host tissues and organs. The outcome of the response depends on the site of implantation, the species of the host, the genetic makeup of the host, the sterility of the implant, and the effect the device has on biological processes. Biological processes involved in host tissue responses to implantable medical devices reflect activation of a series of cascades that require blood proteins or other components found in the blood. Two types of regulatory approvals for medical devices exist in the United States, 510(k) notification and premarket approval (PMA). The specific tests required prior to regulatory approval vary with the type of device and application; however, some general testing is usually recommended. Normally, animal testing is conducted to demonstrate that a medical device is safe, and when implanted in humans the device will reduce, alleviate, or eliminate the possibility of adverse medical reactions or conditions. The American Society for Testing and Materials (ASTM) as well as the International Organization for Standardization (ISO) publishes standards for testing medical devices. The recommended tests include culture cytotoxicity, skin irritation, short-term intramuscular implantation, short-term subcutaneous implantation, mucous membrane irritation, systemic injection, sensitization assays, and mutagenicity testing.

Introduction—What Are Medical Devices?

Medical devices are used for a variety of functions from promoting the healing of small wounds using adhesive bandages to maintaining the flow of blood through arteries narrowed by atherosclerosis using metallic vascular stents. The purpose of this article is not to give an overview of the many devices used in medicine to promote wellness and homeostasis but to elaborate on the types of tests used to evaluate the interactions between man-made devices and host tissues and organs. These man-made devices are called medical devices in the United States and are regulated for interstate distribution by the Federal Food and Drug Administration (FDA). In many cases, medical devices consist of assemblies of polymers, metals, ceramics, and composites that are used in diagnostic procedures and as implants in animals and in humans. In the United States, extensive biocompatibility testing occurs before the devices are marketed to the general public. Prior to 1976, no federal regulations existed to oversee the sale and uses of medical devices in the United States. In 1976, the U.S. Congress enacted the Medical Device Amendments to the Federal, Food, Drug, and Cosmetic Act of 1938, which called for the establishment of three classes of medical devices (Table 1a). Class 1 devices are those that present little or no risk to the user, whereas Class 2 and 3 devices present some risk and a high degree of risk to the user, respectively. These devices are regulated by requiring limited animal testing (Class 2) and extensive animal and human testing (Class 3). The European Union has a system of device classification similar to the United States as recognized by the Medical Device Directive (Table 1b).

The term biocompatible is used widely to infer that an implant is safe for use in the general population. Although this term is used broadly, it may be a misnomer because only materials that are found in living tissues are truly biocompatible. Below, we examine what methods are used to evaluate the biocompatibility of materials used in medical devices.

Biocompatibility—What Is Does it Mean?

The word biocompatibility is a relative term that means that the materials used in a medical device do not elicit a reaction that either 1) makes the device not perform its intended use or 2) causes reactions that affect the functioning and health of the host. All materials used in devices will elicit a response from the host; it could be an immediate response, one that is prolonged, or even a delayed reaction that occurs sometime after contact with the device. The outcome of the response depends on the site of implantation, the species of the host, the genetic makeup of the host, and the sterility of the implant. All implants have a significantly greater rate of infection when compared with the background rate associated with the surgical procedure performed in the absence of the device. At the very least, an implant should not interfere with biological processes that are required for normal homeostasis of the host.

Biological Systems—Which Ones Are Important for Normal Homeostasis and Survival?

Devices in contact with the external tissues such as skin typically are considered separately from a biocompatibility perspective from devices implanted internally. Implantable devices affect biological processes that involve blood; therefore, the testing of these devices is somewhat more complicated. Many skin contact devices are used short term, and therefore biocompatibility testing is limited. However, for permanent internal implants, the required testing can be as long as several years and require analysis of the effects of the device on cells and tissues as well as on healing responses that occur at the interface between the tissue and the device. For this reason, it is important to understand which biological systems may be affected when permanent implants are to be used.

Biological processes involved in host-tissue responses to implantable medical devices reflect the activation of a series of cascades that require blood proteins or other components found in blood. Biological systems activated by implants include blood clotting, platelet aggregation, complement activation, kinin formation, fibrinolysis, phagocytosis, immune responses, and wound healing (1) (Table 2). Wound healing involves several biological processes, including blood clotting, inflammation, dilation of neighboring blood vessels, accumulation of blood cells and fluid at the point of contact, and finally deposition of fibrous tissue around an implant. Vasodilation of blood vessels and accumulation of interstitial fluid around an implant can occur through activation of the kinin and complement pathways (3). Phagocytosis of dead tissue occurs by attraction and migration of inflammatory cells to the site of injury near an implant. The inflammatory cells attracted include neutrophils and monocytes that are present to digest dead tissue and implant materials. Once phagocytosis occurs, it may lead to digestion of implant remnants and formation of fibrous scar tissue around the implant. If a large blood clot surrounds an implant, then fibrinolysis must proceed to remove the clotted blood before the healing process can be completed (1).
Blood proteins are involved in the lysis of foreign cells via the complement pathway (1). This mechanism involves activation of complement proteins in the presence of an antibody–antigen complex attached to the surface of a foreign cell. Components of the complement pathway are sometimes compromised by activation and/or adsorption onto the surface of a medical device. This action leads to complement component depletion that causes the patient to be at risk for bacterial infection and makes evaluation of complement depletion important aspect of the design of cardiovascular devices. Activated complement components also prolong inflammation by generating C3a and C5a, which are agents that cause vasodilation. Complement activation is associated with and contributes to whole-body inflammation, which is observed as a complication to cardiopulmonary bypass. Complement activation is responsible for hyperacute rejection of animal tissue grafts (2) and is important in reactions to implants (3–5).

Most foreign surfaces cause blood to clot as a result of direct contact with a foreign surface. This clotting occurs via the intrinsic clotting cascade or from injury to tissue that develops during implantation as result of activation of Hageman factor and factor IX, which are two proteins found in blood (Table 2). Platelets, which are enucleated cells, are also found in blood; they release factors that contribute to formation of blood clots. Devices used in the cardiovascular system normally are designed to limit their propensity to clot blood. In the case of cardiovascular devices, excessive blood clotting will cause the device to occlude; in these applications, blood clotting is minimized. Because foreign materials typically cause blood clots, they are only used to replace large and medium-sized vessels. Host vessels are used to replace the function of small-diameter vessels. Several tests are used to measure blood clotting and platelet aggregation caused by contact with a medical device (6–8).

In addition to activating blood clotting (9), activated Hageman factor activates prekallikrein of the kinin system, which leads to bradykinin that causes vascular vasodilation. Activation of Hageman factor and blood clotting also leads to the conversion of plasminogen to plasmin which initiates the degradation of fibrin formed during clotting by a process termed fibrinolysis (1).

Phagocytic cells including neutrophils and macrophages, coat medical devices either from direct blood contact or via inflammation and extravascular movement of these cells into the tissue fluids that surround a device. In either situation, first neutrophils and then monocytes arrive in the area around the device and attempt to degrade the implant. If the implant is biodegradable, then these cells remain until the device is totally removed. If the device is nondegradable, then the number of cells surrounding an implant will depend on the how reactive the implant is. For example, although Dacron vascular grafts are permanent devices, monocytes can be observed surrounding the implant for months and years. In some patients, continued reactivity can cause peri-implant fluid accumulation, which if left uncorrected can require implant removal. In other cases where contact of tissue with the implant causes a prolonged inflammatory response, other white blood cells including eosinophils, B cells, and T cells can be observed in the vicinity of the device. These cells are an indication of either an allergic reaction or the formation of antibodies that stimulate prolonged inflammation. Measurement of inflammatory cells surrounding an implant is usually accomplished by direct histological evaluation (10–12).

As phagocytic cells accumulate near the implant, they elaborate hydrolytic enzymes that degrade both the implant and the surrounding tissues; fibroblasts and endothelial cells are also migrating into the area around the device and begin to lay down new extracellular matrix with capillaries and collagen fibrils. Thus, the wound healing process involves inflammation, removal of the implant and tissue components, as well as the deposition of new extracellular matrix. If the implant is nondegradable and nonporous, then a fibrous capsule forms around it. The thickness of the fibrous capsule depends on the degree of inflammation caused by the device. If the implant is porous, the device may biodegrade and lead to the formation of a small amount of fibrous scar tissue in the defect when the implant is removed. In some cases, however, after the implant biodegrades, an abundance of scar tissue can be deposited where the implant

**Tissue**
was previously observed. The thickness of the fibrous capsule formed around an implant is usually measured histologically.

Wear particles generated by a moving device can lead to prolonged inflammation and even implant failure in the case of hip and knee implants. Small polymeric or metallic particles, which are about 1 μm in diameter, are ingested by neutrophils and monocytes and may lead to necrosis of these cells and the release of inflammatory mediators into the wound area. Large particles are surrounded by monocytes, which form multinucleated giant cells that can in many cases be tolerated by tissues without leading to implant failure. However, once wear particles are released from the implant, they can migrate to other tissues or even to local lymph nodes causing swelling and systemic problems. Implant wear particles are quantitatively determined from histological and electron-microscopic studies (13–15).

**Types of Tests—What Types of Tests Are Used?**

Two types of regulatory approvals exist for medical devices in the United States, 510(k) notification and premarket approval (PMA). The types of tests required for approval depend on the classification of the medical device. 510(k) notification involves marketing a device that is substantially equivalent to a device on the market prior to 1976. All devices introduced after 1976 that are not substantially equivalent to devices on the market before 1976 are automatically classified as Class 3 devices and require PMA (16). For a device to be considered substantially equivalent to a device on the market before 1976, it must have the same intended use, no new technological characteristics, and have the same performance as one or more devices on the market prior to 1976. All devices introduced after 1976 marketing a device that is substantially equivalent to a device on the market before 1976, it must have PMA (16). For a device to be considered substantially equivalent to a device on the market before 1976, it must have the same intended use, no new technological characteristics, and have the same performance as one or more devices on the market prior to 1976. All devices introduced after 1976 are automatically classified as Class 3 devices and require PMA (16). For a device to be considered substantially equivalent to a device on the market before 1976, it must have the same intended use, no new technological characteristics, and have the same performance as one or more devices on the market prior to 1976. All devices introduced after 1976 are automatically classified as Class 3 devices and require PMA (16). For a device to be considered substantially equivalent to a device on the market before 1976, it must have the same intended use, no new technological characteristics, and have the same performance as one or more devices on the market prior to 1976.

The testing conducted on biomaterials intended for use in medical devices must address safety and effectiveness criteria that depend on the intended use as described above as discussed in depth the literature (18, 19). The specific tests required vary with the type of device and application; however, some general testing is usually recommended. Normally, animal testing is conducted to demonstrate that a medical device is safe, and when implanted in humans that the device will reduce, alleviate, or eliminate the possibility of adverse medical reactions or conditions (17).

According to the American Society of Testing Materials (ASTM) Medical Devices Standards (Annual Book of ASTM Standards, Section 13, Medical Devices, ASTM 1916 Race Street, Philadelphia, PA 19103; available at: www.astm.org), the type of generic biological test methods for materials and devices depends on the end-use application. The ASTM as well as the International Organization for Standardization (ISO) publishes standards for testing medical devices as listed in **Tables 3 and 4.** Biological reactions that are detrimental to the successful use of a material in one device application may not be applicable to the success of a material in a different end use. A list of potentially applicable biocompatibility tests that are related to the end use of a material and/or a device is given in Table 3 as a starting point. These tests are as follows:

**Cell culture cytotoxicity**

This test is used to evaluate the toxicity of a material in *vivo* or an extract of a material used in a device. Several different tests have been used and have produced a spectrum of biocompatibility assessments on the same material (20–22). The tests used measure the viability of cells in contact with a material or an extract of a material. A variety of cell lines can be used; however, a modified fibroblast line is usually the gold standard. Some tests used include 1) direct cell culture, 2) agar diffusion testing, 3) filter diffusion testing, and 4) barrier testing (22).

As pointed out by Learmonth (23), although the intact implant may not be cytotoxic to cells, any material and mechanical

flexural mismatch may lead to release of wear particles that can excite a cytochemical reaction that culminates in inflammation and cell cytotoxicity. The generation of wear particles and their size is of particular importance to the failure of joint implants through a process termed osteolysis (23).

Skin irritation assay
This test involves applying a patch of the material (or an extract of the material) to an area of an animal that has been shaved; in some cases the skin is abraded before the test material is applied. After 24 hours of contact, the patch is removed, and the skin is graded for redness and swelling. The grading scale can vary from 0 to 4: 0 means no redness and/or swelling and 4 means extensive redness and/or swelling. Standard test materials are used to evaluate skin irritation (24).

Short-term intramuscular implantation
This test is designed to evaluate the reaction of tissue to a device for periods of 7 to 30 days. This test can be conducted in the muscle below the skin in rabbits or rodents including mice, rats, and guinea pigs. At the conclusion of the test period, the samples are graded both visually and based on analysis of histological sections. A test described in the United States Pharmacopoeia (USP) is widely used. The purpose of this test is to evaluate the inflammatory potential (e.g., redness and swelling) grossly. In some cases, histological evaluation of the tissue is performed at the light and electron microscopic levels to look for phagocyte and immune cells. Some investigators use an intramuscular implantation site because the blood supply and hence the inflammatory potential may be easily evaluated. In addition, the results of short-term implantation tests may not reflect material-mediated inflammatory responses that may also occur (25).

Short-term subcutaneous implantation
This test is an alternative for studying the reaction of tissue to a device for a period of days to weeks. In this test, a tissue pocket is made in the skin above the muscle layer, the device is inserted into the pocket, and the pocket is sutured or stapled closed. Normally the device is placed deep into the pocket away from the site of insertion of the device so that reactions at the surface or clip site do not affect the evaluation of biocompatibility.

Although short-term implantation studies do give an analysis of the biocompatibility of a material at a local site, systemic effects can also be observed from corrosion products that develop from vascular implants that migrate to other sites (26).

Blood coagulation
Blood coagulation is normally assessed by determination of clotting times and extent of platelet aggregation initiated by the device surface in either static or dynamic systems. In a dynamic test, blood flows through the device or over a test surface made of the materials used in the device. This test is normally conducted on blood-contacting devices to ensure that the blood-coagulation and platelet-aggregation pathways are not modified. The tests are conducted in vitro using human or animal blood, ex-vivo in a flow chamber using animal blood, or in vivo in an animal model. It has been noted that variability in the results using standard materials is noted in ex-vivo tests of blood compatibility; this finding is attributed to the type of animal model used, the flow velocity, the time of exposure, and the method used to measure blood cell adhesion (27). Studies of stents used in the cardiovascular system illustrate that clot or thrombus formation is dependent on the type and design of the device (28, 29) and may be influenced by the corrosion of metallic implants (30).

Hemolysis
Hemolysis is determined by placing powder, rods, or extracts of a material in contact with human or animal plasma for about 90 minutes at 37°C (31). The amount of hemoglobin released into solution after lysis of the red cells in contact with the device is measured. When red cells undergo lysis, hemoglobin is released from the cells, and the absorbance from released hemoglobin is proportional to the amount of cell lysis. Extensive red-cell lysis is not desirable for devices that are to be implanted in the cardiovascular system. The measurement of hemolysis and its relevance is a question that should be addressed at each device application.

Carcinogenicity
Carcinogenicity testing involves long-term implantation (up to 2 years) in an animal model usually under the skin to look for tumor formation (32). This test is required for devices...
that employ materials that have not been extensively tested. Typically these tests are conducted in rodents, although rodents do form tumors to most solid implants (1).

**Long-term implantation tests**

These tests are covered by ASTM specifications F361 and F469 for muscle and bone, respectively. Implant materials are placed in the muscle as a soft-tissue model and in bone as a hard-tissue model. The implantation site is evaluated grossly and histologically for inflammation, giant cell formation, signs of implant movement, and for tissue necrosis. Although long-term implantation gives some indication of biocompatibility, it does not consider issues such as biofilm formation, infection, and encrustation associated with use of devices such as urologic implants (33). It is recommended that long-term implantation tests be conducted on a model relevant to the intended end use. In addition, the effect of wear particles is an important consideration with long-term implantation (23).

**Mucous membrane irritation**

Mucous membrane irritation is evaluated by placing a material in close proximity to a mucous membrane such as the oral mucosa. The test evaluates the amount of irritation and inflammation from gross and histological measurements. The hamster cheek pouch or oral mucosa is a model frequently used for this test (34).

**Systemic injection**

Systemic injection (acute toxicity) is designed to determine the biological response to a single intravenous or intraperitoneal injection of an extract (50 mg/kg) of a material over a 72-hour time period (35). Extracts are prepared using saline or other solutions that simulate body fluids. Animals are monitored for signs of toxicity immediately after injection and at various time intervals (1).

**Intracutaneous injection**

Intracutaneous injection involves the reaction of an animal to a single injection of a saline or vegetable oil extract of a material. Rabbits are commonly used, and they are studied for signs of inflammation (redness and swelling) at the injection site for a period of 72 hours (36).

**Sensitization assays**

Sensitization assays involve mixing the material or extract that has been in contact with a device with Freund’s complete adjuvant and injection of the test sample into the subcutaneous tissue during a 2-week induction period (37). After 2 weeks, the material or extract is placed on the skin near the injection site for 24 hours, and then the skin is evaluated for redness and swelling.

**Mutagenicity**

Mutagenicity is evaluated using the Ames test or an equivalent test. This test employs genetically altered bacteria (bacteria with altered nutritional characteristics), which are placed in contact with an extract of a material. Mutations are observed that lead to a reversion back to the “wild-type” phenotype that grows only under the original nutritional conditions and not under conditions that allows mutant growth. It has been reported many very small-wear particles are released from metal-on-metal contact in joint replacements, and these particles may cause mutagenic damage in bone cells (23). However, many of these wear particles may also be of concern as carcinegens.

**Pyrogenicity**

Pyrogenicity is used to evaluate fever-producing substances that may contaminate a medical device. They are components of gram-negative bacterial cell membranes (endotoxins) or are materials of chemical origin. The presence of endotoxins is determined by injecting an extract of the device into the circulatory system of a rabbit and measuring temperature in the rabbit’s ear. Another method to measure endotoxins involves contact of the material with cells that are lysed specifically by endotoxins (Limulus Amebocyte Lysate Test). Chemical pyrogens are determined by the rabbit test (38).

**Animal Models—A Variety of Animal Models Are Used**

A variety of animal models is used to evaluate the biocompatibility of medical devices. They include dog, sheep, goat, rabbit, mouse, rat, ferret, and pig. Pearse et al. (39) and Murray et al. (22) give a recent review of animal models in bone and dental device testing, respectively. Factors that lead to choice of a particular animal model include housing requirements as well as cost, maintenance, and care factors, resistance to disease, interanimal uniformity, tolerance to surgery, animal lifespan, the number and size of the implant (39–41). International standards (ISO 10993) provide guidance to determine the number of animals and the species that should be tested for each treatment and time point. Although the rat is one of the most widely used species in medical research because of its size and tissue structure, it is not a good model for testing some medical devices. Although the dog may not be a good model for bone implants because of differences in size and shape of canine bone in comparison with human bone, it is sometimes used because commercially available implants and instruments are available for canine surgery (39). Tissue microstructure, composition, wound healing, and remodeling differences with the human play an important role in animal model selection.

**Summary**

The word biocompatible is perhaps a misnomer; it refers to the ability of materials used in medical devices not to the illicit
adverse reactions that occur when implanted in humans. To assess biocompatibility, several tests have been developed to study the interactions of materials and biological tissues. The biocompatibility of a material or a device requires that it not activate any biological homeostatic systems including blood coagulation, platelet aggregation, inflammation, complement, or fibrinolysis.

Biocompatibility testing of medical devices depends on many criteria. Devices that contact only the skin and are for short-term use require less-stringent testing. These devices do not require long-term testing prior to human use. In contrast, implantable devices require more safety and effectiveness testing before they can be used in humans. The type of testing required depends on the end-use application. Although the term biocompatible is relative, because all devices will lead to some reactions by cells and tissues, it is important that the reactions observed at the device-tissue interface do not lead to implant failure or interfere with the functioning of any biological systems.

Biocompatibility tests vary for short-term versus long-term contact with tissue. Depending on whether the contact is with skin or internally, many standard tests have been developed for biocompatibility screening. Although many tests are predictive of the responses observed during use of devices in humans, biocompatibility of a device is ultimately only verified after extensive human clinical trials and general use in the population.

Controlled Drug Delivery: Pharmacokinetic Considerations, Methods and Systems

Zhong Zuo and Vincent H. L. Lee, School of Pharmacy, The Chinese University of Hong Kong, Shatin, N.T., Hong Kong SAR
doi: 10.1002/9780470048672.wecb099

Controlled drug delivery applies interdisciplinary approaches to engineer systems that improve the therapeutic value of drugs. This review addresses the biological basis of drug delivery, the pharmacokinetic/pharmacodynamic considerations important to the design of controlled release delivery systems, and the methods to fabricate them. The focus of this review will principally be on oral and transdermal applications. Systems at various stages of development for the delivery of more complex molecules, such as proteins, oligonucleotides, genes, and siRNAs will also be discussed.

The frequency of drug dosing is usually determined by the drug’s duration in the body. For drugs that are inherently long lasting, once daily oral dosing is sufficient to sustain adequate drug blood levels and the desired therapeutic effect. Formulation of these drugs as conventional, immediate-release dosage forms is used for the patient. However, many drugs are not inherently long lasting and require multiple doses each day to achieve the desired therapeutic results. Multiple daily dosing is inconvenient for the patient and can result in missed doses, made-up doses, and patient noncompliance with the therapeutic regimen. In addition, sequential therapeutic blood level peaks and valleys (troughs) are associated with each dose. The traditional approach to modifying drug release is to control the rate of drug delivery, as exemplified by extended-release tablets and capsules, which are commonly taken only once or twice daily. Modern drug delivery systems provide an additional targeted drug release dimension at a specific site in the body, spanning subcellular to organ. Thus, the term “controlled drug delivery” has a much broader meaning than just controlling the rate of drug delivery. Controlled drug delivery to the right site of action at the right time can be achieved by either 1) controlling the release rate and duration or 2) controlling the release site (i.e., localized delivery or targeted diseased organs, tissues or cells). Figure (1) has summarized the scheme for the design of the controlled drug delivery. The commonly used types of controlled drug delivery products in terms of its targeted diseases and specific delivery technology involved are summarized in Table (1).

General Introduction of Pharmacokinetics/Pharmacodynamics

Fate of a drug In vivo: ADME process

After administration, the fate of the drug will be determined by four key steps in vivo, namely, absorption (A), distribution (D), metabolism (M), and excretion (E). Effects of the four steps on the administered drug will influence the levels of drug exposure to the site of action and will eventually influence the pharmacological activities of the drug. The details of the four steps are described briefly as follows.

Absorption (A)

Before a compound can exert its pharmacological effect in tissues, it has to be taken into the bloodstream usually via mucosal surfaces such as the digestive tract for intestinal absorption. In addition, uptake of drugs from the bloodstream into targeted organs or cells needs to be ensured. However, this task is not always easy given the natural barriers that exist, like the blood-brain barrier. Extent of absorption for a drug varies with the way it has been administered. Factors such as poor compound solubility, chemical instability in the stomach, and inability to permeate the intestinal wall can all reduce the extent to which a drug is absorbed after oral administration. Absorption critically determines the compound’s bioavailability. Drugs that absorb poorly when taken orally must be administered in some less desirable way, like intravenously or by inhalation.
Distribution (D)

Once the drug gets into the bloodstream, it will be carried to various parts in the body including different tissues and organs, as well as its site of action. Depending on the physicochemical and biological properties of the drug, its degree of distribution to various tissues and organs differs by varying extents.

Metabolism (M)

As soon as the drug enters the body, in addition to being distributed to other parts of the body, it begins to break down. Most small-molecule drug metabolism occurs in the liver by enzymes termed cytochrome P450 enzymes. As metabolism occurs, the parent compound is converted to metabolites, which could be pharmacologically inert or active.

Excretion (E)

Compounds and their metabolites need to be removed from the body via excretion, usually through the kidneys or the feces. Unless excretion is complete, accumulation of foreign substances in the body could affect normal metabolism adversely.

Role of transporters in ADME

The extent of absorption for a drug varies with the way it has been administered. Over the last decade, several important transporters responsible for drug uptake/disposition in various organs have been discovered. They mainly include organic anion transporter, organic cation transporter, multidrug resistant protein, and multidrug resistance-associated protein. Many transporters function in the uptake of drugs into cells, which leads to increased permeability of the drug into cells; other transporters function to export drugs out of cells, which thereby decreases the apparent permeability of the drug. Transport mechanism of drugs and substrate specificities of drug transporters in drug development have become increasingly important. Identification of drugs that are the substrates of the transporters can help to elucidate the pharmacokinetic profiles of these drugs and drug-drug interactions, as well as to improve the therapeutic safety of drugs. Therefore, research that focuses on such membrane transporters is promising, and it leads to rational design strategies for drug targeting delivery. Drug targeting to specific transporters and receptors using carrier-mediated absorption has demonstrated immense significances in the ocular drug delivery (3) and targeted drug delivery across the blood-brain barrier (2).

Concept of pharmacodynamics, biomarkers and pharmacogenetics

Pharmacodynamics is the study of the mechanisms of drug action and the biological and physiological effects of these drugs. Compared with pharmacokinetics, which reveals what the body does to a drug, pharmacodynamics focuses more on what a drug does to the body.

Traditionally, the level of drug in vivo is assumed to be proportional to its pharmacodynamic effect. The identification of various biomarkers provides a more relevant indicator than the in vivo drug concentrations as far as clinical efficacy of a drug is concerned. Biomarkers enable the characterization of patient populations and the quantization of the extent to which new drugs reach intended targets, alter proposed pathophysiologic mechanisms, and achieve clinical outcomes. In genomics, the biomarker challenge is to identify unique molecular signatures within complex biological mixtures that can be unambiguously correlated to biological events to validate novel drug targets and to predict drug response. Biomarkers can stratify patient populations or quantify drug benefit in primary prevention or disease-modification studies in poorly served areas such as neurodegeneration and cancer. A proprieties of biomarkers depends on the strategy and the stage of development, as well as the nature of the medical indication. Biomarkers are perhaps most useful in the early phase of clinical development when measurement of clinical endpoints may be too time-consuming or cumbersome to provide timely proof of concept or dose-ranging information (3).

With the disclosure of the map of the human genome, the effect of human genetic variations on drug metabolism and its related clinical efficacy has become a major concern for clinical practice. Pharmacogenetics is an area of study on the genetic variation in response to drug metabolism with an emphasis on improving drug safety. The aim of drug delivery is to achieve an appropriate drug concentration at the targeted site that can elicit a desired level of response. The concentration of a drug in vivo is highly dependent on the ADME pharmacokinetic processes, whereas the level of response for a drug usually results from the interaction of a drug with a target receptor protein. More and more studies have revealed genetic polymorphisms in drug-metabolizing enzymes, transporters, and target receptors. The genetic basis underlying pharmacokinetic and pharmacodynamic inter-individual variability is essential in the consideration of the design of drug delivery systems (4).

Controlled Drug Delivery: Pharmacokinetic Considerations, Methods and Systems

Pharmacokinetic/Pharmaceutical Dosage Form/Pharmacodynamic Considerations in the Design of A Controlled Drug Delivery System

An ideal controlled-release product is expected to release the drug from the dosage form at a predetermined rate, to maintain the released drug at a sufficient concentration in the gastrointestinal fluids, and to provide sufficient gastrointestinal residence time prior to the absorption of the drug. In general, not every drug is suitable to be developed as a controlled-release product.

Traditionally, the pharmacokinetic properties of drug candidates has always played an important role in their design as a controlled release dosage form. From the pharmacokinetic point of view, the best suited drug candidates should have neither very slow nor very fast rates of absorption and excretion. Drugs with slow rates of absorption and excretion with half-lives of greater than 8 hours are usually inherently long acting, and their preparation into extended release dosage forms is not necessary. Drugs with very short half-lives (i.e., < 2 hours) are poor candidates for extended-release dosage forms because of the large quantities of drug required for such a formulation. Another pharmacokinetic consideration is that the drugs prepared in extended-release forms must have good aqueous solubility, must maintain adequate residence time in the gastrointestinal tract, and must be uniformly absorbed from the gastrointestinal tract. In addition, from the classic dosage form design point of view, the drug candidate should be administered in relatively small doses because each oral dosage unit needs to maintain a sustained therapeutic blood level of the drug.

As indicated in Table 1, because of the nature of the duration of action for a controlled drug delivery system, another important pharmacodynamic consideration for drug candidates is that long-acting drugs are used in the treatment of chronic rather than acute conditions. Regardless of how it is achieved, the prolonged and controlled pharmacodynamic effect is the eventual outcome expected for the controlled drug delivery system. The appropriate drug candidate should possess a reasonable therapeutic index (i.e., the median toxic dose divided by the median effective dose). It should be noted that drugs possessing a longer action than indicated by their quantitative pharmacokinetic half-lives might not be good candidates for a controlled drug delivery system either. Therefore, monitoring the controlled release drug more reliably and accurately in vivo is becoming a challenge and the traditional pharmacokinetic/pharmacodynamic correlations as a standard component of drug development are becoming more complicated than what is usually expected (5). An integrated pharmacokinetic and pharmacodynamic approach for rate-controlled drug delivery has been proposed (6). Should pharmacodynamic measurements eventually replace the traditional pharmacokinetic measurements? With the availability of various biomarkers, the measurements of related biomarkers rather than the plasma concentrations of specific drugs are believed to provide more direct and accurate monitoring of the behavior of the controlled drug delivery system in vivo.

Methods and Systems of Controlled Drug Delivery:

Natural and synthetic polymers, both erodible and nonerodible, play an important role in the fabrication of systems to control drug release. The method of combining polymers with drug candidates, together with the manufacturing process, provides even more control on the release profile desirable of the drug candidate.

Systems to control the release rate and duration of the drug

The rate of drug release from solid dosage forms may be modified by the technologies described below, which in general are based on 1) modifying drug dissolution by controlling access of biologic fluids to the drug through the use of barrier coatings, 2) controlling drug diffusion rates from dosage forms, and 3) chemical reactions or interactions between the drug substance or its pharmaceutical barrier and site-specific biological fluids. The commonly used systems and the related techniques are illustrated as follows.

Coated beads, granules, or microspheres

This system aims to distribute the drug onto beads, pellets, granules, or other particulate systems. The rate at which body fluids can penetrate the coating to dissolve the drug will be adjusted by varying the thickness of the coats and the type of coating material used. The coating techniques include conventional pan-coating or air-suspension coating techniques by which a solution of the drug substance is placed onto small inert nanoparticle seeds or beads made of sugar and starch or onto microcrystalline cellulose spheres. Naturally, the thicker the coat, the more resistant to penetration and the more delayed will be the drug release and dissolution. Typically, the coated beads are about 1 mm in diameter. However, the beads are combined to have three or four release groups among the more than 100 beads contained in the dosing unit. This technique provides the different desired sustained or extended release rates as well as the targeting of the coated beads to the desired segments of the gastrointestinal tract. An example of this type of dosage form is the Spansule capsule from SmithKline Beecham (King of Prussia, PA). Microencapsulated drug

Microencapsulation is a process by which solids, liquids, or even gases may be encapsulated into microscopic sized particles through the formation of thin coatings of "wall" material around the substance being encapsulated. Gelatin is a common wall-forming material, but synthetic polymers, such as polyvinyl alcohol, ethylcellulose, polyvinyl chloride, and other materials, may be used. The typical encapsulation process usually begins with the dissolving of the prospective wall material, such as gelatin, in water. The material to be encapsulated is added and the two-phase mixture is stirred thoroughly. The material to be encapsulated is then broken up into the desired particle size via addition of a solution of a second material, which is usually acacia. This additive material can concentrate the gelatin...
Embedding drug in hydrophilic or biodegradable matrix systems

By this process, the drug substance is combined and made into granules with an excipient material that slowly erodes in body fluids, progressively releasing the drug for absorption. Drugs without excipients provide an immediate drug effect, whereas drug-excipient granules provide extended drug action. The granule mix may be tableted or placed into gelatin capsule shells for oral delivery. Hydroxypropyl methylcellulose (HPMC), which is a free-flowing powder, is commonly used to provide the hydrophilic matrix. Tablets are prepared by distributing HPMC in the formulation thoroughly, preparing the granules by wet granulation or roller compaction, and manufacturing the tablets by compression. After ingestion, the tablet is made wet by gastric fluid, which hydrates the polymer. A gel layer forms around the surface of the tablet and an initial quantity of drug is exposed and released. As water permeates further into the tablet, the thickness of the gel layer is increased, and the soluble drug diffuses through the gel layer. As the outer layer becomes fully hydrated, it erodes from the tablet core. If the drug is insoluble, then it is released as such with the eroding gel layer. Thus, the rate of drug release is controlled by the processes of diffusion and tablet erosion. An example of a proprietary product using a hydrophilic matrix base of HPMC for extended drug release is Omnacortil SR Tablets from Roche Laboratories, Inc. (Columbus, OH), which contains morphine sulfate.

Scientists have been working for decades to expand the number of biodegradable polymers for clinical use, which include polyhydroxyacids, polyglycerides, polyethylene, and polyesters. Of these polymers, poly(lactic acid) (PLA) and poly(D,L-lactide-co-glycolide) (PLGA) are most often used because of their relatively good biocompatibility, easily controlled biodegradability, and good processability. In fact, they belong to one of the two classes of FDA approved synthetic biodegradable polymers to date. These polymers can be used either as matrix devices or as reservoirs. In matrix systems, the drug is dispersed or dissolved in the polymer, whereas the drug is encapsulated in a biodegradable membrane in the reservoir. The release rate of the drug is generally dependent on the degradation of the polymer. Poly(ortho)esters and polyamides erode from their surface, whereas the PLGA and PLA follow bulk erosion (i.e., degradation occurring throughout the whole polymer). By varying the ratios of monomers in the copolymer mix, nearly zero-order drug release produced by matrix degradation at steady rate can be achieved (7).

A few commercial available drug delivery systems are based on biodegradable polymers. Glididdel is a white, dime-sized wafer made up of biodegradable polyanhydride polymer [poly(1,3-bis(carboxyphenoxy)propane-co-sebacic acid)] (PPCP-SA) to deliver carmustine for the treatment of brain cancer. ReGel is an aqueous filter sterilizable ABA tri-block polymer system that consists of PLGA and polyethylene glycol (B). Its suitability to provide sustained interleukin-2 (IL-2) delivery for cancer immunotherapy has been reported. A Trigel is a proprietary delivery system that contains PLA or PLGA dissolved in a biocompatible carrier and can be used for both parenteral and site-specific drug delivery. The system is placed in the body using conventional needles and syringes and solidifies on contact with aqueous body fluids to form a solid implant. For a drug incorporated into such polymer solution, it becomes entrapped within the polymer matrix as it solidifies followed by being slowly released as the polymer biodegrades. Products that have already been approved by the FDA using the A Trigel technology include the Eligard (leuprolide acetate for injectable suspension) prostate cancer products that provide systemic release of leuprolide acetate for 1-, 3-, and 4-month duration and the Atrix (8.5% doxycycline) periodontal treatment product for localized subgingival delivery of doxycycline. With the clinical success of the current available products using biodegradable polymers, their additional applications in the delivery of small molecules, peptides, proteins, monoclonal antibodies, and vaccines are anticipated.

Embedding drug in an inert plastic matrix

By this method, the drug is granulated with an inert plastic material, such as polyethylene, polyvinyl acetate, or poly(methylmethacrylate), and the granulation is compressed into tablets. The compression of the tablet creates the matrix or plastic form that retains its shape during drug diffusion and its passage through the alimentary tract. An immediate-release portion of the drug may be compressed onto the surface of the tablet. The inert tablet matrix, which is expended of drug, is excreted with the feces. The primary example of a dosage form of this type is the Gradusmet from Abbott Pharmaceuticals (Abbott Park, IL).

Ion-exchange resins

A solution of a cationic drug may be passed through a column that contains an ion-exchange resin, which forms a complex by the replacement of hydrogen atoms. The resin-drug complex is then washed and may be tableted, encapsulated, or suspended in an aqueous vehicle. The release of the drug is dependent on the pH and the electrolyte concentration in the gastrointestinal tract. Release is greater in the acidity of the stomach than in the less acidic environment of the small intestine. Examples of drug products of this type include hydrocortisone polistirex and chlorpheniramine polistirex suspension (Tussionone Perorinetic Extended Release Suspension; M edeval) and phentermine resin capsules (Ionamin Capsules; Pharmaxen, Provo, U.T.).
Osmotic controlled release systems

The pioneer oral osmotic pump drug delivery system is the Oros system, which was developed by Alza Corporation (Mountain View, CA). The system is composed of a core tablet surrounded by a semi-permeable membrane coating with a 0.4-mm diameter hole in it that was produced by a laser beam. The core tablet has two layers: one contains the drug and the other contains a polymeric osmotic agent. The system operates on the principle of osmotic pressure. When the tablet is swallowed, the semi-permeable membrane permits water to enter from the patient’s stomach into the core tablet, which dissolves or suspends the drug. As pressure increases in the osmotic layer, it forces or pumps the drug solution out of the delivery orifice on the side of the tablet. Only the drug solution can pass through the hole in the tablet. The rate of inflow of water and the function of the tablet depends on the existence of an osmotic gradient between the contents of the bilayer core and the fluid in the gastrointestinal (GI) tract. Drug delivery is essentially constant as long as the osmotic gradient remains constant. The drug release rate may be altered by changing the surface area, the thickness, or the composition of the membrane, and/or by changing the diameter of the drug release orifice; the rate is not affected by gastrointestinal acidity, alkalinity, fed conditions, or GI motility. The biologically inert components of the tablet remain intact during GI transit and are eliminated in the feces as an insoluble shell. This type of osmotic system, which is termed the “gastrointestinal therapeutic system” (GITS; Pfizer, New York), is employed in the manufacture of Glucotrol XL Extended Release Tablets and Procardia XL Extended Release Tablets (Pfizer).

Gastro-retentive systems

Gastric emptying of dosage forms is an extremely variable process, and the ability to prolong and control the emptying time is a valuable asset for dosage forms, which reside in the stomach for a longer period of time than conventional dosage forms. Gastro-retentive systems can remain in the gastric region for several hours, and hence, they significantly prolong the gastric residence time of drugs. Prolonged gastric retention would therefore improve the bioavailability of drugs by reducing drug waste and by improving solubility for drugs that are less soluble in a high pH environment. It has applications also for local drug delivery to the stomach and proximal small intestines. The controlled gastric retention of solid dosage forms may be achieved by the mechanisms of mucadhesion, flotation, sedimentation, expansion, modified shape systems, or by the simultaneous administration of pharmacological agents that delay gastric emptying. Based on these approaches, classification of floating drug delivery systems has been investigated extensively. Several recent examples have been reported that show the efficiency of such systems for drugs with bioavailability problems. Gastrectensive agents help to provide better availability of novel products with many therapeutic possibilities and substantial benefits for patients. However, because of the complexity of the pharmacokinetic and pharmacodynamic factors for certain drugs, some researchers suggest that the rationale for continuous administration obtained by controlled-release gastroretentive dosage forms should be assessed and established in vivo (3).

Transdermally controlled drug delivery systems

Because of the large surface area of the skin and its bypass of the liver as a first pass step in metabolism, many drug delivery systems have been developed that control the rate of drug delivery to the skin for subsequent absorption. Effective transdermal drug delivery systems of this type deliver uniform quantities of drug to the skin over a period of time. Technically, transdermal drug delivery systems may be classified into monolithic and membrane-controlled systems (9).

Monolithic Systems

The systems incorporate a drug matrix layer between backing and frontal layers. The drug-matrix layer is composed of a polymeric material in which the drug is dispersed. The polymer matrix controls the rate at which the drug is released for percutaneous absorption. In the preparation of monolithic systems, the drug and the polymer are dissolved or blended together, cast as the matrix, and dried. The dried matrix may be produced in a sheet or cylindrical form, with individual dosage units cut and assembled between the backing and the frontal layers. Most transdermal drug delivery systems are designed to contain an excess of drug and thus drug releasing capacity beyond the time frame recommended for replacement.

Membrane-Controlled Transdermal Systems

The system is designed to contain a drug reservoir, usually in liquid or gel form, a rate-controlling membrane, and backing, adhesive, and protecting layers. This system has an advantage over monolithic systems in that as long as the drug solution in the reservoir remains saturated, the release rate of drug through the controlling membrane remains constant. Membrane-controlled systems are generally prepared by preconstructing the delivery unit, filling the drug reservoir, and sealing it off, or by a process of laminating, which involves a continuous process of construction, dosing, and sealing.

The first transdermal therapeutic system designed to control the delivery of a drug to the skin for absorption was developed in 1980 by the Alza Corporation. The system, marketed as Transderm-Scop by CIBA, is a circular, flat adhesive patch designed for the continuous release of scopolamine through a rate-controlling microporous membrane. Soon after, nitroglycerin, which is a drug substance used for the treatment of angina, became another candidate for transdermal delivery. The drug has a relatively low dose, short plasma half-life, high peak plasma levels, liver first pass metabolism, and inherent side effects when taken sublingually (a popular route for its administration). Since then, several nitroglycerin-containing systems have been developed including: Deponit (Wyeth-Ayerst), Minitran (3M Riker, St. Paul, MN), TransdermNitro (CIBA-Geigy, Summit, NJ), Nitro-Dur (Key Pharmaceuticals, Kenilworth, NJ), Nitroine (Schwarz Pharma, Monheim, Germany), and Nitrodisc (Searle). As indicated in Table 1, the application of the transdermal therapeutic system products covers various aspects with the most emphasis on its use in central nervous system disease, cardiovascular disease, and hormonal therapy.

Future developments in the field of transdermal drug delivery should address problems that relate to irritancy, sensitization,
It consists of unilamellar bilayer liposomes that are less than 100 nm in diameter with amphoterocin B intercalated within the membrane. Injectable liposome-based drug delivery systems of anti-cancer drugs are the most widely used drug nanoparticle in cancer (15). In addition to a PEG coating, most stealth liposomes also have some sort of biological species attached as a ligand to the liposome to enable binding via a specific receptor for the targeted drug delivery site. These targeting ligands could be monoclonal antibodies (named as immunoliposome), vitamins, or specific antigens. Targeted liposomes can home to nearly any cell type in the body and deliver drugs that would otherwise be systemically delivered. It is expected that the side effects of extremely toxic drugs could be drastically reduced if the drugs were only delivered to diseased tissues using such techniques (16).

Nanoparticles

A nanoparticle is a microscopic particle with a diameter less than 100 nm. Nanoparticles were first developed around 1970, and initially they were devised as carriers for vaccines and anticancer drugs. Nanoparticle research is currently an area of intense scientific research because of a wide variety of potential applications in biomedical, optical, and electronic fields. To enhance tumor uptake, the strategy of drug targeting was employed, and as a first important step, research focused on the development of methods to reduce the uptake of the nanoparticles by the RES cells. Simultaneously, the use of nanoparticles for ophthalmic and oral delivery was investigated (17, 18). Recent advancement of nanoparticles and nanosuspensions was caused by their application for pulmonary drug delivery (19, 20).

The size of nanoparticles generally varies from 10 to 1000 nm. The drug is usually dissolved, entrapped, encapsulated, or attached to a nanoparticle matrix, and depending on the method of preparation, nanoparticles, nanospheres, or nanocapsules can be obtained. Nanocapsules are vesicular systems in which the drug is physically and uniformly dispersed. In recent years, biodegradable polymeric nanoparticles using poly(D, L-lactide), PLA, poly(D, L-glycolide) (PLG), PLGA, and poly(caproacrylate) (PCA) have attracted considerable attention as potential drug delivery devices in view of their applications in the controlled release of drugs, their ability to target particular organs/tissues, as carriers of DNA in gene therapy, and in their ability to deliver proteins, peptides, and genes through a peroral route of administration. The PLA, PLG, and PLGA polymers have been used as controlled release formulations in parental and implantation drug delivery applications.

Nanomedicine is undergoing explosive development as it relates to the development of nanoparticles for enabling and improving the targeted delivery of therapeutic and diagnostic agents. The use of nanoparticles for specific delivery to malignant tumors, to the central nervous system, and across the gastrointestinal barriers has received great attention (21). The additional development of nanoparticles is highly dependent on the advancement of the material sciences. For nanotechnol-ogy rationally to generate materials useful in human therapy,
it will need to progress in full recognition of all the require-
ments biology places on the acceptability of exogenous ma-
terials (22). In particular, nanostructured porous materials, in
particular silicon-based photonic and templated materials, offer
a degree of control in both the rate and the location of drug
delivery that is just beginning to be recognized (23).

Dendrimers

Dendrimers are macromolecules characterized by their highly
branched structure and globular shape. They are attractive drug
carriers by virtue of the flexibility in precisely controlling their
molecular size, shape, branching, length, and surface func-
tionality. An active area of research is the development of
nontoxic, biodegradable, and biocompatible dendrimers. Var-
ious kinds of dendrimer-drug conjugates have been tried us-
ing polyamidoamine, polyphosphoester, and polyester dendrimers
and anticancer drugs such as doxorubicin, methotrexate, and
5-fluorouracil. The hydrophobic core and hydrophilic shell of
dendrimers could encapsulate hydrophobic drugs or diagnostic
agents in their interior and release them slowly. With an interior
of basic environment, dendrimers could also encapsulate acidic
drugs, such as methotrextate.

A unique characteristic of dendrimers is that they can act as
a particulate system while retaining the properties of a
polymer. Dendrimers can significantly improve pharmacoki-
etic and pharmacodynamic properties of low molecular weight
and protein-based therapeutic agents. The surface modified den-
drimers with various kinds of ligands, such as sugars, folate
residues, and poly (ethylene-glycol), could serve as a drug car-
rrier with targeted cell specificity. Poly (ethylene glycol) modi-
fied (PEGylation) dendrimers can generally overcome clearance
by RES system. Attachments of targeting moiety on the sur-
face of partially PEGylated dendrimer raised the possibility of
a delivery system that can cross biological barriers and deliver
the bioactive agent near the vicinity of its target site. Recent
successes also demonstrate potential of PEGylated dendrimers
in magnetic resonance imaging contrast agent and in carbonyl
metallic immunoassay (24, 25).

Erythrocytes/Cells

Erythrocytes, which are also known as red blood cells, have
been studied extensively for their potential carrier capabili-
ties for the delivery of drugs and drug-loaded microspheres.
Such drug-loaded carrier erythrocytes are prepared simply by
collecting blood samples from the organism of interest, sepa-
rating the erythrocytes from the plasma, entrapping the drug
into the erythrocytes, and resealing the resultant cellular carri-
ers. Hence, these carriers are called resealed erythrocytes. The
overall process is based on the response of these cells to os-
motic conditions. On reinfusion, the drug-loaded erythrocytes
serve as slowly circulating depots and target the drugs to the
RES system. The advantage of erythrocytes as drug carriers is
mainly caused by their biocompatibility within the host, par-
icularly when autologous cells are used, and hence triggering an
immune response is not possible.

Several methods, that include physical (e.g., electrical-pulse
method), osmosis-based systems, and chemical methods (e.g.,
chemical perturbation of the erythrocyte membrane), can be
used to load drugs or other bioactive compounds into erythro-
cytes.

Resealed erythrocytes have several possible applications in
various fields of human and veterinary medicine. Such cells
could be used as circulating carriers to disseminate a drug over
a prolonged period of time in circulation or in target-specific
organs, including the liver, spleen, and lymph nodes. Most drug
delivery studies that use drug-loaded erythrocytes are in the
preclinical phase. In a few clinical studies, successful results
have been obtained.

The ability of resealed erythrocytes to accumulate selectively
within RES organs makes them a useful tool for the treatment of
hepatic tumors and for the treatment of parasitic diseases.
Moreover, the first report of successful clinical trials of the
resealed erythrocytes loaded with enzymes for replacement ther-
apy was that of (beta)-glucosidase in the treatment of Gaucher’s
disease, in which the disease is characterized by an
inborn deficiency of lysosomal (beta)-glucosidase in RES cells. This
deficiency thereby leads to an accumulation of
(beta)-glucosidase in macrophages of the RES. Recently,
the same concept was also extended to the delivery of biophar-
macueticals that include therapeutically significant peptides and
proteins, nucleic acid-based biologicals, antigens, and vaccines
(26). In addition, the possibility of using carrier erythrocytes for
selective drug targeting to differentiated macrophages increases
the opportunities to treat intracellular pathogens and to develop
new drugs. Moreover, the availability of an application that
permits the encapsulation of drugs into autologous erythrocytes
has made this technology available in many clinical settings and
competitive with other drug delivery systems (27).

Summary

During the past four decades, formulations that control the
rate and the period of drug delivery (i.e., time-release medi-
cations) and that target specific areas of the body for treatment
have become increasingly common and complex. Because of re-
searchers’ ever-evolving understanding of the human body and
because of the explosion of new and potential treatments that re-
sult from discoveries of bioactive molecules and gene therapies,
pharmaceutical research hangs on the precipice of yet another
great advancement. However, this next leap poses questions and
challenges not only for the development of new treatments but
also for the mechanisms by which to administer them.

The current methods for drug delivery exhibit specific prob-
lems that scientists are attempting to address. Therefore, the
goal of all sophisticated drug delivery systems is to deploy
medications intact to specifically targeted parts of the body
through a medium that can control the therapy’s administra-
tion by means of either a physical or a chemical trigger.

To achieve this goal, researchers are turning to advances in the
worlds of microtechnology and nanotechnology. During the past
decade, systems that contain polymeric materials, such as poly-
meric microspheres and nanoparticles, have all been shown to be
effective in enhancing drug targeting specificity, lowering sys-
temic drug toxicity, improving treatment absorption rates, and
providing protection for pharmaceuticals against biochemical degradation. Peptides, proteins, and nucleotides or DNA fragments are the new generation of drugs; They are becoming attractive because of fast development within the biotechnology field. The administration of such molecules, however, may pose problems such as sensitivity of the molecules to certain temperatures, instability of the molecules at some physiological pH values, a short plasma half-life, and a high molecular dimension, which hinders diffusional transport and makes, at the moment, the parenteral route the only possible way of administering such molecules. Controlled drug delivery that uses the development of new administration routes could be the answer to these problems in administration of these molecules. The rationale of drug delivery is to change the pharmacokinetic and pharmacodynamic properties of drugs by controlling their absorption and distribution. Rate and time of drug release at absorption site could be programmed using a so-called delivery system. Various techniques, that include chemical technologies (such as pro-drugs), biological technologies, polymers, and lipids (such as liposomes) as well as the invention of new routes of administration, have been proposed to achieve controlled drug release. In fact, it could increase drug absorption and reduce the effects of the active ingredient in those regions not requiring therapy. Drug delivery systems that allow for an effective in vivo release of new molecules, such as recombinant anti-idiotypic antibodies with antibiotic activity devoted to the treatment of pulmonary tuberculosis and pneumocystosis and mucosal (candidiasis) diseases, fall into that category.

By mimicking Darwinian evolution in the test tube, directed evolution has become a powerful tool for engineering novel enzymes for basic and applied biology research and medicine. Unlike structure-based rational design, directed evolution is capable of altering single or multiple functional properties such as activity, specificity, selectivity, stability, and solubility of naturally occurring enzymes in the absence of detailed knowledge of enzyme structure, function, or mechanism. More recently, directed evolution has also been used to engineer metabolic pathways, viruses, and whole microorganisms, and to address fundamental problems in biology. The success of directed evolution has been largely fueled by the development of numerous molecular biology techniques that enable the creation of genetic diversity through random mutagenesis or homologous or nonhomologous recombination in the target genes and the development of powerful high throughput screening or selection methods as well as by novel applications. This review will highlight the key developments in directed evolution and focus on the design and engineering of novel enzymes through directed evolution and their implications in chemical biology.

Enzymes are truly remarkable catalysts that are essential to every biological process. They can catalyze a broad range of chemical transformations with exquisite selectivity (stereo-, regio-, and chemo-) and specificity. In addition, most enzymes are very efficient and operate at mild conditions. It is, therefore, not surprising that enzymes have been increasingly used as biological catalysts or therapeutic agents in various industries, including the chemical, pharmaceutical, agricultural, and food industries. However, the number and diversity of enzyme-based applications are still modest compared with the total number of enzymes identified so far (~5000 enzymes) (1). One main reason for this functional gap is that naturally occurring enzymes are the products of Darwinian evolution and are not designed for optimal industrial applications. To address this limitation, several enzyme engineering approaches have been developed in the past few decades, among which directed evolution stands out as a particularly attractive approach. This entry discusses the brief history of directed evolution, the main methods of directed evolution, and their applications in engineering enzymes for basic and applied biology research. For more in-depth information on directed evolution, interested readers are referred to the Further Reading list.

A Primer for Directed Evolution

Before the advent of recombinant DNA technology in the 1970s, the ability to engineer novel enzymes was limited to chemical modification methods in which specific residues in an enzyme...
Directed evolution bypasses the bottleneck of rational design and mimics natural evolution in a test tube to evolve proteins without knowledge of their structures. What fundamentally differentiates directed evolution from natural evolution is its power to significantly accelerate the process of evolution. As shown in Fig. 1, directed evolution uses various methods to generate a collection of random protein variants, called a library, at the DNA level. Followed by screening/selection of the library, protein variants with improvement in desired phenotypes are obtained. Usually, the occurrence of these functionally improved protein variants is a rare event; thus, this two-step procedure has to be iterated several rounds until the goal is achieved or no further improvement is possible.

Methods for Directed Evolution

A successful directed evolution experiment involves two key components: creating genetic diversity and developing a high throughput screening or selection method. In the past decade, many experimental methods and protocols for library construction and screening/selection have been developed. For more information on this topic, interested readers are referred to the two books edited by Arnold and Georgiou in the Further Reading list.

Library creation

Numerous molecular biology methods have been developed to introduce genetic diversity into the target gene, all of which can be grouped into three categories: methods of random mutagenesis, methods of gene recombination, and methods of semirational design. As shown in Fig. 2 random mutagenesis starts from a single parent gene and randomly introduces point mutations or insertions/deletions into the progeny genes. In comparison, gene recombination usually starts from a pool of mutants from a single gene or a pool of closely related or even non-related parental genes of different origin and creates blockwise exchange of sequence information among the parental genes. Finally, semirational design combines rational design and directed evolution by focusing mutagenesis on a few selected important residues or regions in a target gene.

Random mutagenesis

As a result of its simplicity and efficiency, error-prone polymerase chain reaction (EP-PCR) is the most widely used random mutagenesis method. It is essentially a variation of the standard PCR with slightly modified reaction conditions. There are many different protocols to implement EP-PCR, and the most popular one includes the following adjustments to normal PCR conditions: 1) use of nonproofreading DNA polymerases, such as Taq DNA polymerase; 2) use of low or unbalanced amount of dNTPs; 3) use of high concentration of Mg²⁺ (up to 10 mM); and 4) incorporation of Mn²⁺. The fourth modification has made EP-PCR more popular, because the error rate can be controlled precisely by the Mn²⁺ concentration. In general, 1-2 amino acid substitutions are introduced during each round of EP-PCR, which requires approximately 1-5 base mutations per kilobase of DNA. Higher mutagenic rates are not normally used because they often damage enzyme function and lead to an increased tendency to negate positive mutations. In addition, higher mutagenic rates result in a larger library size, which in turn requires an often unattainable robust screening/selection method to identify positive variants. On the other hand, a higher mutation rate increases the frequency of multiple mutations with synergistic effects, resulting in an overall enrichment of unique protein variants, and up to 30 mutations per gene have been reported.

Fig. 2 Random mutagenesis, directed evolution uses various methods to generate a collection of random protein variants, called a library, at the DNA level. Followed by screening/selection of the library, protein variants with improvement in desired phenotypes are obtained. Usually, the occurrence of these functionally improved protein variants is a rare event; thus, this two-step procedure has to be iterated several rounds until the goal is achieved or no further improvement is possible.

Directed evolution by focusing mutagenesis on a few selected important residues or regions in a target gene. In addition, more research has recently started addressing more complex systems, such as pathways (metabolic engineering), viruses, and even genomes.
Directed Evolution, Novel and Improved Enzymes through...

The great success of EP-PCR in engineering all aspects of enzyme properties has established this method as a cornerstone in directed evolution. It should be noted, however, that this technique is not truly random and suffers a number of limitations. In addition to the intrinsic bias of DNA polymerases (transitions are favored over transversions), EP-PCR can only access 5-6 amino acids substitutions on average at each residue because of the degeneracy of genetic codons and the low probability of two mutations occurring right next to each other. Another limitation of EP-PCR is associated with the low mutation rates normally used, such that the progeny protein variants have similar phenotype to the parent. Thus, novel functions are difficult to evolve using this method alone even after several rounds of iteration. To search the sequence space more extensively, EP-PCR is used in combination with other DNA diversity generation methods, such as gene recombination.

Gene recombination

Gene recombination can be implemented both in vivo and in vitro. However, the latter is used much more often because of its simplicity, higher recombination efficiency, and flexibility. Therefore, only in vitro methods will be discussed here. Note that all the available in vitro gene recombination methods fall into two main categories: homology-dependent and homology-independent.

Homology-dependent gene recombination

As nature has found homologous recombination a useful evolving tool, biologists have also recognized its power of achieving “long jump” in adaptive molecular evolution (8). And the advances in molecular biology made it possible to mimic this process in vitro. The first and most frequently used gene recombination method, DNA shuffling, also known as “sexual PCR”, was developed by Stemmer in 1994 (9). As shown in Fig. 3, the target gene is digested by DNaseI into random fragments, of which 100–300 bp fragments are purified and reassembled in a self-priming (no primers are added) PCR reaction according to their sequence homology. Recombination occurs when a fragment derived from one sequence anneals to a fragment derived from another sequence. This method was later adapted to recombine a family of naturally occurring homologous proteins from diverse species under modified conditions, which is called “family shuffling” (10). It was demonstrated that family shuffling significantly accelerated the rate of improvement of enzyme functions in comparison with EP-PCR and DNA shuffling.

As with every method, both DNA shuffling and family shuffling have their own limitations. First of all, both methods require relatively high homology, typically more than 70-75%, between the parental genes, because libraries created from more divergent sequences have a strong tendency to reassemble into parental genes. Various homology-independent methods have been developed to address this issue and will be discussed in the next session. Second, crossovers during template switching are favored in regions of high sequence identity, restricting the sequence space that can be explored. Third, fragments generated by DNaseI are not truly random, thus the diversity of the shuffled library is further decreased. Finally, there are also some nontechnical problems, such as limited access to natural sequence diversity and patent issues.

To address some of these limitations, a group of homologous gene recombination methods that do not involve DNA fragmentation but require addition of primers were developed, and staggered extension process (StEP) (11) was the first among them (Fig. 3). This method is essentially a modified PCR that uses very short extension time so that the elongation of short DNA fragments is staggered. During the subsequent rounds of DNA amplification, the fragments are repeatedly separated from the parental strand and prime a different one, resulting in multiple crossovers. StEP has several advantages over the original DNA shuffling method: 1) it needs only a small quantity of parental genes; 2) no digestion of DNA purification is needed, thus it is easy to be carried out; and 3) it avoids the DNaseI-induced bias. However, it should be noted that the StEP PCR conditions need to be optimized before a good library can be obtained, which might take a considerable amount of time.

Nonhomologous gene recombination

Incremental Truncation for the Creation of Hybrid enzymes (ITCHY) was the first developed homology-independent recombination method (12). Incremental truncation of two parental

genes from both ends by exonuclease III under nonideal conditions generates a collection of all possible truncated fragments, which are subsequently blunt polished and ligated to give genes of various lengths. There are several limitations of ITCHY. First, the key to creating a successful ITCHY library is the tight control of the exonuclease digestion conditions, and aliquots of digestion mixture have to be taken at various time points to quench the reaction. Therefore, it can be very time-consuming and labor-intensive. To address this issue, the same group developed a modified method, called THIO-ITCHY (13). The incorporation of α-phosphothioate nucleotide analogs at low frequency in genes inhibits exonuclease III activity, thus avoiding the requirement for frequent removal of digestion samples. The second limitation of ITCHY is that because it is a single crossover process, the diversity of the created library is rather limited. A different method, named SCRATCHY (14), was developed by the same group to achieve multiple crossovers by shuffling two ITCHY libraries, thus increasing the diversity of the library. Third, the ITCHY library of hybrids is not full-length and thus the two truncated genes are not necessarily fused at sites where the gene sequences align (15). It was shown previously that although insertions or deletions at the fusion portion of two parental genes might not necessarily have a deleterious effect on the enzyme function, the predominance of crossovers at positions of precise alignment in the selected active hybrids (12) indicates the importance of the alignment. This problem led to the birth of another method, sequence homology-independent protein recombination (SHIPREC) (15). In this method, two parental genes are fused by a linker containing multiple restriction sites. After digestion by DNase I at both ends of the fusion gene, full-length genes are selected, circularized, and digested by restriction enzyme in the linker region to give linear chimerical genes. The selection of a full-length gene helps maintain the sequence alignment of two genes and gives a larger fraction of functional hybrids. Finally, not only ITCHY, but all the methodologies discussed above, have one common limitation: only two parental genes can be recombined. Therefore, a few other multiple-parental homology-independent recombination methods have been developed, such as exon shuffling (16) and nonhomologous random recombination (NRR) (17).

Semirational design

Although rational design enables efficient targeting at critical protein sites, this approach is often hindered by limited availability of crystal structures and poor understanding of the structure-function relationship. To circumvent the limitations of rational design, directed evolution found its position as the “blind watchmaker.” However, as it is a “blind” searching process, the diversity pool must be as extensive as possible, which leads to the bottleneck of directed evolution: library screening. Therefore, any means to decrease the library redundancy would be beneficial. More importantly, when the engineering goal is to dramatically alter an enzyme function, it usually requires multiple close mutations in the active site, which are difficult to access by full-length gene random mutagenesis and require an even larger library to be screened. Therefore, to allow a more focused and more useful sequence space to be explored, the most logical way would be to combine the best features of the two extreme methodologies. This process gave birth to the third library creation method, called semirational design.

The most popular semirational design strategy is targeted saturation mutagenesis. Functionally important residues are identified by analysis of protein crystal structures and mutated individually (18) or in combination (19) into the other 19 natural amino acids using degenerate primers (NNN or NNS, N = A/T/G/C, S = G/C). It should be noted that protein crystal structures are no longer the only source for identification of functionally important residues. When no protein structure information is available, key residues can be identified by EP-PCR, bioinformatics, or homology modeling. Another expanding area is in silico directed evolution, the ability of which to rationalize a huge protein database and to guide engineering experiments holds the possibility to create novel enzymes beyond the natural realm. Various algorithms have been developed recently to optimize library creation conditions, library design, and library
Spatial compartmentalization are two ways of tagging. (phenotype) followed by screening/selection (phenotype analysis) that is compatible with the tagging. Physical linkage and (genotype) and the protein it encodes in each category, a common principle underlying these assays through. Although various technologies have been developed its throughput is relatively low and it can only be used to screen As screening requires individual analysis of each protein variant, the analysis method must be prudently chosen or developed, because of the first principle of directed evolution "you get what you select (screen) for." There are two main categories of library analysis methods: screening and selection. Screening involves examining every mutant individually for the desired property, whereas selection is a method whereby only proteins with the desired property are carried through. Although various technologies have been developed in each category, a common principle underlying these assays exists: tagging the DNA and the protein it encodes (phenotype) followed by screening/selection (phenotype analysis) that is compatible with the tagging. Physical linkage and spatial compartmentalization are two ways of tagging.

Screening technologies
A screening requires individual analysis of each protein variant, its throughput is relatively low and it can only be used to screen small libraries (up to a size of ~10^4). The 96-well plate is the most widely used screening format due to its versatility, although higher spatial density formats can be used, such as 384- or 1536-well microtiter plates or even protein microarrays. In a microtiter plate assay, not only are the protein and its encoding DNA compartmentalized in one well, but also the whole reaction; therefore, it is most suitable for enzyme activity assays. In addition, the enzyme is analyzed in the same way as in traditional biochemical assays: Each protein sample in the form of cell cultures, crude lysates, or purified proteins is transferred into one well and then examined, thus the reaction conditions can be controlled to mimic the final practical conditions as closely as possible. With the aid of an automatic colony picker and liquid handler, the assays can be easily adapted into this high throughput format and automated. Although the microtiter plates only provide compartmentalization for the DNA-protein pair, methods are needed to analyze the proteins. Currently, colorimetric or fluorometric assays are the most popular and convenient screening methods, whereby the positive variants can be easily identified by visual check or by measuring UV-Vis absorbance or fluorescence using a plate reader. However, they are not available for all enzymes. Other generic screening tools, such as HPLC, capillary electrophoresis, and thermistor arrays, have also been applied to engineering of enzymes.

To address the low throughput limitation associated with most screening methods, various fluorescence-activated cell sorting (FACS) based screening methods have been developed. Unlike the above mentioned screening methods, FACS can analyze and sort up to 100,000 cells per second in a quantitative manner (22). The first application of FACS to directed enzyme evolution was demonstrated by Georgiou and his coworkers in 2000 (23). By coupling with bacterial surface display (see the Surface Display subsection to follow), FACS was successfully used to engineer a protease variant with improved catalytic activity. A fluorescence resonance energy transfer (FRET) substrate was designed to assay the protease activity in which a fluorescent dye is quenched by its FRET quenching partner via a target scissile bond recognized by the protease. Enzymatic cleavage of the scissile bond results in the release of the FRET quenching partner while the fluorescent dye is retained on the cell surface, allowing isolation of active clones by FACS. Remarkably, this method achieved 5000-fold enrichment of active clones in a single FACS round.

Selection technologies
Compared with screening technologies, library selection applies certain selection pressure/criteria to the mutant library so that only positive variants are carried to the next round while unwanted variants are discarded. Therefore, a much larger library of enzyme variants (more than 10^11) can be assessed. However, the selection methods are normally developed for a specific system or for analyzing a particular enzyme property. Many properties, such as enzyme activity at extreme temperatures or pH, or organic solvents, are not directly amenable to selection. As a result, screening is usually more applicable than selection. Based on the DNA-protein pair tagging method, selection methods can be divided into two categories: surface display and compartmentalization.

Surface display
Display technologies, employing nucleic acids, phage, yeast, or bacteria, were initially developed for binding assays and have made great success in engineering high affinity receptors, such as antibodies and T-cell receptors (24). Several inherent features of the display technologies made them suitable for directing enzyme evolution. First of all, display of proteins on the surface establishes a physical linkage between DNA and protein. Second, the proteins on the surface are accessible to external molecules, such as substrates or other target molecules.

Finally, the DNA is restricted inside the phage particle or microbial cells, enabling easy tracking of the genotype. With the need for enzyme engineering growing, researchers recognized the potential of display technologies and progressively adapted them for enzyme engineering.

Phage display is the most commonly used technique for in vitro selection. Filamentous bacteriophages (e.g., M13) are used for protein display for their ability to infect host cells without killing them (25). In a practical enzyme phage display experiment, a phagemid DNA library is constructed first in vitro and then transformed into competent bacterial cells. The DNA that encodes the enzyme of interest is fused to one of the coat protein genes (pVIII for high copy display, pII for low copy display), thus the enzyme is expressed as a fusion to the phage coat protein. During the phage assembly process, the target DNA is encapsidated inside the nascent phage particle as a part of its genome while its encoding enzyme is displayed on its surface; as a result, a physical linkage is established.
Directed Evolution, Novel and Improved Enzymes through...

between the phenotype and genotype through the phage particle. Phage particles are then harvested as a batch and selected for those displayed enzymes with improved/novel functions. Phage display selection is naturally based on binding. More specifically, a phage library is selected by passing it through an affinity matrix whereby binding phages are captured while nonbinding phages are washed away. Therefore, to adapt the phage display technique to engineer enzyme properties such as activity, selectivity, and stability, the key is to couple enzyme properties to the capture or release of the phage from the affinity matrix, for example, by codisplaying the enzyme and substrate on the same phage particle. As shown in Figure 4 upon catalysis, the product is displayed on the surface and recognized by the solid support. In contrast, phages displaying inactive enzymes cannot bind the affinity matrix and are washed away. Phage display has been successfully used to engineer enzymes with improved activity, altered substrate specificity, improved stability, and even novel function (25-28). However, it is almost impossible to develop a generic phage display system for all applications and phages lack posttranslation modification mechanisms that might be critical for functional expression of some enzymes.

Compartmentalization

Just as in microtiter plate format based screening, compartmentalization is also used in selection methods; each DNA-protein pair is spatially isolated in an individual compartment, which is either a cell (in vivo selection) or a manmade compartment (in vitro selection) instead of individual wells. Wherever accessible, in vivo selection is very powerful and can assess large numbers of mutants. The ultimate in vivo selection method would be, under a given selection pressure, only mutants harboring proteins with improvements could grow into colonies or show a significant phenotypic difference. Although it is a very powerful technique, the utility of in vivo selection is very limited, because most enzymes are of little direct biological relevance. Another reason is that the sophisticated genetic regulation networks of the host microorganism have evolved to encounter rapid changes in the environment, and thus the applied selection pressure may result in mutations out of the target genes. In vitro selection overcomes some of the limitations of in vivo selection. In vitro compartmentalization (IVC) (29) links the genotype and phenotype by colocalizing single genes together with necessary transcription and translation biochemical components in the aqueous compartments of a water-in-oil emulsion droplet. In most compartments, there is either no gene or only one gene that is later transcribed and translated in vitro within the same compartment. The enzymatic reaction is later carried out in the same droplet. To a certain extent, IVC is similar to microtiter plates but on a much smaller size scale with volumes close to those of bacteria (29). As the gene is transcribed and translated in vitro, general cloning is avoided and the library size is no longer limited by transformation efficiency. However, it seems that IVC can only be used to select enzymes that directly or indirectly act on DNA. For analyzing other enzyme properties, the droplets still need to be screened one by one, as in the case of 96-well plate screening. However, by combining with other technologies, such as FACS (30) or microbeads (31), IVC still holds promise for future enzyme engineering.

Applications of Directed Evolution

Directed evolution has been successfully used to alter existing enzyme properties and even to create novel enzyme functions. In addition to creating enzymes for specific industrial applications, directed evolution has also been increasingly used to address fundamental questions in biology, such as the evolutionary mechanisms of novel protein functions, protein structure-function relationship, and protein folding mechanisms.

Improving enzyme properties by directed evolution

Directed evolution has enjoyed great success in improving existing enzyme characteristics. In the following sections, only...
a few selected examples will be highlighted. Alterations have been made for almost all aspects of enzyme properties, such as substrate specificity, product specificity, selectivity, activity, stability, or folding/ solubility. Such alterations are required for enzymes to become practically useful biocatalysts or therapeutics.

**Substrate specificity**

Although the analogy of lock and key is sometimes used to describe the relationship between an enzyme and its substrate, in reality, the level of specificity varies. A particular enzyme may perform similar reactions on a range of related substrates or it may show tremendous specificity to one molecule. This aspect of enzymes can be exploited to develop variants with altered substrate recognition. In some cases, it may be beneficial to expand the range of substrates acted on. For example, poly-chlorinated biphenyls (PCBs) are a class of organic compounds whose use is decreasing due to concerns over their long-term environmental persistence and health effects. Certain bacteria can degrade some of these compounds by oxygenation reactions. Shuffling of two biphenyl dioxygenases from different bacteria resulted in higher activity, and activity on novel substrates such as toluene (32). In another example, EP-PCR was used to convert E. coli aspartate aminotransferase into a valine aminotransferase (33). A mutant enzyme with 17 amino acid substitutions was created that shows a $2.1 \times 10^6$-fold increase in the catalytic efficiency for a non-native substrate, valine.

Structural analysis of the mutant enzyme by protein crystallography indicated a remodeled active site and altered subunit interface caused by the accumulative effects of mutations. Most surprisingly, only one of the mutations directly contacts the substrate, which underscores our limited understanding of enzyme substrate specificity. These mutations would be difficult, if not impossible, to be identified and introduced to the mutant enzyme by a rational design approach.

**Product specificity**

In addition to altering an enzyme’s substrate, the product of an enzymatic reaction can be modified by using directed evolution. One example of product specificity engineering that has received attention is that of carotenoid pathway enzymes. Farnesylgeranyl diphosphate synthase catalyzes the condensation of isopentenyl diphosphate into a C25 isoprenoid molecule. The conversion of this isopentenyl diphosphate into a C25 isoprenoid molecule can be achieved by increasing the $k_{cat}$ or decreasing the $K_m$. A high throughput screening system was used with family shuffling of the thymidine kinase gene from herpes simplex virus I and II to increase the specificity of AZT phosphorylation (40). The authors used a robot to pick around 10,000 clones at each of four rounds of family shuffling, and they measured colony growth on different levels of AZT. Variants were found that conferred sensitivity to E. coli when exposed to 32-fold less AZT compared with HSV 1 thymidine kinase. These variants contained multiple crossovers and mutations affecting the binding site. A more stable enzyme was obtained using compartmentalization, which was used with site-directed saturation mutagenesis to screen libraries of phosphotriesterase for increased activity (31). Despite this enzyme already being very active, the $K_m$ was increased from $2280 \text{ s}^{-1}$ to $144,300 \text{ s}^{-1}$ (63-fold). The $k_{cat}$/$K_m$ was only increased slightly due to an increase in $K_m$, but at $1.76 \times 10^8 \text{ M}^{-1}\text{s}^{-1}$, it is approaching the diffusion-limited rate of catalysis.

**Selectivity**

Chiral molecules have important roles in the pharmaceutical and chemical industries. Enzymes have the capability to be exquisitely enantioslective, and applications of directed evolution in this area have been reviewed (37). Pioneering work was carried out on a lipase from Pseudomonas aeruginosa, by EP-PCR and saturation mutagenesis. Using a model reaction, the hydrolysis of 2-methyldecanoic acid-2-nitrophenyl ester, the enantioselectivity was increased from $E = 1.1$ to $E = 25.8$ (38). Carbohydrates are a large class of chiral molecules with essential roles in biology, and they can serve as useful precursors in chemical synthesis of complex organic molecules. Directed evolution has been used to alter the preferred stereoproducit of the condensation of dihydroxyacetone phosphate and glyceroldehyde 3-phosphate (39). Depending on the enzyme, these substrates can yield D-fructose-1, 6-bisphosphate or D-tagatose-1, 6-bisphosphate, which differ in the C4 stereocchemistry. DNA shuffling of tagatose-1, 6-bisphosphate aldolase shifted the preference from $>99:1$ in favor of tagatose-1, 6-bisphosphate to 4:1 in favor of fructose-1, 6-bisphosphate, due to mutation of four residues within the substrate binding pocket.

**Activity**

Enzymes show a wide variety of reaction rates, which can be expressed in terms of either their turnover number or catalytic efficiency. For practical purposes, a high reaction rate is desirable, and it can be achieved by increasing the $k_{cat}$ or decreasing the $K_m$. A high throughput screening system was used with family shuffling of the thymidine kinase gene from herpes simplex virus I and II to increase the specificity of AZT phosphorylation (40). The authors used a robot to pick around 10,000 clones at each of four rounds of family shuffling, and they measured colony growth on different levels of AZT. Variants were found that conferred sensitivity to E. coli when exposed to 32-fold less AZT compared with HSV 1 thymidine kinase. These variants contained multiple crossovers and mutations affecting the binding site. A more stable enzyme was obtained using compartmentalization, which was used with site-directed saturation mutagenesis to screen libraries of phosphotriesterase for increased activity (31). Despite this enzyme already being very active, the $K_m$ was increased from $2280 \text{ s}^{-1}$ to $144,300 \text{ s}^{-1}$ (63-fold). The $k_{cat}$/$K_m$ was only increased slightly due to an increase in $K_m$, but at $1.76 \times 10^8 \text{ M}^{-1}\text{s}^{-1}$, it is approaching the diffusion-limited rate of catalysis.

**Stability**

A common aim of directed evolution is to increase the stability of an enzyme to conditions of practical use that may be very different from those the enzyme naturally functions in. Factors such as heat, altered pH, and the presence of oxidants or organic solvents can lead to denaturation or loss of enzyme function. Many researchers have successfully increased the stability of an enzyme to thermal denaturation (41, 42). Work with p-nitrophenyl esterase increased the melting temperature $14^\circ C$ after six rounds of EP-PCR and recombination without forfeiting enzyme activity (41). As another example, phosphate dehydrogenase catalyzes the formation of phosphate from phosphite, by reducing NAD$^+$ to NADH. However, the usefulness...
of this enzyme as a means of regenerating NADH cofactors for industry was impeded by the low stability of the wild-type enzyme isolated from Pseudomonas putida. Four rounds of EP-PCR were used to identify 12 mutations that increased the half-life of the enzyme at 45°C by 7000-fold (42). Notably, family shuffling of 26 subtilisin genes produced variants with improved activity at either heat, pH 10, pH 5.5, or the presence of 35% dimethylformamide (43). Certain clones also showed better performance under combinations of these conditions.

Folding/solubility
Low solubility or improper folding may sometimes hamper the use of enzymes, particularly when expressed in a non-native host. A method of expressing proteins with a C-terminal GFP fusion to use fluorescence as a measure of the amount of correctly folded protein has been introduced (44). DNA shuffling produced variants of ferritin that showed increased solubility, even when they were recoloned without the GFP fusion. This assay has been used to produce proteins for X-ray crystallography structure determination (45). The protein nuclease diphosphate kinase from Pyrobaculum aerophilum is insoluble when expressed in E. coli, but after DNA shuffling, a functional variant with six mutations was found to have 90% solubility, which enabled its crystallization, and its structure was determined.

Creating enzymes with novel functions by directed evolution
One of the aspirations of directed evolution is to create new function in enzymes, which may be to carry out a reaction that has not been found in nature or may involve adding new control modalities. The challenge that the field is embracing is a significant one. Nature is conservative when it comes to the generation of new enzymes, as it retools existing structures for new functions rather than inventing a new scaffold for each different reaction. The (g)lu-8 barrel scaffold, for example, is the most common protein structure found in enzymes, and different enzymes with this scaffold carry out many different types of reactions. Protein engineers can take hope and inspiration from this in their attempts to create novel function in enzymes.

Novel substrate specificity
As already discussed, enzyme activity can be broadened to include substrates not previously acted on. But directed evolution can also yield enzymes with substrate recognition different from the starting point (46). DNA shuffling of two highly homologous triazine hydrolases produced variants that acted on triazines that neither parent had activity toward, which showed that examining small differences in sequence space can reveal new activities.

Altering substrate specificity sometimes follows a process of relating, followed by tightening. Collins et al. (47) used a clever dual selection strategy to alter the response of the LuxR transcription factor to different acyl-homoserine lactones. This type of research can produce modifiers of transcription with fine control by a desired ligand chosen so as to not interfere with other biological pathways. The response of LuxR was initially broadened from 3-oxo-hexanoyl-homoserine lactone (3OC6HSL) to accept a variety of straight-chain acyl-homoserine lactones. Negative selection was performed against response to 3OC6HSL, resulting in a variant that responded to straight-chain acyl-HSLs but not the original activator.

Novel activity
Novel functions can be incorporated within existing protein scaffolds that naturally have no activity for the desired reaction. Working within the β-lactamase enzyme scaffold, the activity of β-lactamase has been successfully introduced into glyoxalase II by a combination of rational design and directed evolution (48), which involved deletion of the original glyoxalase II substrate-binding domain, followed by the introduction of loops designed by examining metallo β-lactamases, EP-PCR, and DNA shuffling. The resulting enzyme had activity as a β-lactamase, albeit at much lower efficiency than seen for the native enzyme. New activity can also be incorporated into a noncatalytic protein scaffold, as demonstrated by the creation of triose phosphate isomerase activity within ribose-binding protein by computational design and EP-PCR (49). Current applications in this area rely on seminal design, with directed evolution typically used to increase the initial activity produced.

New ways of controlling enzyme function can also be introduced. Natural enzymes often exhibit some form of posttranslational regulation that affects their activity, which could take the form of interaction with a small molecule to enhance or inhibit activity in a particular environment. The maltose-binding protein can function as a switch when inserted into a gene such as β-lactamase (50), which enables a level of control over the desired reaction, based on the presence or absence of a molecule such as maltose.

Understanding natural enzyme evolution
The power of directed evolution to create and analyze tens of millions of protein variants not only enables one to engineer enzymes with desired properties for practical applications and to study the structure and function of proteins, but it also provides researchers the means to understand natural evolutionary processes. Rather than being restricted to the snapshot of sequence space found in extant genes, researchers can conduct evolutionary experiments on catalytic mechanisms or protein structure to better understand how current genes arose. As little as one mutation has been shown to confer on an enzyme the ability to carry out a new reaction. Single mutations were discovered that allowed two members of the mucenate lactonizing enzyme subgroup of the enolase superfamily to catalyze an additional reaction, that of the enzyme α-succinylbenzate synthase (51). Other work has revealed the ease through which a promiscuous enzyme function can be improved by orders of magnitude, with comparatively little effect on the enzyme’s main function (52).

Proposed pathways of protein fold evolution have been examined for the DNA methyltransferase superfamily, showing that the circularly permuted variants seen in nature can be generated in the laboratory via intermediates that retain function (53).
Directed evolution has been demonstrated to be very useful in modifying enzymes for practical applications, producing better stability, higher activity, and altered substrate specificity or product formation. Its influence will only increase, by producing enzymes that are more versatile and adaptable to future medical, industrial, and agricultural demands. The future is likely to see an increased pairing of rational design and directed evolution, as researchers generate more protein structures and improve their ability to identify optimal target areas of proteins for randomization. Ambitious applications are also likely to continue, leading to new ways of controlling enzyme activity and examples of dramatic reconfiguration of the starting enzyme’s function. It is still a long way off until researchers have the ability to design from first principles an enzyme for any given task, and, as such, directed evolution will continue to be an incredibly useful tool for many years to come.

References

Fear and anxiety can be a normal adaptive reaction to help cope with stress in the short term, but when the emotional, cognitive, and physical manifestations are long lasting, extreme, and disproportionate to threat, whether real or perceived, anxiety is maladaptive and has become a disabling disorder. Anxiety disorders may be deconstructed to elementary behaviors/symptoms that can be conceptualized as quantitative characters determined by the combined effects of several risk genes and nongenetic factors (e.g., early-life adversity). Progress in neurogenetics, molecular and cellular neuroscience, and neuroimaging is beginning to yield significant insights of how genetic and nongenetic factors contribute to specific manifestations of anxiety disorders. The aim of this overview is to summarize and integrate the current knowledge on anxiety-related macromolecular pathways and mechanisms initiated by genetic risk and environmental factors. These pathways interact with each other, often during specific periods of development, and could lead to alterations in the formation and function of neuronal circuits that encode emotional behavior.

Anxiety Disorders: Macromolecular Pathways and Interactions

Miklos Toth, Department of Pharmacology, Weill Medical College of Cornell University, New York, New York
doi: 10.1002/9780470048672.wecb665

Anxiety is a state characterized by feelings of fear, apprehension, and worry. Emotionally, anxiety causes a sense of dread or panic, and behaviorally, it can be associated with both voluntary and involuntary behaviors such as escaping or avoiding the source of anxiety. Also, anxiety is associated with specific physical manifestations including increased heart rate and blood pressure. Although anxiety is clinically different from depression, the two disorders are often comorbid. Indeed, it is generally difficult to find individuals with pure anxiety and pure depression. Here we focus on anxiety exclusively but will mention and discuss depression when the separation is not clear. Anxiety, similarly to other psychiatric disorders, has a significant genetic basis, and it is relatively stable in individuals over time (trait anxiety). Recent studies implicated candidate genes, each with a small contribution to the risk of anxiety disorders (1). Several of these candidate genes encode proteins that regulate neurotransmitter synthesis and metabolism or correspond to neurotransmitter receptors. Studies implicate an equally important role for environmental factors, including early-life adversity and maternal care, in the development of anxiety and anxiety-like behavior in animals (2–4). Some of these environmental effects also converge on neurotransmitter systems. Because the risk genes or environmental factors individually represent only a small contribution to anxiety, the current view is that interactions between several risk genes and environmental effects are necessary to lead to the symptoms of anxiety. This overview focuses on molecular systems related to anxiety such as neurotransmitters, their receptor, and, when known, downstream intracellular signaling pathways that ultimately regulate the development and function of neuronal networks that underlie the behavioral anxiety response.

Neuroticism and Anxiety

Neuroticism is a personality trait characterized by an enduring tendency to experience negative emotional states. Personality traits are underlying characteristics of an individual that can explain the major dimensions of human behavior. Neuroticism represents a continuum between emotional stability and instability, and most people fall in between the extremes (5–9). Neuroticism has a wide individual variability, but it is relatively stable in individuals over time (10). People with a high level of neuroticism respond more poorly to stress and are more likely to interpret ordinary situations as threatening and frustrating.
In addition, autonomic arousal is an integral part of neuroticism characterized by increased heart rate and blood pressure, cold hands, sweating, and muscular tension. Extroversion and openness, two other personality traits, are also part of the NEO Personality Inventory (NEO-PI) and the revised (R) NEO-PI (11), and Gray and McNaughton (12) argued that anxiety proneness is primarily captured by measures of neuroticism, together with a smaller contribution from the dimension of extroversion. Specifically, rotating the dimensions of neuroticism and extroversion by 45°, two new dimensions, anxiety (N+, E–), and impulsivity (N−, E+), were proposed (12).

Although neuroticism is not a disease per se, it predisposes individuals to anxiety disorders (12, 13). Neuroticism is a vulnerability factor for all forms of anxiety (14–16). A system established by the Diagnostic and Statistical Manual for Psychiatric Disorders in the United States, currently in its 4th edition (DSM-IV) text revision (TR) (American Psychiatric Association, 2000), sets the boundary at which a particular level of behavior becomes an anxiety disorder—a level often based on the number and the duration of symptoms. DSM is a categorical system based on the qualitative separation of disease states from the state of well-being. The DSM-IV TR category of anxiety disorders currently includes generalized anxiety disorder (GAD), simple phobia, posttraumatic stress disorder (PTSD), panic disorder, social phobia, and obsessive compulsive disorder (OCD) as discrete anxiety disorders. The International Classification of Diseases-10 (IC-10) is a similar system, but it is less frequently used in research (17).

Although DSM-IV and IC-10 are widely used for the clinical diagnosis of anxiety disorders, these categorical models are not based on the underlying biological pathophysiology and may not be optimal for the identification of genetic and environmental factors involved in anxiety disorders. The main reason is the complexity and heterogeneity of anxiety disorders that makes the association of genetic and/or environmental effects with overt anxiety phenotypes difficult. An alternative approach is to deconstruct anxiety disorders to elementary behavioral manifestations or specific symptoms that may represent less complex biological traits and/or environmental influences. The rationale is that a specific phenotype that consists of few elementary behaviors is likely linked to a more limited number of genes and environmental effects than complex disease phenotypes. These elementary behaviors are primarily state-independent (manifest in an individual regardless of whether illness is active). Similar to this principle is the term “endophenotype,” although it usually refers to an internal phenotype along the pathway between the genotype and disease. Evidence suggests that elementary behaviors/endophenotypes of psychiatric disease may be understood as quantitative traits (Fig. 1). This model is based on the notion that risk gene variants carried by a given individual in combination with various nongenic factors such as early-life adversity and nutrition produce anxiety symptoms with variable onset and severity depending on the strengths of the genetic and environmental factors (Fig. 3).

### Genes, Their Protein Products, and Associated Biological Pathways Implicated in Anxiety and Anxiety-Like Behavior

Using the techniques of quantitative behavior genetics, it became clear that roughly 20–60% of the variation in most personality traits has a genetic base, and broad personality traits are under polygenic influence (18, 19). Similarly, genetic epidemiological studies estimate that heritability in anxiety varies between 23 and 50% (1, 20, 21). Recently, genome-wide linkage studies have been performed by using Eysenck personality questionnaire (EPQ) (22, 23) to identify chromosomal regions associated with neuroticism. A two-point and multipoint non-parametric regression identified 1q, 4q, 7p, 11q, 12q, and 13q (24), whereas another similar study using multipoint non-parametric allele sharing and regression identified 1q, 3cen-t, 6q, 11q, and 12p (25), which confirms some links in the previous study. Still another study using a broad anxiety definition instead of the DSM-IV classification identified a linkage at chromosome 14 between 99 and 115 cM (26), and this finding replicated a linkage for a broad anxiety phenotype in a clinically based study (27). However, these studies have not yet identified specific genes. So far, the candidate gene approach has been more productive than linkage and association studies in implicating gene polymorphisms related to neuroticism and anxiety disorders. The candidate gene approach relies on prior biochemical studies that implicate various molecules, primarily neurotransmitters, their receptors, and signaling in anxiety. Anxiety disorders traditionally have been viewed as disturbances in neurotransmitter systems including the serotonin (5-HT), gamma-aminobutyric acid (GABA), and corticotropin releasing hormone (CRH) systems, among others. Many of these neurotransmitters and their receptors have also been identified as sites of action for anxiolytic drugs. Neurotransmitter systems and corresponding neurobiological pathways that are well established in anxiety both in human studies and animal experiments are discussed below.

A nimal studies, especially rodent studies, significantly contributed to the current knowledge on how genes, the environment, and their interaction may produce anxiety. As people with a high level of neuroticism respond more poorly to stress, certain inbred, selectively bred (28, 29), and knockout rodents strains (see below) have increased emotional reactions to stress.
(emotional activity). These behavioral responses include avoidance, hypoactivity/frezing, and autonomic arousal among others. Although some similarities are found between human and murine stress responses, complex anxiety phenotypes cannot be reproduced in animals. Nevertheless, emotional stress reactions in animals represent relatively simple behaviors that are evolutionarily conserved and quantifiable. A multitude of tests can measure emotional activity in rodents (30–34). Although all behavioral tests use a novel environment and/or fearful situation to produce avoidance, hypoactivity/frezing, and/or autonomic arousal, it seems that the underlying pathophysiology is test specific. Indeed, data with recombinant inbred mouse strains indicate that open field and elevated plus maze behaviors are linked to specific but partly overlapping sets of quantitative trait loci (35, 36). Furthermore, even these relatively simple behaviors can be dissected to more elementary behaviors with a smaller assembly of quantitative trait loci (36). However, it is not clear currently if mouse QTL data can be directly extrapolated to humans.

Many recently developed genetically manipulated mouse strains exhibit increased emotionality, often referred to as anxiety-like behavior. Most strains have constitutive genetic inactivation, but some strains are also available with a conditional allele. Although constitutive gene inactivation may elicit compensatory processes that can complicate the phenotype, this occurrence is not necessarily a disadvantage. Indeed, genetic risk in humans is also constitutive and present from early life. Probably more important is that polymorphisms in risk genes do not cause a complete functional loss; therefore, it may be more appropriate to analyze the behavioral phenotype of mice with a heterozygous inactivation of the risk gene.

### The 5-HT pathway and associated genes involved in anxiety

5-HT has long been associated with emotion and anxiety (37). 5-HT is synthesized from tryptophan by the rate-limiting enzyme tryptophan hydroxylase (TPH) in serotonergic neurons in the dorsal raphe nucleus and stored in axon terminals, respectively. In addition, the synaptic and extracellular levels of 5-HT are regulated by the 5-HTT transporter (S-HTT). Genetic risk for anxiety has been associated with all of these macromolecules.

#### Tryptophan hydroxylase

The two isozymes of TPH are as follows: 1) the classical TPH isoform, now termed TPH1, that is detected in the periphery, especially in the duodenum and in blood but not in the brain, and 2) the relatively recently identified TPH2 expressed exclusively in the brain (38). Several common single nucleotide polymorphisms are found around the transcriptional control region of TPH2. T allele carriers of a functional polymorphism in the upstream regulatory region of TPH2 (G-703T) were found to be overrepresented in individuals with anxiety-related personality traits (39, 40). In agreement with these data, T carriers have been shown to exhibit relatively greater activity in the amygdala than do G-allele homozygotes to affective expressions (41). Aactivation of the amygdala, indicated by increased blood flow, is a typical reaction to stress and to unpleasant and potentially harmful stimuli.

#### The serotonin transporter

The transporter removes 5-HT after its release into the synaptic cleft and returns it to the presynaptic terminal, where it is metabolized by monoaminooxidases or stored in secretory vesicles and results in the termination of postsynaptic serotoninergic effects (42). 5-HTT is the target of the selective serotonin reuptake inhibitors (SSRIs) that have been shown to be effective in certain anxiety disorders and depression (43).

The 5HTT transporter belongs to the family of Na^+K^+- dependent transporters, which shows a certain degree of similarity with the GABA and the dopamine transporters (42, 44). The 5-HTT has 12 transmembrane domains (TM) with a large extracellular loop between TM 3 and 4. Both the N- and C-termini are located within the cytoplasm. Growing evidence suggests that 5-HTT forms a homomultimer in the plasma membrane, although most studies suggest an autonomous function for each monomer (45). Amino acid substitution experiments indicate the importance of TM 1 as an important contributor to substrate, ion, and inhibitor interactions (46). In addition to TM 1, TM 3 has also been shown to play a role in substrate and inhibitor binding (47). Recently, it has been demonstrated that Tyr-95 and Ile-172 in transmembrane segments 1 and 3 of human 5-HTT interact to establish the high-affinity site for antidepressants (48). Although SSRIs have a rapid action on the transporter, their anxiolytic and antidepressant actions are delayed. It is believed that one factor involved in this delay is the activation of 5-HT₄ autoreceptors on serotonergic neurons that effectively reduces neuronal firing and 5-HT release rebalancing extracellular 5-HT levels (43). As the SSRI treatment is prolonged, the 5-HT₄ autoreceptors desensitizes, and firing activity is restored. The notion that an adaptive change underlies, at least partly, the delayed therapeutic effect of SSRIs is supported by the acceleration of the anxiolytic and antidepressant response by the concomitant administration of the 5-HT₄ antagonist pindolol (49). Once 5-HTL levels are significantly increased during chronic SSRI administration, it is assumed that the elevated 5-HT L levels act on specific 5-HT receptors to elicit anxiolytic and antidepressant effects. Although at least 13 different types of 5-HT receptors exist in mammals, a recent report using a specific behavioral test (novelty induced suppression of feeding) showed that the presence of post synaptic 5-HT₄ receptors is necessary for the anxiolytic effect of the SSRI fluoxetine (50).

Lesch et al. demonstrated that a functional 5-HT₄ promoter polymorphism is associated with the factor “neuroticism” in the revised NEO personality inventory (51). Specifically, individuals who carry the s/s (short promoter repeat) alleles of the 5-HTT, as compared with individuals with s/l (long) or l/l alleles, have increased neuroticism. Extension of these genetic studies to anxiety disorders by the same authors showed no differences in 5-HTT genotype distribution between anxiety patients and comparison subjects, but among anxiety patients, carriers of the s alleles exhibited higher neuroticism scores (52).
Anxiety Disorders: Macromolecular Pathways and Interactions

Figure 2  Anxiety pathways and their interactions. Two fundamentally different mechanisms involved in anxiety and anxiety-like behavior are proposed. The first mechanism is developmental, and its consequences are manifested later in life. Both genetic and environmental factors linked to anxiety can have a developmental origin, as illustrated by the example of the s allele of the 5-HTT, the deficiency in the 5HTT receptor, and variability in maternal care. The second possible mechanism is not developmental but based on “acute” or current molecular abnormalities that result in anxiety or anxiety-like behavior. Examples include deficiencies in GABAergic neurotransmission and abnormalities in the central CRH system, which have the direct behavioral output of anxiety. It is also proposed that the developmental mechanisms lead to anxiety by converging on the “acute” mechanisms.

Several later reports found association between the 5-HTT promoter polymorphism and anxiety-related traits (53–55). Also, recent meta-analyses of several prior studies found a small but significant association between 5-HTT polymorphism and some but not all measures of neuroticism/anxiety (56–58). Interestingly, imaging data found a significant increase in amygdala activity in subjects who carry the s allele, which indicates a functional link between 5-HTT polymorphism and anxiety (59). Consistent with these data, genetic inactivation of the 5-HTT gene in mice results in an increased anxiety-like phenotype (60).

The s allele is associated with reduced 5-HTT mRNA expression in vitro and in lymphoblasts (51), but functional imaging studies and postmortem samples generally show no effect of the 5-HTT genotype on 5-HTT expression in adult subjects (61, 62). To resolve this discrepancy, it has been hypothesized that the s allele acts primarily during development and less so in adult brain and would primarily affect brain development leading to anxiety in later life (Fig. 2). Consistent with this idea, pharmacological blockade of the 5-HTT in rats and mice during early postnatal life (that mostly corresponds to the third trimester in human) results in changes in emotional behavior (63, 64). However, it is not known how increased 5-HT levels during development lead to lifelong anxiety nor what 5-HT receptors are involved.

The 5-HT1A receptor

The G-protein-coupled 5-HT1A receptor emerged as another candidate gene in anxiety as early studies indicated a deficit in the receptor in panic disorder patients (65, 66). These data seem to be consistent with the anxiolytic effect of partial 5-HT1A receptor agonists in the treatment of generalized anxiety disorder, but the pharmacological inhibition of the receptor in animals does not elicit anxiety (67). Then in 1998, it was shown that the genetic inactivation of the 5-HT1A receptor in mice results in enhanced anxiety-like behaviors (68–70) along-side reduced immobility in the forced swim test (70) and tail suspension test (68, 69). Anxiety-related tests in these and follow-up studies included open field, elevated plus maze, zero maze, novelty-induced suppression of feeding, and some fear conditioning paradigms (68–71). More recently, human studies strengthen the association between a 5-HT1A receptor deficiency and certain forms of anxiety. A preliminary neuroimaging study reported a significant negative correlation between 5-HT1A receptor binding in the dorsolateral prefrontal, anterior cingulate, parietal, and occipital cortices and indirect measures of anxiety in healthy volunteers (72). Then, reduced receptor levels were reported in the anterior cingulate, posterior cingulate, and raphe by positron tomography in patients with panic disorder (73). No such association was found in posttraumatic stress disorder (74).

5-HT1A receptors are expressed at both postsynaptic locations in 5-HT target areas (including the amygdala, hippocampus, and cortex) and presynaptic sites on 5-HT neurons in the raphe nucleus as somatodendritic autoreceptors. Because autoreceptors control neuronal firing and consequently 5-HT release, and because an increase in extracellular 5-HT levels during development (see previous section) has been implicated in anxiety, it initially was believed that the anxiety-like phenotype of 5-HT1A receptor-deficient mice was because of increased 5-HT release. However, basal 5-HT levels are not altered, as measured by in vivo microdialysis, in 5-HT1A receptor-deficient mice, presumably because of the compensatory action of presynaptic 5-HT1B.
receptors (75–77), and expression of 5-HT$_{1A}$ receptors in forebrain regions rescued the anxiety phenotype of 5-HT$_{1A}$ receptor knockout mice (78), which suggests that the behavioral phenotype results from the absence of postsynaptic rather than the presynaptic 5-HT$_{1A}$ receptors. The anxiety-like phenotype of 5-HT$_{1A}$ receptor-deficient mice has been shown to be associated with background-specific perturbations in the prefrontal cortex GABA-glutamate system and in GABA$_A_\alpha$ receptor subunit expression in this region as well as in the amygdala (79, 80) (Fig. 2). Our recent studies implicate hippocampal abnormalities in some manifestations of the anxiety-like phenotype in 5-HT$_{1A}$ receptor-deficient mice (unpublished data). Presumably the lack of 5-HT$_{1A}$ receptors during development at these postsynaptic areas leads to neuronal network abnormalities that underlie the exaggerated behavioral responses in anxiogenic environments.

Considering the many studies with 5-HT$_7$ polymorphism (see above), it is surprising that relatively little is known about 5-HT$_{1A}$ receptor alleles in the context of anxiety. Although the common genetic polymorphism (–1019G/C) in the promoter region of the 5-HT$_{1A}$ receptor gene has been associated with panic disorder (81), more is known about the link of this polymorphism to depression/suicide (82) (but see Reference 83) and to antidepressant treatment response (84, 85). Nevertheless, the –1019C/G polymorphism has been found to have functional effects on gene expression. Specifically, the 5-HT$_{1A}$ G(–1019) allele fails to bind Deaf-1 and Hoxd5, two transcriptional repressors, in raphe-derived cells leading to upregulation of autoreceptor expression. Consistent with these data, an increase in 5-HT$_{1A}$ autorreceptor expression in individuals with the G/C genotype has been observed (86, 87). However, as mentioned earlier, autoreceptors may not be implicated in anxiety-like phenotypes least not in the mouse model. Deaf-1 has an opposite effect in neurons that model the postsynaptic site as it enhances 5-HT$_{1A}$ receptor promoter activity, and this enhancement is attenuated by the presence of the G allele (88). This cell-specific activity of Deaf-1 in 5-HT$_{1A}$ gene regulation could account for the region-specific decrease of receptor levels in postsynaptic 5-HT$_{1A}$ receptor described in anxiety and mood disorders (see above).

The GABA pathway

Abnormalities in GABA levels have been noted in subjects with anxiety disorders. Magnetic resonance spectroscopy studies have shown lower occipital cortex GABA concentrations in subjects with panic disorder (89) and with major depression (90), compared with healthy controls. GABA is synthesized from glutamate by glutamic acid decarboxylase (GAD). Its two isoforms, GAD65 and GAD67, are products of two independently regulated genes, GAD2 and GAD3, respectively. GAD65 is responsible for the synthesis of a small pool of GABA associated with nerve terminals and synaptic vesicles and can be rapidly activated in times of high GABA demand (91, 92). In contrast, GAD67 is responsible for the majority of GABA synthesis, and it is important in developmental processes (92). GABA interacts with the ionotropic GABA$_A_\alpha$ and metabotropic GABA$_B_\alpha$ receptors. GABA$_A_\alpha$ receptors in particular have been associated with anxiety as they control neuronal excitability. The GABA$_A_\alpha$ receptor is a pentameric ion channel composed of subunits from seven families (α1-3, β1-3, γ1-3, ε, δ, and θ)(93). Receptors that express α1 and α2, together with a β subunit and the γ2 subunit, are the predominant forms in the central nervous system.

GAD and anxiety

GABA neurotransmission has been linked to anxiety disorders, and therefore genes that encode GAD are reasonable candidate susceptibility genes for these conditions. In a multivariate structural equation model, several of the six single-nucleotide polymorphisms tested in the GAD3 region (encoding GAD67) formed a common high-risk haplotype that contributed to individual differences in neuroticism and impacted susceptibility across a range of anxiety disorders, including generalized anxiety disorder, panic disorder, agoraphobia, and social phobia, and also major depression (94). No such association was found with single-nucleotide polymorphisms in GAD2 (encoding GAD65) in this study. Nevertheless, genetic inactivation of GAD65 results in anxiety-like behavior in mice (95). These mice also show increased seizure sensitivity, but otherwise they show no overt developmental phenotype (91). It is not possible to study anxiety in GAD67$^{-/-}$ mice because they die of severe cleft palate during the first morning after birth (92). The less severe and more specific phenotype of GAD65$^{-/-}$ mice is probably because the overall GABA content is normal in GAD65$^{-/-}$ tissues and only the K$^+$ stimulated GABA release is reduced, whereas in GAD67$^{-/-}$ mice a severe depletion of GABA occurs.

GABA$_A_\alpha$ receptors and anxiety

A deficit in GABA$_A_\alpha$ receptors has been identified in the hippocampus and parahippocampus of patients with panic disorder and generalized anxiety disorders (96–98). Also, GABA$_A_\alpha$ receptor antagonists elicit anxiety in patients with panic disorder, which suggests an underlying deficit in receptor function in these individuals (99).

Animal studies suggest that a reduction in GABA$_A_\alpha$ receptors that contain α2 subunits is associated with withdrawal-induced anxiety (100, 101). Genetic inactivation of some other subunit genes has a similar effect. For example, heterozygous γ$^2$ mice have reduced numbers of GABA$_A_\alpha$ receptors and display anxiety phenotype in the elevated plus maze and the dark-light box tests (100, 102). In addition, γ$^2$ mice show increased responses in the passive avoidance paradigm. These behavioral alterations are associated with a lower single channel conductance, a pronounced deficit of functional receptors, and a reduction in α2/β3/δ2S subunit and the ε2S subunit of the GABA$_A_\alpha$ receptor clusters in cortex, hippocampus, and thalamus. Transgenic mice overexpressing either the mouse y$_{90}$ or γ$_{95}$ subunit of the GABA$_A_\alpha$ receptor showed no difference in anxiety-related behavior as compared with wild-type littermates (103). Compensation at the level of GABA$_A_\alpha$ receptor subunit expression and assembly often occurs when subunit expression is disturbed, which may explain the lack of phenotype in these mice. In contrast to the γ2 subunit, the deletion of the also abundant α3 subunit (104) does not increase anxiety or elicit other behavioral abnormalities (105–107), probably because lack of the α3 subunit is compensated and substituted by other α subunits (105). Although α2 subunit-deficient mice have been generated and

WILEY ENCYCLOPEDIA OF CHEMICAL BIOLOGY © 2008, John Wiley & Sons, Inc.
a point mutation in this subunit (H105-R) abolishes the anxiolytic effect of diazepam (108, 109), it is not entirely clear whether these mice have a change in anxiety-related behavior. Mice deficient for the α1 subunit show a faster habituation to a novel environment, which is not a typical measure of anxiety (110). A mentioned earlier, a strain of 5-HT1A receptor−/− mice have reduced expression of both the α2 and α1 subunits that could explain, at least partly, their increased anxiety phenotype (79). Fig. 2. “Knock-in” mice in the α9 subunit (H105-R) display enhanced trace fear conditioning to threat cues (102). More analysis showed that these knockin mice exhibit a 33% reduction in hippocampal (CA1 and CA3) α9 receptor subunits (102); thus, the phenotype may be simply because of a partial knock out. Finally, the genetic inactivation of β2, a predominant α subunit, resulted in a more than 50% reduction in the total number of GABA_A receptors and increased locomotor activity in open field, which suggests that these receptors may control motor activity (106). Taken together, these studies in general support the notion that a deficiency in GABA_A receptors results in anxiety and anxiety-like behavior, but it is difficult to assign specific subunit-containing receptors to anxiety.

## The BDNF pathway in anxiety

BDNF is a secretory protein that belongs to the neurotrophin family. A large proportion of neuronal BDNF is secreted in the proform (proBDNF), which is subsequently converted to mature (m) BDNF by extracellular proteases such as plasmin or matrix metalloproteinases (111). A functional single nucleotide polymorphism that produces a valine (Val)–to–methionine (Met) substitution at α6. 66 in pro-BDNF, first described as altering the intracellular trafficking and activity-dependent secretion of BDNF (112), has been studied extensively in association studies. The outcome of these studies has been variable. One study found that the Met 66 may be a risk allele for anxious temperament as measured by the Tridimensional Personality Questionnaire (113). Another study however concluded that the Val 66 allele is associated with greater neuroticism (114), whereas still another has shown no difference in neuroticism between the Val and Met genotypes (115). A more definitive outcome of the Val–Met polymorphism was reported with mice. Because the mouse does not have the Met allele, it was generated by knockin (116). BDNF/+/− mice exhibited increased anxiety-related behaviors in a variety of behavioral paradigms including the elevated plus maze, open field, and novelty-induced hypophagia tests (116). Although BDNF expression in BDNF+/− mice is equivalent to that in BDNF+/+ mice, a ∼30% deficit in activity-dependent release of BDNF from neurons occurs. This deficit suggests that the anxiety phenotype of BDNF+/− mice can be linked to the activity-dependent release of BDNF. Similarly to the BDNF+/− mice, BDNF+/+ mice have an anxiety phenotype that has BDNF levels lower than normal (by 50%); thus, it seems that a partial deficit in BDNF is sufficient to elicit anxiety. The receptor for mBDNF is TrkA, a receptor tyrosine kinase (117). Consistent with the increased anxiety phenotype of BDNF+/−, conditional BDNF−/−, and BDNF+/− mice (116, 118), transgenic mice overexpressing TrkA in postmitotic neurons in a pattern similar to that of the endogenous receptor display less anxiety in the elevated plus maze test (119).

Similarly to the serotonin-related genes and their polymorphisms, the Met allele of BDNF causes developmental brain abnormalities. Humans heterozygous for the Met allele have smaller hippocampal volumes (120) and perform poorly on hippocampal-dependent memory tasks (112, 121). Consistent with these data, BDNF+/− or BDNF+/− mice have a significant decrease in hippocampal volume as compared with WT mice (116). Also, a significant decrease in dendritic complexity in dentate gyrus neurons occurs in BDNF+/− and BDNF+/− mice. These data raise the possibility that the Met allele contributes to anxiety by modulating brain development (Fig. 2).

## The central CRH–CRH-R pathway and anxiety

CRH is a 41-amino acid neuropeptide in mammals (122), and it is an important mediator of the central stress response (122, 123). The biological function of CRH is determined by the amino end of the peptide C-terminus that binds to the extracellular binding pocket of the receptors CRH-R1 and R2, whereas its N-terminus contacts other sites on the receptor to initiate signaling (124, 125). CRH-R1 in the anterior pituitary is thought to be the subtype through which hypothalamic CRH primarily initiates its effect on pituitary ACTH release (123, 126). ACTH then induces the secretion of corticosteroids in the adrenal. CRH via CRH-Rs, however, has functions outside the hypothalamic–pituitary–adrenal (HPA) axis, in particular in the amygdala. Indeed, data support the notion that extra-hypothalamic CRH, presumably via the central nervous systems, is significantly involved in anxiety (127), whereas dysregulation of the HPA axis via hypothalamic CRH seems to be more characteristic for depression (128).

CRH An association between behavioral inhibition and three single nucleotide polymorphisms in the CRH gene, including a point mutation in the coding sequence of the gene, was found in children at risk for panic disorder (129). Behavioral inhibition is a trait that involves the tendency to display fearful, avoidant, or shy behavior in novel situations. In animal experiments, the central administration of CRH produces behavioral effects that correlate with anxiety, such as reduced exploration in a novel environment or enhanced fear response (130). Also, an anxiety-like phenotype has been described in transgenic mice overexpressing CRH (131, 132). However, mice with a deleted CRH gene, although they had significantly decreased basal corticosterone levels, showed no anxiety (133, 134). One possible explanation is that the central CRH system is redundant. Indeed, CRH-like peptides, in 1-3 (that also bind CRH-Rs), are present in the CNS (135-138). Two groups have generated mice with a deletion of the urocortin 1 gene (139, 140), but only one of these studies found an increased anxiety-like phenotype (139). Currently, no obvious explanation is found for the significant difference observed between the two urocortin 1-deficient mice. Finally, deletion of the CRH binding
protein, that normally binds and inactivates CRH, resulted in increased anxiety (141). The authors hypothesized that the inactivation of CRH-BP may increase the "free" or unbound levels of CRH or urocortin that lead to anxiety. As described earlier, hypothalamic CRH regulates the HPA axis. Some reports have indicated the dysregulation of the HPA axis in PTSD and panic disorders. Small but significant decreases in plasma cortisol levels and increased HPA axis sensitivity to low glucocorticoid negative feedback signals have been reported in PTSD (142). In contrast, other studies showed persistent increases in salivary cortisol levels in pediatric PTSD patients (143) and significantly greater CRH-induced ACTH and cortisol responses in women with chronic PTSD (144). In panic patients, abnormal HPA axis regulation, including increased basal cortisol secretion and overnight hypercortisolemia, have also been documented (129). These HPA axis changes, however, may not be specific for anxiety disorders but rather reflect the presence of comorbid depression (145).

CRH-Rs
No significant association was found between an intron 2 polymorphism in CRH-R1 and the "neuroticism" dimension of personality as assessed by the Revised NEO Personality Inventory in healthy Japanese subjects (146). Similarly, three CRH-R2 gene polymorphisms had no association with panic disorder in another study (147).

The role of CRH-Rs in anxiety-like behavior has been studied extensively by using knockout mice. Whereas mice lacking CRH-R1 display decreased anxiety in the light-dark box and the elevated plus maze (148-150), CRH-R2-deficient mice, generated independently by three groups, exhibit varying degrees of anxiety-related behavior. In one study, increased anxiety was reported in the elevated plus maze and open field but not in the light-dark box test (151); another study found anxious behavior in both the elevated plus maze and light-dark box, but only in males (152). However, this latter study showed an increased time spent by the knockout mice in the center of an open field, which is more consistent with reduced anxiety. Still another report found no significant change in anxiety behavior in the elevated plus maze or open field (153). More recently, a mouse with a conditional deletion of the CRH-R1 in forebrain, hippocampus, and the amygdala, but with normal expression in the anterior pituitary, showed markedly reduced anxiety-like behavioral responses in two avoidance tests, and it exhibited normal ACTH and corticosterone secretion to stress (154).

Taken together, some of behavioral data obtained with various CRH and CRH-R knockout mice suggest that extrahypothalamic CRH and/or urocortin mediate a dual modulation of anxiety behavior. A deletion of CRH-R1 seems to be anxiogenic, whereas activation of CRH-R2 is anxiolytic. Therefore, it may not be surprising that dual CRH-R1/2 knockout mice have only a subtle behavioral phenotype (155).

CRH signaling and anxiety
CRH-R1/2 are coupled to several signaling pathways, including the adenyl cyclase-protein kinase A (PKA)-CREB and the ERK/mitogen-activated protein kinase (MAPK) pathways (156). These pathways can also be linked to anxiety. For example, genetic inactivation of adenyl cyclase type B results in reduced anxiety-like behavior (157). Mice with mutations of the PKA RIIa subunit and CREB also exhibit abnormal anxiety responses (158-160), and activation of CREB in amygdala produces anxiety-like behavior (160). Thus, anxiety-like responses may be initiated and regulated by Gs-coupled CRH receptor signaling, at least partly, via the cyclic AMP–PKA–CREB pathway. The involvement of the ERK–MAPK pathway can also be implicated in CRH-related anxiety-like behavior. ERK1/2 is strongly activated in hippocampal CA1 and CA3 pyramidal cells and basolateral amygdala by the intracerebroventricular administration of CRH (161), and CRH-induced phosphorylation of ERK1/2 was absent in mice with a conditional knockout of forebrain and limbic CRH-R1 exhibiting a low level of anxiety (162). One may hypothesize that processing of anxiogenic stimuli is altered in the amygdala, hippocampus, or other relevant brain region as a result of abnormal CRH signaling that consecutively leads to the behavioral manifestations of anxiety (Fig. 2).

Environmental Factors and Related Biological Pathways Involved in Anxiety
Stressful life events and anxiety
Although most frequently associated with depression (163), stressful life events have also been linked to anxiety disorders (164-166). Kendler et al. attempted to determine if anxiety, specifically GAD symptoms and depression, are associated with different dimensions (humiliation, entrapment, loss, and danger) of stressful life events associated with high contextual threat. Onset of GAD symptoms was predicted by higher ratings of loss and danger, whereas depression was associated with the combination of humiliation and loss, which indicates that event dimensions that predispose to pure GAD episodes versus pure depression can be distinguished with moderate specificity (164). Unfortunately, little is known about the molecular and cellular mechanisms elicited by stressful life events and how these events predispose an individual to anxiety or depression. However, animal studies provided mechanistic insights of how early-life events can contribute to the development of adult anxiety (discussed below).

Maternal care and adult life anxiety in rodents
Brief "handling" of rat pups results in a lifelong decrease to behavioral and endocrine effects of stress, whereas animals separated from their mothers/litters for longer periods of time, for example, for several hours, exhibit increased anxiety (167). Later studies determined that the critical effect of short-term handling is the increase in maternal care (licking and grooming) after the return of the pups to the nest (3). More studies showed that rat pups nursed by mothers selected for either a high or a low level of licking and grooming
Interaction Between Genetic and Environmental Factors

Although the interaction of genes and environment in shaping behavior is well accepted, direct experimental evidence to support their role in the pathogenesis of psychiatric diseases has been difficult to obtain. However, recent association studies with the 5-HTT polymorphism have indicated, at least in depressive disorders, that genetic and environmental factors act together, enhancing the phenotype beyond the level established by either factor alone. In 2003, Caspi et al. reported that carriers of the short allele of the 5-HTT polymorphism have indicated, at least in depressive disorders, that genetic and environmental factors act together, enhancing the phenotype beyond the level established by either factor alone. In 2003, Caspi et al. reported that carriers of the short allele of the 5-HTT polymorphism have increased risk for depression, anxiety, and related disorders. The 5-HTT short allele is associated with increased transcriptional activity, increased expression of the serotonin transporter, and decreased availability of serotonin in the synaptic cleft. This, in turn, affects the sensitivity of the postsynaptic receptors and their ability to respond to serotonin, leading to an increased risk for depressive and anxiety disorders.

Convergence of Anxiety-Related Pathways and Mechanisms

Two fundamentally different mechanisms associated with anxiety and anxiety-like behavior seem to exist: one that has a developmental origin with the cause and the adult manifestations of the phenotype separated in time and another mechanism that presents itself in "acute" settings. Typical examples for developmental anxiety are those caused by the short allele of the 5-HTT, the deficiency in the 5HT1A receptor and BDNF, whereas monkeys reared normally were not. In rodents, several environments × gene interaction studies related to anxiety behavior have been conducted. For example, maternal care. Perhaps more plausible mechanisms are the numerous neurochemical changes related to differences in maternal care. For example, rat pups of high LG–ABN dams show altered GABAergic receptor subunit expression in the amygdala, locus coeruleus, medial prefrontal cortex, and hippocampus that could contribute to their reduced anxiety-like behavior as compared with pups from low LG–ABN dams (172, 173) (Fig. 2). In addition to the GABAergic system, other potential factors mediating the environmental effects include the glutamatergic system and neurotrophins such as BDNF. Liu et al. found that increased LG–ABN of offspring resulting in increased hippocampal mRNA expression of NR2A and NR2B NMDA receptor subunits at postnatal day 8, a change that was sustained into adulthood (174). Also, increased levels of BDNF, but not NGF or NT-3, mRNA were observed in the dorsal hippocampus of 8-day old high LG–ABN pups (174). Neuronal network changes that could directly explain the behavioral consequences of maternal care have also been found as adult offspring of high LG–ABN dams show increased hippocampal synaptogenesis as compared with low LG–ABN offspring, and it has been found that this change could be normalized when low LG–ABN pups are cross-fostered to high LG–ABN dams (174) (Fig. 2).
and the variability in maternal care. All of these produce their effect in adults only when present during prenatal and/or early postnatal life. Indeed, genetic inactivation of the 5HT1A receptor during adult life is not accompanied by anxiety. Because the individual genetic risk factors mentioned above have subtle effects, a combination of them may be necessary to lead to a significant level of anxiety. For example, 5-HT1A and 5-HT2C dual mutants show a more pronounced anxiety phenotype as compared with singly heterozygous mice (189).

In other anxiety forms and models, developmental mechanisms do not seem to play a role. A typical example is represented by a deficient GABAergic neurotransmission (as a result of less GABA availability or altered composition of the GABA receptors) that results in reduced neuronal inhibition and increased excitation. The direct behavioral output of these neuronal and neuronal network changes is anxiety (Fig. 2). Another example is the central CRH system as its pharmacological manipulation acutely alters anxiety levels. Because many developmentally relevant anxiety genes and environmental effects and their corresponding mechanisms (see above) modulate GABAergic and glutamatergic transmission as well as central CRH signaling, it is possible that the developmental mechanisms converge on and are interconnected sequentially to the "acute" mechanisms that ultimately lead to the anxiety behavior (Fig 2).

In summary, it seems that anxiety in many cases has a developmental origin whether it is elicited by genetic polymorphisms or environmental effects. Because individual genetic influences have small effects, it is believed that multiple genetic risk genes, together with adverse environment, are required to have a large enough impact to cause anxiety. Although some early signs of anxiety may be manifested during childhood, anxiety becomes more apparent in predisposed individuals as the brain and behavior mature during adolescence. Although relatively little is known about how early developmental mechanisms lead to anxiety in later life, data suggest that long-lasting alterations in neurotransmitter systems (GABA, glutamate, and CRH) and/or the morphology and function of neuronal networks (amygdala, hippocampus, etc.) are involved. Additional environmental influences during adolescence and adulthood can increase the incidence and severity of anxiety.

doi: 10.1002/9780470048672.wecb673

Airway obstruction in chronic obstructive pulmonary disease (COPD) is caused by narrowing of small airways as a result of inflammation and fibrosis and the disruption of their alveolar attachments as a result of emphysema. COPD is characterized by a complex inflammatory disease process that increases as the disease progresses, which leads to increasing airflow limitation. Many inflammatory cells and mediators have now been implicated in the pathogenesis of COPD. Increased numbers of macrophages, neutrophils, T-lymphocytes (particularly CD8+ cells) and B-lymphocytes have been observed, as well as the release of multiple inflammatory mediators (lipids, chemokines, cytokines, growth factors). Macrophages seem to play an important role in orchestrating the inflammatory process, which includes the recruitment of neutrophils and T-cells into small airways and lung parenchyma and the secretion of proteinases that lead to emphysema. A high level of oxidative and nitrative stress may amplify this inflammation through the reduction in histone deacetylase-2, which also results in corticosteroid resistance.

Chronic obstructive pulmonary disease (COPD) has now become a major global epidemic, and it is predicted to become the third leading cause of death and fifth leading cause of disability over the next decade (1). The increase in COPD is a particular problem in developing nations; in developed countries, it is the only common cause of death that is increasing. COPD now has a world-wide prevalence of over 10% in men and is increasing toward this figure in women (2). Because of the enormous burden of disease and escalating health-care costs, there is now renewed interest in the underlying cellular and molecular mechanisms of COPD (3) and a search for new therapies (4). The definition of COPD adopted by the Global Initiative on Obstructive Lung Disease encompasses the idea that COPD is a chronic inflammatory disease, and much recent research has focused on the nature of this inflammatory response (5). COPD is an obstructive disease of the lungs that slowly progresses over many decades leading to death from respiratory failure unless patients die of comorbidities such as heart disease and lung cancer before this stage. Although the most common cause of COPD is chronic cigarette smoking, some patients, particularly in developing countries, develop the disease from inhalation of wood smoke from biomass fuels or other inhaled irritants (2). However, only about 25% of smokers develop COPD, which suggests that genetic or host factors may predispose patients to its development, although these factors have not yet been identified. The disease is relentlessly progressive, and only smoking cessation reduces the rate of decline in lung function; as the disease becomes more severe, there is less effect of smoking cessation, and lung inflammation persists.

COPD as an Inflammatory Disease

The progressive airflow limitation in COPD is caused by two major pathological processes: remodeling and narrowing of small airways and destruction of the lung parenchyma with consequent destruction of the alveolar attachments of these airways as a result of emphysema (Fig. 1). This disease results in diminished lung recoil, higher resistance to flow and closure of small airways at higher lung volumes during expiration, which traps air in the lung. This trapped air leads to the characteristic hyperinflation of the lungs, which causes the sensation of dyspnea and limits exercise capacity. The major symptom of COPD is shortness of breath on exertion. Both the small airway remodeling and narrowing and the emphysema are
Chronic Obstructive Pulmonary Disease (COPD), Inflammatory Mechanisms of  

Figure 1 Small airways in COPD patients. The airway wall is thickened and infiltrated with inflammatory cells, predominately macrophages and CD8\(^+\) lymphocytes, with increased numbers of fibroblasts. In severe COPD, lymphoid follicles are observed, surrounded by T-lymphocytes and thought to indicate chronic exposure to antigens (bacterial, viral, or autoantigens). Similar changes are also reported in larger airways. The lumen is often filled with an inflammatory exudate and mucus. Peribronchial fibrosis occurs, and it results in progressive and irreversible narrowing of the airway. Airway smooth muscle may be increased slightly.

Figure 2 Amplification of lung inflammation in COPD. Normal smokers have a mild inflammatory response, which represents the normal (probably protective) reaction of the respiratory mucosa to chronic inhaled irritants. In COPD, this same inflammatory response is markedly amplified, and this amplification increases as the disease progresses. It is increased even more during exacerbations triggered by infective organisms (Fig. 2). The molecular basis of this amplification of inflammation is not yet understood but may be, at least in part, determined by genetic factors. Cigarette smoke and other irritants in the respiratory tract may activate surface macrophages and airway epithelial cells to release chemotactic factors that then attract circulating leukocytes into the lungs. Among chemotactic factors, chemokines predominate and therefore play a key role in orchestrating the chronic inflammation in COPD lungs and its amplification during acute exacerbations (8). These events might be the initial inflammatory events that occur in all smokers. However in smokers who develop COPD, this inflammation progresses into a more complicated inflammatory pattern of adaptive immunity and involves T- and B-lymphocytes and possibly dendritic cells along with a complicated interacting array of cytokines and other mediators (9).

Differences from asthma  

Histopathological studies of COPD show a predominant involvement of peripheral airways (bronchioles) and lung parenchyma, whereas asthma involves inflammation in all airways (particularly proximal airways) but usually without involvement of the lung parenchyma (10). In COPD, the bronchioles become narrow, with fibrosis and infiltration with macrophages and T-lymphocytes, along with destruction of lung parenchyma and an increased number of macrophages and T-lymphocytes, with a greater increase in CD8\(^+\) (cytotoxic) than CD4\(^+\) (helper) cells (6). Bronchial biopsies show similar changes with an infiltration of macrophages and CD8\(^+\) cells and an increased number of neutrophils in patients with severe COPD. Bronchoalveolar lavage (BAL) fluid and induced sputum demonstrate a marked increase in macrophages and neutrophils. In contrast to asthma, eosinophils are not prominent except during exacerbations or when patients have concomitant asthma (10).
Inflammatory Cells

For many years it was believed that the inflammatory reaction in the lungs of smokers consisted of neutrophils and macrophages and that proteases from these cells were responsible for the lung destruction in COPD. More recently it has been recognized that there is a prominent T-cell infiltration in the lungs of patients with COPD, with a predominance of CD8+ (cytotoxic) T-cells, although CD4+ (helper) T-cells are also numerous. Although abnormal numbers of inflammatory cells have been documented in COPD, the relationship between these cell types and the sequence of their appearance and their persistence are not yet understood in detail (3). Most studies have been cross-sectional based on selection of patients with different stages of the disease, and comparisons have been made between smokers without airflow limitation (normal smokers) and those with COPD who have smoked a similar amount. Nonserial studies have been conducted, and selection biases (such as selecting tissue from patients suitable for lung volume reduction surgery) may give misleading results. Nonetheless, a progressive increase in the numbers of inflammatory cells in small airways and lung parenchyma are observed as COPD becomes more severe, even though the patients with most severe obstruction have stopped smoking for many years (6). This finding indicates the existence of some mechanisms that perpetuate the inflammatory reaction in COPD. This characteristic is in contrast to many other chronic inflammatory diseases, such as rheumatoid arthritis and interstitial lung diseases, in which the inflammation tends to diminish in severe disease. The inflammation of COPD lungs involves both innate immunity (neutrophils, macrophages, eosinophils, mast cells, NK cells, γδ T-cells, and dendritic cells) and adaptive immunity (T and B cells).

Epithelial cells

Epithelial cells are activated by cigarette smoke to produce inflammatory mediators, which include tumor necrosis factor (TNF)-α, interleukin (IL)-1β, IL-6, granulocyte-macrophage colony-stimulating factor (GM-CSF), and CXCL8 (IL-8). Epithelial cells in small airways may be an important source of transforming growth factor (TGF)-β, which then induces local fibrosis. Vascular endothelial growth factor (VEGF) seems to be necessary to maintain alveolar cell survival and blockade of VEGF receptors in rats induces apoptosis of alveolar cells and an emphysema-like pathology, which may be mediated via the sphingolipid ceramide (11). Airway epithelial cells are also important in defense of the airways, with mucus production from goblet cells, and secretion of antioxidants, antiproteases and defensins. It is possible that cigarette smoke and other noxious agents impair these innate and adaptive immune responses of the airway epithelium, which increases susceptibility to infection. The airway epithelium in chronic bronchitis and COPD often shows squamous metaplasia, which may result from increased proliferation of basal airway epithelial cells, but the nature of the growth factors involved in epithelial cell proliferation, cell cycle, and differentiation in COPD are not yet known. Epithelial growth factor receptors (EGFR) show increased expression in airway epithelial cells of smokers and may contribute to basal cell proliferation, which results in squamous metaplasia and an increased risk of bronchial carcinoma (12).
Neutrophils

Increased numbers of activated neutrophils are found in sputum and BAL fluid of patients with COPD (13); yet neutrophil levels are increased relatively little in the airways or lung parenchyma. This finding may reflect their rapid transit through the airways and parenchyma. The role of neutrophils in COPD is not yet clear; however, neutrophil numbers in induced sputum are correlated with COPD disease severity (13) and with the rate of decline in lung function. Smokers have a direct stimulatory effect on granulocyte production and release from the bone marrow and survival in the respiratory tract, which is possibly mediated by GM-CSF and G-CSF released from lung macrophages. Smoking may also increase neutrophil retention in the lung. Neutrophil recruitment to the airways and parenchyma involves adhesion to endothelial cells and E-selectin, which is upregulated on endothelial cells in the airways of COPD patients. A different neutrophil then migrate into the respiratory tract under the direction of neutrophil chemotactic factors. Several chemotactic signals have the potential for neutrophil recruitment in COPD, which include leukotriene (LT)BA, CXCL8, and related CXC chemokines, including CXCL1 (GRO-α) and CXCL5 (ENA-78), which are increased in COPD airways (14). These mediators may be derived from alveolar macrophages T-cells and epithelial cells, but the neutrophil itself may be a major source of CXCL8. Neutrophils from the circulation migrate in the pulmonary circulation and adhere to endothelial cells in the alveolar wall before passing into the alveolar space. The neutrophils recruited to the airways of COPD patients are activated because increased concentrations of granule proteins, such as myeloperoxidase and human neutrophil lipocalin, are found in the sputum supernatant (15). Neutrophils secrete serine proteases from neutrophils, which include neutrophil elastase, cathepsin G, and proteinase-3, as well as matrix metalloproteinase (MMP)-8 and MMP-9, which may contribute to alveolar destruction. Neutrophils have the capacity to induce tissue damage through the release of serine proteases and oxidants. However, whereas neutrophils have the capacity to cause elastolysis, this ability is not a prominent feature of other pulmonary diseases in which chronic airway neutrophilia is even more prominent, including cystic fibrosis and bronchiectasis. This comparison suggests that other factors are involved in the generation of emphysema. Indeed, neutrophils are not a prominent feature of parenchymal inflammation in COPD. It is likely that airway neutrophilia is more linked to mucus hypersecretion in chronic bronchitis. Serine proteases from neutrophils, which include neutrophil elastase, cathepsin G, and proteinase-3, are all potent stimulants of mucus secretion from submucosal glands and goblet cells in the epithelium. A marked increase in neutrophil numbers is observed in the airways in acute exacerbations of COPD, which accounts for the increased purulence of sputum. This finding may reflect increased production of neutrophil chemotactic factors, which include LTBA and CXCL8 (16, 17).

Macrophages

Macrophages seem to play a pivotal role in the pathophysiology of COPD and can account for most of the known features of the disease (13) (Fig. 4). A marked increase (5–10-fold) in the numbers of macrophages in airways, lung parenchyma, BAL fluid, and sputum in patients with COPD. A careful morphometric analysis of macrophage numbers in the parenchyma of patients with emphysema showed a 25-fold increase in the numbers of macrophages in the tissue and alveolar space compared with normal smokers (19). Furthermore, macrophages are localized to sites of alveolar wall destruction in patients with emphysema, and a correlation is observed between macrophage numbers in the parenchyma and severity of emphysema (20). Macrophages may be activated by cigarette smoke extract to release inflammatory mediators, which includes TNF-α, CXCL8, and other CXC chemokines; CCL2 (MCP-1); LTB4; and reactive oxygen species. This release is a cellular mechanism that links smoking with inflammation in COPD. Alveolar macrophages also secrete elastolytic enzymes, which include MMP-2; MMP-9; MMP-12; cathepsins K, L, and S; and neutrophil elastase taken up from neutrophils (21). A leukovascular macrophages from patients with COPD and with exposure to cigarette smoke secrete more inflammatory proteins and have a greater elastolytic activity at baseline than those from normal smokers (21). Macrophages demonstrate this difference even when maintained in culture for 3 days, and therefore they seem to be intrinsically different from the macrophages of normal smokers and nonsmoking normal control subjects (21). The predominant elastolytic enzyme secreted by alveolar macrophages in COPD patients is MMP-9. Most inflammatory proteins that are upregulated in COPD macrophages are regulated by the transcription factor nuclear factor-κB (NF-κB), which is activated in alveolar macrophages of COPD patients, particularly during exacerbations (22).

The increased numbers of macrophages in smokers and COPD patients may be caused by increased recruitment of monocytes from the circulation in response to the monocyte-selective chemokines CCL2 and CXCL1, which are increased in sputum and BAL of patients with COPD (14). Monocytes from patients with COPD show a greater chemotactic response to GRO-α than cells from normal smokers and nonsmokers, but this finding is not explained by an increase in CXCR2 (23). Interestingly, whereas all monocytes express CCR2, which is the receptor for CCL2, only ~30% of monocytes express CXCR2. It is possible that these CXCR2-expressing monocytes transform into macrophages that are more inflammatory. Macrophages also release the chemokines CXCL9, CXCL10, and CXCL11, which are chemotactic for CD8+ Tc1 and CD4+ Th1 cells, via interaction with the chemokine receptor CXCR3 expressed on these cells (24).

The increased numbers of macrophages in COPD are mainly caused by increased recruitment of monocytes, as macrophages have a very low proliferation rate in the lungs. Macrophages have a long survival time so the macrophage level is difficult to measure directly. However, in macrophages from smokers, a markedly increased expression of the antiapoptotic protein Bcl-2 and increased expression of p21WAF1 is observed in the cytoplasm (25). This finding suggests that macrophages may have a prolonged survival in smokers and patients with COPD. Once activated, macrophages will increase production of reactive oxygen species, nitric oxide, and lysosomal enzymes...
CCL2, and CD8
steroid resistance.
peroxynitrite formation (29). COPD patients may be mediated through oxidative stress and secretion of cytokines like TNF-α. HDAC activity in macrophages is correlated with increased receptors to switch off inflammatory genes. The reduction in recruited to activated inflammatory genes by glucocorticoid are inhibited by corticosteroids, whereas corticosteroids are ineffective in macrophages from patients with COPD (27). The reasons for resistance to corticosteroids in COPD and to a lesser extent macrophages from smokers may be the marked reduction in activity of histone deacetylase-2 (HDAC2) (28), which is recruited to activated inflammatory genes by glucocorticoid receptors to switch off inflammatory genes. The reduction in HDAC activity in macrophages is correlated with increased secretion of cytokines like TNF-α and CXCL8 and reduced response to corticosteroids. The reduction of HDAC activity on COPD patients may be mediated through oxidative stress and peroxynitrite formation (29).

Eosinophils
Although eosinophils are the predominant leukocyte in asthma, their role in COPD is much less certain. Increased numbers of eosinophils have been described in the airways and BAL of patients with stable COPD, whereas others have not found increased numbers in airway biopsies, BAL, or induced sputum. The presence of eosinophils in patients with COPD predicts a response to corticosteroids and may indicate coexisting asthma (30). Increased numbers of eosinophils have been reported in chronic bronchitis and BAL fluid during acute exacerbations of chronic bronchitis (31). Surprisingly, the levels of eosinophil basic proteins in induced sputum are as elevated in COPD, as in asthma, despite the absence of eosinophils, which suggests that they may have degranulated and are no longer recognizable by microscopy (15). Perhaps this finding is caused by the high levels of neutrophil elastase that have been shown to cause degranulation of eosinophils.

Dendritic cells
Dendritic cells play a central role in the initiation of the innate and adaptive immune response, and it is believed that they provide a link between them (32). The airways and lungs contain a rich network of dendritic cells that are localized near the surface, so that they are located ideally to signal the entry of foreign substances that are inhaled. Dendritic cells can activate a variety of other inflammatory and immune cells, which include macrophages and neutrophils, as well as T- and B-lymphocytes, so dendritic cells may play an important role in the pulmonary response to cigarette smoke and other inhaled noxious agents. However, an increase in dendritic cells is not observed in the airways of COPD patients in contrast to asthma patients (33).

T-lymphocytes
An increase in the total numbers of T-lymphocytes is observed in lung parenchyma as well as in peripheral and central airways of patients with COPD; a greater increase is observed in CD8+ than CD4+ cells (6, 24). A correlation is observed between the numbers of T-cells and the amount of alveolar destruction and the severity of airflow obstruction. Furthermore, the only significant difference in the inflammatory cell infiltrate in asymptomatic smokers and smokers with COPD is an increase in T-cells, mainly CD8+, in patients with COPD. An increase in the absolute number of CD4+ T-cells, albeit in smaller numbers, is evidenced in the airways of smokers with COPD, and these cells express activated STAT-4, which is a transcription factor that is essential for activation and commitment of the Th1 lineage, and IFN-γ.

The ratio of CD4+/CD8+ cells are reversed in COPD. Most T-cells in the lung in COPD are of the Th1 and Th1 subtypes (24). A marked increase is observed in T-cells in the walls of
small airways in patients with severe COPD, and the T-cells are formed in lymphoid follicles, which surround B-lymphocytes (6).

The mechanisms by which CD8+ and to a lesser extent CD4+ cells, accumulate in the airways and parenchyma of patients with COPD is not yet understood (34). However, homing of T-cells to the lung must depend on some initial activation (only activated T-cells can home to the organ source of antigenic products), then adhesion and selective chemotaxis. CD4+ and CD8+ T-cells in the lung of COPD patients show increased expression of CXCR3, which is a receptor activated by the chemokines CXCL9, CXCL10, and CXCL11, all of which are increased in COPD (35). Increased expression of CXCL10 by bronchiolar epithelial cells is observed, and it could contribute to the accumulation of CD4+ and CD8+ T-cells, which preferentially express CXCR3 (36) (Fig. 5). CD8+ cells are typically increased in airway infections, and it is possible that the chronic colonization of the lower respiratory tract of COPD patients by bacterial and viral pathogens is responsible for this inflammatory response. It is possible that cigarette-induced lung injury may uncover previously sequestered autoantigens, or cigarette smoke itself may damage lung interstitial and structural cells and make them antigenic (37). The role of increased numbers of CD4+ cells in COPD, particularly in severe disease, is also unknown (38); however, it is now clear that T-cell help is required for the priming of cytotoxic T-cell responses, for maintaining CD8+ T-cell memory, and for ensuring CD8+ T-cell survival. It is also possible that CD4+ T-cells have immunological memory and play a role in perpetuating the inflammatory process in the absence of cigarette smoking. In a mouse model of cigarette-induced emphysema, there is a predominance of T-cells that are directly related to the severity of emphysema (38).

The role of T-cells in the pathophysiology of COPD is not yet certain, although they have the potential to produce extensive damage in the lung. CD8+ cells have the capacity to cause cytolysis and apoptosis of alveolar epithelial cells through release of perforins, granzyme B, and TNF-α (39, 40). An association between CD8+ cells and apoptosis of alveolar cells is observed in emphysema (41). A possible explanation is that cigarette-induced lung injury is responsible for this inflammatory and structural abnormality. In addition, CD8+ T-cells also produce several cytokines of the Th1 phenotype, which include IFN-γ, lymphotoxin, and TNF-α, and evidence suggests that CD8+ T-cells in the lungs of COPD patients express IFN-γ (42). All these cytokines would enhance the inflammatory reaction in the lung besides the direct killing by CD8+ T-cells. COPD has been considered an autoimmune disease triggered by smoking, as previously suggested (37), and the presence of highly activated glioblastoma T-cells in emphysema patients supports this conclusion (43). Evidence suggests that anti-elastin antibodies exist in experimental models of COPD and in COPD patients (44). In addition to activated Th1 cells, some evidence indicates an increase in Th2 cells that express IL-4 in BAL fluid of COPD patients in COPD patients (45).

Mediators of Inflammation

Many inflammatory mediators have now been implicated in COPD, which include lipids, free radicals, cytokines, chemokines, and growth factors (7). These mediators are derived from inflammatory and structural cells in the lung and interact with each other in a complex manner.

Lipid mediators

The profile of lipid mediators in exhaled breath condensates of patients with COPD shows an increase in prostaglandins and leukotrienes (46). A significant increase in PGE2 and F2α, and an increase in LTB4 but not cysteinyl-leukotrienes is observed. This increase is a different pattern to that observed in asthma, in
which increases in thromboxane and cysteinyl-leukotrienes have been shown. The increased production of prostanoids in COPD is likely to be secondary to the induction of cyclo-oxygenase-2 (COX2) by inflammatory cytokines, and increased expression of COX2 is found in alveolar macrophages of COPD patients. LTB₄ concentrations are also increased in induced sputum, and concentrations of LTB₄ are increased even more in sputum and exhaled breath condensate during acute exacerbations (16). LTB₄ is a potent chemoattractant of neutrophils, which acts through high-affinity BLT₁-receptors. A BLT₁-receptor antagonist reduces the neutrophil chemotactic activity of sputum by approximately 25% (47). Recently BLT₁-receptors have been identified on T-lymphocytes, and evidence indicates that LTB₄ is involved in recruitment of T-cells.

Oxidative stress

Oxidative stress occurs when reactive oxygen species (ROS) are produced in excess of the antioxidant defense mechanisms and result in harmful effects, which include damage to lipids, proteins, and DNA. Increasing evidence suggests that oxidative stress is an important feature in COPD (48). Inflammatory and structural cells that are activated in the airways of patients with COPD produce ROS, such as neutrophils, eosinophils, macrophages, and epithelial cells. Superoxide anions (O₂⁻) are generated by NADPH oxidase and converted to hydrogen peroxide (H₂O₂) by superoxide dismutases. H₂O₂ is then dismutated to water by catalase. O₂⁻, OH⁻, and H₂O₂ may interact in the presence of free iron to form the highly reactive hydroxyl radical (OH). O₂⁻ may also combine with NO to form peroxynitrite, which also generates OH. Oxidative stress leads to the oxidation of arachidonic acid and the formation of a new series of prostanoid mediators called isoprostanes, which may exert significant functional effects, such as bronchoconstriction and plasma exudation (49) (Fig. 6).

The normal production of oxidants is counteracted by several antioxidant mechanisms in the human respiratory tract (48). The major intracellular antioxidants in the airways are catalase, SOD, and glutathione, which is formed by the enzyme γ-glutamyl cysteine synthetase and glutathione synthetase. In the lung, intracellular antioxidants are expressed at relatively low levels and are not induced by oxidative stress, whereas the major antioxidants are extracellular. Extracellular antioxidants, particularly glutathione peroxidase, are markedly upregulated in response to cigarette smoke and oxidative stress. Extracellular antioxidants also include the dietary antioxidants vitamin C (ascorbic acid) and vitamin E (α-tocopherol), uric acid, lactoferrin, and extracellular superoxide dismutase, which is highly expressed in human lung, but its role in COPD is not yet clear. ROS have several effects on the airways and parenchyma and increase the inflammatory response. ROS activate NF-κB, which switches on multiple inflammatory genes resulting in amplification of the inflammatory response. The molecular pathways by which oxidative stress activates NF-κB have not been fully elucidated, but several redox-sensitive steps must be followed in the activation pathway. Oxidative stress results in activation of histone deacetylase activity, which opens up the chromatin structure and is associated with increased transcription of multiple inflammatory genes (50). Exogenous oxidants may also be important in worsening airway disease. Considerable evidence suggests increased oxidative stress in COPD (48). Cigarette smoke itself contains a high concentration of ROS. Inflammatory cells, such as activated macrophages and neutrophils, also generate ROS, as discussed above. Several markers of oxidative stress may be detected in the breath, and several studies have demonstrated increased production of oxidants, such as H₂O₂, 8-isoprostane, and ethane, in exhaled air or breath condensates, particularly during exacerbations (16).

Figure 6 Oxidative stress in COPD. Oxidative stress plays a key role in the pathophysiology of COPD and amplifies the inflammatory and destructive process. ROS from cigarette smoke or from inflammatory cells (particularly macrophages and neutrophils) result in several damaging effects in COPD, which include decreased antiprotease defenses, such as α1-antitrypsin (AT) and secretory leukoprotease inhibitor (SLPI), activation of NF-κB resulting in increased secretion of the cytokines CXCL8 and TNF-α, increased production of isoprostanes, and direct effects on airway function. In addition, recent evidence suggests that oxidative stress induces steroid resistance.

WILEY ENCYCLOPEDIA OF CHEMICAL BIOLOGY © 2008, John Wiley & Sons, Inc.
The increased oxidative stress in the lung epithelium of a COPD patient may play an important pathophysiological role in the disease by amplifying the inflammatory response in COPD. This increase may reflect the activation of NF-κB and AP-1, which then induce a neutrophilic inflammation via increased expression of CXC chemokines, TNF-α, and MMP-9. Oxidative stress may also impair the function of antiproteases such as α1-antitrypsin and SLPI, and thereby accelerates the breakdown of elastin in lung parenchyma. Corticosteroids are much less effective in COPD than in asthma and do not reduce the progression or mortality of the disease. Alveolar macrophages from patients with COPD show a marked reduction in responsiveness to the anti-inflammatory effects of corticosteroids, compared with cells from normal smokers and nonsmokers (27). In patients with COPD, a marked reduction in activity of HDAC and reduced expression of HDAC2 is observed in alveolar macrophages and peripheral lung tissue (28), which is correlated with increased expression of inflammatory cytokines and a reduced response to corticosteroids. This finding may result directly or indirectly from oxidative stress and is mimicked by the effects of H2O2 in cell lines (51).

Nitrative stress
The increase in exhaled NO is less marked in COPD than in asthma, partly because cigarette smoke reduces exhaled NO. Recently, exhaled NO has been partitioned into central and peripheral portions and this shows reduced NO in the bronchial fraction but increased NO in the peripheral fraction, which includes lung parenchyma and small airways (52). The increased peripheral NO in COPD patients may reflect increased expression of inducible NO synthase in epithelial cells and macrophages of patients with COPD (53). NO and superoxide anions combine to form peroxynitrite, which nitrates certain tyrosine residues in protein, and increased expression of 3-nitrotyrosine is observed in peripheral lung and macrophages of COPD patients (53). Tyrosine nitration of HDAC2 may lead to impaired activity and degradation of this enzyme, which results in steroid resistance (51).

Inflammatory cytokines
Cytokines are the mediators of chronic inflammation, and several have been implicated in COPD (7). An increase in concentration of TNF-α is observed in induced sputum in stable COPD with an additional increase during exacerbations (13, 17). TNF-α production from peripheral blood monocytes is also increased in COPD patients and has been implicated in the cachexia and skeletal muscle apoptosis found in some patients with severe disease. TNF-α is a potent activator of NF-κB, which may amplify the inflammatory response. Unfortunately, anti-TNF therapies have not proved to be effective in COPD patients. IL-1β and IL-6 are other proinflammatory cytokines that may amplify the inflammation in COPD and may be important for systemic circulation.

Chemokines
Chemokines are small chemotactic cytokines that play a key role in the recruitment and activation of inflammatory cells through specific chemokine receptors. Several chemokines have now been implicated in COPD and have been of particular interest since chemokine receptors are G-protein coupled receptors, for which small molecule antagonists have now been developed (8). CXCL8 concentrations are increased in induced sputum of COPD patients and increase even more during exacerbations (13, 17). CXCL8 is secreted from macrophages, T-cells, epithelial cells, and neutrophils. CXCL8 activates neutrophils via low-affinity specific receptors CXCR1, and is chemotactic for neutrophils via high-affinity receptors CXCR2, which are also activated by related CX3 chemokines, such as CXCL1. CXCL1 concentrations are markedly elevated in sputum and in BAL fluid of COPD patients, and this chemokine may be more important as a chemoattractant than CXCL8, acting via CXCR2 that are expressed on neutrophils and monocytes (14). CXCL1 induces significantly more chemotaxis of monocytes of COPD patient compared with those of normal smokers, and it may reflect increased turnover and recovery of CXCR2 in monocytes of COPD patients (23). CXCL8 shows a marked increase in expression in airway epithelial cells during exacerbations of COPD; this increase is accompanied by a marked up regulation of epithelial CXCR2.

CCL2 is increased in concentration in COPD sputum and BAL fluid (14) and plays a role in monocyte chemotaxis via activation of CCR2. CCL2 seems to cooperate with CXCL1 in recruiting monocytes into the lungs. The chemokine CCL5 (RANTES) is also expressed in airways of COPD patients during exacerbations and activates CCR5 on T-cells and CCR3 on eosinophils, which may account for the increased eosinophils and T-cells in the wall of large airways that have been reported during exacerbations of chronic bronchitis. As discussed above, CXCR3 are upregulated on T-cells and T-cells of COPD patients are more responsive to the chemokine CXCL9 than to CXCL8, which is important as a chemoattractant than CXCL8, acting via CXCR2 that are expressed on neutrophils and monocytes (14). CXCL1 induces significantly more chemotaxis of monocytes of COPD patient compared with those of normal smokers, and it may reflect increased turnover and recovery of CXCR2 in monocytes of COPD patients (23). CXCL8 shows a marked increase in expression in airway epithelial cells during exacerbations of COPD; this increase is accompanied by a marked up regulation of epithelial CXCR2.

Growth factors
Several growth factors have been implicated in COPD and mediate the structural changes that are found in the airways. TGF-α is expressed in alveolar macrophages and airway epithelial cells of COPD patients, and it is released from epithelial cells of small airways. TGF-β is released in a latent form and is activated by various factors, which include MMP-9. TGF-β may play an important role in the characteristic peribroncholar fibrosis of small airways, either directly or through the release of connective tissue growth factor (Fig. 7). TGF-β downregulates β-adrenergic receptors by inhibiting gene transcription in human cell lines, and it may reduce the bronchodilator response to β-agonists in airway smooth muscle. Alveolar macrophages produce TGF-α in greater amounts than TGF-β, which may be a major endogenous activator of EGFR that plays a key role in regulating mucus secretion in response to many stimuli, which include cigarette smoke. Cigarette smoke induces TNF-α-converting enzyme on airway epithelial cells, which results in the shedding of TGF-α and the activation of EGFR, resulting in increased mucus secretion (54) (Fig. 8).

VEGF is a major regulator of vascular growth and is likely to be involved in the pulmonary vascular remodeling that occurs as a result of hypoxic pulmonary vasoconstriction in
fibroblasts or indirectly via the release of CTGF. TGF-α activates MMP-9. This may cause fibrosis directly through effects on fibroblasts or indirectly via the release of CTGF. TGF-β may also desensitize TGF-α receptors on cells such as airway smooth muscle to diminish the bronchoconstrictor response to β-agonists.

In summary, cigarette smoke exposure induces a florid inflammatory response in the lung that involves structural and inflammatory cells and a large array of inflammatory mediators. The interaction of these complex steps eventually leads to airway remodeling and obstruction and emphysema, albeit in only about 25% of chronic smokers. Of interest, the main difference between smokers who develop COPD and the ones who do not seems to be the presence of an adaptive immune response with CD8+, CD4+, and B-cells, which express obvious signs of being activated effector cells. It is likely that genetic and epigenetic factors (such as histone acetylation) are involved in determining the progression of the inflammatory cascade, as it is supported by animal models, where different strains seem to have different sensitivities to cigarette smoke. COPD is a complex inflammatory disease, and the interactions between different inflammatory cells and mediators are still uncertain. More research into these mechanisms is needed to identify novel targets that may lead to the discovery of more effective therapies that can prevent disease progression and reduce the high mortality of this common disease.

Chronic Obstructive Pulmonary Disease (COPD). Inflammatory Mechanisms of

Although the etiology of depression remains to be elucidated, our knowledge of the neurobiology and biochemistry of this mental disorder has been updated increasingly. Early research focused on the biogenic amines norepinephrine (NE; noradrenaline) and 5-hydroxytryptamine (5-HT; serotonin). The biogenic amine (monoamine) hypothesis of depression states that depression is the result of a functional deficiency of NE and/or 5-HT at central synapses. However, it soon became obvious that other factors were also important in the neurobiology of depression. Dopamine is thought to be involved in various aspects, which include reward and locomotion. The amino acids gamma-aminobutyric acid (GABA) and glutamate, their receptors, and various neuroactive steroids that act as allosteric modulators at GABAA and/or NMDA glutamate receptors have been proposed to have an important role. Stress and the hypothalamic-pituitary-adrenal (HPA) axis play a central role, and it has been proposed that increased secretion of corticotropin releasing factor (CRF) may be critical in producing the symptoms of depression. Various other neurochemicals have also been implicated in depression, and in several cases they have links to the HPA axis. Abnormal levels of Substance P have been reported in depression. Cell loss seems to occur in some brain areas (e.g., hippocampus) in depression, and such loss can be produced by stress and prevented by antidepressants (which also increase expression of various neurotrophic and transcription factors). Agonists at melatonin receptors have been proposed in recent years as effective antidepressants. The possible involvement of the various neurochemicals mentioned above in depression will be reviewed, and some other neurochemicals that are being examined will also be mentioned.

Introduction

Depression (referring here to major depressive disorder in the Diagnostic and Statistical Manual of the American Psychiatric Association, volume IV; DSM-IV) is a common, chronic, functionally limiting clinical syndrome that likely reflects a heterogeneous group of underlying disorders (1, 2). In the DSM-IV (DSM-IV-TR is the most recent version), characteristic symptoms of a major depressive episode listed include five or more of the following symptoms, which have been present nearly every day in most cases during the same 2-week period and represent a change from previous functioning: 1) depressed mood; 2) markedly diminished interest or pleasure in all, or almost all, activities; 3) significant weight loss or gain; 4) insomnia or hypersomnia; 5) fatigue or loss of energy; 6) feelings of worthlessness or excessive or inappropriate guilt; 7) feelings of worthlessness or excessive or inappropriate guilt; 8) diminished ability to think or concentrate, or indecisiveness; and 9) recurrent thoughts of death or suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide. Note: of the five symptoms, at least one is either 1) or 2) above. The lifetime prevalence of depression in the United States has been estimated at 5–12% in men and 10–25% in women (2). Depression has been shown to impact individual...
quality of life significantly (3), carry a heavy economic burden (4), and affect brain structure and function (5). Despite research into many potential causative factors, a putative etiology for depression remains elusive (6, 7). Research in the twentieth century initially focused on a decreased functional availability of the monoamine neurotransmitters norepinephrine (NE) and 5-hydroxytryptamine (5-HT) as the possible agents of depressive illness, and it was supported in part by the pharmacological properties of available antidepressants. However, a growing body of literature suggests that multiple contributory chemical systems, many of which are intertwined, are involved in producing the depressive phenotype (8–10).

Biogenic Amines

Endogenous biogenic amines in the brain include catecholamines [NE (norepinephrine, NA), dopamine (DA)], epinephrine (adrenaline), 5-HT, histamine, and the so-called trace amines (β-phenylethylamine, tyramine, tryptamine, and octopamine). These amines have in common aarrièreamine structure, and all have been implicated in the etiology of one or more psychiatric disorders and/or in therapeutic and/or adverse effects of drugs used to treat such disorders. In this review on depression, the focus is on the case of biogenic amines will be on 5-HT, NE, and DA, although epinephrine and histamine and trace amines have also been implicated (see the section on “Other Antidepressant Approaches and Targets”). Early studies on the origins of depression focused on the monoamine neurotransmitters NE (a catecholamine) and 5-HT (an indolamine) (for reviews, see References 7, 11, and 12) (Fig. 1). The antihypertensive and antipsychotic medication reserpine depletes central stores of NE, 5-HT, and DA and is known to produce symptoms of depression in some patients (13). Iproniazid is an antitubercular drug that was noted to produce mood elevation in tuberculosis patients and was shown to be an inhibitor of monoamine oxidase (MAO), which is a major catabolic enzyme for monoamines, including NE, 5-HT, and DA (another catecholamine neurotransmitter). In addition, studies in animals with drugs that caused depletions of NE and/or 5-HT demonstrated changes in locomotor activity, sleep, and sexual activity; these symptoms are similar to physiological symptoms observed in depressed patients. These observations led to catecholamine (14) and indolamine (15, 16) hypotheses, which are now generally combined into the biogenic amine (monoamine) hypothesis that states that depression is the result of a functional deficiency of NE and/or 5-HT at specific synapses in the central nervous system (12). In addition to the effects of the MAO inhibitors (several of which became approved antidepressants), the hypothesis was supported by the actions of the tricyclic antidepressants (TCAs), which inhibit the reuptake of NE and 5-HT back into nerve terminals. Such reuptake is a major inactivation mechanism for the catecholamines and 5-HT, and inhibition of this process leaves more NE and 5-HT available in the synaptic cleft between neurons to interact with postsynaptic receptors (Fig. 2). Indeed, most antidepressants developed subsequently inhibit NE and/or 5-HT reuptake and/or act on presynaptic receptors that affect synthesis and release of biogenic amine neurotransmitters (see Fig. 2).

Serotonin (5-Hydroxytryptamine, 5-HT)

Regulation of mood, sleep, and aggression have all been shown to involve the serotoninergic system (17–19), and most antidepressant drugs currently being used inhibit 5-HT reuptake and/or act on 5-HT receptors (of which there are several subtypes). 5-HT is produced centrally from the amino acid tryptophan, and depressed mood can be induced experimentally by acute tryptophan depletion in healthy individuals. This effect is accentuated in those with a family history of depression (18–21). Similarly, depressive relapse can be initiated in individuals treated with MAO inhibitors or selective serotonin reuptake (SSRI) inhibitors by depleting tryptophan (22, 23).

A major problem with the biogenic amine hypothesis of depression is the discrepancy in the time course between relatively rapid biochemical and pharmacologic effects (e.g., inhibition of reuptake, inhibition of MAO) of the antidepressants and their clinical beneficial effects, which often require administration for 2–3 weeks or longer. This discrepancy led to the studies in both laboratory animals (receptor-binding studies and electrophysiological investigations) and humans (postmortem studies and in vivo neuroimaging studies) on possible dysregulation of receptors for the biogenic amines in depression and effects of antidepressants on that dysregulation (24–28). It has been suggested that antidepressants normalize the density and/or function

![Figure 1] Structures of NE, 5-HT, and DA.

![Figure 2] Sites of actions of antidepressants at the synapse (presynaptic nerve terminal, postsynaptic nerve cell), and synaptic cleft between the two are shown. MAO is present in mitochondria, and the shaded circles represent synaptic vesicles that contain neurotransmitter amines.
of 5-HTT1 and 5-HTT2 receptors, but there are inconsistencies in the literature in this regard. Electroconvulsive shock in rats (an approximate animal model of electroconvulsive therapy in humans) seems to cause an opposite effect on 5-HTT2 receptor regulation to that of several antidepressants (24, 25, for a review see Reference 26).

The 5-HT transporter protein (5-HTT) is critical for the reuptake of 5-HT into the presynaptic neuron. Decreased 5-HTT binding has been reported in depressed patients both in postmortem samples and in functional imaging studies (28, 29). Two common alleles of the gene that encode this protein have been identified, with the short (s) form of the allele being less active, which results in decreased transcription and reduced expression of 5-HTT. Studies have suggested that the s allele occurs more frequently in depressed patients as well as in suicide victims, and homozygous individuals are more likely to have family histories of depression. This finding seems paradoxical, as the s allele of the gene results in decreased serotonin reuptake, which thereby increases the duration of 5-HT in the synapse. It has been suggested that this observation may be explained by the lifelong duration of the genetic polymorphism compared with the acute effect of medication administration (28, 29).

Norepinephrine (Noradrenaline)

Investigations have also been conducted on the regulation of NE receptors in depression and after chronic administration of antidepressants (11, 30–32). In animal models, induced chronic stress has been used as a model for depression. Chronic stress antecedents (11, 30–32). In animal models, induced chronic stress has been shown to reverse antidepressant responses in individuals treated with antidepressants that inhibit NE reuptake, which suggests a direct role of this neurotransmitter in the course of depression (31).

Dopamine

Although the focus on monoamine neurotransmitters in depression has been on NE and 5-HT, it is generally considered that DA (Fig. 1) also plays a role, and readers are referred to several comprehensive papers that review basic science and clinical evidence for the involvement of DA (11, 33–35). Motor, psychomotor speed, concentration, andanhedonia have all been linked to dopaminergic circuits. Most DA-producing neurons have nuclei located in the brain stem. Projections from dopaminergic neurons form three primary paths to the cortical and subcortical structures: The nigrostriatal pathway is involved in motor planning and execution; the mesocortical pathway is concerned with concentration and executive functions; and the mesolimbic pathway is important in motivation, pleasure, and reward. Mesolimbic DA dysfunction is observed in animal models of depression, with subsequent antidepressant use causing enhanced dopamine signaling (11, 33–35). Decreased levels of DA in the nucleus accumbens of rats are associated with a decreased response to rewards. Animals that experience learned helplessness have decreased levels of DA in the caudate nucleus and nucleus accumbens; exposure to antidepressant medications has been reported to increase the level of DA in the same regions (11, 33, 34).

In humans, genetic studies have shown that particular polymorphisms of the D1 and D2 DA receptors are associated with depressed phenotypes. In studies of CSF concentrations of homovanillic acid (HVA), which is a metabolite of DA, lower levels than controls have been reported in some depressed patients. Conversely, depressed individuals with psychotic symptoms have been reported to have increased CSF levels of HVA and DA compared with controls (33).

Classes of Antidepressants

The three neurotransmitter monoamines mentioned above do not operate independently, but rather they interact with one another and are influenced by various central and peripheral biological processes. The actions of most commercially available antidepressant medications continue to target the monoamine neurotransmitter systems. The structures of these antidepressants are shown in Fig. 3. The MAO inhibitors (tranylcypromine, phenelzine, and moclobemide) prevent metabolic breakdown of the amines; the TCA's (represented by imipramine and desipramine Fig. 3, although several other structurally related TCAs are available) are inhibitors of reuptake of NE and 5-HT back into the presynaptic neuron, which results in increased levels of these amines in the synaptic cleft; the tetra cyclic maprotiline is a NE reuptake inhibitor; buproprion and its metabolites inhibit reuptake of NE and 5-HT back into the presynaptic neuron, which results in increased levels of these amines in the synaptic cleft; the tetracyclic maprotiline (an approximate animal model of electroconvulsive therapy in humans) seems to cause an opposite effect on 5-HTT2 receptor regulation to that of several antidepressants (24, 25, for a review see Reference 26).

The 5-HT transporter protein (5-HTT) is critical for the reuptake of 5-HT into the presynaptic neuron. Decreased 5-HTT binding has been reported in depressed patients both in postmortem samples and in functional imaging studies (28, 29). Two common alleles of the gene that encode this protein have been identified, with the short (s) form of the allele being less active, which results in decreased transcription and reduced expression of 5-HTT. Studies have suggested that the s allele occurs more frequently in depressed patients as well as in suicide victims, and homozygous individuals are more likely to have family histories of depression. This finding seems paradoxical, as the s allele of the gene results in decreased serotonin reuptake, which thereby increases the duration of 5-HT in the synapse. It has been suggested that this observation may be explained by the lifelong duration of the genetic polymorphism compared with the acute effect of medication administration (28, 29).

Norepinephrine (Noradrenaline)

Investigations have also been conducted on the regulation of NE receptors in depression and after chronic administration of antidepressants (11, 30–32). In animal models, induced chronic stress has been used as a model for depression. Chronic stress antecedents (11, 30–32). In animal models, induced chronic stress has been shown to reverse antidepressant responses in individuals treated with antidepressants that inhibit NE reuptake, which suggests a direct role of this neurotransmitter in the course of depression (31).

Dopamine

Although the focus on monoamine neurotransmitters in depression has been on NE and 5-HT, it is generally considered that DA (Fig. 1) also plays a role, and readers are referred to several comprehensive papers that review basic science and clinical evidence for the involvement of DA (11, 33–35). Motor, psychomotor speed, concentration, and anhedonia have all been linked to dopaminergic circuits. Most DA-producing neurons have nuclei located in the brain stem. Projections from dopaminergic neurons form three primary paths to the cortical and subcortical structures: The nigrostriatal pathway is involved in motor planning and execution; the mesocortical pathway is concerned with concentration and executive functions; and the mesolimbic pathway is important in motivation, pleasure, and reward. Mesolimbic DA dysfunction is observed in animal models of depression, with subsequent antidepressant use causing enhanced dopamine signaling (11, 33–35). Decreased levels of DA in the nucleus accumbens of rats are associated with a decreased response to rewards. Animals that experience learned helplessness have decreased levels of DA in the caudate nucleus and nucleus accumbens; exposure to antidepressant medications has been reported to increase the level of DA in the same regions (11, 33, 34).

In humans, genetic studies have shown that particular polymorphisms of the D1 and D2 DA receptors are associated with depressed phenotypes. In studies of CSF concentrations of homovanillic acid (HVA), which is a metabolite of DA, lower levels than controls have been reported in some depressed patients. Conversely, depressed individuals with psychotic symptoms have been reported to have increased CSF levels of HVA and DA compared with controls (33).

Classes of Antidepressants

The three neurotransmitter monoamines mentioned above do not operate independently, but rather they interact with one another and are influenced by various central and peripheral biological processes. The actions of most commercially available antidepressant medications continue to target the monoamine neurotransmitter systems. The structures of these antidepressants are shown in Fig. 3. The MAO inhibitors (tranylcypromine, phenelzine, and moclobemide) prevent metabolic breakdown of the amines; the TCA's (represented by imipramine and desipramine Fig. 3, although several other structurally related TCAs are available) are inhibitors of reuptake of NE and 5-HT back into the presynaptic neuron, which results in increased levels of these amines in the synaptic cleft; the tetracyclic maprotiline is a NE reuptake inhibitor; buproprion and its metabolites inhibit reuptake of NE and 5-HT back into the presynaptic neuron, which results in increased levels of these amines in the synaptic cleft; the tetracyclic maprotiline (an approximate animal model of electroconvulsive therapy in humans) seems to cause an opposite effect on 5-HTT2 receptor regulation to that of several antidepressants (24, 25, for a review see Reference 26).

The 5-HT transporter protein (5-HTT) is critical for the reuptake of 5-HT into the presynaptic neuron. Decreased 5-HTT binding has been reported in depressed patients both in postmortem samples and in functional imaging studies (28, 29). Two common alleles of the gene that encode this protein have been identified, with the short (s) form of the allele being less active, which results in decreased transcription and reduced expression of 5-HTT. Studies have suggested that the s allele occurs more frequently in depressed patients as well as in suicide victims, and homozygous individuals are more likely to have family histories of depression. This finding seems paradoxical, as the s allele of the gene results in decreased serotonin reuptake, which thereby increases the duration of 5-HT in the synapse. It has been suggested that this observation may be explained by the lifelong duration of the genetic polymorphism compared with the acute effect of medication administration (28, 29).

Norepinephrine (Noradrenaline)

Investigations have also been conducted on the regulation of NE receptors in depression and after chronic administration of antidepressants (11, 30–32). In animal models, induced chronic stress has been used as a model for depression. Chronic stress antecedents (11, 30–32). In animal models, induced chronic stress has been shown to reverse antidepressant responses in individuals treated with antidepressants that inhibit NE reuptake, which suggests a direct role of this neurotransmitter in the course of depression (31).

Dopamine

Although the focus on monoamine neurotransmitters in depression has been on NE and 5-HT, it is generally considered that DA (Fig. 1) also plays a role, and readers are referred to several comprehensive papers that review basic science and clinical evidence for the involvement of DA (11, 33–35). Motor, psychomotor speed, concentration, and anhedonia have all been linked to dopaminergic circuits. Most DA-producing neurons have nuclei located in the brain stem. Projections from dopaminergic neurons form three primary paths to the cortical and subcortical structures: The nigrostriatal pathway is involved in motor planning and execution; the mesocortical pathway is concerned with concentration and executive functions; and the mesolimbic pathway is important in motivation, pleasure, and reward. Mesolimbic DA dysfunction is observed in animal models of depression, with subsequent antidepressant use causing enhanced dopamine signaling (11, 33–35). Decreased levels of DA in the nucleus accumbens of rats are associated with a decreased response to rewards. Animals that experience learned helplessness have decreased levels of DA in the caudate nucleus and nucleus accumbens; exposure to antidepressant medications has been reported to increase the level of DA in the same regions (11, 33, 34).

In humans, genetic studies have shown that particular polymorphisms of the D1 and D2 DA receptors are associated with depressed phenotypes. In studies of CSF concentrations of homovanillic acid (HVA), which is a metabolite of DA, lower levels than controls have been reported in some depressed patients. Conversely, depressed individuals with psychotic symptoms have been reported to have increased CSF levels of HVA and DA compared with controls (33).

sufficient targets for research into the etiology and treatment of depression. In recent years, extensive research has focused on other possible causative factors, and the literature in this area will now be reviewed.

Beyond Biogenic Amines

\( \gamma \)-Aminobutyric Acid (GABA) and Glutamate

The amino acids GABA and glutamic acid (glutamate) (Figs. 4 and 5, respectively) are major inhibitory and excitatory neurotransmitters, respectively, in the central nervous system, and a requisite balance between the two operates in normal brain. Aberrations in the functions of one or both of these neurotransmitters have been implicated in the pathogenesis of several neurological and psychiatric disorders, which include depression (36–38).

Modulators of alpha-amino-3-hydroxy-5-methyl-4-isoxazolopropionic acid (AMPA) and N-methyl-D-aspartate (NMDA) ionotropic (associated directly with ion channels) glutamate receptors as well as metabotropic (linked to G-proteins and second messenger systems) glutamate receptors have been investigated for antidepressant properties (39–42). NMDA receptor antagonists have shown effects similar to other antidepressants in animal models of depression. In humans, plasma levels of glutamate have been reported to be correlated with the severity of depression (43), and NMDA receptor abnormalities have been observed in postmortem brain tissue of suicide victims and individuals with depression. Clinical trials of intravenously administered ketamine, which is an NMDA receptor antagonist, have produced rapid diminishment of depressive symptoms after a single administration (44). Concern has been raised over the psychotogenic side effects of NMDA receptor antagonists; however, memantine, which is a lower-affinity NMDA receptor antagonist without these side effects, has been investigated and did not show clinical improvement (42). Less evidence exists...
Depression, Chemical Mechanisms of

for the role of the AMPA receptor in depression. Tricyclic antidepressants have affinity for this receptor, and in a rat model of depression, AMPA receptor density increases with chronic antidepressant treatment (44).

Decreased GABAergic effects have also been associated with depression. In vivo evidence of GABAergic dysfunction in patients with depression includes decreased levels of GABA in the CSF, plasma, and occipital cortex (45, 46). Premenstrual dysphoric disorder (PMDD), which is a condition of depressive symptoms prior to menstruation, has been associated with a reduced variability in cortical GABA levels across the menstrual cycle (47). The MAO inhibitor antidepressant phenelzine has been shown to also cause marked increases in brain levels of GABA when administered to rats (48, 49). Using magnetic resonance spectroscopy, SSRI antidepressants have been demonstrated to increase brain levels of GABA in humans (50). Both GABA and glutamate are important beyond their direct effects as neurotransmitters. They interact with several other neurotransmitter and neuromodulatory systems and have effects on the regulation of the hypothalamic-pituitary-adrenal (HPA) axis, which may contribute to hyperactivity in this circuit in depression. The HPA axis will be discussed later in this article.

Neuroactive steroids

In recent years, a great deal of interest has focused on the possible involvement of several so-called neuroactive steroids (Fig. 6) in the etiology and pharmacotherapy of a variety of neurologic and psychiatric disorders, which include depression (51-53). These compounds are rapid-acting steroids that act as positive or negative allosteric modulators at many receptors, which include GABA-A and NMDA receptors. These steroids include pregnanolone, pregnenolone, allopregnanolone, isopregnanolone, 3α,5β-tetrahydroprogesterone (THP), 3β,5α-THP, 3α,5α-tetrahydrodeoxycorticosterone (THDOC), dehydroepiandrosterone (DHEA), DHEA sulfate, and pregnenolone sulfate. Allopregnanolone and THDOC are strong positive modulators at the GABA receptor and are potent anxiolytics (Note: Most antidepressants drugs also have anxiolytic properties). The ratios of these various neuroactive steroids are altered in several psychiatric disorders, and allopregnanolone seems to be of particular interest with regard to depression. Allopregnanolone has
been reported to produce antidepressant-like actions in ovariec-
tomized rats when given as an intra-accumbens infusion (54),
and SSR1 antidepressants have been shown to increase brain
levels of allopregnanolone in rats at doses lower than those
required to inhibit 5-HT reuptake (55). Blunted responses to al-
lopregnanolone in women with PMDD correlate with the degree
of depression in these subjects (56).

The Hypothalamic-Pituitary-Adrenal (HPA) Axis

A vast amount of literature indicates a relationship between
stress and depression, and in this regard it is interesting that the
HPA axis, which is involved in the coordination of neuroen-
docrine responses to stress, has been shown to be hyperactive
in many depressed patients (57, 58). In their diathesis-stress hy-
pothesis of mood disorders, Stout et al. (58) propose that the
HPA axis is the principal site where genetic and environmental
influences converge to cause mood disorders.

In healthy subjects, stress activates the hypothalamus, which
results in the release of corticotropin releasing factor (CRF),
which in turn results in release of adrenocorticotropic hormone
(ACTH). The ACTH activates the secretion of the glucocorti-
coid cortisol from the adrenal cortex (Fig. 7). The HPA axis has
an autoregulating mechanism mediated via negative feedback
by cortisol acting at glucocorticoid receptors in the hypothalamus
and the pituitary; but in many depressed patients, this regulation
is impaired, which results in higher circulating levels of CRF
and cortisol. This impairment probably occurs as a result of a
decrease in the number or sensitivity of glucocorticoid recep-
tors, which can be affected by gene expression, monoamines,
and early childhood expression (58, 59). It has been reported
that depressed patients exhibit decreased ACTH secretion in
response to exogenously administered CRF and increased se-
cretion of cortisol in response to a given ACTH level (58, 59).
Aripiprazole has been reported to result in return of HPA
functioning to control levels (59, 60), and it has been proposed
(9) that normalization of the HPA axis is a requirement for the
successful attenuation of depressive symptoms.

Chronic administration of corticosterone to rats results in be-
haviors associated with depression (61). Indeed, inhibitors of
cortisol synthesis (e.g., ketoconazole and metyrapone) and glu-
corticoid receptor antagonists (e.g., mifepristone) have been
tested clinically. Although preliminary studies with these drugs
promising, the former drugs have an unfavorable side effect
profile, and the latter suffer from lack of specificity (61, 62).

The development of CRF1 receptor antagonists has been a ma-
jor thrust by several research and pharmaceutical companies
in recent years. Increased levels of CRF in the hypothalamus
and CSF and an increased number of CRF neurons in the par-
ventricular nucleus of the hypothalamus have been observed
in major depressive disorder (10). Intracranial administration of
CRF to rats or overexpression of CRF in mice leads to sleep
disturbances, reduced appetite, and diminished sexual activity.
These symptoms appear in many depressed patients (58, 63).

Researchers continue to discuss whether the CRF antagonists
currently under investigation are acting primarily through block-
ade of prefrontal and limbic CRF1 receptors rather than having
an effect on the HPA axis. In addition, CRF2 receptors are ob-
served in the brain, and although their function is less clear,
drugs that act at these receptors are also of investigative inter-
est (58).

As indicated in other parts of this review, the HPA axis
interacts with most neurochemicals that are thought to be
important in depression, and many researchers consider that this
axis plays a central role in depression.

Substance P

The peptide Substance P acts primarily on neurokinin 1 (NK1)
receptors that are coupled to the Gs subunit of G proteins. Sub-
stance P has been of interest with regard to depression because
of its increased expression and that of NK1 receptors in fear-and
anxiety-related circuits. Substance P is released in animals in
response to fear-invoking stimuli and there is a high degree of
colocalization of substance P with 5-HT or its receptors in hu-
man brain (9). Kram et al. (64) reported that chronic treatment
of humans with a nonpeptide NK1 receptor antagonist resulted
in clinical improvement in depressed subjects; this finding was
replicated by some groups but not by others (9). It stimulated ad-
dditional research on NK1 antagonists. Although clinical findings
with substance antagonists have been disappointing overall, this
class of drug continues to be of interest, and recent studies in
laboratory animals and humans suggest that some useful anti-dep-
ressant agents may develop (66-69). Recent studies indicate
that NK1 antagonists act through serotonergic and noradrenen-
gic neurons (70), and it has been suggested that these drugs may
be useful agents in combination with traditional antidepressants
(71).

Cytokines

In recent years, researchers have shown interest in the role
of the immune system in depression (72, 73), and the cy-
tokine theory of depression proposes that alterations in the
immune response result in behavioral, cognitive, and neuroen-
docrine changes in depression. Cytokines can be proinflam-
matory or anti-inflammatory, and it has been postulated that
depression may be caused by, or at least related to, excessive
Depression, Chemical Mechanisms of

amounts of proinflammatory cytokines such as interleukin-1 and tumor necrosis factor-alpha (74). Indeed, it has been observed that antiviral treatment with the cytokine interferon results in “sickness behavior” characterized by symptoms such as weight loss, anorexia, depressed mood, sleep disturbances, social withdrawal, and fatigue, which are also observed in depression (9). It is also of interest that cytokines are potent stimulators of the HPA axis via activation of CRF release, and proinflammatory cytokines can also decrease 5-HT levels by increasing 5-HT secretion and diverting metabolism of tryptophan metabolism away from formation of 5-HT by tryptophan hydroxylase as well as increasing metabolism by the indolamine-2,3-dioxygenase (IDO) pathway (75). Although the evidence for abnormal cytokine levels and/or inflammatory responses in depression is inconsistent to date, this area is very interesting for future exploration and should lead to more studies on glial cells that synthesize and release cytokines.

Intracellular signaling cascades and neurotrophic factors

As the acute increase in synaptic monoamines produced by antidepressant drugs does not correlate with timing of clinical effects, the intracellular signaling pathways that their receptors interact with have been investigated as targets for novel antidepressants. Several such pathways are observed, and an example is given in Fig. 8 (76).

Several serotonergic and DA receptors and the β₁ noradrenergic receptor activate the Gs pathway, whereas others activate the Gq pathway. These signaling cascades result in activation of protein kinases A and C, with a net effect of increasing phosphorylation of cyclic adenosine monophosphate (cAMP)-regulated element binding protein (CREB). CREB acts as a regulator in the expression of many genes, some of which have been implicated in neuroplasticity and neurogenesis. For example, transcription of brain-derived neurotrophic factor (BDNF), tyrosine kinase B (trkB) (which is a BDNF receptor), and the glucocorticoid receptor are activated by CREB. Inhibition of transcription of CRF and subunits of the NMDA receptor occurs in the presence of CREB. Alterations in CREB levels have been observed in depressed individuals, and increases in CREB function have been associated with reduction or production of depressive symptoms in animals, which depends on the area of the brain involved (77, 78).

The most researched area of interest for antidepressant activity related to signaling pathways is the hippocampus (79–85). The volume of the hippocampus is reduced in patients with multiple episodes of major depression, as observed in imaging studies and in postmortem samples (81–84). Animal models of inescapable stress are associated with decreased hippocampal neurogenesis (84). Neurogenesis is also evident in the hippocampus of humans (85). The neurogenesis hypothesis states that depression is a consequence of impaired...
neurogenesis in the hippocampus and that antidepressants exert their effect by stimulating neurogenesis (86). Controversy exists as to whether neurogenesis is necessary for the efficacy of antidepressant medications in animal models (87), with some evidence suggesting that when neurogenesis is inhibited, antidepressant effects are lost (84, 88).

In the hippocampus, CREB seems to mediate antidepressant effects, and a variety of antidepressants, which includes electroconvulsive therapy, increases CREB expression (77). Experimentally increasing the expression of CREB in the hippocampi of depressed rats seems to have an antidepressant effect. Evidence suggests that the role of CREB in mediating antidepressant effects of medication is related to the expression of CREB-regulated neural growth factors, such as BDNF (79, 89). In humans, BDNF levels are reduced in postmortem samples of depressed individuals when compared with nondepressed controls (90). A antidepressant therapy increases serum BDNF levels in depressed humans (91). In animals, chronic stress models are associated with reduced expression of BDNF (79) and decreased cell proliferation in the hippocampus (83), which can be prevented or reversed by treatment with antidepressant drugs. However, researchers debate whether genetic disruption of the signaling pathways that involve BDNF and trkB causes depressive behavior (See Reference 92 for a review). It is also of interest that chronic administration of antidepressants has been reported to upregulate expression and activity of the neuroprotective enzyme superoxide dismutase and, depending on the dose and antidepressant, to increase immunostaining of BDNF and/or the antiapoptotic protein Bcl-2 (93, 94).

The picture with CREB is far from straightforward. Increased expression of CREB in the nucleus accumbens of rats produces depression-like effects, which include anhedonia (77, 89) and increased helplessness, in learned-helplessness models (81). Increases in BDNF expression in the mesolimbic DA system of rats are associated with induction of depressive effects in certain animal models. However, studies that use systemic administration of BDNF and activators of the cAMP-CREB cascade seem to have a net therapeutic effect in behavioral models of depression (90, 86, 89, 95).

**Metatonin (N-acetyl-5-methoxytryptamine)**

Depression and seasonal affective disorder, which is a form of depressive illness characterized by symptoms with onset and course related to season of the year, have been noted to be cyclic and possibly related to alterations in circadian rhythms (96). Alterations in the circadian functioning of the HPA axis and the hypothalamic-pituitary-thyroid axis occur in some patients with major depression (96). Disruption in the sleep/wake cycle and insomnia are common in depression. Melatonin (Fig. 9), which is a hormone derived centrally in the pineal gland from serotonin, is instrumental in many biological functions with circadian variability. Several studies have shown that depressed individuals have a deficiency of melatonin secretion, but a body of evidence shows increased nocturnal melatonin production in the brains of depressed subjects with increased urinary excretion of its metabolite, 6-hydroxymelatonin sulfate (96, 97). This finding may reflect differences in subtypes of depression. As melatonin is secreted in a rhythmic fashion, the timing of the melatonin peak has been studied in depressed individuals. Phase shifts toward both earlier and later onset of peak secretion have been noted. Both treatment with antidepressant medications and electroconvulsive therapy have been associated with increases in melatonin excretion in depressed individuals. The pineal gland receives input from noradrenergic neurons, and it has been suggested that alterations in melatonin secretion merely reflect dysfunction in monoamine systems (96, 97). Agomelatine, which is a melatonin receptor agonist and 5HT2c receptor antagonist, has been shown to have antidepressant properties in animals and humans (98-101). Agomelatine targets the M1/M2 melatonin receptors and mimics melatonin in its effect on circadian rhythms. A combination of activity at melatonin receptors and monoaminergic receptors may represent a novel method of antidepressant drug action (97-100).

**Other Antidepressant Approaches and Targets**

Electroconvulsive therapy (ECT) is considered to be the most efficacious treatment for depression, although its side-effect profile limits its use, and it is associated with a high relapse rate (10, 102). The exact mechanism of action of ECT is still unknown, although effects on monoaminergic systems, CRF, neurotrophic factors, and neuroendocrine systems have been suggested (102). Because DA probably plays a role in the pathophysiology of depression, triple reuptake inhibitors that inhibit reuptake of NE, 5-HT, and DA have now been developed and are undergoing preclinical and clinical testing (10). Numerous reports in the literature suggest that trace amines (so-named because their absolute levels in the brain are much lower that those of the classic neurotransmitter amines) are involved in the etiology and pharmacotherapy of several neurologic and psychiatric disorders, which include depression (103-106). Researchers have shown an increased interest in these trace amines, which include β-phenylethylamine, tyramine, tryptamine, and octopamine, in recent years with the discovery of a family of G-protein coupled receptors that bind to and are activated by these amines (107, 108). Epinephrine is present in much lower concentrations than NE and DA in the brain, but it is a major stress hormone in the periphery and could be a contributing factor in depression (109). Histamine is present in lower concentrations in brain than NE, DA, or 5-HT as well, but it has also been implicated in the etiology of depression (110).
Reports in the literature indicate that atypical (second generation) antipsychotics are useful antidepressant agents when combined with standard antidepressants (10); several researchers suggest that in some cases they and/or their metabolites may be useful antidepressants in their own right. It is interesting that some of these atypical antipsychotics have been reported to have several neuroprotective actions, which include effects on neuroprotective enzymes and factors that affect apoptosis (programmed cell death) (111). Preliminary reports suggest similar effects of antidepressants (93, 94). Some other areas related to the chemistry of depression and its treatment that contain conflicting reports in the literature but are of interest include the following: the relationship of serum cholesterol and the use of statins (cholesterol-lowering drugs) to depression, anxiety, aggression, and suicide (112, 113); omega-3 fatty acids and mood disorders (114–118); the use of herbal products such as St. John’s wort extracts and 5-adenosine/methionine as antidepressants (119–123); and the possible involvement of CB1 cannabinoid receptors, galanin, Neuropeptide Y, histone deacetylases, and tissue plasminogen activator in depression (See Reference 9 for a review). Other reported or putative neurobiological antidepressant treatments that we have not mentioned previously in this review include deep brain stimulation, vagus nerve stimulation, and transcranial magnetic stimulation; the reader is referred to the review of Holtzheimer and Nemeroff (10) and the references contained therein for details.

Concluding Remarks

Although a great deal has been learned about brain function in the search for newer antidepressants and some very interesting potential drug targets have been identified, our knowledge of the causes of depression remains inadequate. We still lack antidepressant drugs that are sufficiently rapid acting and effective in a large enough percentage of depressed patients. Problems that continue to make studies on depression difficult include the following: the heterogeneous nature of depression itself, gender issues, the involvement of multiple interacting neurotransmitters and neuromodulators in the etiology of depression, the inadequacy of current animal models, the involvement of various brain regions in the symptomatology of depression, disagreements about the neurogenesis hypothesis of depression and about the relative importance of the hippocampus in depression, regional differences in the effects of transcription factors such as CREB, and the differing effects of some antidepressants on the HPA axis.

Hemozoin: A Paradigm for Biominerals in Disease

Melissa D. Carter, Anh N. Hoang and David W. Wright, Vanderbilt University, Nashville, Tennessee
doi: 10.1002/9780470048672.wecb649

Biomineralization is the formation of organic–inorganic composites by organisms. Originally evolved as a protective mechanism, this complex process has also become a recognized contributor to several disease states, which range from kidney stone disease (nephrolithiasis) to parasitic diseases like malaria. The characteristic three-step process for the formation of biominerals is defined by the supramolecular preorganization of a nucleating template, the interfacial molecular recognition of crystal nuclei and the cellular processing of resultant aggregates. Hemozoin formed in the heme detoxification pathway used by the malarial parasite *Plasmodium falciparum* represents a paradigm for pathogenic biominerals. Current research indicates that a supramolecular lipid template organizes heme released previously during hemoglobin catabolism. Nucleation and growth of the heme aggregate serves to protect the parasite from the toxic effects of free heme. Given the mechanisms of biomineralization, it is not surprising to discover that century-old antimalarial compounds function by disrupting key interactions between the heme substrate and template. Subsequently, the heme-aggregate is released into the host vasculature and deposits in patients’ brains, spleens, and livers where it disrupts host innate immune response. The underlying basis of this immunomodulating activity seems to result from hemozoin mediated lipid peroxidation. Understanding the relationships between hemozoin formation and its pathogenic activity with the host immune response represents a significant challenge to chemical biology.

Biomineralization is the biologic formation of organic–inorganic composites generally organized on a nucleating template of organic material. During bone and teeth formation, hydroxyapatite, which is a calcium phosphate derivative enriched with carbonate, mineralizes on a template of collagen fibrils and other proteins (1). Likewise, calcium oxalate monohydrate crystals mineralize on a biologic matrix of proteins in both plants and humans. Although these crystals function as tissue support in plants (2), they cause painful inflammation in humans (3). In fact, biomineralization is associated with several human diseases. Nephrolithiasis is the mineralization of calcium oxalate in the urinary tract of patients as kidney stones. In gout or metabolic arthritis, monosodium urate crystals accumulate in the articular joints. A patient’s innate immune response or the on-rush of monocytes and neutrophils at the sites of crystal sedimentation causes the characteristic tissue inflammation and pain associated with these diseases. Biomineralization can also contribute to the pathology of parasitic diseases like malaria and schistosomiasis. When the malarial protozoa *Plasmodium falciparum* deposits heme-derived aggregates in host vasculature, these aggregates travel through the bloodstream and collect in the brain, spleen, and liver. When they are phagocytosed by innate immune cells such as monocytes and neutrophils, the cells’ ability to produce reactive oxygen and nitrogen species is impaired. This immunomodulation is typical of the pathogenesis caused by many biomineral-associated diseases.

Heme Homeostasis

Over 40% of the world’s population is at risk from malaria. The disease causes severe illness in over 500 million people and results in over 1.7 million deaths each year (4). Transmission is most prevalent in the world’s poorest countries, predominantly sub-Saharan Africa, and accounts for 40% of public healthcare costs. In addition, a 2007 World Health Organization report estimates a 1.3% decline in annual economic growth for countries.
with high rates of malarial infection (4). Compounded over time, this drop contributes significantly to GDP disparities between those countries where malarial infection is endemic and those where it is not.

Challenges of heme homeostasis

Over 100 Plasmodium species contribute to the spread of malaria, but only four of these (P. falciparum, P. vivax, P. ovale, and P. malariae) account for human infection, the deadliest being P. falciparum. The malaria life cycle exists first in a mosquito, and then it passes to a human host. An infected female Anopheles mosquito is the host of the parasite’s sporogonic life cycle. Mature P. falciparum sporozoites reach the salivary glands of the mosquito, and the parasite is transmitted to a human host when the mosquito feeds. During this blood meal, sporozoites are released into the bloodstream where they penetrate hepatic cells and mature into schizonts. The liver cells rupture after approximately two weeks, discharging merozoites into the bloodstream whereupon they infect red blood cells (RBCs). Every 48 to 78 hours, mature merozoites rupture from spent RBCs and either they differentiate into gametocytes or they infect more RBCs. This blood stage is responsible for the clinical manifestation of the disease (5).

P. falciparum ingest and degrade up to 80% of host erythrocyte hemoglobin (Hb) (5) to provide the parasite with essential amino acids for growth and maturation. During high parasitemia (20%), up to 100 g of the 750 g of circulating host Hb can be catabolized by the parasite (5). Hb is broken down in the parasite’s acidic (pH 4.5–5.2) digestive food vacuole (DV) by a suite of proteases that includes four aspartic acid proteases (plasmepsins PfPM1, PfPM2, PfHAP, and PfPM4), three cysteine proteases (falcipains PfFP2, PfFP2′, and PfFP3), and a metalloproteinase (falcilysin) (Fig. 1) (6). This ordered catabolic process is initiated by PfPM1 and PfPM2, which cleave between residues ω33Phe and ω34Leu in the hinge region of Hb. Recent quadruple knockout studies show individual plasmepsin redundancy and suggest that although each aspartic proteinase may not be essential to the intraerythrocytic stage, they could play unique roles outside Hb digestion. On plasmepsin cleavage, the protein unfolds, which releases free heme and exposes

![Diagram of hemoglobin catabolism](image)

Figure 1 Ordered pathway of hemoglobin catabolism. Host Hb cleavage is initiated by PfPM1 and PfPM2. Hb unfolds, releases heme and exposes other peptide bonds to the falcipains. Resultant protein fragments are degraded even more by falcilysin and transported to the cytosol where they are broken down into needed amino acids. The heme released in the first step aggregates via biomineralization to form HZ.
The processes of crystal nucleation and growth are driven by the chemistry of biomineral formation and unicellular silver deposits. The formation of these biominerals is recognized commonly in a range of functional structures including silicon, into crystal aggregates evolved as a protective mechanism for inorganic matrices such as protein and lipid networks. The propagation and continued growth of a stable crystal phase is the foundation for the second-order assembly of inorganic species.

### Biomineralization

Over 570 million years, the complex process of organizing inorganic molecules, which generally contain calcium, iron, or silicon, into crystal aggregates evolved as a protective mechanism for organisms. Fossil records show that biomineralization surfaced first in the form of organism scales and skeletons during the neoproterozoic era (9), and now, biominerals are recognized commonly in a range of functional structures including shells (10), vertebrate teeth, and bone (11, 12), diatom silicates (13) and unicellular silver deposits (14). The formation of these materials is attributed to two processes: 1) biologically-induced mineralization, which is the deposition of minerals via adherent precipitation (15) and 2) biologically-controlled mineralization, which is the regulated formation of minerals that have a specific function and structure (16). Generally, induced minerals are heterogeneous in character, whereas minerals that result from cellulyarly controlled processes exhibit uniform composition and morphology (17).

### Chemistry of biomineral formation

The processes of crystal nucleation and growth are driven by the basic laws of thermodynamics in which a greater free energy must exist in the original solution phase than the resultant crystalline phase (17). However, it must be noted that the free energy distribution at the crystal surface differs from these phases (3). Because molecules on the crystal surface are not bound as strongly as molecules in the preliminary bulk solution, their free energy contribution to the system is greater. This energy difference between molecules at the surface and in solution is known as the interfacial free energy. Acting on the destabilization of crystal nuclei, the interfacial free energy can cause either nucleus dissolution or growth of the nucleus to a large enough size that its stability prevails over the affects of surface free energy, and a crystal is formed. The nucleation pathways that lead to the most stable crystal phase are the foundations of the Ostwald-Lussac law of phases, which explains that nucleation occurs in a series of pathways with increasing stability before reaching the final crystalline state (3). The propagation and continued growth of a stable crystal is attributable to a uniform nucleation template from which a new phase is formed from an old phase that has become higher in free energy (3, 18).

In the context of crystal nucleation and growth, the formation of biominerals can be cast as a three-step process that involves the supramolecular preorganization of a template, the interfacial molecular recognition of crystal nuclei, and the cellular processing of resultant aggregates (19). The first-order assembly of organic matrices such as protein and lipid networks provides a foundation for the second-order assembly of inorganic species. Typically, these frameworks have functionalized surfaces that behave as templates for inorganic nucleation and are governed by electrostatic, structural, and sterochemical complementarity of the organic-inorganic interface. Without cellular intervention to control the flux of metal ions, crystal nucleation would continue to grow along these scaffolds, proceeding to their bulk state. Clearly, such unconstrained growth represents a danger to cellular integrity. The final stage of biomineral construction is cellular processing, which is often the distinguishing step between native biomineral morphology and that of its synthetic analogs. The intracellular or extracellular environment in which a crystal grows ultimately influences its crystallographic structure and morphology (19) and ensures the function of laden cells.

**Search for hemozoin's bionucleating template**

Investigations into the mechanisms of HZ formation have centered on protein or lipid-rich nucleating templates. Early hypotheses of a catalytic heme-polymerase in trophozoite lysates were abandoned because of failed attempts at identification and purification of the enzymatic activity. An alternative to such a heme polymerase was proposed by Sullivan (20) from their investigations of a family of histidine-rich proteins (HRP) isolated from the DVs of *P. falciparum*. HRPII is a 30 kDa protein with 76% of its composition being His or Ala residues. HRPIII is 27 kDa and is 56% His or Ala residues. Both proteins have repeats of the tripeptide Ala-His-His, 51 repeats in HRPII, and 28 repeats in HRPIII. This Ala-His-His recurring domain provides an archetypal biomineralization scaffold for the nucleation and propagation of free heme into HZ. When HRPII or HRPIII were...
templates bound 17 molecules of heme, mediated the formation of *P. falciparum* nucleating domain of HRP II of bionucleating templates (BNT I and II) were composed of the stochiometric amounts of Fe(III)PPIX, although substrate specificity experiments suggested that substrate recognition was dependent on the porphyrin moiety rather than specific metal recognition. Moreover, HRP substrate recognition was not shown to be mediated by histidine axial ligation to a metal ion, but rather it was attributed to stacking and electrostatic interactions. Chloroquine inhibition of the bionucleating templates was comparable with HRP II and III impaired formation of HZ when treated with the antimalarial (21).

These templates, like HRP II, were shown to promote HZ formation at a parasite DV relevant pH 4.0-4.5. In fact, HRP II is active from pH 4.5 to pH 6.0. HZ formation slows at pH values below 2.0 and above 5.0 (22). Although an increase in pH does cause an increase in binding of heme to HRP II, the HZ produced actually decreases leading, instead, to the formation of μ-β-β-heme dimers (22). Therefore, the bis-histidyl heme binding observed on other proteins like histidine-rich glycoprotein (HRG) at physiological pH 7.0 differs from the HRPII nucleation of HZ in the parasite's acidic DV (23), although a pH 7 HRP II model was attempted by Schneider and Marletta in 2005 (24). At this pH, binding is consistent with a nucleating template that serves as an organizing function rather than a tight heme-binding function.

Subsequent experiments revealed, however, that the HRP's were not the likely template for HZ formation. Double deletion mutants of HRP II and HRP III did not prevent the formation of HZ in the DV (20), which suggests the existence of an alternative template. In addition, HRP II is not located solely in the DV, but rather it is secreted into the serum of victims at high concentrations. Histology labeling experiments show that HRPs in the DV are simply captured during the endocytosis of host hemoglobin and not specifically targeted to the DV (20). Such surreptitious colocalization would also suggest the existence of a non-HRP template. In light of these experimental results, the search for HZ's biomineralization template turned toward other possibilities.

Lipids are a possible template for HZ biomineralization. As a bionucleating template, lipids can increase the solubility of Fe(III)PPIX, localize high concentrations of Fe(III)PPIX, and provide a layer of free heme intercalation. The propionate groups of free heme within the lipid layer can then effectively charged Fe(III) centers, which weakens any hydrogen bonds with water and enables the hydrogen bonds of Fe(III)PPIX dimers. Fitch et al. (25) showed that HZ formation could be mediated at pH 5.0 in the presence of fatty acids like arachidonic acid and glyceral of oleic acid as well as detergents like polyoxyethylene sorbitan monolulate (TWEEN 80). Increasing support for a lipid template led to the membrane sacrifice theory by Hemplemann et al. (25), which suggested that inner membranes of RBC transport vesicles in the parasite cytosome were degraded by free heme, releasing lipids that increase heme solubility and aggregation. In the sacrifice of the inner membrane, the outer membrane is preserved to prevent additional oxidative damage to the parasite (26). In vitro lipid-initiated HZ crystallization was reported by Egan et al. (27) using a range of lipids that includes myristoyl, detyl, and palmitoyl glycerides; phospholipid; and cholesterol to initiate HZ formation along the lipid–water interface. Simulations of HZ formation in these studies indicated that the hydrophobic Fe(III)PPIX dimer was more stable in the lipid layer to foster hydrogen bonds between the protonated propionic acid groups and thus, HZ crystal assembly (27). Transmission electron microscopy images of HZ localized in lipid nanospheres within an infected trophozoite stage RBC provided increased support of a lipid-mediated HZ biomineralization process. The extraction of these fatty acyl glycerides (including monostearic, monopalmitic, dipalmitic, diloetic, and diolein glycerides) and their incubation with substrate heme, developed a competent in vitro template for HZ formation (28).

**Target of antimalarials**

Interruption of the parasite heme biomineralization pathway is a logical target of antimalarial drug development. As antimalarials amass in the parasite's DV, HZ formation is inhibited, and the parasite becomes flooded in toxic heme. Beginning with the hypothesis that neutral lipid droplets indeed serve as biomineralization templates for the formation of HZ, a variety of limiting cases exist in which inhibitors may disrupt the aggregation of HZ (Fig. 2). An inhibitor may bind the heme substrate in such a manner that the heme-inhibitor complex cannot be recognized by the template. Alternatively, a drug could interact with the template, blocking the heme binding site. Finally, a HZ aggregation inhibitor might trap the heme bound to the template, which prevents formation of the dimeric unit or nucleation of the extended crystal. These possible modalities, which are derived from the paradigm of biomimetic formation, can be used to understand the mechanism of action of some antimalarial compounds.

Well-known quinoline-based drugs like chloroquine and amodiaquine are thought to target this HZ biomineralization pathway. These drugs have been the standards in treatment of malaria, but growing parasite resistance threatens their use. Quinoline-based drugs include the well-known 4-aminoquinoline derivatives chloroquine, amodiaquine, halofantrine, quinine, and bayspinone (29). These drugs are thought to trap monomeric heme or bind the μ-β-β-dimer of oxidized heme to prevent HZ formation. The μ-β-β interactions at the (001) heme face control resultant adduct formation. Computational models of HZ and quinoline interactions indicated that drug adsorption occurred on the (001) and (011) crystal faces (Fig. 3) (30). These highly symmetrical crystals also showed tapering at each drug-bound (001) or (011) ledge, which suggested weakening of the quinoline inhibition along the crystal's c-axis which resulted in thinner crystal cross-sections (30).

Other inhibitors of HZ formation are thought to act similarly to the quinoline family. Binding of the antifungal azole-based drugs clotrimazole, ketoconazole, and miconazole to heme is thought to damage parasite cell membranes and cause...
Figure 2: Modes of hemozoin inhibition. On a neutral lipid droplet template (T), heme can aggregate to form the biomineral HZ. Antimalarials may inhibit this aggregation by binding heme substrate, interacting with the lipid template or trapping heme bound to the template. All actions serve to prevent the formation of HZ.

Figure 3: Hemozoin-chloroquine binding model. Chloroquine is thought to bind to the (001) and (011) faces of heme as well as π–π stacking at the (010) face. To prevent HZ formation completely, chloroquine would have to bind both faces of each heme monomer or crystal extension would be blocked in only one direction as shown.
The isonitrile terpenes (diisocyanoadociane and axisonitrile-2), isolated from marine sponges and the synthetically derived methylene blue analogs (acures A, B, and C; thion; celestine blue; and phenosaphranin) most likely prohibit HZ formation by binding monomeric heme. The xanthone family of animalarals, such as the hydroxynamethanes and the bis-(N,N-dibutylamino)ethoxy xanthones, were found also to bind at the HZ crystal faces (001) and (031). Specifically, the drugs’ terminal amino groups bind the carboxyl group exposed at each face, which inhibits the nucleation and growth of the crystal (30). The crystal engineering prospect of future drug design is an interesting one that beckons additional exploration and promises applications in a variety of biomimetic-associated diseases.

Hemozoin Characterization

Prior to the definitive X-ray powder diffraction characterization of HZ, the true structure of the aggregate remained elusive because of its limited solubility. HZ was soluble only in NaOH, which completely degraded the structure and prevented any attempt to determine the intramolecular atomic interactions. The insolubility of the product rendered useless many “standard” experimental methods for the characterization of bioorganic systems. This aspect of the biomimetic’s identification undoubtedly contributed to Ridley’s description of HZ as “a black insoluble mass of material that can be soul-destroying to work with” (31).

Physical characterization

Studies by Slater et al. (31) provided an initial “fingerprint” of HZ’s chemical structure by applying Fourier-transform IR (FT-IR) spectroscopy to intact HZ crystals. The IR spectrum of HZ revealed intense absorbance patterns at 1664 and 1539 cm⁻¹, which indicate the axial propionate C–O and C–O stretching, respectively (Fig. 4a). These peaks were absent from the spectra of the synthetic substrates hemin chloride and hematin. These data suggested a direct coordination from the spectra of the synthetic substrates hemin chloride and hematin. The IR spectroscopy of intact HZ crystals. The IR spectrum of HZ revealed intense absorbance patterns at 1664 and 1539 cm⁻¹, which indicate the axial propionate C–O and C–O stretching, respectively (Fig. 4a). Identification of native lipid components of hemozoin

In vivo native HZ transmission electron microscopy images from trophozoite-infected RBCs depicted the localization of HZ crystals within neutral lipid nanospheres (28). Trophozoite DVs were isolated using Percoll/sucrose bottom separation techniques, and the lipid content of these isolates was extracted by Bligh-Dyer (chloroform/methanol) lipid extraction. Methylenediacetic acid characterization by gas chromatography-MS (GC-MS) and lithium (Li⁺) adduct electrospray ionization mass spectrometry of trophozoite fractions revealed a suite of neutral lipids adhered to the crystal’s surface. When these lipid extracts were separated using reverse phase-, normal phase-, and chiral phase high performance liquid chromatography and sub-sequent analysis revealed the presence of substrate hemin, HZ formation was observed (28). This competent nucleating template of fatty acyl glycerides is consistent with the hypothesis of a lipid scaffold for heme aggregation in P. falciparum. Also extracted from native HZ were polar hydroxylated fatty acids derived presumably from cellular arachidonic and linoleic acids. Native HZ was purified from infected RBCs by a series of centrifugation steps followed by organic extraction of its lipid coat. Analysis of the lipid coat revealed the presence of hydroxylated polysaturated fatty acids. These polar lipids were separated using reverse phase-, normal phase-, and chiral phase high performance liquid chromatography and subsequent analysis revealed the presence of 15-, 12-, 11-, 9-, and 5-hydroxyeicosatetraenoic acids (HETEs) as well as 13- and 9-hydroxyoctadecadienoic acids (HODEs) (35).
Chemical reactivity

Native HZ produced in the parasite DV most likely encounters cellular debris such as arachidonic and linoleic fatty acids or other lipids when released from a bursting RBC. Redox cycling of surface exposed heme units within HZ can lead to the initiation of lipid peroxidation (LPO). A abstraction of a bisallylic hydrogen atom from a fatty acid such as arachidonic acid results in an unpaired electron on the methylene carbon. This unpaired electron promotes the rearrangement of the double bonds adjacent to the methylene group that produces an alkyl radical (L•). In the presence of oxygen, alkyl radicals react to form peroxy radicals (LOO•) that can abstract a hydrogen atom that yields a lipid peroxide (LOOH) and can propagate more reactions. Reduction of the peroxy radical would result in the production of racemic mixtures of hydroxylated fatty acids like the HETEs and HODEs described previously in the HZ lipid coat. Secondary oxidation and chain \( \beta \)-cleavage results in reactive 4-hydroxy-2-nonenal (HNE) (Fig. 5). Lipid peroxidation was demonstrated in vitro by reacting arachidonic acid with native HZ purified of all cellular lipid and protein content. Resultant HETE products were extracted from the reaction supernatant and identified using reverse phase high performance liquid chromatography (37). Recent studies of BH reactions with arachidonic acid revealed an identical reaction profile to that of HZ with all six positional HETE isomers identified by ultra high pressure reverse phase and chiral phase liquid chromatography tandem MS/MS (chiral-RP-LC-MS/MS) (38). LC-MS analysis has enabled the separation and identification of these cellular metabolites at femtomole levels of detection. The presence of these oxidation products in the lipid coat of native HZ and their formation upon arachidonic acid incubation with purified HZ and BH strongly supports the HZ-mediated LPO of cellular fatty acids. Additionally, the known immunomodulatory activity of these lipid peroxidation products is intriguing given the reported ability of HZ to disrupt the function of innate immune cells.

Basis of Hemozoin

Immunomodulation

Once thought to be a simple “inert” detoxification biomineral, an increasing appreciation exists of HZ’s reactivity and subsequent
Hemozoin: A Paradigm for Biominerals in Disease

Figure 5  Hemozoin-mediated lipid peroxidation. Redox cycling of iron in complexes like HZ can initiate lipid peroxidation of fatty acids like arachidonic acid (15-HETE). Abstraction of the bisallylic hydrogen leaves an unpaired electron on the methylene carbon that can rearrange to form a reactive alkyl radical (L•). Oxidation of this radical leads to a peroxyl radical (LOO•), and on reduction, forms a lipid peroxide (LOOH) that can undergo additional reactions to yield a variety of secondary oxidation products.

perturbation of the host immune response. HZ reactivity in the modulation of innate and adaptive immunity has been attributed to a range of effects that include toll-like receptor 9 (TLR9) activation, cytokine production, LPO, and dendritic cell development. Recent studies found that the P. falciparum DNA that remained on native HZ extracts was the true source of TLR9 activation, and once native HZ was treated with nuclease, no activation was observed (39). HZ disruption of dendritic cell function was shown to cause a decline in T cell activation that led to a weakened adaptive immune response. The role of HZ as an immunoreactive aggregate may impact the high rates of patient secondary infection as well as the decline in vaccine efficacy.

Functionally, phagocytosis of HZ has been reported to impair macrophage oxidative burst, to downregulate iNOS activation, and to perturb cytokine profiles in infected patients. It has also been shown to correlate with increased levels of immunomodulatory LPO products such as prostaglandin E2 (PGE2), HNE, and HETEs (40) in monocytes. The biologic activity of these compounds is generally derived from either of two mechanisms. In the first mode of action, the reactive intermediates or products may form adducts to DNA or proteins. Thus, a variety of
chain-terminating reactions of peroxy, alkyl, or epoxyperoxyl radicals can result in oxidative cross-links to DNA or proteins. Furthermore, the electrophilic alkenals, such as HNE, readily form Schiff-base adducts to lysine residues and Michael addition adducts to histidine and cysteine residues to perturb the function of many proteins (41). In the second mode of action, the LPO products may act as alternate ligands to sever-eral different proteins and receptors to initiate an ultimately pathogenic signaling cascade. The hydroxylated fatty acids 9- and 13-HODE, as well as 15-HETE have all been found to be activators of the important nuclear receptor protein PPAR-γ, which is involved in key cellular regulatory and differentiation functions in monocytes (42). 15-HETE has also been found to stimulate RBC adherence to capillary endothelia, to enhance vascular permeability and edema, and to induce chemotaxis and chemokinesis, although the precise pathways remain unclear. From these examples, it is easy to imagine how such promis-cuous reactivity often manifests itself in the pathogenesis of disease states. These findings suggest that HZ’s ability to rec-tify cellular responses may actually be caused by formation of primary and secondary LPO products (40).

To study this hypothesis, BH was incubated with ghost RBC membrane lipids, which are similar to those that the native biomineral would be exposed to upon RBC rupture (40). RAW macrophage-like cells were treated with the supernatant of this reaction, and reactive oxygen and nitrogen species (ROS and RNS) produced via the NADPH oxidase and iNOS pathways were inhibited. The levels of inhibition paralleled the effects of individual LPO products such as 15-HETE or HNE at patologically reported concentrations. Additionally, treatment of cells with either BH or unreacted ghost supernatant did not result in a decrease in ROS and RNS production, which indicates that the products of HZ-mediated LPO were responsible for the observed disruption of macrophage function, not the dimeric home component of the aggregate itself (40). Mechanisms for such material host-pathogen interactions and, more broadly, biomineral-to-cell relationships are primarily undefined, which creates a significant treatment barrier. Unraveling the formation and role of HZ in the infection may provide additional insight into the prevention and treatment of a variety of diseases that result from pathogenic biominerals.

Summary

Biomineralization results in an expansive array of complex ma-terials. These natural biominerals often represent unique crystal forms that extend over several size domains that are synthesized under ambient conditions. Increasingly, it is understood that biomineralization processes play important roles in the patholo-gies of several diseases. In malaria, the parasite forms the HZ biomineral in response to the heme released during hemoglobin catabolism. HZ serves an important detoxification role that al-lows the organism to maintain homeostasis during its intraery-throcytic phases. Despite the fact that HZ represents a validated drug target for P. falciparum, many fundamental questions re-main concerning its formation; questions such as how or if the parasite assembles neutral lipid droplets specifically, how the home is transported and deposited in these lipid domains, and whether new strategies exist that could be used to design drugs to disrupt this process. Tackling the rational drug design prob-lem from a crystal engineering perspective offers an enticing direction for drug discovery, whether designing crystal-specific antibodies or fabricating selectively binding compounds. Con-sequently, studies on the in vivo formation of HZ afford an opportunity for chemists with a variety of interests (e.g., or-ganic, inorganic, biologic, supramolecular, materials) to make significant contributions in attacking this neglected and devas-tating disease.

A second, emerging area of research is the pathophysiologic responses between biominerals and immune cells. A common-ality between the diseases that maintain a pathogenic biomineral is the inflammatory response. Be it an auto immune reaction, as in the case of gout, or down regulation of the innate im-mune system as in malaria, it is clear that the interface between biominerals and cells is important in mitigating these responses. In the case of HZ, growing evidence suggests that the bimini-eral reacts with cellular fatty acids to produce a suite of reactive oxidized eicosanoids. The immunoreactivity of these oxidation products is likely a significant contributor to the inflammation and discomfort experienced by patients. Developing therapies for these effects and for the cause of infection could provide a dual approach in the treatment of many pathogenic bimin-erals and proffers the potential for novel initiatives in disease prevention and treatment.

Hemoglobin: A Paradigm for Biominerals in Disease

Hemoglobin is a complex protein found in red blood cells that transports oxygen throughout the body. It is composed of four polypeptide chains, each containing a heme group. The heme group is a porphyrin ring with an iron atom at its center, which binds oxygen. In disease, hemozoin (a form of heme) can be produced, which may play a role in various pathological processes.

Hypoxic Response and Associated Diseases

Emily Flashman, Christoph Loenarz, and Christopher J. Schofield, Chemistry Research Laboratory and Oxford Centre for Integrative Systems Biology, Mansfield Road, Oxford, U.K.

doi: 10.1002/9780470048672.wecb232

Animals must respond efficiently to changes in oxygen levels. This response is achieved via oxygen-dependent regulation of a heterodimeric hypoxia-inducible transcription factor (HIF), which enables upregulation of genes that assist in the hypoxic response. Posttranslational hydroxylation of the HIF-α subunit at either of two conserved prolyl residues enables binding to the von Hippel–Lindau protein elongin C/B complex that targets HIF-α for degradation via the ubiquitin proteasome pathway. Hydroxylation of an asparaginyl residue in the C-terminal transcriptional activation domain of HIF-α blocks its interaction with the transcriptional coactivator p300. The HIF prolyl and asparaginyl hydroxylases are oxygen dependent; therefore, their regulation of HIF directly links changes in oxygen concentration and the physiological response to hypoxia. The hypoxic response is implicated in a range of disease states, including cancer, ischemia, and heart disease. Manipulation of the HIF system for therapeutic advantage is therefore an area of medicinal interest.

In the late nineteenth century, François Viault observed that red blood cell production increased as humans moved from sea level to high altitude (1). The mechanism by which this response to an environment of limiting oxygen is induced has been a long-standing problem in physiology. A breakthrough in molecular understanding came when Semenza et al. (2) identified a transcription factor, hypoxia-inducible factor (HIF), which is responsible for the regulation of erythropoietin (EPO). EPO is a primary modulator of red blood cell production and therefore oxygen capacity in mammals, and consequently it is upregulated in conditions of hypoxia (3). An enhancer region upstream (5’) of the EPO gene was identified and was found to bind HIF in an oxygen-dependent fashion (2, 4). HRE sequences have subsequently been found upstream of numerous genes that are upregulated in response to hypoxia, including those involved in erythropoiesis, angiogenesis, metabolism, and cell growth (5). This review summarizes research on the HIF system with a focus on our current understanding of the chemistry that determines how the HIF system senses changes in oxygen availability.

Overview of the HIF System

HIF is an α,β-heterodimeric transcription factor whose transcriptional activity is regulated via its oxygen-dependent, posttranslational hydroxylation. In the presence of sufficient oxygen, HIF-α in humans is hydroxylated in both its oxygen-dependent degradation domain (ODDD) and its C-terminal transactivation domain (C-TAD). Prolyl-4-hydroxylation in the ODDD allows HIF-α to bind to the von Hippel–Lindau protein elongin C/B complex (VCB), which targets HIF-α for degradation via the ubiquitin proteasome pathway. Asparaginyl hydroxylation at the C-TAD prevents HIF-α interacting with the p300 protein, which is part of the transcriptional coactivator complex for HIF target genes. All four identified human HIF hydroxylases are Fe(II)– and 2-oxoglutarate (2OG)-dependent oxygenases with an absolute requirement for oxygen as a cosubstrate. When oxygen availability is limited, HIF-α hydroxylation is incomplete or absent. HIF-α can then dimerize with HIF-β, interact with the transcriptional coactivator complex via p300 binding, and bind to conserved pentanucleotide hypoxia response elements (HREs: TAGTC) to promote transcription of genes that enable a response to the challenge of hypoxic conditions. An overview of the HIF regulatory system is shown in Fig. 1.
Hypoxic Response and Associated Diseases

Figure 1 Overview of the HIF dual regulatory system. In the presence of oxygen (O2), the HIF-α subunits are downregulated and inactivated by active HIF hydroxylases—the PHDs and FIH, respectively. The PHDs catalyze hydroxylation of HIF-α prolyl residues, which enhances binding of HIF-α to the von Hippel-Lindau tumor suppressor complex (VCB) ∼1000-fold and enables subsequent ubiquitin-mediated proteasomal degradation of HIF-α subunits. FIH catalyzes hydroxylation of an HIF-α asparaginyl residue; this substance blocks p300 coactivator recruitment and results in transcriptional inactivation. Limiting oxygen levels (hypoxia) reduce HIF hydroxylase activity. This limitation permits heterodimerization of HIF-α with HIF-β subunits, translocation into the nucleus, and recruitment of transcriptional coactivators including p300. Subsequent binding to HREs on HIF target genes upregulates their transcription, enabling the body’s hypoxic response.

HIF-α/β and Its Interaction with DNA

Both α and β subunits of HIF are basic helix-loop-helix PAS proteins (HIF-1α/β) (6, 7), as observed in other transcription-factor proteins (Fig. 2). The short, basic region of HIF-1α/β proteins is directly responsible for DNA binding, and the adjacent helix-loop-helix domain allows dimerization of the two HIF subunits after translocation of HIF-α to the nucleus. The PAS domain (PAS-A/PAS-B/PAS-C, PAS: PER (periodic circadian protein), aryl hydrocarbon receptor nuclear translocator (ARNT), single-minded protein (SIM) (7); PAC: motif C-terminal to PAS motifs) is involved in more specific interactions between the two subunits (for review see Reference 8). It is proposed that the specific interaction between the HIF-α and HIF-β subunits promotes folding and dimerization of the HIF-α region that enables subsequent DNA binding (8). HIF-α is a Class I bHLH-PAS protein, which means that it can homodimerize and heterodimerize; HIF-β (also known as ARNT, which is a ubiquitously expressed protein) is a Class I bHLH-PAS protein, which heterodimerizes with Class I bHLH-PAS proteins (6, 9). The general PAS domain structure comprises a central β-sheet region flanked by several α-helices; NMR and mutation studies on HIF-1α have identified a hydrophobic region on the β-sheet as being responsible for the specific interaction with HIF-β, as well as homologous interactions between other PAS domains (10).

High-resolution structural data are not yet available on the interaction between the HIF heterodimer and the HRE. Interactions between bHLH proteins and DNA have shown that a conserved His-Glu-Arg triad in the bHLH binds in the DNA major groove (11). Modeling studies predict that the HIF-β domain binds to HREs in a similar fashion. HIF-α, however, only retains the Arg residue of this conserved triad, and the interaction of HIF with DNA is predicted to be mediated by other residues, specifically a serine and two alanines (12). These proposals are supported by mutagenesis studies (13).

HIF-α contains a large, central regulatory region. The oxygen-dependent degradation domain of HIF-α contains two sites of...
HIF-1α forms (31, 32). HIF-1α transcription is under hypoxia (30), and two variants that include HIF-1α compared with the intensively investigated HIF-1/2 isoforms. Three isoforms of HIF-1β (ARNT, ARNT2 (21), and ARNT3 (22)) exist; HIF-1α lacks the C-TAD that exists in both HIF-1α isoforms as it apparently has no subunit (23). mRNAs levels of HIF-1α are not affected by oxygen levels (7, 24, 25), but levels of HIF-1α mRNA increased after two hours of hypoxia (26, 27).

Additional interactions mediated by p300/CBP, as well as other coactivator mechanisms (15), are then responsible for optimal target gene expression.

### Types and Roles of Different HIF-α Isoforms

Three isoforms of HIF-α [HIF-1α, HIF-2α (endothelial PAS domain protein), and HIF-3α] have been defined in humans and are encoded by distinct loci (19, 20). HIF-1α and HIF-2α are more important than HIF-3α in the hypoxic response. Three isoforms of HIF-α (HIF-1α [ARNT], ARNT2 (21), and ARNT3 (22)) exist; HIF-1α (ARNT) is the most common form. Each HIF-α isoform can interact with any HIF-β subunit (23). mRNAs levels of HIF-1α, HIF-2α, and HIF-3α are reportedly not affected by oxygen levels (7, 24, 25), but levels of HIF-1α mRNA increased after two hours of hypoxia (26, 27).

HIF-1α and HIF-2α have the same domain architecture and common mechanisms for DNA binding, dimerization, oxygen-dependent degradation (NODD and CDDD domains), and transcriptional activation. The sequences of these domains are related closely but contain differences that may have functional consequences (e.g., with respect to HIF hydroxylation selectivity). The interdomain sequences are related less closely, and the differences may enable differential binding of regulatory proteins to HIF-1α and HIF-2α. HIF-3α is more markedly different from the other two HIF-α isoforms and apparently has no functional NODD domain, and only the CDDD domain within the N-terminal TAD has been identified. Additionally, HIF-3α lacks the C-TAD that exists in both HIF-1α and HIF-2α (28). Relative little is known about the importance of HIF-3α as compared with the intensively investigated HIF-1α isoforms.

Five HIF-1α splice variants have been reported (29). These variants include HIF-1α56, which lacks the C-TAD but not the C-terminal nuclear localization signal (NLS) and is transcriptionally active under hypoxia (30), and two variants that lack the C-terminal ODD and act as dominant negative isoforms (31, 32). HIF-3α has at least six different splice variants (HIF-3α 1–6), of which only HIF-3α 1–3 contain the ODD domain (33). HIF-3α negatively regulates HIF-mediated gene expression in murine comea by dimerizing with HIF-1α in the cytosol, maintaining an avascular phenotype under hypoxia (34), but it is upregulated by HIF-1α, which represents a negative feedback regulatory circuit (35).

Both HIF-1α and HIF-2α genes are expressed widely in human tissues but with different patterns of expression both in terms of organs and individual cell types within organs. For example, both HIF-1α and HIF-2α are expressed abundantly in the kidney but in breast cancer cell lines, HIF-1α is the major isoform that is hypersponically induced (36). Importantly, HIF-1α and HIF-2α seem to have different profiles with respect to the genes that they regulate. Expression of carbonic anhydrase IX seems to be predominantly regulated by HIF-1α, whereas erythropoietin is predominantly regulated by HIF-2α (37, 38). HIF-1α and HIF-2α null mice also give different phenotypes that support proposals of different roles for the two isoforms (39–42). An important objective is to develop a molecular understanding of how the selectivity, which is apparent in terms of the different expression profiles for HIF-1α and HIF-2α, is achieved.

### The Role of Hydroxylation

The direct interface between HIF-α regulation and oxygen is its posttranslational hydroxylation. In humans, in addition to constituting the crucial step in mammalian oxygen homeostasis (43), hydroxylation seems to be special (to date) amongst post-translational modifications (PTMs) in that only a single atom is incorporated, as compared with other additive PTMs that entail sterically more demanding groups such as phosphorylation, acetylation, glycosylation, and ubiquitylation (44). The dependence of HIF-1α stability on oxygen was demonstrated by the hydroxylation-dependent von Hippel-Lindau protein (pVHL) capture of HIF-1α peptides, which gradually increased in vivo from ambient to hypoxic oxygen levels (45). In normoxia, HIF-1α protein is hydroxylated at Pro402 (in the N-terminal ODD) and/or Pro564 in the C-terminal ODD. Both prolyl hydroxylation sites from part of a conserved motif, LXXLAP (14). Prolyl hydroxylation results in binding of pVHL and rapid degradation by the proteasome (46, 47). Under normoxia, HIF-α is thus essentially not detectable (7). The affinity of HIF-α ODD peptides for VCB increases about 1000-fold by trans-4-prolyl hydroxylation (48). Crystallographic analyses have revealed that the optimal arrangement of the new hydroxyproline alcohol group stabilizes a hydrogen bonding network in VCB between Ser111 and His115 of pVHL (Fig. 3) (48, 49). Notably, the precise positioning of the hydroxyl group may be induced by the stereoelectronic gauche effect within the vicinal N-C=C-OH arrangement, as the pyrrolidine ring of hydroxyproplyl 364 was observed in the C=C exo conformation. This conformation is the same as in collagen, in which hydroxyproplyl residues serve to stabilize the triple helix (50); a deficiency of collagen prolyl-hydroxylation leads to the disease scurvy (51). The α-domain (residues 155–213) of pVHL binds to elongin C, which nucleates a complex that contains elon- gig B, cullin-2 and Rbx1, forming the VCB-Cul2 RING-type E3 ubiquitin ligase (52). Provided oxygen is not limiting, the
that Asn803 is part of an activator complex CBP/p300 (17, 28, 57). NMR studies indicate that the hydrophobic parts of the K349 and R350 side chains. Additionally, a deeply buried in the protein–protein interface, packed against I353 and at N803 abrogates its binding to the p300 CH1/TAZ1 domain. N803 is deeply buried in the protein–protein interface, packed against I353 and the hydrophobic parts of the K349 and R350 side chains. Additionally, a network of N803 side-chain hydrogen-bonding interactions including the medicinally important 2-histidine-1-carboxylate motif, which is characteristic of this enzyme family.

### The HIF Hydroxylases

The enzymatic, posttranslational prolyl and asparaginyl hydroxylation of HIF-α was found to be dependent on oxygen and Fe(II), enhanced by ascorbate, and inhibited by 2OG analogs (28, 62–64), all suggestive of the enzymes responsible being part of the large family of Fe(II)- and 2OG-dependent oxygenases. This finding led to the identification of three human HIF prolyl hydroxylases (PHDs or EGLNs 1-3) and FIH (factor inhibiting HIF) as the enzyme that catalyzed asparaginyl hydroxylation (45, 65). These substances all contained the iron-coordinating 2-histidine-1-carboxylate motif, which is characteristic of this enzyme family.

The Fe(II) and 2OG-dependent oxygenase family is a subset of the nonheme iron (II)-dependent oxygenases, and they catalyze a wide range of oxidative reactions, often involving cleavage of an otherwise unreactive C–H bond. Examples of reaction types catalyzed by this class of enzymes include oxidative cyclization, epimerization, desaturation, C–C bond cleavage, ring fragmentation, and hydroxylation (for reviews see References 66 and 67). These reactions are often not reproducible in nonenzyme catalyzed reactions. The enzymes and the substrates on which they act are found throughout nature.

In plants and bacteria, they are known to act on small molecule substrates, for example, TauD in Escherichia coli can desulfonate taurine to provide a source of sulfur for growth (68) and anthocyanidin synthase in plants catalyzes a desaturation step in flavonoid biosynthesis (69). The enzymes also play a role in the biosynthesis pathways of antibiotic production, including the medicinally important β-lactam antibiotics (70), and can catalyze chlorination of C–H bonds (71). In higher organisms, Fe(II)/2OG-dependent oxygenases have been found to be involved in important biological processes such as DNA repair (e.g., ABH2/3 (72)) and collagen biosynthesis. Recently, a protein linked to increased fat mass in humans (FTO) has been found to be a Fe(II)/2OG-dependent oxygenate, catalyzing DNA demethylation (73).

#### Catalytic activity of the HIF hydroxylases

A consensus mechanism for the Fe(II)/2OG-dependent oxygenases has been proposed (Fig. 4). In most cases, iron is coordinated octahedrally at the active site by two histidines and the carboxylate group of a glutamate or an aspartate residue. The other three coordination positions are occupied by ligated water molecules. 2OG binds to the active site by ligating in a bidentate fashion to two coordination positions on the Fe(II) (replacing two water molecules) via its 1-carboxylate and 2-oxo...
groups. Binding of substrate (close to but not in contact with the Fe) causes a conformational change that results in alteration of the Fe(II) geometry to five-coordinate square pyramidal, and the last bound water molecule is released. This binding leaves a position free for an oxygen molecule to ligate to the Fe(II), possibly occupying the position whereby it is directed toward the target substrate. The reaction then seems likely to proceed via an Fe(III)-superoxo species, which attacks the 2-oxo group of the 2OG (susceptible to such an attack as it has been activated by the Lewis acidity of the Fe) to form a peroxide. This compound can then collapse to form carbon dioxide, iron coordinated succinate, and a highly reactive Fe(IV)-oxo species. This ferryl-oxo species is positioned adjacent to the target C–H bond such that either direct insertion of oxygen into the C–H bond occurs or the hydrogen atom is abstracted. Then, rapid rebound of the hydroxyl group is generated onto the carbon radical. Hydroxylated substrate and succinate are released from the enzyme active site, and the vacant coordination positions are once again occupied by water molecules.

Evidence to support this proposed mechanism comes from a variety of sources. The crystal structure of a cephalosporin synthase (74) showed the coordination of Fe(II) and 2OG at the active site before addition of oxygen or substrate. These complexes have subsequently been observed in multiple other structural studies (reviewed in Reference 66). EPR, circular dichroism, and UV-Vis spectroscopy studies on TfdA and CAS2 also confirmed the six-coordinate nature of the active site in solution, and they demonstrated the loss of water molecules and change in coordination environment promoted by substrate binding (75–77). Generation of data to support the later stages of the proposed reaction mechanism were more challenging, as the species involved are highly reactive and consequently unstable. Breakthrough experiments carried out on TauD however managed to demonstrate the existence of the postulated Fe(IV)-oxo species using rapid stopped-flow UV-Vis and freeze-quench Mossbauer and EPR techniques (78). The same species was later observed in a viral prolyl hydroxylase (79), which supports the hypothesis that this species is indeed the key reactive intermediate in a conserved mechanism of these enzymes.

The mechanism of the HIF hydroxylases is likely to be similar to the consensus mechanism of the Fe(II)/2OG-dependent oxygenases described above. However, the role of these particular enzymes as oxygen sensors means that their mechanism of action is of interest, particularly in terms of their dependence on oxygen. Although the intermediates in the reaction cycles of FIH and the PHDs have not been characterized to date, studies on these enzymes provide clues as to how they conform and/or differ from other enzymes in this family. Steady-state kinetic work has monitored the K_m of these enzymes with respect to their substrates and also to oxygen. These enzymes have found that in terms of oxygen sensitivity, the HIF hydroxylases (at least in an in vitro oxygen consumption assay) do not differ from other Fe(II)/2OG-dependent oxygenases (specifically TauD and PAHX) (80). Different studies are not in agreement as to whether the PHDs are more sensitive to oxygen than FIH, but all studies have reported that these enzymes are suited to their roles as oxygen sensors (80–82). Differences in the range of reactions catalyzed by the PHDs are recognized (e.g., hydroxylating NODD and/or CODD in HIF-1α-3); specific interactions are more or less likely to occur in different cell types and environments (14, 81, 83–91). For example, PHD3 has been shown to be more active on HIF-2α, which is predominantly expressed in the lung, endothelium, and carotid body (19), than on HIF-1α.

Other cellular factors are also likely to influence the catalytic activity of the HIF hydroxylases. Many Fe(II)/2OG-dependent oxygenases are known to require ascorbate for optimal activity, and ascorbate has been shown to affect cellular HIF levels accordingly (92). The role of ascorbate in the reaction cycle is not clearly understood, although one possibility is that it reduces Fe(III) to Fe(II) when 2OG has been decarboxylated in

Figure 4  Proposed outline reaction mechanism for the Fe(II)/2OG-dependent oxygenases.
the absence of prime substrate (uncoupled turnover), as is the case with collagen prolyl hydroxylase (93). Reactive oxygen species have also been proposed to reduce HIF hydroxylase activity, by oxidizing Fe(II) to Fe(III) via the Fenton reaction, decreasing its cellular availability (94). A scorbate may “repair” this situation, thus playing a general role of ensuring maximum availability of active enzyme (94, 95). In the absence of 2OG, ascorbate and Fe(II)/Fe(III) can lead to oxidative damage to the active site of some 2OG oxygenases/realted enzymes (96).

Evidence suggests that elevated levels of the tricarboxylic acid cycle intermediates fumarate and succinate (the latter a product of hydroxylase catalysis) in some tumors may lead to activation of the HIF system via hydroxylase inhibition (97, 98). Both succinate and fumarate are PHD2 inhibitors competing with 2OG for binding to Fe(II) (99, 100).

The interface between NO and the HIF system is complex and requires additional investigation (for review see Reference 101). Under hypoxic conditions, NO inhibits HIF-1α stabilization. However, under normoxic conditions, NO upregulation causes HIF-1α to accumulate. Because NO can act as an oxygen analog binding to 2OG oxygenases (102), it is tempting to speculate that the latter effect is caused by direct inhibition of the HIF hydroxylases. However, the far reaching effects of both NO and HIF on the cell biology mean that additional work is required to dissect the opposing effects of NO under normoxic and hypoxic conditions.

The situation is even more complex in the case of the interaction between reactive oxidizing species (ROS) and the HIF system (for review see References 103, 104). Quantifying the role of ROS, such as superoxide, is difficult because of their reactivity and ability to affect many cellular processes. Good evidence suggests that under stress conditions ROS can regulate HIF, possibly via interaction with the HIF hydroxylases (see e.g., References 94, 105, and 106), but the molecular mechanisms are unclear, as is the relevance of ROS regulation of HIF under normal physiological conditions.

The role of ascorbate, NO, and ROS, as well as other cellular factors, in oxygen sensing is not yet fully clear and requires more investigation. Additionally, other signaling pathways could likely be integrated with HIF regulation as indicated by studies showing that in HIF-1α, Thr-796 phosphorylation blocks A-803 hydroxylation by FIH (107).

Structural studies on the HIF hydroxylases

Since the first crystal structure of IPNS (108), which is an enzyme closely related to the Fe(II)/2OG-dependent oxygenases, structures have been determined for many Fe(II)/2OG-dependent oxygenases, all revealing a consensus core double-stranded β-helix (DSBH) fold or jelly-roll motif (46, 109). Typically this core consists of two four-stranded antiparallel β-sheets, with the major sheet supported by closely packed α-helices. The DSBH core is stabilized even more by internal hydrophobic interactions. The active site and HX/D/E, H iron binding motif reside within this core structure. A additional or varying structural features from the DSBH domain define different structural subfamilies of this class of enzyme (46). Crystal structures of FIH and PHD2 (catalytic domain) have been solved (Fig. 5C 109–112). These structures have shown that both enzymes contain the predicted core DSBH helix, but they belong to two different subfamilies of the Fe(II)/2OG-dependent oxygenases. The C-termini of FIH was shown to be involved in the formation of a functionally important dimer (107), whereas this finding was not the case for PHD2. Although in the absence of substrate, PHD2 crystallizes in a trimeric form, it does not reflect the situation in solution where PHD2 is monomeric (112). The entrance to the active site of PHD2 was also much narrower than that of FIH and other man Fe(II)-2OG-dependent oxygenases. This finding may have functional implications for this particular enzyme (e.g., in terms of the kinetics of substrate binding) and also rationalizes the observed unusually strong interaction with 2OG and iron observed for PHD2 (113). The active sites of the two enzymes show that the iron binding triad is in a similar position; however, the 2OG 1-carboxylate group coordinates to the iron in a different position in the two enzymes. The residues that stabilize the 2OG 5-carboxylate group also differ, which is characteristic of their belonging to different subfamilies of the Fe(II)/2OG-dependent oxygenases. The structure of FIH in complex with its HIF-α CAD peptide substrate shows that during substrate binding, the enzyme undergoes an induced-fit conformational change involving local conformation of specific amino acids that make contact with the substrate (110). Although structural data have not yet been published for PHD2 in complex with its substrate, it is likely that a flexible loop in PHD2 will be involved in NODD and CODD binding, perhaps changing conformation to act as a “lid” over the active site to enclose the substrate within it (112). In both PHD2 and FIH, it is necessary for substrate binding to place the target amino acid close to the active site iron, enabling efficient hydroxylation on oxygen binding.

Structures for the other human HIF hydroxylases, PHDs 1 and 3, are not yet reported, but sequence comparison and modeling studies suggest that they will be very similar to PHD2. The structure and functional implications of the N-terminal region of PHD2, which contains a MADII-like zinc finger (114), which reportedly can inhibit the hydroxylation activity of the catalytic domain, are unknown.

Alternative substrates for the HIF hydroxylases

Alternative substrates may exist for the PHDs; proposed examples include RNA polymerase II and ICB kinase (which is negatively regulated by PHD1) (115, 116). However, unequivocal evidence (e.g., demonstration of hydroxylation by mass spectrometry) has not yet been demonstrated for these proteins. In contrast, FIH has been shown to catalyze hydroxylation of asparaginyl repeat domain (ARD) proteins from the NF-κB (nuclear factor κB) and Notch family at highly conserved asparaginyl residues (117, 118). The ARD is a common protein motif, with over 200 human members of the ARD protein family being predicted. Evidence that ARD hydroxylation occurs frequently in human cells supports the assertion (117, 118) that posttranslational hydroxylation of cytoplasmic proteins in
Hypoxic Response and Associated Diseases

Eukaryotes is actually more common than previously thought (119). The significance of ARD hydroxylation is unclear, and it may serve to stabilize the ARD fold in a similar way that prolyl-4-hydroxylation stabilizes the collagen triple helix (50). ARD proteins were found to compete with HIF-α for FIH binding, and it was thus proposed that the hydroxylation status of the pool of ARD that can interact with FIH regulates the amount of FIH that is "free" to hydroxylate HIF-α (120). Recently, FIH-mediated ARD hydroxylation has been observed in ASB4 (ankyrin repeat and SOCS box protein 4), allowing it to target substrate proteins for ubiquitin-mediated degradation (121) in an oxygen-dependent fashion. This observation indicates that hypoxic regulation by the HIF hydroxylases may extend beyond the HIF system.

Diseases Associated with the HIF System

The hypoxic response plays an important role in mammalian biology (122), and alterations in tissue oxygenation are hallmarks of many human diseases including stroke, heart disease, vascular disease, and cancer (123). Across a range of cancers, observed associations between aggressive phenotypes and micro-environmental hypoxia have focused attention on the molecular dissection of hypoxia pathways (124).

The most direct link (125) between genetic events predisposing to cancer and the HIF system occurs in von Hippel–Lindau (VHL) disease, which is an autosomal dominant inherited cancer syndrome affecting 1/35,000 humans (126). VHL disease is often regarded as a model syndrome among the oxygen-dependent diseases and is characterized by renal cell carcinomas (RCC), as well as tumors in the central nervous system, retina, adrenal glands, and pancreatic islet cells (127); malignant tumors also occur in the inner ear, pancreas, and epididymis (128). VHL syndrome is caused by mutations in the VHL gene that can result either in prematurely truncated protein transcription or in point mutations of specific amino acids. RCC are a common form of kidney cancer, and mutations in both alleles of the VHL gene cause ~80% of sporadic RCC (129). Mutations in the VHL gene affect the function of the pVHL protein, and the resultant disease phenotype has been partly rationalized by crystal structures of the pVHL E3 ligase complex with HIF-α (48, 49). VHL disease is associated with significant stabilization of HIF-α (130), as mutation of pVHL in either its α or β domain results in an inability to recruit other E3 ligase complex subunits or to recognize hydroxylated HIF-α, respectively. HIF overproduction and subsequent overexpression of HIF targets stimulates excessive blood vessel formation and nutrient uptake, which leads to formation of highly vascular tumors (131).

Another disease that develops from VHL mutations is the increase in red blood cell production, or polycythemia, endemic in the Chuvash population (132). The Chuvash disease does not manifest in tumors but is associated with venous abnormalities and a tendency toward arterial thrombosis (133). It is an autosomal recessive disorder in which mutations that affect pVHL (e.g., R200W) result in modulation of the HIF pathway (134–136).

Figure 5

Comparison of the overall structures of FIH and PHD2 (upper panel) and differences in the active site of these enzymes (lower panel). Note the different orientation of the 2OG cosubstrate or cosubstrate analog, relative to the triad of Fe binding residues.
RCC cells show a bias toward relative overexpression of HIF-2α rather than HIF-1α (137, 138), and subsequent inhibition of HIF-2α was shown to be sufficient to suppress tumor growth (129). Consequently, it was proposed that their different transcriptional selectivity of HIF-1α and HIF-2α affects retardation or promotion of RCC tumor growth, respectively; the former promotes expression of proangiogenic factors, whereas the latter activates expression of protumorigenic genes such as cyclin D1, TGF-α, and VEGF (140). Recently, ablation of HIF-2α in mice after birth was reported to result in tumor suppression, suggesting that HIF-2α may be the critical isoform that regulates EPO under physiological and stress conditions in adults (141).

Recent clinical findings underline the proposed role for PHD2 as the key oxygen sensor involved in HIF regulation in normoxic tissues (86). An inherited heterozygous PHD2 P317R was shown to be associated with familial erythrocytosis (142). PHD2 Pro317 is located only two residues from the iron-binding Asp315 in a p-helix and its proximity to P317 R was shown to be associated with familial erythrocytosis (86). An inherited heterozygous PHD2 mutation, R371H, which caused decreased HIF binding and catalytic activity (143).

Changes in the levels of HIF are also associated with a range of other disease states. HIF-1α levels have been reported to increase as an early response to myocardial ischemia in patients undergoing coronary bypass surgery (144). Ischemic tissues induce the production of proangiogenic cytokines that stimulate blood vessel remodeling and growth (145). In elderly patients with atherosclerotic narrowing of blood vessels, these proangiogenic responses are impaired, which can lead to critical limb ischemia (146). Impaired recovery from this ischemia was attributed to age-related impairment of HIF-1α protein expression, as observed in mice: HIF-1α gene therapy was reported to counteract these pathogenic effects of aging (147).

Recently, complex interactions between HIF and proinflammatory signaling cascades have emerged. Oxygen delivery to sites of tissue damage, for example from trauma, inflammation, or infection, may be compromised or insufficient for metabolic demands. Recent work has provided direct evidence for the regulation of the innate immune response by the HIF/p300 pathway (148), and the key pro-inflammatory transcription regulator NF-κB has been linked to HIF-1α-dependent and independent proinflammatory macrophage cytokine release (149). Intriguingly, both ankyrin repeats within the NF-κB repressor IκBα, and the p105 subunit of NF-κB itself have been shown to be posttranslationally hydroxylated by the asparaginyl hydroxylase FH (117) that also hydroxylates HIF-α, blocking interaction with its transcriptional coactivators.

**Therapeutic Possibilities**

Therapeutic possibilities that involve the HIF system may be divided into those that upregulate or those that downregulate HIF target genes or proteins (for reviews see References 150–152 and others). Because strong evidence suggests that HIF-α upregulation occurs in many human tumors (reviewed in Reference 153), downregulation of HIF-α is an attractive anticancer strategy. The HIF target gene VEGF induces angiogenesis and is of particular interest with respect to tumor therapies; it has already been targeted successfully (154).

Several screens looking to identify small molecules that downregulate HIF-α have been conducted (155–157). For example, the mammalian target of rapamycin is involved in protein synthesis, and although it seems to be a generic target, specific inhibitors of this protein have been found to result in lower cellular levels of HIF and are in clinical development as anticancer agents (158). Curcumin, a constituent of the spice and colorant turmeric that has been linked to cancer treatment, has been found to minimize the availability of HIF by promoting degradation of HIF-α (159). Heat-shock protein 90 (HSP90) is known to stabilize HIF-α by binding to the PAS B domain, preventing nonspecific degradation in hypoxia before nuclear translocation (160); HSP90 inhibitors (e.g., geldanamycin) have also been shown to reduce HIF-1α levels (161). Of course, promoting the activity of the HIF hydroxylases would also reduce the availability of HIF: to this end, treatment with 2OG has shown decreased VEGF production and angiogenesis in vitro (162), although it is unclear whether 2OG is likely to be limiting in vivo.

Anticancer drugs can also be designed to prevent HIF from performing its functions, for example targeting the dimerization of the α and β subunits, DNA binding, or preventing HIF from binding to its cotranscriptional activators, specifically p300. Some progress has been made taking advantage of the latter opportunity. For example, the interesting natural product chetomin, which is a disulphide that contains diketopiperazine, blocks binding of HIF-α to p300, resulting in abrogation of the transcription of hypoxically regulated genes both in vitro and in vivo (163). DNA-binding small molecules can also prevent HIF binding to the HRE, which results in decreased VEGF expression in cell cultures (164).

The hypoxic response can also be inhibited using gene therapy, by downregulating either HIF itself or, more specifically, the HIF-target genes such as erythropoietin and VEGF. However, the effects of HIF-silencing are not straightforward, and they do not necessarily correspond with a decrease in tumor size or vasculature (reviewed in Reference 165), as hypoxia-mediated cell death helps impede tumor growth.

EPO is very widely used for the treatment of anemia, which demonstrates the potential for upregulation of HIF target genes in medicine. HIF itself could be directly upregulated; a recent study has successfully shown that adenosine transfer of constitutively active HIF-α was tolerated and shown to improve the condition of humans with peripheral limb ischemia (166). In aging mice, the same treatment resulted in improved blood flow in ischemic tissue (147). Alternatively, upregulation of the HIF-target genes can be therapeutically advantageous, and many studies have involved increasing VEGF levels with encouraging outcomes (reviewed in Reference 167).

Little evidence exists for most individuals that moderately limiting oxygen causes long-term health defects. Thus, the points at which oxygen availability is sensed by the HIF system (i.e., the HIF hydroxylases) are arguably preferred targets for therapeutic intervention. Very good precedent was set for...
targeting metalloenzymes by small-molecule inhibitors (e.g., cyclooxygenases), so significant efforts are being developed toward the generation of HIF hydroxylase inhibitors. The requirement of the HIF hydroxylases for Fe(II) also suggests that competition for binding at the metal site by other metals may be a therapeutic possibility. Indeed, Co(II) ions have long been known to induce the hypoxic response (168). However, this strategy is likely to be nonspecific. Instead, following the demonstration that the 2OG analog, N-oxalylglycine, acts as a PHD inhibitor (45, 169), efforts have focused on identifying other organic inhibitors (45, 169–176). To date, all of those reported likely act as 2OG competitors and chelate to the active site Fe(II). In some cases, inhibitors have been shown to target the HIF hydroxylases in primates, which resulted in reportedly well-tolerated VEGF production (177).

It will be clearly desirable to develop HIF hydroxylase inhibitors that are selective for their targets (e.g., over other 2OG oxygenases). Another important question with targeting the HIF system is to what extent selectivity in terms of modulating the level of specific combinations of HIF target genes is desirable. For some diseases, it may be optimal to mimic the "natural" hypoxic response as closely as possible, whereas for others, possibly anemia, it may be best to target specific genes. The availability of HIF hydroxylase inhibitors as small-molecule probes, together with knockout mouse studies, should help to address questions as to the therapeutic use of targets within the HIF system.

Acknowledgments

We thank the E.P.S.R.C., the Rhodes Trust, the B.B.S.R.C., the Wellcome Trust and the National Institutes of Health for funding. We also thank all members of our laboratory and our close collaborators, especially the Ratcliffe/Pugh group, for their contributions.

Lysosomal storage disorders are a group of over 50 different genetic diseases that result from lysosomal dysfunction. This disruption of lysosomal function can involve either a specific lysosomal hydrolase deficiency, a defect in lysosomal protein processing, or impaired lysosomal biogenesis. To appreciate the pathogenesis of lysosomal disorders fully, it is important to understand the dynamics of endosome–lysosome organelles, their capacity for the uptake and degradation of complex macromolecules, and how lysosomal biogenesis and hydrolisis are altered by substrate storage. The focus of this article will be on recognized lysosomal disorders and what is known about the composition and the function of endosome–lysosome organelles in these diseases. The lysosomal network will be discussed with a view to correlating the main site of endosome–lysosome degradation and the site of substrate accumulation in lysosomal disorders. A major unanswered question for lysosomal storage disorders is how an enzyme deficiency and the resulting storage of undegraded macromolecules impact on cells to cause organ dysfunction and disease.

A patient with possible Hurler syndrome was first described by Berkhan in 1907 (1), and it may be the first report of a lysosomal storage disorder. Nonetheless, the first detailed clinical description of a patient with a lysosomal storage disorder was by Charles Hunter, who described two brothers who are now recognized as having Hunter syndrome (2). Soon after this report, Meinhard von Pfaundler and Gertrud Hurler described Hurler-Pfaundler syndrome, which is now known as Hurler syndrome (3). A more detailed history of syndrome identification and the subsequent recognition of other lysosomal storage disorders have been documented by Whitley in 1993 (4).

In the 1960s, Hers and colleagues (5, 6) recognized that Pompe disease was caused by a deficiency of α-glucosidase and, using electron microscopy, evidence of storage vacuoles was reported. The identification of this enzyme deficiency, together with De Duve and colleagues’ description of lysosomes and their contents (7, 8), led to the concept of “lysosomal storage disorders.” This finding resulted in two seminal publications by Hers and Van Hoof that described “Lysosomes and Storage Diseases” (9, 10). It should be noted that much of the basic knowledge about the cell biology of lysosomes was contributed to strongly by these initial investigations on lysosomal storage disorders.

In 1999, Meikle and colleagues (11) reported the prevalence of lysosomal storage disorders as 1 in 7,700 live births for an Australian study that involved 27 different diseases. Since then, several new disorders have been recognized, and it is now accepted that, as a group, more than 50 different lysosomal storage disorders exist. Moreover, in some populations the prevalence of certain lysosomal storage disorders has been reported to be high, including 1 in 18,500 for aspartylglucosaminuria in the Finnish population (12) and 1 in 3,900 for Tay-Sachs in the Ashkenazi Jewish population (13). This finding led to past speculation that the combined incidence of lysosomal storage disorders may be as high as 1 in 1500 births (14), and more recent estimates suggest this prevalence is approximately 1 in 1000 births (http://www.science.org.au/sats2007/hopwood.htm). Lysosomal storage disorders are now recognized as a substantial group of genetic diseases that result in lysosomal dysfunction, leading to a failure to degrade specific substrates, which then accumulate in endosome–lysosome organelles.

Endosomes and Lysosomes
From early observations, De Duve defined lysosomes as cytoplasmic particles that were associated with a range of acid hydrolases (7). At the electron microscope level, membrane-bound vacuoles or compartments were recognized and shown to contain acid hydrolases that were detectable by cytochemical staining (15). The definitive description of a lysosome (16) includes a membrane-bound organelle compartment that is acidic and
Lysosomal Disorders

contains a range of mature acid hydrolases (e.g., proteases and glycosidases). This organelle represents the most distal compartment in the endocytic pathway (Fig. 1) and is distinct from the prelysosomal compartment and endosomal compartments based on the absence of mannose-6-phosphate receptors (the receptors that are responsible for the targeting and trafficking of soluble lysosomal enzymes; see below). Lysosomes are heterogeneous in size, shape, and composition, and they exhibit high density in organelle fractionation experiments. The lysosome is the most distal compartment for lysosomal enzymes trafficking from the biosynthetic pathway. As defined by Storrie in 1988 (16), the lysosome must be the principal domicile of a “lysosomal protein,” but the presence alone of a lysosomal protein in an organelle structure does not necessarily establish that organelle as a lysosome (for example, lysosomal proteins can also be detected in endosomes and phagosomes).

Lysosomes are now known to be essential organelles involved in the turnover and the reuse of cellular macromolecules such as proteins, lipids, glycoproteins, and glycosaminoglycans. Lysosomes have other diverse functional roles in immune function, pigmentation, signaling, cell adhesion/motility, and membrane repair, and essentially they are a dynamic interface with the extracellular environment. Numerous subcellular events are required for the synthesis and the delivery of functional degradative enzymes to lysosomes and for the assembly of functional lysosomal organelles (17). This process is referred to as lysosomal biogenesis, and the transport of newly synthesized lysosomal proteins proceeds through another set of organelle compartments called endosomes (Fig. 1).

Endosomes mediate the delivery of degradative enzymes from the biosynthetic compartments to both lysosomes and the extracellular milieu and function in the processing and transport of secretory products (Fig. 1). Endocytic organelles are also involved in the internalization and the delivery of material from the extracellular milieu and cell surface to compartments inside the cell (18, 19). These two main intracellular pathways from the biosynthetic compartment and cell surface are convergent (Fig. 1) (20). Other specialist compartments exist within the network of endocytic organelles, which include phagosomes that sequester cytoplasmic material, and organelles for turnover and recycling. This complexity of endosome and lysosome organelles necessitates strict control of targeting and trafficking events. Intracellular traffic between these compartments can occur through specific vesicle formation that involves budding and fusion of membrane to and from different organelles, but other types of transient interaction are possible (see below).

Components of Endosomes and Lysosomes

One crucial role of the membrane that encloses the endosomal and lysosomal compartments is the isolation of the potent acid

![Diagram of intracellular organelles](image)
hydrolyses that are key constituents of these compartments (21). The limiting membrane of lysosomes has proteins involved in membrane structure, compartment acidification (ATPase), ion transport, and vesicular traffic. Approximately 20-30 major polypeptides of molecular mass 15-200 kDa exist in lysosomal extracts, and most of these are highly glycosylated (16, 22). Typically, the mannose-6-phosphate receptors that target luminal lysosomal proteins are absent from the end-stage lysosomal compartment but are present in endosomes. The lysosome is composed of at least 20 known membrane proteins and over 50 luminal lysosomal proteins (22). The 50 or more known lysosomal storage disorders mostly relate to a dysfunction of one or more of the soluble acid hydrolases that are normally involved in macromolecular break-down, which includes proteases, glycosidases, sulfatases, phosphatases, and lipases. However, several lysosomal storage disorders involving membrane proteins, transporters/channels, and altered vesicular trafficking machinery have been recognized (23).

The major lysosomal associated membrane proteins—LAMP-I and LAMP-II—are type-I integral membrane proteins; they have a single membrane-spanning sequence, a highly glycosylated luminal domain, and a short cytoplasmic tail sequence involved in targeting/trafficking (24). Two other major lysosomal integral membrane proteins—LIMP-I/CD63 and LIMP-II—are both type II integral membrane proteins, with four and two membrane-spanning domains, respectively. Newly synthesized LAMP and LIMP molecules traffic via the trans-Golgi network (from the biosynthetic compartment) to endosomal/lysosomal compartments based on either tyrosine (LAMP-I, LAMP-II, LIMP-I/CD63) or di-leucine (LIMP-II)-sorting signals in the cytoplasmic domains of these molecules (25, 26). At steady-state, most LAMP-I and LAMP-II molecules are localized to the limiting membrane of endosomes and lysosomes. However, LAMP-I and LAMP-II are also detected in autophagic vacuoles. A major proportion of LIMP-II molecules are localized to endosomes and seem to have a role in the biogenesis of these organelles (27). LIMP-I/CD63 is primarily localized to the internal membranes of endosomal vesicles of multivesicular bodies and, to a lesser extent, is found at the limiting endosome-lysosome membrane and cell surface. Functionally, LAMP-II has been shown to have an important role in autophagy and seems to have the capacity to compensate for a LAMP-I deficiency (28). The exact function(s) of LIMP-I/CD63 is unclear, but it seems to have a role in immune cell activation, where it is subsequently expressed at the cell surface. LIMP-I/CD63 is a member of the tetrascaran family of proteins (29), which have also been implicated in the control of membrane and cell volume, as well as cell adhesion, cell motility, and antigen presentation.

Specific membrane and membrane-associated proteins also control the organelle traffic and fusion events that are associated with the movement of proteins between different intracellular compartments. Membrane proteins of the secretory and endocytic pathways depend on sorting signals that reside in their cytoplasmic domains. Many proteins exhibit multiple signals that determine their passage along these diverse pathways. Therefore, the steady-state distribution of any given membrane protein is dictated by the specific combination of sorting signals in the protein and the interaction of these signals with specific recognition molecules (26). This intracellular network of organelles and vesicles (Fig. 1) is in constant and dynamic flux.

Glycerophospholipids, cholesterol, and sphingolipids are the essential building blocks for all eukaryotic cell membranes (30). The lysosomal membrane, like other eukaryotic membranes, is composed not only of highly glycosylated proteins but also is enriched in amphiphilic lipids (30, 31). The lipid and protein composition of the lysosomal membrane is believed to be very complex, and this complexity ensures selective degradation such that the lysosomal membranes remain intact. This finding has led to the assumption that at least two distinct pools of lipid exist in the lysosomal membrane (32). Glycerophospholipids are important components of lysosomal membranes, which are involved directly in lipid rafts, and these are involved in both membrane transport and signaling (31). The early studies on the glycosphingolipidoses (a subgroup of lysosomal storage disorders) suggested that aggregates of lipids accumulated as multivesicular storage bodies in lysosomal compartments (33, 34). Notably, cholesterol is normally enriched in the membranes of early endocytic organelles but not in lysosomes.

Targeting of Protein Constituents to Lysosomes

Most lysosomal proteins have either high mannose or complex oligosaccharide side chains that are attached to asparagine residues in the polypeptide at consensus (NXS, NAT sites) where N is asparagine, S is serine, T is tyrosine, and X is any amino acid) glycosylation sites (16, 35, 36). In the case of soluble lysosomal proteins, N-linked glycosylation is attached to the growing polypeptide chain in the endoplasmic reticulum, and this forms the basic structure that is modified to generate the mannose-6-phosphate targeting signal that are involved in targeting these proteins to the lysosome (37). This latter processing event occurs in the cis-Golgi apparatus and involves the enzyme N-acetylglucosamine-1-phosphotransferase, which adds an N-acetylglucosamine-1-phosphate to certain mannose oligosaccharides. The removal of the N-acetylglucosamine residue in the trans-Golgi exposes the mannose-6-phosphate targeting signal that then allows soluble lysosomal hydrolases to interact with mannose-6-phosphate receptors for trafficking to endosomes and delivery to lysosomes (reviewed in References 37–39).

Thus, within the lumen of organelle compartments, integral membrane proteins act as cargo receptors that recruit soluble molecules for traffic within the network of organelles comprising the secretory, endocytic, and lysosomal pathways. For example, the cation-dependent mannose-6-phosphate receptor (CD-MPR; 46-kDa dimer, which requires calcium (40)) and cation-independent mannose-6-phosphate receptor (C1-MPR; 300-kDa, also called the IGF II receptor (38)) are involved in binding soluble lysosomal proteins in the trans-Golgi network for targeted delivery of these enzymes to the endosome.
lysosome system. Mannose-6-phosphate receptors are type I glycoproteins (have a single transmembrane sequence) and recycle between the trans-Golgi network, endosomal compartments, and the cell surface. Surprisingly, this recycling process does not seem to depend on whether the receptor is loaded with ligands (26). Mannose-6-phosphate receptors normally release their lysosomal enzyme cargo molecules in the prelysosomal compartment as a result of the low pH environment (pH 5.0–6.0). The free mannose-6-phosphate receptor is then returned to the trans-Golgi for subsequent cargo delivery. Therefore, lysosomes are defined as acid hydrolase-rich organelles that lack both the CD-MPR and CI-MPR, which distinguishes them from endosomes (42).

Sorting signals that are either lysosine-based (NPXY, YXX; where N is asparagine, P is proline, and X is any amino acid) or leucine-based (DE)XXXL(LI), DXXLL; where D is aspartic acid, E is glutamic acid, L is leucine, I is isoleucine, and X is any amino acid) are found within the cytosolic domains of transmembrane proteins (26). Sorting occurs through coated areas of membranes comprised of proteins such as the adaptor protein (AP) complexes and Golgi gamma ear adaptin (GGA 1–3) proteins, which act to bind targeting motifs (26). The NPXY motif, which is found within a subset of type I membrane proteins, mediates internalization from the plasma membrane alone. The YXX motif is found in the CI-MPR and the CD-MPR, LAMP-1, LAMP-2, and CD63, and it is involved in a wide variety of sorting processes. Positioning of the motif relative to the membrane is also critically important for the recognition of these targeting signals. The YXX–AP-2 interaction is facilitated by a conformational change induced by phosphorylation, which is part of targeting regulation. The dileucine signal (DE)XXXL(LI) found in many type I, type II, and multispansing proteins also binds to AP complexes. The LL and LI motifs exhibit a distinct preference for the complexes that are critical for the fine specificity of targeting. The DXXLL motif is found within several transmembrane receptors, CI-MPRs and CD-MPRs, which cycle between the trans-Golgi network and the endosomes. Mannose-6-phosphate receptors bind the VHS domain of GGA proteins only via this signal, which is regulated by phosphorylation of serine residues. GGA1 and GGA3 also have the DXXLL motif within their hinge regions. Binding the hinge region with the VHS domain invokes an auto-inhibitory effect. Phosphorylation of the GGA serine results in auto-inhibition and transfer of the mannose-6-phosphate receptors from GGA1 to AP-1. Ubiquitin has been shown to be involved in sorting at the cell surface, endosomes, and trans-Golgi network. Endocytic proteins, which include epin, Hrs, and STAM, have a ubiquitin-interacting motif that binds directly to ubiquitin, which suggests that they could act as adaptors for sorting ubiquitinated cargo at discrete intracellular sites (26).

Interaction of Endosomes and Lysosomes and the Site of Substrate Hydrolysis

Many ligands that enter the endocytic pathway via receptor interaction are either sorted for traffic along specific organelle pathways (Fig. 1) or transit to the late endosome where ligands are dissociated from the receptors in the acid pH environment. For lysosomal enzymes, this dissociation event from mannose-6-phosphate receptors allows additional traffic to the most distal element of the endocytic machinery, the lysosomal compartment. A constant flux of membrane proteins seems to occur between late endosomes and lysosomes (43). It has been postulated that lysosomes fuse with endosomes to form a transient compartment that seems to be the major organelle involved in macromolecule degradation [i.e., “the cell stomach” (44)]. This finding implies that lysosomes are effectively a reservoir for acid hydrolases that are then tapped when required, whereas the late endosome is the degradative compartment. Moreover, lysosomal constituents can be recovered from the prelysosomal compartment and reformed as a lysosomal organelle (43). This theory helps to explain the heterogeneity of endocytic organelles, but it is consistent with the initiation of proteolytic/hydrolysis of macromolecules in endosome and prelysosomal compartments. The molecular machinery that mediates these vesicular traffic, fusion, and budding processes is yet to be defined fully. However, studies on a FYVE finger protein localized to early endosomes called Hrs and the endosomal-sorting complex required for transport (ESCRT) have indicated that a group of proteins that recognize ubiquitin motifs are involved directly in endosomal sorting and recruitment of proteins into multivesicular endosomes (45–48).

The mechanism for the transfer of endocytosed material between endosomes and lysosomes has generated many theories, which include maturation of endosomes into lysosomes, vesicular transport between endosomal and lysosomal compartments, transient interaction via channel formation (“kiss and run”), and direct fusion (44). Depending on the cargo involved, all of these mechanisms seem to be used (perhaps in different degrees) to regulate the level of hydrolytic capacity in any given compartment. Thus, lysosomes can interact with not only endosomal compartments but also phagosomes, autophagosomes, and the plasma membrane to effect different functional roles. For a lysosomal storage disorder, this model of lysosomal function would predict that endocytic cargo, such as glycosaminoglycan that is destined for degradation after internalization from the cell surface, would be delivered to a late endosome for degradation. In an attempt to degrade the substrate, lysosomes would either infuse lysosomal hydrolases into the late endosome and/or fuse directly to the late endosome to generate a hybrid organelle. The latter would provide maximum delivery of hydrolases, and a mechanism by which the cell could try to compensate for the reduced catalytic capacity that develops from a hydrolase deficiency. However, a failure to degrade the substrate contents may result in the maintenance of these hybrid endosome-lysosome organelles.
Evidence that the latter model of endosome-lysosome fusion and lysosomal recovery is valid comes from the lysosomal storage disorder mucolipidosis type IV (MLIV), which involves a defect in a Ca\(^{++}\) channel that seems to prevent the retrieval of lysosomes from the hybrid organelle (49). Thus, intra-organellar Ca\(^{++}\) is presumed to be required for the condensation process that leads to lysosomal organelle reform. The trafficking of the glycosphingolipid lactosylceramide is inhibited in MLIV and, in common with other lipids, it may then accumulate inappropriately because of this blockage. In other lysosomal storage disorders that involve a hydrolase deficiency, the failure to degrade intraorganelar substrate(s) may signal an incomplete process of degradation and, in the same way, potentiate the hybrid organelle and lead to the same adverse effects on cell function. Similarly, a defect in the organelle trafficking machinery can also impact on endosome-lysosome degradation to generate similar compartments, which also then accumulate undegraded storage material. Thus, a recent report of a defect in the endosomal sorting complex required for transport (ESCRT-III) machinery (50) impacts directly on late endosomes (multivesicular bodies), which generates compartments with a morphology remarkably similar to that observed in other lysosomal storage disorders that are caused by hydrolase deficiencies (e.g., Sanfilippo syndrome). This finding raises questions about the similarity between the vesicular pathology in different lysosomal storage disorders and whether common points for pathogenesis lead to similar clinical outcome.

Commonalities for Lysosomal Storage Disorders in Terms of Clinical Phenotype and Vesicular Pathology

Most patients with lysosomal storage disorders are born with no clinically obvious signs of disease, but in the severe forms of the disease, onset and progression of symptoms is rapid. In most cases, the severe form of each disorder is devastating (see Table 1) (51, 52) and results in an early death. Lysosomal storage disorders have been classified based on the clinical presentation, substrates stored, or similarities in the defect (53). For the purposes of this discussion, we have grouped some representative examples of lysosomal storage disorders according to the type of defect: mucopolysaccharidosis (defects in glycosaminoglycan degradation), oligosaccharidoses (defects in glycoprotein and glycolgen degradation), sphingolipidoses and lipidoses (defects in glycolipid degradation), and finally protein processing and transport defects (Table 1). Short stature, skeletal dysplasia, coarse facial features, joint problems, visceromegaly, cardiac disease, CNS (central nervous system) pathology, and early death are all common disease manifestations, but these features are not present in all disorders (Table 2). This finding implies that a common mechanism for pathology may occur in some disorders, but some unique features presumably relate to the type of substrate being stored and/or the relative organ distribution and turnover rate of the substrate.

Potentially compartment specific differences exist between each lysosomal storage disorder. For example, in Pompe disease, the storage of glycogen in endosome-lysosome organelles results from sequestration of cytoplasmic material and involves a phagosomal compartment. In contrast, other lysosomal storage disorders involve material that has undergone traffic from different endosome/phagosome compartments. Thus, compartment-specific storage effects may occur, although it may still result in a common molecular mechanism by impact at a certain point in the endosome-lysosome pathway. Some commonalities observed in lysosomal storage disorder pathology may result from substrate being turned over in similar organs. Thus, the rate of substrate turnover will impact directly on the level of storage and thus cell and organ dysfunction.

Primary and Secondary Storage Materials

Most known lysosomal storage disorders result from a single gene defect that results in the reduction of a single catabolic event, and hence the accumulation of a specific substrate. Although this concept is apparently simple, the reality is that the storage of a primary compound can result in a complex cascade of dysfunction (51). Glycosphingolipid substrates such as GM2 and GM3, and unesterified cholesterol can, for example, accumulate after the deposition of undegraded glycosaminoglycans, and this accumulation is evident in the lysosomal storage disorders mucopolysaccharidosis types I, II, and III. Thus, progressive disease manifestations such as skeletal dysplasia, heart disease, and CNS dysfunction may be more the result of this secondary storage than from the primary storage material. In turn, these manifestations may reflect a general disruption to lysosomal dysfunction and account for some commonalities in clinical presentation for lysosomal storage disorders.

Impact of Storage on Vesicular Structure and Traffic

Secondary storage in response to a primary defect and its associated stored substrate suggests a common process of lysosomal dysfunction in some storage disorders. Thus, GM2 and GM3 gangliosides have been observed to not only accumulate in GM2 gangliosidosis, Tay Sachs, and Sandhoff patients, but also in a range of other storage disorders including mucopolysaccharidosis types I, II, and III, and Niemann-Pick type C (54). In these disorders, vesicular structures with characteristic multilamellar inclusions, membrane swirls, and internal vesicles have been observed, which resemble either autophagosome or multivesicular endosome structures (52). Moreover, in mucopolysaccharidosis type III, the storage compartments have been reported to contain different amounts of the primary storage material heparin sulphate, GM2, and GM3 gangliosides (54). In addition, spheron structures that contain ubiquitin have been reported (54). Chloroquine toxicity also results in vesicular structures that have similar morphology, which include whorled inclusions.
### Table 1

A representative sample of 37 known (50 or more) lysosomal storage disorders and the common clinical symptoms observed in these patients at the severe end of the clinical spectrum (adapted from References 51 and 52).

of lipid, multivesicular endosome-like structures and zebra bodies. In turn, this toxicity has been reported to be almost identical to the vesicular pathology in Fabry disease (55). This commonality of vesicular structures and pathology could be explained by the general impact on lysosomal function created by the primary storage material. Although these examples involve an enzyme deficiency and could therefore tend to support this concept, other lysosomal storage disorders involve dysfunction in either membrane transporters or vesicular machinery, and they generate similar vesicular pathology. For example, a defect in the lysosomal transporter mucolipin-1 (the cation channel that is involved in calcium export and necessary for the recovery of lysosomes from late endosome–lysosome hybrid organelles) causes the storage of lipids and gangliosides in enlarged multivesicular lamellar structures. Moreover, a dysfunction of the ESCRT-III vesicular machinery, which results in neuropathology, has also been reported to cause the formation of similar multivesicular structures in a mouse model and these vesicles are almost identical to that reported in a mouse model of mucopolysaccharidosis IIIA (58). Possible explanations for these commonalities in vesicular pathology might therefore include the impact of storage on a critical event in lysosomal function, such as vesicle formation/recovery or vesicular traffic.

**Treatment Strategies and Ability to Correct Residual Pathology**

Treatment strategies are available for lysosomal storage disorders and include hematopoietic stem cell transplantation, enzyme replacement therapy, substrate reduction therapy, chemical chaperones, and gene therapy (recently reviewed in References [57–61]). In practice, however, the clinical spectrum observed in lysosomal storage disorders means that—at the present time—a single therapeutic strategy is unlikely to treat all sites of pathology effectively. Thus, hematopoietic stem cell marrow transplantation is used currently for many patients with neuropathology, but it is not optimal (not effective for some disorders) and has significant risks. Hematopoietic stem cell transplantation is currently recommended for patients at risk of cognitive impairment and has been evaluated in combination with enzyme replacement therapy (62). Enzyme replacement therapy by intravenous infusion is being used for patients at the attenuated end of the clinical spectrum, in some lysosomal disorders (e.g., MPS-I [mucopolysaccharide] (58, 62)), but it is of limited use for the treatment of those disorders with neuropathology. Recently, small molecule therapeutic strategies have been employed as potential alternatives or adjunct treatment strategies (reviewed in Reference 63). For example, substrate deprivation therapy uses small molecule inhibitors to reduce substrate synthesis, whereas enzyme enhancement therapies have been investigated using chemical chaperones (63) to improve the folding of mutant protein and thus enhance the level of residual enzyme activity in patient cells. Both new therapeutic strategies have been investigated in Gaucher disease (64), and substrate reduction therapy is in clinical practice. The complex pathology that can result from lysosomal storage and particularly to clear residual pathology. Thus, in general, the earlier the treatment is implemented the more likely an effective therapeutic outcome will be achieved. The optimum treatment strategy to cure lysosomal storage disorders may be gene replacement therapy, but it is still in the developmental stages and will likely be a long way from widespread clinical practice. Nonetheless, therapeutic strategies that result in significant improvement in the quality of life for lysosomal storage disorder patients are in clinical practice.

Obesity, type 2 diabetes (T2D), lipid disorders, and hypertension are chronic and disabling diseases that afflict hundreds of millions of individuals worldwide. In this article, they are collectively referred to as "cardiometabolic diseases," because they have "common ground." They increase the risk of cardiovascular disease (CVD) morbidity and mortality. Considerable research has been performed to understand the etiology of cardiometabolic diseases and to translate this research into effective treatment paradigms. However, it has been challenging to understand the initiation and progression of cardiometabolic diseases. This difficulty is attributed to the complexities involved in metabolic regulation, a resultant "snowballing" effect, and a downward spiral as disease progresses. The first line of therapy for treating obesity, T2D, and/or dyslipidemia is lifestyle intervention, which can impact significantly on disease and decrease CV risk, but is usually not effective because of lack of patient compliance. Patients are then given a plethora of drugs to treat the individual risk factors. However, new therapies are critically needed, because most patients require multiple drugs, some drugs may treat one CVD risk factor and exacerbate another, and most patients do not meet treatment goals. A "magic bullet" that treats the underlying causes that contribute to cardiometabolic risk has been a longstanding goal but remains elusive. Ongoing research to uncover novel targets holds promise for future therapeutics that might treat multiple facets of cardiometabolic diseases. This introductory review focuses on the epidemiology and etiology of cardiometabolic diseases, current therapies, and future treatment strategies.

It is difficult to separate obesity, type 2 diabetes (T2D), dyslipidemia, and hypertension because they are a consequence of a dysregulation in metabolism, are interrelated, and each might drive disease progression of the other. These comorbidities are usually found as a cluster within patients, but each can occur in the absence of the others. Lifestyle (high caloric intake, low physical activity, and cigarette smoking) along with a genetic predisposition result in alterations in metabolism that lead to cardiometabolic diseases and increase the risk of CVD. The multiple factors that contribute to CVD are summarized in Fig. 1 (1). Recent studies have provided insight into the mechanisms by which metabolic abnormalities impair insulin-receptor signaling, trigger inflammation and endothelial dysfunction, and increase CVD risk. This finding might provide new opportunities to treat the multiple risk factors that result in insulin resistance and cardiovascular disease. (Author’s note: The author recognizes that numerous "landmark" studies have been published that have contributed to the understanding of cardiometabolic diseases, but she has chosen to reference newer publications and review articles in this introductory overview. Also, a list of abbreviations is provided at the end of this review.)

The Global Crisis in Obesity, Diabetes, and CV Risk

CVD is attributed to disorders of the heart and blood vessels, and it includes coronary heart disease (heart attacks), stroke, hypertension, peripheral artery disease, rheumatic heart disease, congenital heart disease, and heart failure. On a global perspective, 30% of all deaths are from CVD, which ranks it the number
Obesity

Overweight and obesity occurs when an energy imbalance exists within the body, in which energy intake exceeds energy used, resulting in an increase in body fat. The cause of an energy imbalance for each individual may be different, and it is the result of interplay between environmental and genetic factors, which makes it a complex disease to understand and treat. Although some societies might be more genetically prone to obesity, changes in environmental factors, particularly the quantity and quality of food consumed and a sedentary lifestyle, are the key drivers for the global obesity epidemic (3).

For adults, overweight and obesity are easily defined by the body mass index (BMI). This value is calculated from a person’s weight in kilograms divided by the square of the person’s height in meters (kg/m²); conversion tables are available for body weight in pounds and height in inches. An adult who has a BMI between 25 and 29.9 is considered overweight; an adult who has a BMI of 30 or higher is considered obese (4). Estimates of overweight and obesity for children and adolescents take age and gender into consideration.

Diabetes

Epidemiologic studies have established a strong relationship between obesity and the risk for T2D (8, 9). Therefore, because of the obesity epidemic, diabetes rates are soaring. WHO data indicate that over 240 million people have diabetes worldwide; the number is expected to reach 380 million by 2025 (5). The five countries with the largest numbers of people with diabetes are India, China, the United States, Russia, and Germany. For the U.S. population, 20.6 million people or 7% of the population have diabetes. Adults with diabetes have heart disease and risk of stroke about 2 to 4 times higher than adults without diabetes (10, 11). The CDC reports that diabetes is the sixth leading cause of death among adult Americans, and that two thirds of diabetics die from CVD and stroke (6). Diabetes is the major cause of renal disease, adult blindness, and lower-limb amputation. The economic burden of diabetes in the United States totals $174 billion annually; this figure has increased by 32% since 2002 (12).

Diabetes can manifest in several forms, and this review will focus on T2D, which affects 90–95% of all diabetics. (For an overview of diabetes diagnosis, classification, and standard of care, see References 12–15.) T2D is a metabolic disorder resulting from an interplay between environmental and genetic factors, which makes it a complex disease to understand and treat.
that is attributed to a defect in the secretion of insulin by the β-cells of the pancreas in response to metabolic signals, combined with the inability of cells to respond to insulin (i.e., insulin resistance), which results in impaired nutrient uptake and use and increased hepatic glucose output (Fig. 2). T2D is considered a “silent” disease, which progresses over decades, and it is usually diagnosed after a complication is evident or a cardiovascular event occurs.

A biopsy studies in humans have indicated that a curvilinear relationship is observed between β-cell mass and fasting blood glucose concentration, and a steep increase in blood glucose concentration is associated with β-cell deficiency (16). The data have provided research incentives focused on restoring β-cell mass to reverse diabetes or preventing diabetes by protection of β-cell mass. Abnormalities in β-cell function are therefore critical in defining the risk and development of T2D, particularly in obese subjects (17). The adipose tissue of obese individuals releases high levels of nonesterified fatty acids (NEFA), glycerol, hormones, proinflammatory cytokines, and other factors that increase insulin resistance (Fig. 2). When insulin resistance is accompanied by impaired insulin secretion by β-cells, blood glucose levels are not controlled, which results in overt diabetes.

Diabetes is diagnosed by a Fasting Plasma Glucose Test (FPG) or an Oral Glucose Tolerance Test (OGTT) (18). A FPG level of ≥ 126 mg/dL indicates diabetes. In the OGTT test, a blood glucose level 2 hours after drinking a glucose solution of ≥ 200 mg/dL indicates diabetes. A stable measure of long-term glucose status is to determine the percent of a glycosylated isoform of hemoglobin in blood (termed % HbA1c), which is a slowly turning over protein within the body that is modified by high blood glucose. Current treatment guidelines are to reduce HbA1c to <7% (13), because it reduces the patient’s risk of developing microvascular complications (nephropathy, retinopathy, and neuropathy) as well as macrovascular disease (cardiovascular disease and stroke) (19).

Dyslipidemia and hypertension

Abnormal circulating lipids (i.e., high LDL concentration (LDLc), low HDL concentration (HDLc), hypertriglyceridemia, Lp(a), and small dense LDL), and hypertension are strongly associated with CVD risk (2,20–22). These lipids are often found in obese and/or diabetic patients. Data from the Framingham Heart Study is used to estimate a person’s 10-year risk for “hard” CHD outcomes (myocardial infarction and coronary death), in which risk is calculated based on age, gender, total and HDL cholesterol, systolic blood pressure, and whether the individual is on blood-pressure-lowering medications or is a smoker. Numerous primary and secondary intervention studies have shown that improving lipid profile and lowering blood pressure significantly reduces disease morbidity and mortality (22, 23). Improved control of blood lipids in diabetics can reduce cardiovascular events by 20–50% (15, 24). In addition to lipids and blood pressure, inflammation and a procoagulant and prothrombotic state are additional CVD risk factors that need to be addressed, particularly in obese and insulin-resistant patients (25, 26). Results from a subgroup analysis of the Pravastatin or Atorvastatin Evaluation Trial (PROVE IT) (27) showed that intensive lipid-lowering intervention significantly reduced acute coronary events in diabetics, but most patients did not reach the dual goal of LDLc <70 mg/dL and high sensitivity C-reactive protein <2 mg/L. (CRP is an inflammatory marker associated with CV risk). The data highlight the need for additional strategies in this high-risk group, particularly those that target inflammation.

Figure 2 Model for the critical role of impaired insulin release in linking obesity with insulin resistance and T2D. Impaired insulin secretion results in decreased insulin levels and decreased signaling in the hypothalamus, which leads to increased food intake and weight gain, decreased inhibition of hepatic glucose production, reduced efficiency of glucose uptake in muscle, and increased lipolysis in the adipocyte. These results lead to increased plasma NEFA levels. The increase in body weight and NEFA contribute to insulin resistance, and the increased NEFA suppresses the β-cell’s adaptive response to insulin resistance. The increased glucose levels together with the elevated NEFA levels can synergize to affect β-cell health and insulin action adversely, which is often referred to as “glucolipotoxicity.” From Reference 17, with permission.
Metabolic syndrome versus additive cardiometabolic risk factors

Cardiometabolic diseases may present as separate diseases but more often cluster within patients. Because of this clustering, the concept of "The Metabolic Syndrome" (also termed insulin resistance syndrome or syndrome X) has been put forth. Several definitions of the Metabolic Syndrome are available, with the overall viewpoint that multiple interrelated risk factors increase the risk for atherosclerotic cardiovascular disease and increase the risk for T2D. Guidelines to define the metabolic syndrome have been developed by the WHO, National Cholesterol Education Program-Adult Treatment Panel (NCEP-ATP), and International Diabetes Federation (IDF), which are reviewed in Reference 28. Each definition includes traditional risk factors: obesity and an abdominal fat distribution, insulin resistance, diabetes, dyslipidemia (high TG, low HDL) and hypertension.

Shown in Table 1 are the new IDF definition (29) and the revised National Cholesterol Education Program-Aduit Treatment Panel III (NCEP-ATP IIII) definition (30), which are the most widely used. Each definition has its strengths and weaknesses, and both groups are working toward harmonizing criteria (31).

According to CDC statistics that use the NCEP criteria (32), the metabolic syndrome is found in 20% of the U.S. adult population. Its prevalence increases with aging, and it is highest in Hispanic women with 35% prevalence. According to the WHO, 25% of the world's population and at least two thirds of diabetics have the metabolic syndrome. Considerable evidence suggests that the metabolic syndrome is a significant predictor of CVD and T2D, and risk increases with increasing number of risk factors (33). However, a recent assessment (34) states that "the Metabolic Syndrome is a stronger predictor of T2D than CHD and it does not predict CHD as well as the Framingham Risk Score," but it serves as a simple clinical tool for identifying high-risk subjects predisposed to CVD and T2D.*

The clinical significance of the metabolic syndrome came into question in 2005, after "A Critical Appraisal of the Metabolic Syndrome" that was jointly written by the American Diabetes Association (ADA) and the European Association for the Study of Diabetes (EASD) (35). These organizations questioned the clinical value of diagnosing the metabolic syndrome, stating that CV risk is not greater than the sum of the individual risk factors, and treatment of the syndrome is no different than the treatment for each of its components. Their recommendation was to continue efforts to understand the relationships of risk factors that contribute to CVD. Numerous rebuttals to the ADA/EASD statement have been given, particularly by the American Heart Association (AHA) (36). In 2007, the AHA and ADA jointly issued a publication that attempted to harmonize the recommendations of both organizations where possible, and recognized areas where they differ (24). Overall, it is feasible that common ground will be reached in the near future.

**Underlying Mechanisms that Lead to Insulin Resistance and CVD**

Chronic excessive nutrient intake leads to the deposition of fat, in not only its normal storage site, which is the adipose tissue, but also in liver and skeletal muscle. Nutrient excess also triggers an inflammatory response, with the release of inflammatory cytokines (tumor necrosis factor-alpha (TNF-α), interleukin-6 (IL-6), and CRP). These inflammatory mediators, along with the intracellular accumulation of lipid metabolites, lead to impaired insulin receptor signaling and defective metabolism in skeletal muscle and liver (37, 38). Nutrient excess also damages cells by generating reactive oxygen species, which results in not only its normal storage site, which is the adipose tissue, but also in liver and skeletal muscle. Nutrient excess also triggers an inflammatory response, with the release of inflammatory cytokines (tumor necrosis factor-alpha (TNF-α), interleukin-6 (IL-6), and CRP). These inflammatory mediators, along with the intracellular accumulation of lipid metabolites, lead to impaired insulin receptor signaling and defective metabolism in skeletal muscle and liver (37, 38). Nutrient excess also damages cells by generating reactive oxygen species, which results

**Limitations:** Central obesity is required, criteria and cutoff values might need to be further defined

*Information was obtained from References 29 and 30.

* Central obesity not necessary if three of the other risk factors are present.
in protein modifications and in the depletion of nitric oxide that maintains vascular tone. These changes lead to cell dysfunction, alterations in blood lipids, elevated blood pressure, coagulation; fibrinolysis, and additional inflammation, which drive the downward spiral of insulin resistance, endothelial dysfunction, and atherosclerosis (39).

**Metabolic stress and impaired cellular function**

Nutrient excess leads to the intracellular accumulation of long chain acyl-CoA and diacylglycerol, and in the activation of several serine/threonine kinases, which include protein kinase C isoforms, inhibitor of kappa B kinase (IKK), and c-jun N-terminal kinase (JNK) (37). A key step in insulin receptor signaling is the tyrosine phosphorylation of IRS1 and 2, which regulates carbohydrate, lipid, and protein metabolism. The ac-
tivation of several serine/threonine kinases results in serine phosphorylation of IRS1 and 2, which inhibits insulin receptor signaling. The activation of the two principal inflammatory pathways, IKKα/IKKβ and JNK, by nutrient excess and inflammatory cytokines, also impairs insulin receptor signaling and propagates the stress response (37). In skeletal muscle, it results in impaired insulin action on cell metabolism, which includes decreased insulin-stimulated glucose transport and decreased glycogen synthesis, leading to impaired glucose use and hyperglycemia. In the liver, glycogen synthesis is decreased, and gluconeogenesis is stimulated, which results in an increase in hepatic glucose production and hyperglycemia (38, 40).

Recently, the sphingolipid ceramide, which is a product of fatty acyl-CoA, has been identified as the link between excess nutrients (i.e., saturated fatty acids) and inflammatory cytokines (i.e., TNFα), to the induction of insulin resistance. Moreover, ceramide has been shown to be toxic to pancreatic β-cells, cardiomyocytes, and endothelial cells, which contributes to diabetes, hypertension, cardiac failure, and atherosclerosis (41). However, the role of ceramide in mediating insulin-resistance humans is still unclear (42).

The endoplasmic reticulum (ER) is a network of membranes in which secreted and membrane proteins are assembled into their secondary and tertiary structures. The ER seems to be the site for sensing metabolic stress and to translate this stress into inflammatory signals (43). Under certain stress conditions, such as energy excess, lipids, and pathogens, the ER activates a complex response system known as the unfolded protein response to slow down protein synthetic pathways and to restore function integrity to the organelle. Data from experimental models have shown that obesity leads to ER stress, which activates both JNK and IKK, and initiates pathways that trigger inflammation and insulin resistance. In the pancreatic β-cell, ER stress impairs insulin secretion and contributes to progression of T2D.

**Metabolic Diseases, Biological Mechanisms of**

**Inflammation**

Obesity, and particularly the accumulation of abdominal fat, creates an inflammatory milieu that is the key driver of insulin resistance and CVD (44–46). In the normal state, adipose tissue coordinates regulates the synthesis and secretion of peptides that regulate numerous processes in the body (47, 48), which include fat mass, nutrient homestasis and energy expenditure, the immune response, blood pressure control, hemostasis, bone mass, and reproductive function. In obesity, adipose tissue inflammation results in the secretion of proinflammatory peptides and reduction of anti-inflammatory peptides, which lead to dele-
terious effect on the liver, muscle, and the vasculature (Fig. 3). A reduction in abdominal fat improves the atherogenic lipid pro-
file, reduces inflammation, and decreases blood pressure, which thereby decreases CV risk (44, 49). Current strategies are fo-
cused on identifying additional inflammatory markers that put the patient at cardiometabolic risk.

**Chronic hyperglycemia induces numerous alterations in the vasculature that accelerate the atherosclerotic process. Several major mechanisms contribute to the pathological alterations in blood vessels in diabetes, including:** 1) the nonenzymatic glycosyl-
lation of proteins and lipids, which form advanced glycation endproducts (AGEs) that can interfere with their normal func-
tion; and 2) the induction of oxidative and nitrosative stress, as well as exacerbation of proinflammatory responses (50). These abnormalities lead to impaired endothelial platelet inhibition and platelet activation, which could result in arterial thrombosis, and consequently myocardial infarction and stroke (51).

**Impaired endothelial function**

Because of metabolic stress, the endothelium loses its ability to balance vasodilating and vasoconstricting factors to maintain homestasis. Nitric oxide (NO) is the most important mediator of vasodilation, and loss of NO bioavailability contributes to the loss of vessel tone and damage to the endothelium. This dam-
age is particularly evident in the insulin-resistant state, in which insulin plays a key role in maintaining endothelial function and stimulating NO production. In diabetes, defective insulin signaling in the endothelial cell results in an imbalance be-
 tween the vasodilating agent NO and the vasoconstricting agent endothelin-1, which results in additional endothelial dysfunction and hypertension (52). Furthermore, markers of an activated endothelium appear prior to the presentation of overt diabetes, which suggests that the endothelium plays a primary role in the disease process.

A dysfunctional endothelium makes it susceptible to dam-
age by adhesion molecules, inflammatory cytokines, activated platelets, and lipids, which culminates in atherosclerosis (46, 53). In the kidney, endothelial dysfunction impairs glomerular filtration and leads to the progressive loss in renal function. En-
dothelial dysfunction can be addressed by treating the patient with angiotensin-converting enzyme inhibitors (ACEI) and an-
giotensin II receptor blockers (ARBs), which block the deleteri-
owns effects of an activated renin-angiotensin-aldosterone system (RAAS) on the endothelium (54). Reviews of endothelial dam-
age and current treatment strategies can be found in References 53 and 55. Novel therapies are needed to prevent progressive endothelial damage, whereas early intervention might improve endothelial function, offering an opportunity to protect against both CVD and organ damage. The consequences of metabolic dysregulation on endothelial damage and organ injury that culminate in CVD are summarized in Fig. 4.
Figure 3. Adipokine expression and secretion by adipose tissue in insulin-resistant, obese subjects. Obesity results in adipose tissue inflammation with macrophage infiltration. This result leads to 1) a decrease in adiponectin, which is an anti-inflammatory adipokine, that is positively correlated with insulin sensitivity and plays a protective role on the vasculature; and 2) an increase in inflammatory cytokines (TNFα, IL-6, and resistin) which causes insulin resistance, inflammation, and atherosclerosis. From Reference 47 with permission.

Figure 4. The contribution of impaired metabolism to cardiovascular risk. A dysregulation in nutrient metabolism contributes to cardiovascular risk by the following mechanisms: 1) impaired β-cell function, tissue damage, and insulin resistance; 2) an atherogenic lipid profile that is characterized by high TG, low HDL, and abnormal lipoproteins; 3) hypertension and vascular dysfunction; and 4) alterations in cytokines and adipokines that lead to a proinflammatory and procoagulant state.
Current and Next Generation Therapeutics

Numerous drugs are marketed to treat metabolic diseases, which include weight reducing agents, antidiabetics, lipid-lowering treatments, and antihypertensives. The pharmacology, positive attributes, efficacy, and limitations for each drug class are summarized in Tables (2-5) (56, 57).

Weight-loss agents

The three currently marketed weight-loss drugs are listed in Table 2. Orlistat is a pancreatic lipase inhibitor that acts at the level of the gastrointestinal (GI) tract to inhibit the absorption of dietary fat. Sibutramine and rimonabant act at different transporters or receptors to modulate central and peripheral metabolism. The paucity of weight loss agents that are available is attributed to the hurdles in developing weight-loss drugs. Large placebo-controlled trials are required; the placebo group is given a low-calorie diet and exhibits weight loss. A variation is observed in response and a significant number of nonresponders, and safety considerations often emerge. Most weight-loss treatments are associated with improvement in insulin sensitivity and lipids, but the drugs have side effects that generally limit use.

Antidiabetic agents

Current marketed antidiabetic treatments are shown in Table 3. These drugs may act to: improve insulin sensitivity, decrease hepatic glucose output, decrease the absorption of glucose in the GI tract, or stimulate the secretion of insulin. Numerous studies have shown that antidiabetic and weight-loss interventions, either by lifestyle or by drug treatment, prevent the development of diabetes in patients at risk for developing that disease (58). However, antidiabetic and weight-loss drugs are not prescribed as preventative agents. Because diabetes is a complicated disease, a treatment paradigm has been developed, and multiple treatments are generally required (57). However, a patient’s diabetes still progresses even when given several antidiabetic drugs in combination. This progression seems to be caused by the progressive loss of β-cell function despite multiple treatments (59).

Orlistat (oral) is a pancreatic lipase inhibitor that acts at the level of the gastrointestinal (GI) tract to inhibit the absorption of dietary fat. Sibutramine and rimonabant act at different transporters or receptors to modulate central and peripheral metabolism. The paucity of weight loss agents that are available is attributed to the hurdles in developing weight-loss drugs. Large placebo-controlled trials are required; the placebo group is given a low-calorie diet and exhibits weight loss. A variation is observed in response and a significant number of nonresponders, and safety considerations often emerge. Most weight-loss treatments are associated with improvement in insulin sensitivity and lipids, but the drugs have side effects that generally limit use.

Antidiabetic agents

Current marketed antidiabetic treatments are shown in Table 3. These drugs may act to: improve insulin sensitivity, decrease hepatic glucose output, decrease the absorption of glucose in the GI tract, or stimulate the secretion of insulin. Numerous studies have shown that antidiabetic and weight-loss interventions, either by lifestyle or by drug treatment, prevent the development of diabetes in patients at risk for developing that disease (58). However, antidiabetic and weight-loss drugs are not prescribed as preventative agents. Because diabetes is a complicated disease, a treatment paradigm has been developed, and multiple treatments are generally required (57). However, a patient’s diabetes still progresses even when given several antidiabetic drugs in combination. This progression seems to be caused by the progressive loss of β-cell function despite multiple treatments (59).

Orlistat (oral) is a pancreatic lipase inhibitor that acts at the level of the gastrointestinal (GI) tract to inhibit the absorption of dietary fat. Sibutramine and rimonabant act at different transporters or receptors to modulate central and peripheral metabolism. The paucity of weight loss agents that are available is attributed to the hurdles in developing weight-loss drugs. Large placebo-controlled trials are required; the placebo group is given a low-calorie diet and exhibits weight loss. A variation is observed in response and a significant number of nonresponders, and safety considerations often emerge. Most weight-loss treatments are associated with improvement in insulin sensitivity and lipids, but the drugs have side effects that generally limit use.
It is cosecreted with insulin by another regulatory hormone involved in glucose homeostasis. via sitagliptin, which is an oral DPP-IV inhibitor. Amylin is tentatively endogenous GLP-1 action by inhibiting its degradation to inject a GLP-1 protein mimetic (i.e., exenatide) or 2) to physiological treatments to promote GLP-1 action are as follows: 1) central effect to inhibit food intake. Two approved pharmacological treatments to promote GLP-1 action are as follows: 1) to inject a GLP-1 protein mimetic (i.e., exenatide) or 2) to potentiate endogenous GLP-1 action by inhibiting its degradation via sitagliptin, which is an oral DPP-IV inhibitor. Amylin is another regulatory hormone involved in glucose homeostasis. It is cosecreted with insulin by -cells and decreases PPG excursions by slowing gastric emptying and decreasing glucagon secretion. Pramlintide, which is an injectable analog of amylin, is approved to treat both T1 and T2D patients.

Lipid-lowering agents

Many lipid-lowering agents are used alone or in combination to achieve lipid goals (Table 4). Although numerous lipid-lowering agents are available, which are used alone and in combination, additional therapies are required to decrease other atherogenic components and to enhance reverse cholesterol transport. The "statins" inhibit HMGCoA reductase, which results in an inhibition of cholesterol synthesis and upregulation of LDL clearance. This result leads to a marked reduction in LDLc, with additional positive effects to decrease TG modestly and to increase HDLc. Bile acid sequestrants may elicit an antidiabetic effect (61); a newer seqeustrant colesevelam HCl received approval to treat both T2D and high LDL cholesterol.

New targets include potentiating the effects of glucagon-like peptide-1 (GLP-1) and amylin, which are reviewed in Reference 60. GLP-1 is a key regulatory hormone that is secreted by the L-cells of the intestine. This hormone stimulates intestinal glucose absorption, inhibits gastric emptying and glucagon secretion, and has a central effect to inhibit food intake. Two approved pharmacological treatments to promote GLP-1 action are as follows: 1) to inject a GLP-1 protein mimetic (i.e., exenatide) or 2) to potentiate endogenous GLP-1 action by inhibiting its degradation via sitagliptin, which is an oral DPP-IV inhibitor. Amylin is another regulatory hormone involved in glucose homeostasis. It is cosecreted with insulin by β-cells and decreases PPG excursions by slowing gastric emptying and decreasing glucagon secretion. Pramlintide, which is an injectable analog of amylin, is approved to treat both T1 and T2D patients.
the "statin" dose to reduce side effects. However, the "Enhance" clinical trial results (62) have raised concerns about the lack of vascular benefit with ezetimide, and additional outcome trials are ongoing.

The fibrates act at the level of the liver to decrease VLDL-TG substantially and to increase HDLC secretion. Nicotinic acid also decreases TG and is considered to be the most potent agent to increase HDLC. The effects of fibrates and nicotinic acid on TG and HDLC are generally greater than those observed with "statins," which are generally the most effective LDLc-lowering agents.

Blood pressure agents

Several classes of blood-pressure-lowering agents are available and are often used in combination to achieve goals (Table 5). Results of large clinical trials have indicated that the benefits of antihypertensive treatment is caused by the lowering in blood pressure and largely independent of the drugs employed (22). A challenge has been to understand why differential responses to a specific class or combination are observed.

Three antihypertensives (ACEI, ARB, and renin blockers) block different steps the RAAS pathway, which results in a downstream blockade of AT1 receptors that result in vasodilation, decreased secretion of vasopressin, and decreased secretion of aldosterone, contributing to a blood pressure-lowering effect. The decrease in aldosterone decreases sodium and water resorption in the kidney and decreases potassium excretion, which leads to a lowering in blood pressure. These drugs are often used to treat hypertension, diabetics nephropathy, and congestive heart failure (63). ACEI also blocks the bradykinin pathway, which induces nitric oxide and vasodilation, but it is often associated with the persistant dry cough and/or angioedema that may limit ACEI therapy. This side effect is rarely observed with ARBs. Although ACEI and renin antagonism decrease circulating angiotensin II, ARBs block its activity at the AT1 receptor. ARBs increase angiotensin II levels by uncoupling the negative-feedback loop, and increase its stimulation of AT2 receptors, which is associated with beneficial and negative effects. A direct renin inhibitor has recently entered the market, which may result in more complete inhibition of the RAAS system inhibition than with ACEI or ARBs, but more clinical experience and outcome trial results are necessary to assess its potential adequately (64).

Beta adrenergic receptor antagonists reduce cardiac output (caused by negative chronotropic and inotropic effects), decrease renin release from the kidneys, and cause smooth muscle relaxation. However, blockage may also decrease secretion of insulin from pancreatic β-cells, which limits its use in T2D. Calcium channel antagonists act on L-type voltage gated channels in the heart and blood vessels to reduce vascular resistance and arterial pressure. Diuretics are also widely used to decrease blood pressure, particularly in the elderly and hypertensive black populations.

Future treatment strategies

Future treatments are focused on correcting the metabolic dysregulation, which contributes to cell damage and tissue dysfunction. A list of selected novel targets for treating cardiometabolic diseases is shown in Table 6. The focus for new antibiostasis approaches has been to target the gut-brain axis to regulate feeding behavior and energy expenditure, as well as modulating peripheral metabolism (65). These targets should also be effective in treating obese T2D. However, it has been difficult to target feeding behavior, because considerable redundancies...

exist in the regulation of food intake. A nother focus to treat the metabolic dysregulation in insulin-resistant and diabetic patients is to augment insulin receptor signaling and also to treat β-cell impairment. Future approaches to treating vessel wall damage include activating reverse cholesterol transport and novel anti-hypertensive targets. Several challenges are faced in developing novel therapeutics to treat cardiometabolic disorders. These challenges include identifying and validating novel targets, using predictive animal model of human efficacy, identifying responsive patient populations, obtaining an acceptable safety and tolerability profile for chronic treatment, and positioning a product in a huge, competitive marketplace. However, there is a high unmet medical need and room for new, differentiated products. Recent advances hold promise for novel therapies for treating multiple risk factors for T2D and CVD.

Mitochondrial Medicine, Biochemical Evaluation of Mitochondrial Function

Richard J.T. Rodenburg and Jan A.M. Smeitink, Nijmegen Center for Mitochondrial Disorders, Radboud University Nijmegen Medical Centre, The Netherlands
doi: 10.1002/9780470048672.wecb343

Mitochondrial medicine is an emerging field in medicine that focuses on diseases in which the mitochondrial energy generating system plays a central role. These diseases include the “classical” mitochondrial disorders, in which a (genetic) defect in the mitochondrial energy generating system is the primary cause of the disease, but also more common disorders such as Parkinson and cancer, in which mitochondrial energy metabolism plays an important role in the pathogenesis. In this review, we present an overview of the mitochondrial energy generating system, starting at the conversion of pyruvate into acetyl-CoA by pyruvate dehydrogenase, via the TCA cycle in which reduction equivalents are formed, to the oxidative phosphorylation system, where the reduction equivalents are used to convert ADP into ATP. The mitochondrial energy generating system can be examined by global assays that measure the rate of pyruvate conversion, the rate of oxygen consumption, or the rate of ATP production. In addition, an overview is given of the spectrophotometric assays that are available to measure PDHc, several TCA cycle enzymes, and the enzymes of the oxidative phosphorylation. In the diagnostic analysis of patients suspected to suffer from a mitochondrial disorder, these assays are applied to evaluate the functioning of the mitochondrial energy generating system in muscle biopsies and other types of patient samples. In addition, the results provide clues for further investigations at the molecular genetic level. Thus, the biochemical analysis of patient material is an important step in establishing the diagnosis of a mitochondrial disorder.

The importance of mitochondria in health and disease has given rise to a new area in medicine, called mitochondrial medicine. The foundation for this medical discipline lies in the recognition of diseases in which disturbances in one of the many steps of mitochondrial energy production are present. The role of mitochondria in energy metabolism disorders is well recognized and has been the subject of study for many decades. The increasing awareness of the relationship between mitochondria and several more common disorders, like Parkinson disease and cancer, makes a thorough understanding of the chemistry of the mitochondrial energy generating system, and the analytical methods to examine the functioning of this system, necessary for an increasing variety of medical and biochemical specialists. Here, we review a) how the cell’s energy currency, ATP, is produced, and b) assays to determine the overall capacity of the system as well as single enzymes in relation to genetic disorders of energy production.

Biological Background

Mitochondrial disorders

Mitochondrial disorders can be defined as disorders that are caused by a defect in the mitochondrial energy generating system (MEGS). The clinical spectrum is very broad, but in almost all cases involve one or more tissues that have a high energy demand, in particular skeletal muscle and neuronal tissue. In addition, heart, liver, kidney, and other tissues can be involved as well. The severity and the course of the disease are
The production of ATP by the MEGS is a complex process involving many different transporters and enzymes (4). Mitochondrial ATP is the end product of the oxidation of pyruvate (alpha-keto propionic acid). Pyruvate is the final product of the glycolysis, the anaerobic catabolism of glucose. Other substrates for the MEGS are fatty acids and several amino acids, in particular glutamine. Pyruvate is transported into the mitochondrion where it is metabolized into acetyl-CoA. The acetyl-CoA is oxidized in the tricarboxylic acid (TCA) cycle, during which both NADH and FADH$_2$ are produced. These reducing equivalents are oxidized by the respiratory chain, which leads to the translocation of protons out of the mitochondrial matrix. The mitochondria use the resulting proton-motive force to generate ATP from ADP and phosphate. The ATP is released in the mitochondrial matrix, and can be exported to the cytosol. The MEGS is described in more detail in the next section.

The Chemistry of the OXPHOS System

The conversion of pyruvate to acetyl-CoA involves two key players. Pyruvate is imported into the mitochondrion by a specific transporter. To date, only one case has been described in which a pyruvate carrier deficiency could be shown by functional assays (5). However, no genetic defect responsible for pyruvate carrier deficiency has been identified yet. After pyruvate has entered the mitochondrial matrix, it is converted into acetyl-CoA by the pyruvate dehydrogenase complex, PDHc.

This large enzyme complex has a molecular mass of approximately 9 MDa and contains multiple copies of three enzyme subcomplexes: 20-30 copies of alpha-ketoacid dehydrogenase (E3; EC 1.2.4.1), 60 copies of dihydrolipoamide acyltransferase (E2; EC 2.3.1.2), and 6 copies of dihydrolipoamide dehydrogenase (E1; EC 1.8.1.4), as well as 12 copies of the structural building block E3 binding protein (6). The E1 subcomplex consists of a tetramer of two E1α and two E1β subunits. PDHc de-carboxylates pyruvate and esterifies the resulting acetyl-group to CoA. During this reaction, NAD$^+$ is reduced to NADH. PDHc requires 5 different cofactors, namely NAD$^+$, CoA, thiamine pyrophosphate, FAD, and lipoic acid. The activity of PDHc is tightly regulated. First of all, the activity is controlled in an allosteric manner by the reaction products acetyl-CoA and NADH. In addition, two specific enzymes regulate PDHc activity via a phosphorylation site in the E1 subunit. PDH kinase (EC 2.7.11.2) is ATP dependent and inactivates PDHc by phosphorylating the E1 component when the ATP/ADP ratio is low (7). This enzyme is also activated by high NAD$^+$ and acetyl-CoA levels, and inactivated by high pyruvate levels. Four isoforms of PDH kinase have been identified, each having a different tissue distribution. By contrast, when the ATP/ADP ratio is high and the pyruvate levels are high, PDH kinase is not active and PDHc is dephosphorylated by PDH phosphatase (EC 3.1.3.43), of which two isoforms are known (8). Due to this tight regulation, the oxidation rate of pyruvate by PDHc is directly coupled to the mitochondrial ATP production rate.

The generation of reduction equivalents in the TCA cycle

The acetyl-CoA generated by PDHc fuels the TCA cycle. Three dehydrogenases of the TCA cycle are responsible for the reduction of NAD$^+$ into NADH. These are isocitrate dehydrogenase (EC 1.1.1.42), a-ketoglutarate dehydrogenase (consisting of 3 enzymatic subunits E1 (EC 1.2.4.2), E2 (2.3.1.61), and E3 (EC 1.8.1.4), and malate dehydrogenase (EC 1.1.1.37). In addition, the TCA cycle enzyme succinate dehydrogenase (EC 1.3.9.1) converts FADH$_2$ into FAD. Furthermore, succinate-CoA ligase generates GTP or ATP, depending on the isotype of this enzyme complex (EC 6.2.1.4 and EC 6.2.1.5, respectively). The formation of these high-energy molecules is accompanied by the release of CO$_2$ in two of the reactions of the TCA cycle. In addition to acetyl-CoA, other metabolites can fuel the TCA cycle as well. This includes glutamine, which enters the TCA cycle at the site of 2-oxoglutarate. In tissues that catabolize fatty acids, the end product of the beta-oxidation is acetyl-CoA, which is converted into the ketone bodies 3-hydroxybutyrate and acetacetate (in the liver) or enters the TCA cycle (in most other tissues) and in this way contributes to the synthesis of ATP.

The oxidative phosphorylation system

NADH and FADH$_2$ are oxidized by the OXPHOS system to generate ATP. This is a coordinated multistep process that involves 5 large enzyme complexes: the respiratory chain complexes I, II, III, and IV, and ATP synthase (complex V). Complex I (NADH ubiquinone oxidoreductase; EC 1.6.5.3) is by far the largest respiratory chain enzyme complex. It consists of 45 different subunits and has a molecular weight of approximately 1 MDa. Complex I oxidizes NADH and the electrons that are released from NADH are transferred to a flavin mononucleotide present in complex I and subsequently via a channel of 8 iron sulfur clusters within the peripheral arm of the complex towards CoQ$_2$ that is present in the inner mitochondrial membrane (9). The redox reaction of complex I is directly coupled to the pumping of protons by complex I from the mitochondrial matrix across the mitochondrial inner membrane to the mitochondrial intermembrane space, which is in direct connection with the cytosol for small ions. Complex II (succinate dehydrogenase; EC 1.3.5.1) oxidizes FADH$_2$ and transfers electrons towards the respiratory chain.
CoQ₁₀ Complex II is the only respiratory chain complex that does not contribute to the mitochondrial proton gradient. Complex III (ubiquinol:cytochrome c oxidoreductase; EC 1.10.2.2) translocates the electrons from CoQ₁₀ to cytochrome c, a small, haeme-containing protein that acts as an electron carrier between complexes III and IV of the respiratory chain. The last step of the respiratory chain is complex IV (cytochrome c oxidase; EC 1.9.3.1), that oxidizes cytochrome c and transfers the electrons to molecular oxygen, which leads to the generation of water. The pumping of protons by the respiratory chain complexes I, III, and IV across the inner mitochondrial membrane increases the pH of the mitochondrial matrix and generates a potential difference between matrix and intermembrane space. Complex V (adenosine triphosphatase; EC 3.6.1.3) utilizes the potential energy of the proton gradient to convert ADP and phosphate into ATP.

Defects in the mitochondrial energy generating system

In theory, a defect in any of the transport proteins and enzymes mentioned above could result in a reduced mitochondrial energy generating capacity. To date, primary defects at the protein and DNA level have been found in PDHc, fumarase (EC 4.2.1.2) (10), α-ketoglutarate dehydrogenase (2-oxoglutarate dehydrogenase) (12), succinate-CoA ligase (12, 13), complexes I (9), II (14), III (15), IV (16), and V (17), the phosphate carrier (18), and α-NT. A functional defect in the pyruvate carrier has been identified as well (5). In addition to these structural components of the mitochondrial energy generating system, there are many additional proteins involved in the production of these structural components. These include the chaperones required to assemble the enzyme complexes of the respiratory chain. The structural building blocks of the OXPHOS system are encoded by multiple genes. Except for complex II, these genes are located in both the nuclear and the mitochondrial genomes. Most nuclear genetic defects in these structural genes result in an isolated enzyme deficiency, although several examples have been described of patients with a mutation in a complex I gene that also result in reduced enzyme activities of other enzyme complexes, e.g. complex III and PDHc, indicating that these complexes have a higher order of organisation that can be disturbed by defects in one of the complexes. The existence of the so-called supercomplexes has become more apparent by functional and structural studies in the last few years. Many different pathogenic point mutations and rearrangements in the mtDNA have been found in the last two decades. Depending on the type of mutation, these can cause either isolated or combined deficiencies of complexes I, III, IV, and V (18). The mitochondrial genome (or mtDNA) is replicated by a dedicated polymerase, POLG. Defects in the POLG gene leads to depletion of, and/or deletions in, the mtDNA. This causes isolated or combined deficiencies of the mtDNA encoded OXPHOS complexes I, III, IV, and V. Furthermore, defects in proteins involved in nucleotide metabolism can lead to mtDNA depletion and OXPHOS deficiencies as well. Depletion has also been observed in patients suffering from a defect in the TCA cycle enzyme succinate-CoA ligase, although the underlying mechanism is not yet fully understood (12, 20).

The transcription and translation of mtDNA encoded proteins involves several mitochondria-specific proteins, in which defects also lead to combined OXPHOS enzyme deficiencies (21, 22). A special class of defects are those leading to a CoQ₁₀ deficiency. The biosynthesis of CoQ₁₀ is a multistep process that has been completely elucidated in yeast. In humans, several steps of this process have been shown to exist as well, and three different genetic defects in this pathway have been identified to date (23).

Tools and Techniques to Study the OXPHOS System

There are several approaches to perform biochemical analyses of the OXPHOS system. This chapter will focus on assays to perform structural analyses, enzyme activity assays, and ATP production, oxygen consumption and substrate oxidation assays.

Structural analysis of the OXPHOS system

Blue-Native PAGE is a technique that is very suitable to study the relative amounts and the assembly status of OXPHOS complexes (24, 25). It can be performed as either a 1D or a 2D assay. In the 1-dimensional approach, the complexes are separated on a non-denaturing acrylamide gel containing the Commassie dye Serva Blue G. All 5 complexes can be visualised in this way. In the 2-dimensional approach, the second dimension is a denaturing SDS-PAGE, resulting in the separation of the OXPHOS complexes into their individual protein building blocks. After blotting, more specific staining methods can be performed, e.g. using anti-OXPHOS complex antibodies. This can provide detailed information on the assembly status of the OXPHOS complexes. A rather powerful tool to perform structural analysis of OXPHOS complexes is by immunopurification followed by mass spectrometric analysis of the isolated complexes. Using this approach, it has been shown that bovine complex I (and presumably also human complex I) consists of 45 different subunits (26). Recently, this technique has lead to the identification of Ecst as a protein involved in complex I assembly, as it was found to be associated with complex I (27). This is quite an unexpected finding, as Ecst was previously known as a cytosolic protein involved in a pro-inflammatory signal-transduction pathway from a Toll-like receptor and in embryonic development (28). By immunopurification and mass spectrometry, it could be shown that Ecst associates with complex I, and that the N-terminal part of Ecst appears to be required for mitochondrial import (27).

Enzyme activity assays

The traditional way to determine OXPHOS enzyme activities is by spectrophotometry. Several assays have been described for all 5 OXPHOS complexes. The assays are performed in homogenates of tissue samples or cultured cells, in crude mitochondria-enriched 600 g supernatants of tissue/cell homogenates, or in mitochondrial preparations from 14000 g pellets derived from 600 g supernatants. Obviously, the higher the
purity of the mitochondrial preparation, the higher the specific activity of the enzymes measured. Therefore, very high specific activities can be achieved by using immunopurified complexes (29), although this approach is not widely applied yet. In addition to enzyme activity assays in solution, BN-PAGE can be used to estimate OXPHOS enzyme activities by in-gel activity assays (30). In-gel activities are particularly suitable to monitor relative activities, e.g., to evaluate changes in enzyme activities under different experimental conditions. For quantitative enzyme activity measurements, spectrophotometric analysis is the method of choice. Table 1 contains a summary of the most commonly used spectrophotometric enzyme assays for measurement of the OXPHOS enzymes. Below, a brief description of these assays is given.

**Complex I**

Spectrophotometric assays for measuring the activity of complex I (or NADH:ubiquinone oxidoreductase) are usually based on measurements of NADH, which is oxidized by complex I to NAD+. In addition, the assay requires CoQ as a cosubstrate for complex I. Usually CoQ$_1$ or decylubiquinone are used because these have better solubility than CoQ$_{10}$. Assays usually contain bovine serum albumine, which probably is required to stabilize the protein sample and to aid the solubilization of CoQ analogues. The specific activity of complex I can be determined by measuring the rate of NADH conversion at 340 nm in the absence and presence of the specific complex I inhibitor rotenone (31). Recently, our lab described a new assay that measures complex I by including 2,6-dichlorophenolindophenol (DCIP) as a terminal acceptor of electrons that are derived from the oxidation of NADH and the subsequent reduction of the CoQ-analogue decylubiquinone (32). DCIP reduction can be followed spectrophotometrically at 600 nm. As the molar absorption coefficient of DCIP at 600 nm is more than 3 times higher than that of NADH at 340 nm, this new assay has a much higher sensitivity than the assay that measures NADH, with similar specificity. Complex I can also be measured as NADH:cytochrome c oxidoreductase, in which the combined activity of complex I + CoQ$_1$ + III is measured by addition of NADH and oxidized cytochrome c as substrates. The assay measures the rotenone-sensitive reduction of cytochrome c, which can be followed spectrophotometrically at 550 nm.

**Complex II**

Complex II is usually measured in two ways: either as succinate:ubiquinone oxidoreductase or as succinylate:cytochrome c oxidoreductase. The most commonly used assay for succinate:ubiquinone oxidoreductase (or isolated complex II) uses DCIP in the same way as described above for the new complex I assay, only in this case succinate is added as a substrate (instead of NADH). The specificity of DCIP reduction can be determined by measuring in the presence or absence of malonate, a specific inhibitor of complex II. The assay for succinate:cytochrome c oxidoreductase (or complexes II + III) uses succinate and oxidized cytochrome c as substrates and measures the reduction of cytochrome c, which can be followed spectrophotometrically at 550 nm. The assay is also suitable to screen for coenzyme Q deficiencies, as it is dependent on the endogenously present CoQ$_1$. In case of a CoQ$_1$ deficiency, a reduced succinate:cytochrome c oxidoreductase activity will be observed that can be normalized by addition of exogenous CoQ to the reaction mixture (33). Complex III (ubiquinol:cytochrome c oxidoreductase) reduces cytochrome c and oxidizes reduced CoQ. In addition to these substrates, the assay contains a strong complex IV inhibitor (e.g., potassium cyanide) to prevent re-oxidation of reduced cytochrome c. The complex III activity can be derived from the rate of cytochrome c reduction, which can be followed at 550 nm. The specificity of the assay is determined by measuring in the absence or presence of antimycin A, a specific inhibitor of complex III activity.

**Complex IV**

Complex IV (cytochrome c oxidase) is measured by addition of reduced cytochrome c to the reaction mixture. The oxidation of cytochrome c can be followed at 550 nm. This assay has a low background activity, and measurement in the absence and presence of a selective inhibitor is not necessary.

**Complex V**

The activity of the ATP-forming enzyme complex V is usually assessed by determining the reverse reaction ATP → ADP + Pi. The reaction is coupled to reactions catalyzed by pyruvate kinase (ADP + phosphoenolpyruvate → pyruvate + ATP) and lactate dehydrogenase (pyruvate + NADH → lactate + NAD$^+$). This final reaction can be followed spectrophotometrically by measuring NADH at 340 nm. The activity of complex V (ATPase) can be derived from the rate of NADH conversion in the presence and absence of the specific complex V inhibitor oligomycin.

**Other enzymes**

In addition to assays for the OXPHOS enzymes, assays have been described for many other enzymes involved in the MEGS. For PDHc, various types of diagnostic assays have been described and are widely used (33). Also for the TCA cycle enzymes various assays have been described, although to date, pathogenic defects have only been found in α-ketoglutarate dehydrogenase (38), succinicate-CoA ligase (12), and lumanase (39).

**The mitochondrial energy generating system**

As outlined above, the generation of ATP from pyruvate by the mitochondrion involves many different transporters and enzymes. A subset of the individual transporters can be assayed individually (e.g., the respiratory chain enzymes). In addition, the process of ATP generation can be studied by using assays that provide information of the mitochondrial energy generating system (MEGS) in toto, and moreover, on the functioning of individual enzymes in the context of the intact mitochondrion. Several types of assays have been developed and are described below. For all these assays, a crucial factor is the integrity of the mitochondria, since the generation of ATP is dependent on an inner mitochondrial membrane potential. Therefore, it is important to include control experiments that test the coupling of the ATP synthesis to the respiratory chain, as this will provide information on the integrity of the inner mitochondrial membrane.
Monitor different metabolic routes that lead to mitochondrial dehydrogenase. As the ATP production rate is under the control where it is coupled to oxalate that is the product of malate acetyl-CoA that is further metabolized in the citric acid cycle is subsequently metabolized by pyruvate dehydrogenase to pyruvate enters the mitochondria via a pyruvate carrier and ATP synthesis. For example, by addition of pyruvate and malate, tissue homogenates (41). Different substrates can be added to by digitonin (40), or in mitochondria-enriched fractions from The first type is performed in cultured cells permeabilized Two types of ATP production assays can be discriminated.

**ATP production assays**

Two types of ATP production assays can be discriminated. The first type is performed in cultured cells permeabilized by digitonin (40), or in mitochondria-enriched fractions from tissue homogenates (41). Different substrates can be added to monitor different metabolic routes that lead to mitochondrial ATP synthesis. For example, by addition of pyruvate and malate, pyruvate enters the mitochondria via a pyruvate carrier and is subsequently metabolized by pyruvate dehydrogenase to acetyl-CoA that is further metabolized in the citric acid cycle where it is coupled to oxalate that is the product of malate dehydrogenase. As the ATP production rate is under the control of the ADP/ATP ratio, an excess of ADP should be present in the pathway from the pyruvate carrier to ATP can be monitored. Any primary defect in this pathway will result in a decreased ATP production rate. Therefore, this type of assay is very suitable as a diagnostic tool to screen for a defect in the MEGS. The second type of ATP production assay is restricted to cultured cells. In this assay, luciferase is used as an ATP sensor in vivo. Luciferase, an enzyme derived from the firefly, converts its substrate luciferin under the emission of light. This reaction requires ATP, and thus, the amount of light produced is a measure for the amount of ATP. Cells can be stably transfected with an expression vector encoding luciferase (42), infected with a virus that encodes luciferase (43), or microinjected with plasmid DNA encoding luciferase (44). By addition of an appropriate targeting sequence, luciferase can be expressed specifically in the mitochondria in order to monitor intramitochondrial ATP. The ATP levels can be monitored by luminometry. A more sophisticated approach is to determine subcellular (e.g. intramitochondrial) ATP levels by a microscope coupled to a CCD camera. When cells are placed in a flow cell under the microscope/CCD camera system, they can be exposed to different stimuli that regulate ATP production, in particular hormones that lead to intracellular Ca²⁺ fluxes, which stimulate mitochondrial ATP production (43). This can be monitored real-time by means of the camera. In contrast to the first type of ATP assay, this real-time ATP assay is not only dependent on the integrity of the mitochondrial ATP generating machinery, but also on the intracellular mechanisms that regulate ATP production. This set-up is very suitable to perform functional studies of the mitochondrial energy generating system in vivo and the factors that affect the activity of this system, but is less suitable as a diagnostic tool.

**Substrate oxidation rate measurements**

Substrate oxidation rate measurements provide detailed information on the functioning of the MEGS (41). The MEGS performs three decarboxylation reactions, at the level of PDHc, isocitrate dehydrogenase, and 2-oxoglutarate dehydrogenase. By using radiolabeled substrates in which the radiolabel is present at a carboxyl residue, the activity of the MEGS can be followed by measuring the amount of released radiolabeled CO₂. Usually, combinations of radiolabeled substrates and unlabeled

Non-standard abbreviations: UQ₁: ubiquinone-Q₁; DQ: decylubiquinone; DCIP: 2,6-dichlorophenolindophenol, PK: pyruvate kinase; LDH: lactate dehydrogenase; AABS: p-(p-aminophenyl)azo benzene sulfonic acid; ArAt: arylamine acetyltransferase
co-substrates are used, either in the presence or absence of specific inhibitors. An example is the use of radiolabeled pyruvate, which is decarboxylated by PDHc. To force the reaction to proceed at maximum rate, the reaction contains an excess of ADP, in order to maintain a high ADP/ATP ratio. In addition, the acetyl-CoA formed by PDHc has to be removed by addition of an appropriate co-substrate. When carnitine is used as co-substrate, it will be coupled to the acetyl group of acetyl-CoA by carnitine-acetyl transferase. When malate is used as a co-substrate, this will be converted to oxalacetate in the TCA cycle which is subsequently coupled to the acetylgroup of acetyl-CoA by citrate synthase. When these assays are performed in a control sample, e.g., a muscle sample from a healthy individual, the ratio of the pyruvate oxidation in the presence of carnitine or malate will be approximately 1. Also in a sample from a PDHc deficient patient, this ratio will be near 1, however, in that case both reaction rates will be equally reduced due to the PDHc defect. Interestingly, in case of a respiratory chain defect, the ratio between these two reactions will be around 2 in favour of the reaction with carnitine (43). A third reaction that does not directly involve a TCA cycle enzyme is the conversion of pyruvate + malate to oxaloacetate + ATP. The advantage and disadvantage of this reaction is that the latter is the reverse reaction of the reaction catalyzed by PDHc. The reaction with malate as a co-substrate allows the evaluation of this conversion with malate as a co-substrate. As a final example, in case of a complex V defect, the reaction of pyruvate + malate will have a lower rate than in a control sample. Addition of the uncoupler CCCP will result in a normalization of the reaction rate, a phenomenon that is also observed in case of a defect in the phosphate carrier or the ATP:ADP antiporter ANT.

Oxygen consumption assays

In principle, oxygen consumption rate assays can be used for the same purposes as substrate oxidation rate assays. Also in this case, the pathway from the substrate of choice down to molecular oxygen conversion by complex IV can be evaluated, and even the steps beyond complex IV that are of influence on the activity of complex IV, such as complex V (45). The assay can be performed on frozen or tissue extracts or in whole cells in vivo or ex vivo. The classical way to detect molecular oxygen consumption by using a Clark-type oxygen electrode (46). More recently, molecular probes have been developed that make it possible to perform oxygen consumption rate measurements by fluorimetry (46, 47). This latter type of assay has the advantage that small volumes can be tested in 96-well plates using relatively simple laboratory equipment. By using appropriate combinations of substrates, the oxygen consumption rate measurements are suitable to locate primary defects in the MEGS, in a similar manner as with radiolabelled substrate oxidation rate assays.

Diagnostic Biochemical Analysis of the Mitochondrial Energy Generating System

The mitochondrial energy generating system requires efficient interplay between a large number of different proteins and protein complexes, which by themselves can be made up of large numbers of individual subunits that have to be assembled in an ordered manner. This complexity of the mitochondrial energy generating system is probably one of the main reasons for the heterogeneity of mitochondrial disorders. Due to this clinical diversity, establishing the diagnosis “mitochondrial disorder” usually requires a combination of clinical, biochemical, and genetic examination of the patient suspected for a mitochondrial disorder (48–50). The biochemical analysis of a muscle biopsy is the corner stone of the diagnostic examination for mitochondrial disorders. The results will show whether or not the MEGS functions properly in this tissue. Unfortunately, the number of (potentially) mitochondrial disease causing candidate genes is very large, and molecular genetic techniques to rapidly sequence hundreds of candidate genes in a diagnostic setting are not yet available. The biochemical results are not only diagnostic in their own right, but, in combination with the clinical features of the patient, also provide important clues that are used to select candidate genes for molecular genetic analysis. Nevertheless, the diagnosis mitochondrial disorder can not always be made at the molecular genetic level, in particular in those cases in which a comprehensive biochemical analysis has not been performed.

The biochemical diagnostic analysis of a patient suspected for a mitochondrial disorder is usually performed on a muscle biopsy, as this tissue has a very high energy demand and is more likely to exhibit signs of mitochondrial dysfunction than tissues with a relatively low energy conversion rate. Depending on the clinical features, it could be considered to examine other types of tissue, such as liver or heart. It has been shown that in mitochondrial depletion syndromes with liver involvement, e.g., due to mutations in DGUOK or MPV17, muscle tissue may not always show biochemical aberrations while liver shows clear signs of enzyme deficiencies (51, 52). Obvious drawbacks of organ or muscle biopsies are that an invasive procedure is required to obtain the tissue sample. Technically, it is possible to measure in fibroblasts or even blood samples, but these do not always express the mitochondrial defect. Nevertheless, these types of samples do have a very important added value to the biochemical diagnosis. First of all, a positive or a negative fibroblast result in combination with a positive muscle result has consequences for the selection of candidate genes for subsequent molecular genetic analysis. For example, in case of a mitochondrial depletion syndrome due to mutations in the POLG gene, very severe enzyme deficiencies can be observed in muscle and/or liver, whereas fibroblasts often show normal enzyme activities (53). By contrast, in case of a mitochondrial translation defect, respiratory chain enzyme deficiencies are observed both in muscle and in fibroblasts. A second important aspect of fibroblast (or lymphocyte) analysis is that a systemic expression of a biochemical defect may allow for prenatal diagnosis on the basis of biochemical analysis of chorionic tissue or amniocytes in families of mitochondrial patients in which the underlying molecular genetic defect has not (yet) been identified (54).

The amyloidoses are a class of conformational diseases that arise from the conversion of normally unfolded or globular proteins into fibrillar aggregates that are either pathogenic or non-functional. At present there are more than 20 proteins that are associated with human amyloid diseases. This review focuses on three natively unfolded proteins that form fibrillar aggregates; amyloid-\(\beta\) (\(A\beta\)), islet amyloid polypeptide (‘amylin’), and \(\alpha\)-synuclein, the diseases they contribute to and chemical and biophysical approaches that are used to investigate these proteins’ aggregation.

Introduction

Conversion of native conformational folded proteins or peptides into highly-ordered insoluble fibrillar aggregates termed ‘amyloid’ has been demonstrated to be clinically-relevant in several diseases. Misfolded proteins are deposited in a variety of tissues, leading to serious and even fatal human diseases. To date there are over 20 proteins and peptides that are known to induce pathological conditions associated with protein misfolding (Table 1). These proteins include the amyloid-\(\beta\) peptides, prion proteins, \(\alpha\)-synuclein, transthyretin and polyglutamine-containing peptides (1). The hypothesis that these diseases are in fact caused by misfolded protein and the misfolded protein does not arise as a side effect of the disease is supported by familial disease, where proteins containing mutations that facilitate aggregation result in more severe and early onset disease variants.

Diseases arising as a result of protein misfolding are classified based on the location of the protein deposition. Thus, the amyloidoses are generally classified as either neuronal or systemic. The majority of conditions arise sporadically, with only 10% of the cases being linked to hereditary causes. The familial forms of the diseases are caused by mutations that make a protein more prone to aggregation, or by mutations in processing proteins like proteases. Under rare circumstances (5% of protein misfolding diseases), protein aggregation can be initiated by infection and transmission. All diseases caused by misfolded protein share the problem of definitive diagnosis as they are difficult to identify in vivo, especially during early stages of symptoms.

Precursors of amyloid are quite diverse, ranging from small unstructured peptides like amyloid-\(\beta\) peptides to large oligomeric multi-domain proteins like p53. Despite the differences in structure of the monomers, the structures of the misfolded \(\beta\)-sheet rich forms share similar features. In recent years it has become apparent that the proteins that form amyloid share common features, and it has been suggested that many if not all proteins share the intrinsic predisposition to form amyloid under the right conditions (2, 3). This hypothesis is affirmed by the absence of a correlation between the propensity of a peptide or protein to misfold and its sequence. Precursor proteins share neither homology in sequence nor structure. However, certain factors such as hydrophobic regions and/or unstable globular protein conformations contribute to a predisposition to form amyloid.

In this review, we will discuss the aggregation of three intrinsically unstructured peptides and proteins and the diseases to which they contribute. Specifically we will concentrate on amyloid-\(\beta\) (\(A\beta\)), islet amyloid polypeptide (IAPP), and \(\alpha\)-synuclein.

Figure 1  Sequences of Aβ, IAPP and α-synuclein.

A key hallmark of AD is the misfolding of two proteins, Aβ and tau, whose extracellular and intracellular aggregates in the brain are coincident with and most likely causative of the disease. The risk of developing AD increases exponentially with age. In the early stage, AD is often overlooked as it manifests in mildly impaired short-term memory. The long-term memory is unaffected. With progression of the disease, the impairment of memory both short and long-term becomes apparent. Patients undergo a change in personality from having paranoid delusions to hallucinations and anxiety. At the late stages of AD, the affected person loses his/her ability to participate in daily life and fails to perform the most basic actions such as eating or walking.

A key hallmark of AD is the misfolding of two proteins, Aβ and tau, whose extracellular and intracellular aggregates in the brain are coincident with and most likely causative of the disease.
that expresses the Swedish mutant APP, a human tau mutant. Recently, a triple transgenic mouse model has been developed in mice develop memory loss but are devoid of neurodegeneration. Other important characteristics of AD, such as NFTs. These (the Swedish mutation) and develop amyloid plaques, but lack murine models, such as Tg2576, express mutated human APP due to the multifactorial nature of the syndrome. Existing sis of the disease makes such a theory unlikely to be pos-

To date, there is no generally accepted theory that accounts for the development of AD pathology. The multifactorial ba-
sis of the disease makes such a theory unlikely to be po-
sible in the foreseeable future. In addition to the NFTs and amyloid-hypothesis of the disease, oxidative stress, systemic levels of redox active metal ions, cardiovascular disease, the apoE4 allele and type 2 diabetes are all clear risk factors for development of AD. However, recent research supports the notion that the Ap build up may be a key event in AD and that other manifestations of the disease, like NFT forma-
tion, result from an imbalance between Ap production and Ap clearance (17).

γ-secretases. Cleavage of APP by α- and γ-secretases releases the non-amyloidogenic fragment p3. Upon cleavage of APP by β- and γ-secretases, Aβ is released. The peptide is characterized by a hydrophobic N-terminus and a hydrophobic C-terminus, corresponding to parts of the extracellular and intramembrane domains of APP, respectively. Aβ exists mainly as a 40 or 42 residue long peptide (Aβ1-40 and Aβ1-42) (Fig. 1). The C-terminally extended, more hydrophobic sequences like Aβ1-42 aggregate faster in vitro than their shorter partners, which might explain why they are more abundant in senile plaques.

Native Aβ is unstructured and its function is still uncer-
tain. Several possible roles have been suggested, including cholesterol transport, antioxidative protection and TGF-β activ-
ity (5-7). Similarly, a definite function for APP is still uniden-
tified. APP is a putative Notch-like receptor for an unknown ligand (8) and has been suggested to play a role in intercellular adhesion (9).

The presence of extracellular plaques consisting of misfolded Aβ in the brain of AD patients led to the widely accepted hypothesis that insoluble aggregates of Aβ are the toxic con-
formation of the native peptide. However, there is a poor cor-
relation between the number of mature fibrils found in brain and neuronal death (10). Studies have now shown that soluble Aβ oligomers are able to damage and kill neurons in central nervous system cultures (11), providing a direct link between Aβ and AD. More recently, dodecamers of Aβ have been iden-
tified as the causative agent in impairment of spatial memory in mice (12), although the relevance of this result in the context of other memory changes is unknown (13). These oligomeric species are most likely precursors or folding intermediates and do not emerge by a distinct pathway (14). It has already been shown that oligomers in the absence of fibrils and monomers can inhibit hippocampal long-term potentiation in rats in vivo (15).

Developing animal models for AD is an ongoing challenge due to the multifactorial nature of the syndrome. Existing marine models, such as Tg2576, express mutated human APP (the Swedish mutation) and develop amyloid plaques, but lack other important characteristics of AD, such as NFTs. These mice develop memory loss but are devoid of neurodegeneration. Recently, a triple transgenic mouse model has been developed that expresses the Swedish mutant APP, a human tau mutant, as well as a human presenilin-1 (PS1) mutant (16). These triple transgenic mice build up misfolded Aβ and tau and more accurately mimic human AD pathology.

Islet amyloid polypeptide (IAPP) and type 2 diabetes

Deposition of amyloid in pancreatic islets is a feature of type 2 diabetes in man, but the factors that contribute to this phe-
nomenon are unknown. Progressive amyloidosis results in loss of insulin-producing cells and increased disease state. The pres-
ence of amyloid depositions in pancreatic tissue was first de-
scribed over a century ago (18). However, it took much effort and time to identify the peptide component of these accumu-
lations as islet amyloid polypeptide (IAPP, also called amylin) (19, 20). IAPP is a 37 residue long peptide (Fig. 1) which is cosecreted with insulin. It originates from a longer precursor, pro-IAPP (67 amino acids). The peptide is co-stored with insulin in β-cell secretory granules and secreted together with insulin in response to β-cell stimulation, primarily glucose intake. Its na-

tive structure both intra- and extracellular prior to aggregation in vivo is still unclear, under physiological concentrations in vitro it adopts a stable random coil structure. During maturation of β-cell secretory granules, the N- and C-termini of pro-IAPP are enzymatically cleaved by pro-hormone convertases 1/3 and 2. The IAPP peptide is naturally present in humans and other species and is usually excused via the kidney. It is unclear if IAPP has any function in vivo although multiple possible roles have been suggested.

IAPP forms insoluble aggregates, confined within the islets of Langerhans, which are usually incidental with the non-insulin-
dependent type 2 diabetes. In contrast to the autoimmune disease type 1 diabetes, which is characterized by the destruction of insulin secreting cells, type 2 diabetes is a late-onset disease with decreased insulin secretion and reduced sensitivity towards insulin of peripheral tissue. Misfolded IAPP is present in over 90% of type 2 diabetes patients (as diagnosed post-mortem), but also in 15% of non-diabetics, indicating that other factors that are not diabetes related may play a role in the aggregation of the 37mer. Unlike Aβ, IAPP is present in concentrations above the critical concentration even in healthy individuals, but aggregation is prevented. It has been shown that insulin but not pro-insulin forms a complex with IAPP that stabilizes the peptide in vitro and possibly in vivo.

The role of amyloid in type 2 diabetes appears to be complex: severe islet dysfunction correlates well with extensive amylo-
odosis; however, the degree of amyloidosis can vary extremely in long term patients. The factors that trigger the onset of the disease are both genetic and environmental. On the other hand, a common qualification of misfolding diseases is that they occur mostly sporadic, without the necessity of mutations.

Mature fibrils formed from IAPP demonstrate β-cell toxicity in vitro (21). Analogous to the toxic-conformation-dissociation with Aβ, it has also been proposed that smaller, soluble oligomers of IAPP have cytotoxic effects (22) and show membrane-disrupting activity.

A link between AD and diabetes?

It has long been suggested that diabetes is a risk factor for AD, and a cohort study on people older that 55 years revealed that patients suffering from diabetes have a 65% increase in the risk
of developing AD compared to the group that did not suffer from diabetes (23). Moreover, the two diseases share similar physiological processes, most notably degeneration and age dependence. Interestingly, insulin receptors are not only found in the peripheral system, but also in neurons in the CNS (24). Therefore, the role of these receptors is not limited to the regulation of blood sugar levels but they are also involved in neuronal differentiation and cell proliferation (25, 26), implicating an intricate connection between insulin and AD. This unexpected link of AD and diabetes has led to the postulation of a new, brain specific “type 3 diabetes” (27), which was further elucidated recently when it was shown that soluble oligomers of Ab disrupt insulin signaling by binding to the insulin receptors on the neuronal surface (28). Given that synaptic failure and memory dysfunction are characteristic for AD, this link is another plausible explanation for the observed symptoms of the disease.

α-Synuclein and synucleopathies

α-Synuclein (Fig. 1) is the protein component associated with synucleinopathies, protein misfolding diseases that are characterized by the presence of α-synuclein deposits. Synucleinopathies include Parkinson disease, Lewy body (LB) dementia, diffuse LB dementia, and also the LB variant of AD.

α-Synuclein has been found to be the major constituent of Lewy bodies (LBs). Intriguingly, these deposits are not extracellular as with Aβ and IAPP, but intracellular inclusion bodies found in dopaminergic and non-dopaminergic neurons and glia. The protein morphology within the inclusions can be distinct; at least five different conformations have been described: LBs, Lewy neurites, glial cytoplasmic inclusions, neuronal cytoplasmic inclusions, and axonal spheroids.

α-Synuclein exits in three isoforms of varying length in humans. The best characterized is the full length, 140 amino acid long protein; the other isoforms are shorter and derived by alternative splicing. The N-terminus of the 140mer is characterized by the presence of a seven eleven amino acid long repeat containing amino acid long protein; the other isoforms are shorter and derived by alternative splicing. The N-terminus of the 140mer is characterized by the presence of a seven eleven amino acid long repeat containing highly conserved hexameric motifs (KTKKEGV). These repeats are thought to be implicated in the interaction with lipids and adopt a helical structure upon contact with lipid vesicles. The central region of the protein is highly prone to aggregation.

α-Synuclein is natively unstructured and a definitive function remains elusive. Possible roles include the regulation of vesicular release and other synaptic tasks as α-synuclein has been found to exist in equilibrium of free protein with vesicle-bound protein. α-Synuclein interacts in vitro with synthetic or purified phospholipid membranes, altering their integrity and suggesting participation in membrane lipid component organization. Moreover, it may also act as inhibitor of lipid organization. An intriguing function of α-synuclein is that it may operate as a molecular chaperone.

α-Synuclein is known to bind many proteins; over 500 proteins interacted in a proteomic analysis of a neuroblastoma cell line. Contact with some proteins or protein complexes promotes aggregation, e.g. fusion proteins and the tau protein, while others, particularly the shorter synucleins, γ1 and γ2, inhibit misfolding. Due to the high plasticity of the protein, it can adopt many different conformations. This conformational diversity of α-synuclein has had the protein labeled as a “protein chameleon”. Under physiological conditions in vitro the protein is unstructured. In the presence of lipid vesicles, its N-terminus can acquire α-helical structure in vitro. It can form non-covalent dimers and higher order oligomers leading to insoluble aggregates. Interestingly, α-synuclein can also form covalent dimers that crosslink via a dityrosine bond, under oxidative conditions.

Evidence points towards the oligomeric state of α-synuclein as the toxic conformation causing neuronal death. It has been suggested that fibril formation is merely an escape route or protection mechanism in the brain to prevent further neuronal damage.

Biophysical Characterization of Fibrils and Molecular Mechanism of their Formation

Although precursor proteins of amyloid are extremely diverse in sequence, the end-product fibrils in general share several structural features such as cross-β sheet assemblies, non-branched fibrils of similar length and structural organization.

Key intermediates in fibril formation

In general, there is a simple picture of the events that occur during oligomerization of natively unstructured protein and peptides: unfolded monomers undergo organized self-assembly via several intermediate assemblies on the pathway to fibrils. Many of these intermediates have been characterized and named based on in vitro studies, but there is no defined nomenclature as of yet. The following intermediates have been identified so far in the fibril polymerization process:

Monomers of the native peptide or protein can either be unfolded or folded. However, even natively unstructured peptides, e.g. Aβ, can adopt some secondary structure depending on the physiological environment, and some proteins exist in a native oligomerized state, like transthyretin. Monomers can arrange into oligomers, which are small globular, possibly spherical, micelle-like assemblies that contain some secondary structure (29). It is still unclear whether these oligomers are direct intermediates of the fibril formation pathway, or whether they occur as part of an “off-pathway”. For the misfolding of Aβ, evidence points towards oligomers being precursors of fibrils (29). Moreover, these oligomers are thought to be the neurotoxic conformation in a variety of misfolding diseases, most importantly AD (11). Structural instabilities of folding intermediates make it difficult to determine the structure of these intermediates, but not impossible (24).

Two unfortunate names that can easily lead to confusion have been given to the “in-pathway” conformations protofibrils and protofibrils. Protofibrils are similar to oligomers, mostly unstructured but linear (31). However, in most cases the term “protofibrils” is used interchangeably with the term oligomer. The name protofibrils refers to linear aggregates with β-sheet structure that have a diameter of 3nm and are usually 50-100nm in length. Mature, elongated protofibrils, also called filaments, interweave to form protein fibrils. Fibrils...
are generally unbranched, approx. 10 nm in diameter and can be several μm long.

**Nucleated polymerization and other models of fibril formation**

The actual mechanism of self-association of monomeric protein into amyloid is complex and three mechanisms of structure conversion have been proposed (32). In **templated assembly**, a monomeric or native state peptide binds to an existing nucleus. Upon binding, there is a change in the secondary structure of the monomer as it is added to the growing chain. **Monomer directed conversion** involves the presence of a misfolded monomer that templates the structure conversion of a native monomer, followed by disassociation and chain formation. The third model is **nucleated polymerization**, which is the most widely accepted model for the fibril growth.

Nucleated polymerization is a crucial process in cells, involved in providing a rigid cytoskeleton by organization of tubulin into microtubules and actin into thin filaments. These processes are under tight control; however, nucleated polymerization of proteins can also be “accidental” and occur to proteins that, in healthy individuals, remain in their native structure. The kinetics of misfolding are characterized by the presence of a lag phase, a rapid growth or elongation phase, and a plateau phase. The overall rate of amyloid aggregation is restricted by the formation of a nucleus, a process that is thought to have either slow kinetics or is driven by an unfavorable equilibrium. A nucleus is defined as the least stable conformer in the aggregation process that is in equilibrium with monomeric protein (33). The formation of a nucleus, a “stochastic” event, is concentration dependent. Nuclei only occur above a critical protein monomer concentration (for Aβ this concentration is approx. 15μM). However, in the presence of preformed seeds the lag phase is completely abolished. Once a nucleus or seed is present, it acts as a template for the conversion of monomers into β-sheet rich conformers that assemble rapidly into protofibrils and fibrils. Upon consumption of monomers there is a plateau phase where no more fibrils are formed. This general model of fibril formation is able to explain the spontaneous onset of most amyloidoses as well as their rapid progression. However, the kinetics of this mechanism can be influenced to a great extent by quite a few factors both in vitro and in vivo: pH, temperature of the sample, presence of preformed seeds, presence of metal ions, and oxidative damage.

Mathematical descriptions of the kinetics of protein misfolding have largely been attempted using non-complex simulations and algorithms. It has been suggested that a complete mathematical analysis of these processes is currently beyond our capability (34).

**Structure of fibrils**

No high resolution structure of fibrils has been published yet, as fibrils are insoluble, non-crystalline material, and therefore the classic structure determination methods like NMR and X-ray crystallography fail.

First experiments to elucidate the structure of the proteins in the fibrillar organization were done by X-ray diffraction. Amyloid fibrils show a characteristic diffraction pattern, the so called β-cross pattern (35), which is indicative of β-sheets parallel to the fibril axis with the protein strands perpendicular to the fibril’s long axis (36, 37). The patterns of amyloid is characterized by reflections at 4.75 Å (along the fibril axis) and 10 Å (perpendicular to the fibril axis) which occur from regular repeats and stacking of monomers.

Further characterization of Aβ fibrils involved solid-state NMR to determine the structure of the peptide subunits. Depending on the experimental constraints applied, several models for full length (e.g., (38)) and fragments of Aβ (e.g., (39, 40)) have been developed, most of them proposing an antiparallel, in-register β-sheet organization. However, it has since been proposed that the monomers composing a fibril associate in parallel, not antiparallel β-sheets (41) with full length Aβ and a model based on these constraints has been determined (42) (Fig. 2).

Within the IAPP polypeptide, three key regions have been identified that are responsible for its misfolding: residues 8-20 (43), 20-29 (44), and 30-37 (45). Residues 20-29 were initially found to be the amyloidogenic chore of IAPP, as peptide fragments corresponding to that sequence was found to form fibrils in vitro. Taken together, these three regions might participate in the formation of an intramolecular β-sheet with both parallel and antiparallel organization (43). Electron paramagnetic resonance spectroscopy of spin-labeled IAPP fibrils suggested a structure similar to that of Aβ, in-register, parallel β-sheet structure with units showing a disordered N-terminal segment (46).

Solid-state NMR studies of α-synuclein fibrils have shown that the β-sheet rich domain is located between at least residues 38-95, with the N-terminal residues being unstructured and...
a rigid backbone starting at residue 22 (47). These results are consistent with data obtained from electron paramagnetic resonance (EPR) of spin-labeled protein, showing an ordered core around residues 31-109, with parallel, in-register β-sheets (42, 43).

**Lessons for drug development**

To date, there is no successful treatment for misfolding diseases. The development of structural models for fibrils and the elucidation of intermediates of fibril formation give insights into possible drug targets. Several approaches are possible using medicinal chemistry in order to improve upon their properties.

**Small molecule inhibitors of Ab assembly**

Several small molecule inhibitors that prevent assembly of Aβ have been reported, however, the literature is far from systematic. Most of the studies listed in Table 2 (references for studies found in (53)) test only a few compounds and do not attempt to derive a structure-activity profile. Moreover, the chemical structures do not lend themselves to good starting points for medicinal chemistry in order to improve upon their properties. To date, the known compounds that inhibit Aβ assembly are weakly potent and are poorly bioavailable, particularly to the brain. Furthermore, progress towards development of aggregation inhibitors in the clinical setting remains elusive due to a clear disconnect between the in vitro and in vivo fibril-formation process. These points are further demonstrated by the fact that the only amyloid-aggregation inhibitors that have advanced to late-stage clinical trials, AlzheWhen™, Crebell™ and Kucta™, do not fit the classical drug-like profile and their in vivo disposition and mechanism of action is not well understood.

**Methods Used for Fibril Structure Determination and Aggregation Assays**

Research on amyloid fibrils was facilitated by the fact that fibrils similar to the ones found in vivo can be formed in vitro from peptides and denatured proteins. However, structure determination of amyloid fibrils has proven to be difficult due to the lack of methods and the complexity of the aggregates. Standard methods for structure determination, primarily solution-state NMR and X-ray diffraction, fail for amyloid fibrils due to the lack of soluble material or the inability to form classic protein crystals. Only recently we have acquired an in-depth understanding of the detailed conformation of fibrils.

The techniques to follow aggregation of amyloidogenic proteins and to determine their molecular conformation range from spectrometric assays (thioflavine T, Congo red) over spectroscopic assays (FTIR and CD) and visualization techniques (AFM and TEM) to methods that provide detailed insight into the atomic coordinates (solid-state NMR and X-ray diffraction). The principal difficulty in studying amyloid formation in vivo is doubtlessly sample preparation and protein quality, as impurities, aggregation conditions (buffer, pH, temperature, etc.) and the chosen deseeding method can have a major impact on the fibril formation kinetics as well as the structure of the fibrils.

**Spectrophotometric assays**

Congo red is a diazo dye with the name-giving characteristic red color. Amyloid stained with Congo red depicts green birefringence under polarized light and this method has been used to diagnose amyloid diseases in histological samples. To date, it is still used to classify proteins aggregates as amyloid. However, due to subjective interpretation and many incidents of “false negatives”, this method is to be used carefully and should be accompanied by a parallel verification method. Congo red can also be utilized in an absorbance assay to quantify the amount of misfolded material (54).

A straightforward method used frequently to follow the misfolding kinetics of previously desired protein is the thioflavin T assay (55). Thioflavin T is a molecule that binds rapidly to protein aggregates but not to monomeric or oligomeric intermediates. Upon binding, a red shift of the excitation and emission wavelength is monitored, allowing observing the kinetics of protein misfolding with a fluorescence microscope or by fluorescence spectroscopy. As this assay detects only β-sheet rich conformers, it is not suitable to identify unstructured intermediates of the misfolding process.

**Spectroscopic assays**

To determine the presence of β-sheet in amyloid samples, spectroscopic techniques such as circular dichroism (CD) and Fourier transform infrared (FTIR) spectroscopy are routinely used. In far U.V. CD spectroscopy, the sample is examined before and after aggregation to record any change in secondary structure. Samples of soluble protein are subjected to left and right handed circular polarized light and the difference in its absorbance at far-U.V. wavelengths is recorded. Obtained spectra are then compared to a reference library to allow an assessment of secondary structural elements. Aβ is unstructured under physiological conditions and exhibits a classic random coil far U.V. CD spectra. However, as aggregation of Aβ progresses, and the monomers fold into protofibrils and fibrils, the CD spectra change to reflect β-sheet formation.

![Chemical Structures](attachment:image.png)
The presence of β-sheet in a protein solution can also be determined using FTIR by inspecting the amide I band, which occurs in the region between 1600 cm⁻¹ and 1700 cm⁻¹, and taking into account possible contributions from side chains. Amyloid fibrils typically have β-sheet peaks below 1620 cm⁻¹. FTIR is not suitable to determine atomic coordinates, but it has given detailed insights into protein structure, and its easy sample preparation and the applicability to most molecules have led to the development of many experimental techniques (reviewed in (56)).

Visualization techniques (AFM and TEM)

Interesting information about the organization of fibrils has been obtained from atomic force microscopy (AFM) and transmission electron microscopy (TEM). Both methods give high resolution images of fibrils and show that fibrils are unbranched, twisted, and several µm long. These techniques are usually used to support data obtained from Thioflavin T assays, as this method gives no information about the presence of fibrils (it only confirms presence of β-sheets).

Molecular structure determination (solid-state NMR and x-ray diffraction)

Initial X-ray experiments on amyloid fibrils defined the classic β-sheet diffraction pattern with reflections at 4.75 Å and 10 Å, indicative of β-sheets parallel to the fibril axis, and the protein strand perpendicular to the fibril’s long axis (29–31). A more detailed view into the 3D organization of a fibril can be obtained by solid-state NMR. Solid-state NMR has the advantage that it can define the spatial arrangement of both the intrachain and intermolecular configurations. Using fibrillar, lyophilized protein, the molecular packing of amyloid can be defined (37, 58). Solid-state NMR spectroscopy revealed a more detailed structure of several β-sheet analogs and truncated sequences as well as the conformation of other peptides like α-synuclein, truncated peptides of transthyretin and the prion protein (Helmus J et al Molecular conformation and dynamics of the Y145Stop variant of human prion protein in amyloid fibrils. Proc Natl Acad Sci USA. 2008 Apr 29;105(17):6284-9, in (59)). The data obtained from β-sheet fibrils allowed the development of a structural model of the fibrillar form.

References

Many diseases are caused by defects in protein trafficking. Protein trafficking diseases occur when a mutant protein is recognized by the endoplasmic reticulum (ER) quality control system (ERQC), retained in the ER, and degraded in the cytosol by the proteasome rather than being trafficked to its correct site of action. Among these diseases are cystic fibrosis, lysosomal storage diseases (Fabry, Gaucher, and Tay-Sachs), nephrogenic diabetes insipidus, oculocutaneous albinism, protein C deficiency, and many others. A characteristic of many of these diseases is that the mutant protein remains functional, but it cannot escape the stringent ER quality-control machinery, and it is retained in the ER. This characteristic suggests that pharmacological interventions that promote the correct folding of the mutant protein would enable its escape from the ER and ameliorate the symptoms of the disease. In this review, we focus on specific examples of protein trafficking diseases in pharmacological or chemical chaperones have been shown to rescue trafficking of the mutant protein.

The etiology of several diseases can be traced to defects in protein trafficking. Recent studies on several different disease mutants have shown that chemicals and small molecules can correct trafficking of these mutants. As these compounds promote correct folding in a fashion analogous to the action of molecular chaperone proteins, these compounds have been termed “correctors” or “chaperones.” Several different classes of chaperones can be designated based on their mechanisms of action. Chemical chaperones are the least specific and the least potent, and which often require millimolar concentrations to function. Pharmacological chaperones are small-molecule correctors that can be subdivided into two classes based on their specificities. Specialized pharmacological chaperones are protein- or mutation-specific small molecules that interact directly with the mutant protein to provide a folding template, such as enzyme active-site inhibitors. Generalized correctors are less specific and are likely to function on the endoplasmic reticulum (ER) retention machinery, ER-associated degradation (ERAD), or other signaling pathways involved in trafficking rather than through a direct interaction with mutant proteins. We will begin with a brief overview of ER quality control, followed by specific examples of protein trafficking diseases and then discuss the different classes of correctors below.

Quality Control in the ER

Proteins that travel along the secretory pathway are subject to many quality-control checkpoints. Inside the ER, proteins must fold into their proper conformation before being sorted into vesicles destined for the Golgi apparatus. Once proteins have translocated into the ER through the translocon (Fig. 1), molecular chaperones, which include the heat shock chaperone family (e.g., Hsp70, BiP), the lectins calnexin and calreticulin, and the oxidoreductases (e.g., PDI), act on the nascent chain to promote the correctly folded conformation. Together with the oxido- reductase ERP57, the lectin chaperones act on the nascent protein in cycles of binding and release through the recognition of a monoglycosylated N-glycan. These cycles are controlled by N-glycan-modifying proteins including UDP-glucose:glycoprotein glucosyltransferase (UGGT) and glucosidases I and II (Fig. 1). Once the protein is correctly folded, the N-glycan is further modified by glucosidase II and proceeds along the secretory pathway. If several cycles of lectin binding do not result in a correctly folded protein, then the α(1→2)-ER mannosidase I (ManI) modifies the N-glycan, which...
Protein Trafficking Diseases. Small Molecule Approaches to

Figure 1  Protein folding in the ER is summarized. Folding pathways that lead to secretion are depicted in the upper half of the ER. Nonproductive folding and its consequences are depicted in the lower half of the ER. For simplicity, some pathways have been omitted, and some proteins are indicated by text alone. Once a protein enters the ER through the translocon, it undergoes N-glycosylation and is acted on by several chaperones including BiP. Glucosidases I and II (GI/GII) remove the terminal glucose on the N-glycan moiety which enables recognition of the protein by calnexin (CNX) or calreticulin (not shown). The oxidoreductase ERp57 is bound to CNX and also acts on the protein. If the resulting protein has a non-native fold, then UGGT recognizes it and adds a terminal glucose to enable rebinding with CNX. Once the protein has folded properly, the N-glycan is modified even more by GI and can be recognized by the Sec24 protein for COPII-dependent secretion. If the protein cannot be folded natively after several cycles of CNX binding, then ManI removes the terminal mannose on the N-glycan which prevents UGGT from reglycosylating it and targets it for destruction through ERAD in a process that involves the EDEM, Derlin, and the p97/valosin-containing protein (VCP) (1). In some cases, the misfolded protein aggregates and accumulates in the ER, which triggers the unfolded protein response.

Three different classes of ERAD-targeting components function depending on the location of the lesion: a cytosolic group, a lumenal group, and a transmembrane group. These proteins somehow sense the folding status of their substrates and triage those with defects for degradation. However, the mechanisms that regulate the decision to undergo ERAD instead of forward transport in the secretory pathway are not known. It is known that to be recruited to coat protomer II (COPII) vesicles...
leave the ER, proteins must be recognized by the Sec24 machin-ery, either directly through an ER exit code or through another receptor that can then interact with Sec24. Several different ER exit codes have been identified, including cytosolic diacidic codes such as the one found in the cystic fibrosis transmembrane conductance regulator (CFTR) protein, ditydrophobic motifs like that in ER-Ga1–intermediate compartment protein 53 (3), and various hydrophobic signals that are found in G-protein coupled receptors (GPCRs) (4). In yeast, simply inhibiting ERAD genetically does not permit ER-retained proteins to enter COPII vesicles, which suggests that some other level of recognition by the ERQC exists. However, even when folding of substrates has improved as judged by tryptic-sensitivity assays, inhibition of ERAD still does not permit entry into COPII vesicles (5). This discrepancy could be explained by the masking of the ER exit signal in the misfolded protein. In yeast, carboxypeptidase Y mutants whose ER exit signal is not obscured can escape ERAD even though other parts of the protein are misfolded (6). For many ER-retained disease mutant proteins, the ERQC performs its function too well and retains otherwise functional proteins. Small molecules that function in any process described above could potentially correct the trafficking of these ER-retained proteins and would be useful therapeutics.

Protein Trafficking Diseases

As many ER-retained mutant proteins are functional, rerouting them to their appropriate subcellular localization would restore the phenotype caused by their mislocalization. In some cases, it is estimated that only a small amount of functional protein (10–15%) is necessary to maintain health. Indeed, for some diseases a critical threshold seems to exist (7). Patients who express functional protein above this threshold have mild or no symptoms of the disease (7, 8), which suggests that even a modest increase in protein rerouting would improve the quality of life for many patients with these diseases. This finding provides the impetus for identifying correctors, even those with modest effects.

Properties of correctable protein trafficking disease mutants

Mutations that destroy protein activity such as those that abolish enzyme active sites are not amenable to rescue with correctors. However, mutations that alter the stability or folding of the protein, but that do not abrogate its activity, are good candidates for rescue by correctors. Most ER-retained missense mutations identified to date fall in this class. Frequently, these mutations are temperature sensitive and show some degree of correction at permissive temperatures (usually ~30°C). Another important feature of diseases that are amenable to rescue with correctors is the degradability of accumulated substrates or byproducts. For example, the lysosomal storage diseases Fabry, Gaucher, and Tay-Sachs all result in substrate accumulation in the lysosome; however, after treatment with pharmacological chaperones and rerouting of the enzymes, the corrected proteins reduce these substrate stores (9–12). In contrast, ER-retention diseases that result in the deposit of toxic or non-native proteins, such as fibrils associated with amyloidogenesis, likely would not be amenable to rescue with correctors because of the cell’s inability to degrade the non-native deposits, unless treatment with the corrector begins before irreversible damage is done. Several examples of trafficking diseases and their correctors are described below.

CFTR delta F508

One of the best-studied examples of a mutation that is amenable to rescue is the deltaF508 mutation in the chloride channel CFTR, which is the gene responsible for cystic fibrosis (13). Cystic fibrosis (CF) is the most common autosomal recessive genetic disease that affects the Caucasian population. It is a lethal disease characterized by severe dehydration of the cells lining the lung, intestine, and exocrine tissues (13). Most cases of CF can be attributed to a single mutation resulting in the deletion of a phenylalanine codon at position 508 in the protein, which is known as deltaF508. DeltaF508 CFTR can be rescued by incubation at permissive temperature (i.e., 27–30°C), by the addition of chemical chaperones such as sodium 4-phenylbutyrate, or other cosolutes such as glycerol, dimethyl sulfoxide, and trimethylamine N-oxide (Fig. 2a) (14–16). Modulation of ER calcium levels with curcumin and thapsigargin (Fig. 2b) has also been shown to correct deltaF508 CFTR trafficking; however, these results remain controversial (17, 18). Recent high-throughput screens have identified several classes of small-molecule correctors of protein trafficking, which include aminobenzothiazoles, aminobenzothiazoles, quinazolinylaminopyrimidinones, bisaminomethylbithiazoles, quinazolinones, khivorins and substituted 1-phenylsulfonpyridazines (19–22).

Three different assays were used to screen for correctors. One assay measured directly the amount of protein that trafficked to the cell membrane using immunofluorescence against an extracellular epitope tag in deltaF508 CFTR (19). The second assay monitored deltaF508 CFTR function by iodide influx with a halide-sensitive YFP construct as readout (20). The third assay also monitored function but through fluorescence energy transfer between a membrane-soluble voltage-sensitive dye bis-(1,2-dibutyryl)barbituric acid (tribromethine oxonol [DBS]AC(2)) and a plasma membrane localized fluorescent coumarin-linked phospholipid CC2-DMPE (22). The compounds identified in these screens are likely to function at different steps of the deltaF508 CFTR folding pathway. Corr4a, which is a bisaminomethylbithiazole, was shown to increase the folding efficiency of deltaF508 CFTR (20). Both Corr4a and the quinazolione VRT-325 were shown to delay ERAD of deltaF508 CFTR (20, 22). Compounds of the aminobenzothiazole class were found to act after ER folding as no increase in folding efficiency was detected, but the stability of deltaF508 was increased at the cell surface (20). VRT-325 also increased the stability of deltaF508 CFTR at the cell surface (22). This compound was shown to correct other CFTR mutants and even a mutant in the human ether-a-go-go-related gene (HERG) (see below). Derivatives of some of these compounds are now in clinical trials.

Lysosomal storage diseases

The lysosomal storage diseases, such as Tay-Sachs, Sandhoff, Gaucher, and Fabry disease, are autosomal recessive loss-of-function disorders. The mutant enzymes fail to degrade their respective lysosomal substrates because of their retention in the ER and subsequent degradation. This result leads to an accumulation of substrates and a variety of phenotypes including enlargement of affected organs, skeletal lesions, neurological abnormalities, and premature death. The current therapies for these diseases include inhibition of substrate production and enzyme-replacement therapy. However, enzyme-replacement therapy is not suitable for neurological phenotypes associated with some types of these diseases because of the impermeability of the blood–brain barrier; hence, other treatments are necessary. Recently, pharmacological chaperones for these diseases have been identified. As these proteins are enzymes, the pharmacological chaperones identified tend to be competitive active-site inhibitors. This finding may seem counterintuitive, but inhibitors are frequently trafficking correctors at subinhibitory doses (see below). The rationalization is that inhibitors stabilize the fold of the mutant proteins at the neutral pH of the ER and allow them to evade the ERQC. When the proteins reach the lysosome, the high concentration of the substrates successfully compete away inhibitor binding thereby enabling degradation of the substrates to occur. Some examples of correctors for each of these diseases are discussed below.

Several active-site specific chaperones have been identified for beta-hexosaminidase A, which is the multisubunit enzyme responsible for Tay-Sachs and Sandhoff diseases (9, 11, 23). The screening assays monitor inhibition of purified enzyme activity fluorometrically using the fluorescent artificial substrate 4-methylumbelliferyl-β-N-acetylglucosamine. These assays are then followed by cell-based assays to determine the amount of functional protein that traffics to the lysosome. Several distinct structural classes of pharmacological chaperones have been identified for these diseases including aza-sugars, pyrimethamine (Fig. 2b), and substituted bicyclic and tricyclic nitrogen-containing heterocycles (9, 11, 23).

Gaucher disease is caused by a deficiency in lysosomal beta-glucosidase activity. Deoxynojirimycins are known inhibitors of several enzymes, which include beta-glucosidase. Several alkylated deoxynojirimycins were screened for correction of N370S Gaucher mutant lysosomal beta-glucosidase activity in an intact cell assay (10). N-(n-nonyl)deoxynojirimycin
Protein Trafficking Diseases: Small Molecule Approaches to hERG Mutants

hERG encodes the pore-forming subunit of the rapidly activating delayed rectifier potassium channel. Mutations or drug treatments that cause retention of hERG in the ER result in cardiac arrhythmias that can lead to sudden death. Hence, drugs are now routinely screened for their effects on hERG function before being pursued in clinical trials. Several ER-retained hERG mutants can be rescued by chemical and pharmacological chaperones. The G601S and N470D mutations can be rescued by growth at permissive temperature or incubation with known hERG channel blockers E-4031, cisapride, and astemizole (Fig. 2b) (38, 39). hERG G601S has recently been used in a small molecule screen to identify correctors of hERG trafficking (40). This assay measured the amount of hERG G601S that trafficked to the cell surface by chemiluminescent detection of an extracellular epitope tag. Several different hERG blockers were found to rescue the ER retained mutant, which is consistent with their action as pharmacological chaperones. Other compounds have also been shown to rescue the trafficking of certain hERG mutants selectively. For example, the sarcoplasmic/ER calcium ATPase (SERCA) inhibitor thapsigargin can rescue the trafficking of G601S and FB60C mutants, but not N470D, whereas E-4031 rescues G601S and N470D mutants but not FB60C mutants (41).

G protein-coupled receptors

Many diseases caused by mutations in GPCRs are also the result of ER retention. Mutations in the vasopressin 2 receptor result in nephrogenic diabetes insipidus, which is a disease characterized by the kidney’s inability to concentrate urine. Trafficking of several different ER-retained mutants can be corrected by small nonpeptide V2R and V1R antagonists (42–46). The V206D mutation can also be corrected with glycerol, DMSO, SERCA inhibitors thapsigargin and curcumin, and the calcium ionophore ionomycin (44). This mutation cannot be corrected by growth at permissive temperature or with the addition of 4-phenylbutyrate (44). In contrast, the A98P, L274P, and R113W mutations can be corrected with the osmolytes trimethylamine N-oxide and DMSO, as well as with growth at permissive temperature (47). However, glycerol treatment does not correct the trafficking of these mutations.

Mutations in another GPCR, which is the gonadotropin-releasing hormone receptor, result in hypogonadotropic hypogonadism. Seventeen mutations in this gene have been characterized as misfolding or misrouting mutants, and most of these can be rescued by incubation with peptidomimetic antagonists (48). These pharmacological chaperones are indoles, quinolones, and erythromycin macrolides. Another example of a GPCR with ER-retained disease mutations is rhodopsin, which when mutated causes retinitis pigmentosa (49). A mild rhodopsin mutant P23H associated with night blindness can be rescued by treatment with 11-cis-retinal, which is its covalently bound chromophore (49).

Alpha-1-antitrypsin Z variant

Alpha-1-antitrypsin mutations are associated with early-onset emphysema and liver disease that results in early death (50). The Z-variant of the disease is the most common and is present in over 95% of cases. This variant has been shown to be rescued in vitro by treatment with proteasome inhibitors (50). Several chemical and pharmacological chaperones have also been shown to correct the secretion of the mutant protein, which include the glucosidase inhibitor castanospermine, as well as the mannosidase inhibitors tifensulfone (Fig. 2b).
and 1,4-dideoxy-1,4-imino-D-mannitol hydrochloride (51). Incubation with the chemical chaperone 4-phenylbutyrate also results in increased trafficking. However, growth at permissive temperature does not result in trafficking correction, although it does decrease the amount of mutant protein that becomes degraded (52).

Correctors of Protein Trafficking

Chemical chaperones

Several different classes of chaperones can be designated based on their mechanisms of action. Chemical chaperones are those that act nonspecifically. Although these chaperones are nonspecific, their use as therapeutics may be limited because of the high concentrations required to achieve correction. The mechanisms of correction employed by chemical chaperones may include the induction of molecular chaperone transcription or the nonspecific stabilization of proteins through masking of hydrophobic domains. For example, 4-phenylbutyrate (4-PBA) is a histone deacetylase inhibitor that activates transcription of different genes including the heat shock proteins (53). Studies on deltaF508 CFTR suggest that 4-PBA reduces the protein levels of the constitutive Hsc70 chaperone (54). This in turn reduces the amount of deltaF508 CFTR that interacts with Hsc70. The decrease in Hsc70 protein levels induces an increase in Hsp70 levels, which has been proposed to be a more effective chaperone, thus helping deltaF508 CFTR to fold and enabling it to escape from the ERQC (55).

Another common mechanism of correction is ER glucosidase inhibition (Fig. 1, star 4), because several ER chaperones require calcium for function. Interestingly, for lysosomal storage diseases, trafficking correction occurs through changing the levels of calcium in the cytosol and not in the ER. These two different mechanisms of correction highlight the importance of calcium signaling in protein trafficking.

Generalized pharmacological chaperones

A further subclass of pharmacological chaperones includes compounds that act through other mechanisms. This subclass includes generalized chaperones—those that rescue the trafficking defects of many or all ER-retained proteins through a universal mechanism. Many different mechanisms of correction are possible. Examples of this subclass of chaperones are described below.

One might expect that simply inhibiting ERAD with proteasome inhibitors would be the most generalized form of correction (Fig. 1, star 3); however, this strategy gives inconsistent results with different ER-retained mutants. The NERG Y611H mutant is not corrected, deltaF508 CFTR is only weakly corrected and alpha-1-antitrypsin Z variant is corrected as visualized by confocal microscopy (50, 59, 60).

As discussed above, for many ER-retained proteins, altering the intracellular calcium levels with SERCA inhibitors or with calcium ionophores corrects trafficking of the mutant proteins, presumably by altering the ER’s capacity for folding (Fig. 1, star 4). However, because several ER chaperones require calcium for function. Interestingly, for lysosomal storage diseases, trafficking correction occurs through changing the levels of calcium in the cytosol and not in the ER. These two different mechanisms of correction highlight the importance of calcium signaling in protein trafficking.

Another common mechanism of correction is ER glucosidase inhibition (Fig. 1, star 2), which prevents the recognition of misfolded proteins by calnexin and calreticulin and presumably allows them to escape the ERQC. Inhibition of glucosidase with castanospermine and miglustat were shown to correct the trafficking of deltaF508 CFTR and alpha-1-antitrypsin (51, 61). Whether this mechanism also works on other ER-retained mutants remains to be determined.

For other small molecules, the mechanism of action is still unclear. For example, silfenal and structural analogs have recently been shown to correct trafficking of deltaF508 CFTR mutants (19, 21). Silidenal is an inhibitor of phosphodiesterase activity; however, the link between this function and CFTR trafficking correction remains to be elucidated.

Pharmacological chaperones may also show mutation-specific profiles. For example, two common mutations in Gaucher disease N370S and G202R are both localized to the catalytic domain of the protein and are both corrected by active-site substrate/cofactor L-Dopa (58). Some specialized pharmacological chaperones are not inhibitors, such as the VRT-325 and Corr4a correctors of deltaF508 CFTR (20). VRT-325 is an interesting compound as it has also been shown to correct trafficking of P-glycoprotein, a protein related to CFTR, and the structurally unrelated G6015 mutant of the NERG potassium channel. This compound has not yet been demonstrated to interact directly with NERG.
Conclusions

The etiology of many genetic diseases can be traced to defects in protein trafficking. Several mutants are functional but are retained in the ER because of the overly stringent ERQC. Corrector compounds that permit the escape of ER-retained mutant proteins from the ERQC have great potential as therapeutics. Several types of trafficking correctors have been identified. Chemical chaperones are nonspecific and require high concentrations to be effective, which thereby limits their potential as therapeutics. Pharmacological chaperones function at much lower concentrations and show greater promise for drug development. Pharmacological chaperones can be classified into specialized chaperones that are protein or mutation-specific or generalized chaperones that can correct the trafficking of many ER-retained mutants. The identification of a generalized pharmacological chaperone that can correct all ER-retained disease mutants without grossly affecting normal proteins would enable treatment of many different protein trafficking diseases. Defining the mechanisms of action for this class of pharmacological chaperones will be the next milestone in trafficking disease research.

Additive effects of correctors have recently been shown for the deltaF508 CFTR mutant (62), which suggests that treatments that combine two or more chaperones may be a good option if no single potent corrector can be identified for a particular trafficking disease. Indeed combinatorial studies are likely to be the next key area of screening for correctors of protein trafficking diseases.

Saliva is a bodily fluid secreted by three pairs of major salivary glands (parotid submandibular and sublingual) and by many of minor salivary glands. Saliva is supplemented with several constituents that originate from blood serum, from intact or destroyed mucosal and immune cells, and from intact or destroyed oral microorganisms that result in a complex mixture of a variety of molecules. Saliva plays an important role in acquired pellicle formation on tooth surfaces, crystal growth homeostasis, bacterial adhesion, plaque formation, and—because of its lubricating effect—in maintaining mucosal integrity of the oral and upper gastrointestinal mucosal surfaces. It also plays an important role in physico-chemical defense, antimicrobial defense, and wound healing. Many saliva constituents including proteins, carbohydrates, lipids, and ions interact under fine regulation to fulfill these important tasks. Local and systemic disorders may disturb and interrupt these complex balanced functions, which can lead to mucosal and tooth damages. In other cases, systemic disorders induce salivary changes without any significant local effects. Many such changes are of high diagnostic interest because they can be rather specific to the causing conditions and can be used for screening and early diagnosis of several local and systemic disorders.

Saliva is a major determinant of the oral environment and serves as an easily available diagnostic tool of systemic conditions. Consequently, more intense saliva research can be observed in recent decades, which leads to a high amount of scientific data presented by numerous engaged researchers of this far-reaching field. With the rapid growth of knowledge, a need exists to summarize the obtained data of this interesting field. This article provides a brief introduction to the most important aspects of the chemical biology of saliva.

Origin of Salivary Chemical Components

Salivary components can originate from several sources, which leads to a rather complex collection of molecules. To understand the importance and meaning of a certain component, it is crucial to know the origin and the excretion mechanism of the component.

Constituents of salivary gland origin

Constituents of salivary gland origin (i.e., water, ions, proteins, carbohydrates, lipids) can be released from major salivary glands such as parotid, submandibular, and sublingual glands, and from minor salivary glands of the labial, buccal, lingual, palatoglossal, and palatal mucosa (1).

Based on the features of secreted primary saliva, secretory endpieces (acini) of salivary glands can be characterized as serous, seromucous, or mucous. The acini of parotid gland are mainly serous and seromucous, those of submandibular gland are mainly seromucous, and those of sublingual gland are mainly mucous. The acini of the minor salivary glands have various features that depend on their location (1).
Primary saliva is modified in the intercalated, striated, and excretory (collecting) ducts that lead from the acini to the mouth. Water and electrolyte transport into the saliva is believed to occur in the intercalated ducts. Striated ducts are responsible for electrolyte transport such as secretion of potassium and reabsorption of sodium ions. A transport of proteins like IgA, lysozyme, and kallikrein (and may be Hsp70 (2)) probably exists in the striated duct as well. An electrolyte transport in the excretory (collecting) ducts is also suspected (3).

**Constituents of other origin**

Each blood constituent may enter the oral cavity via intraoral bleeding. Serum exudates also reach saliva either from the gingival crevicular fluid or through the oral mucosa (mucosal transudate) and from the salivary glands via transcellular diffusion and ultrafiltration (via tight junctions) (3). Oral microbes and their fermentation products, enzymes, RNA, DNA, and structural elements are also usual constituents of the saliva (4). Fragments from the keratinized mucosal surfaces, mucosal cells with intact cell organelles from nonkeratinized surfaces, and some immune cells are also present. Cellular fragments, cytoplasmic products, enzymes, structural elements, membranes, RNA, and DNA of these cells are also usual salivary constituents. Certain amount of expectorated bronchial and nasal secretum, constituents of foods, administered drugs, smoke (from smoking), toothpastes, mouth rinses, and molecules released from dentures can also be found (2, 4).

**Molecular Participants of Saliva**

**Chemical Biology**

According to the above, many constituents exist in human saliva, and it is of scientific interest, only some have the focus of our attention. The most important constitutes are summarized below.

**Inorganic components**

Water is the most abundant constituent of saliva (~94%). The pH value of resting whole saliva is slightly acidic, which varies between pH 5.75 and 7.05, and it increases with increasing flow rate up to pH 8. Besides flow rate, the pH also depends on the concentration of salivary proteins, bicarbonate (HCO$_3^-$) and phosphate (PO$_4^{3-}$) ions that have considerable buffering capacity. Bicarbonate concentration is ~5-10 mM/L in resting conditions, and it may increase up to 40-60 mM/L with stimulation, whereas phosphate concentration is ~4-5 mM/L in saliva rather independently from the flow rate (5). Besides bicarbonate and phosphate, a significant amount of other ions are present to maintain the slightly hypotonic osmolarity of saliva. The most important ions are sodium (1-5 mM/L resting; 1–100 mM/L stimulated), chloride (5 mM/L resting; 70 mM/L stimulated), potassium (15 mM/L resting; 30–40 mM/L stimulated), calcium (1.0 mM/L resting; 3–4 mM/L stimulated), and many other ions such as ammonium (NH$_4^+$), bromide, copper, fluoride, iodide, lithium, magnesium, nitrate (NO$_3^-$), perchlorate (ClO$_4^-$), thiocyanate (SCN$^-$), and so on. They can be found in the saliva in lower concentrations (4, 5). (Data are summarized in Table 1).

**Proteins**

Human whole saliva has a protein content of about 0.5 to 3 mg/mL, and parotid saliva has a protein content of about 0.4 to 4 mg/mL, whereas submandibular and sublingual saliva of about 0.6 to 1.5 mg/mL. The protein concentration is more or less stable and independent from the flow rate (5). Besides maintaining osmolarity and buffer capacity, salivary proteins are also involved in several specific functions. The number of distinct salivary proteins is roughly between 100 and 140 (6, 7), from which roughly 30-40 % are produced by the salivary glands, whereas other proteins are originate from serum, from mucosal and/or immune cells, or from microorganisms (6). The most important proteins of glandular origin are alpha-amylase, glycoproteins with blood-group substances, cystatins, epidermal growth factor (EGF), gluten, histatins (HRPs), lactoferrine, lysozyme, mucins (MUC5B, MUC7), old terms: MGI, MGO), salivary peroxidase, proline-rich proteins (PRPs) and statherin. The most important serum derived proteins are albumin, alpha-antitrypsin, blood-clotting factors (VIII; IXa; XI) and members of the fibrinolytic system (proactivators, traces of plasminogen activator). Most important proteins that originate from immune cells are myeloperoxidase, calprotectin (Ca$^{2+}$ binding L1 leukocyte protein), cathepsin G, defensins, elastase, immunoglobulins (90% to 98% sIgA, 1% to 10% IgG, a few IgM, IgD, IgE). Finally, the most important protein constituents of microbial-unknown or mixed origin are alpha-2-macroglobulin, cystein peptides, DNases, RNases, kallikrein, secretory leukocyte protease inhibitor (SLPI), fibronectin, molecular chaperone (Hsp70), and streptococcal inhibitor. (Data are summarized in Table 2).

**Carbohydrates**

A significant amount of protein bound carbohydrates exists in the saliva. Some proteins may contain carbohydrates up to 80% of the molecule (i.e., MUC5B mucins) but 10-40% of carbohydrate moiety is rather usual in the case of any glycoproteins (4). The most important constituents are aminosugars, galactose, mannose, and sialic acid (N-acetylmuramic acid). Carbohydrate chains of mucins contain predominantly sialic acid and sulphate residues, although chains with blood group antigen properties contain about equal amounts of 6-deoxygalactose.

...aceaminoglycosamine, galactosamin, and galactose (5). Other usual constituents of the carbohydrate chains of salivary glycoproteins are also N-acetylglucosamin, N-acetylgalactosamin, and glucuronic acid (5). The total amount of protein-bound carbohydrates in the saliva is 300–400 µg/mL, of which the amount of sialic acid is usually about 50 µg/mL (up to 100 µg/mL (8)). The most important function of protein-bound carbohydrates is the increase of viscoelasticity of the saliva, prevention of proteolysis through holding proteases at a distance, prevention of acid precipitation in case of several glycoporteins (i.e., acid soluble blood group antigens, mucins), and labeling/antigen function.

Lipids

Whole saliva contains about 10–100-µg/mL lipids (9). The most frequent lipids in the saliva are glycolipids (i.e., neutral and sulphated glyceroglucolipids), neutral lipids (i.e., free fatty acids, cholesterol ester, triglycerides, and cholesterol), and a somewhat lower portion of phospholipids (i.e., phosphatidylethanolamine, phosphatidylcholine, sphingomyelin, and phosphatidylserine) (10). Salivary lipids are mostly of glandular origin, but some (such as cholesterol and may be some fatty acids) are believed to diffuse directly from serum (11). Lipids originate from several membranes such as secretory vesicles, microsomes, lipid rafts, and other plasma and intracellular membrane fragments of lysed cells and bacteria, although the lower percentage of phospholipids indicate that the salivary lipids are not primarily of membrane origin (9). A large portion of salivary lipids is associated with proteins, especially to high molecular weight glycoproteins (i.e., mucins) and to PRPs (12). Salivary lipids may play a role in the acquired pellicle, dental plaque, calculus, sialolith, and caries formation.

Other molecules

As mentioned, many other molecules exist in the saliva, including nucleic acids (RNA, DNA), several hormones, growth factors and neurotransmitters, amino acids and their derivatives, urea, lactate, citrate, vitamins, creatinine, prostaglandins, several drugs, and chemical constituents of foods, cosmetics, tooth pastes, dental materials, and several other molecules originated from body and environment.

Chemical Biology of Saliva in Health and Disease

Saliva constituents play a role in several oral processes, and they perform important defense functions in the oral cavity. Moreover, saliva may be used for diagnostic purposes. The most important knowledge related to these fields will be summarized briefly in the following section.

Saliva and bacterial adhesion

The basis of bacterial adhesion is given by the acquired pellicle formation on tooth surfaces. This pellicle is a thin (~0.5–1 µm) layer of several salivary proteins with calcium hydroxide-binding properties. The most important such proteins are salivary amylase, cystatins (S, SA, and SN type), histatin (HRP1), mucin (MG1), acidic PRPs, statherin, and immunoglobulins (sIgA) (4, 7).

The surface binding of these proteins occurs mostly through ionic interaction of positively charged groups of the proteins’ polypeptide chain and the negatively charged tooth surface (globular proteins wring on the tooth surface during binding). Although tooth surface is negatively charged, in some cases negatively charged protein regions are responsible for binding (i.e., N-terminal region of PRPs). Calcium bridging (Ca²⁺ complex formation) between the negatively charged groups may be a mechanism of such binding (13).

First, bacterial adhesion (usually gram-positive cocci and filamentous bacteria) occurs primarily through a Ca²⁺ complex formation between carboxyl (COO⁻) and phosphate (HPO₄⁻) groups of bacterial surface and acquired pellicle. Although van der Waals’ forces and repulsive electrostatic forces are also present, some specific bacterial surface proteins also serve as adhesins for specific receptors on acquired pellicle. Pellicle-integrated immunoglobulins also bind bacteria specifically.

WILEY ENCYCLOPEDIA OF CHEMICAL BIOLOGY © 2008, John Wiley & Sons, Inc.
Saliva and bacterial biofilm (plaque) formation

After the adhesion of the first layer of bacteria (i.e., Streptococcus mutans) the bacterial accumulation process is initiated by the activity of secreted extracellular glucosyltransferases (GTFs) of S. mutans. In the presence of sucrose, GTFs synthesize several forms of high-molecular-weight branched extracellular glucans (i.e., dextran), which leads to sticky polysaccharide products resulted in stronger binding to the surface and facilitation of adhesion of more bacteria via glucan-binding proteins of the bacterial surface. Food rests in the saliva may serve as store of sucrose during this process (4).

Saliva and crystal growth homeostasis

In general, saliva (as well as plaque fluid) is supersaturated with respect to calcium-phosphate salts, and they prevent tendency to dissolve minor crystals of teeth. Moreover, precipitation of calcium-phosphate salts that include hydroxyapatite may also occur (remineralization) in early lesions of tooth surfaces injured by acidic bacterial products (i.e., lactic acid). Salivary fluoride facilitates calcium-phosphate precipitation, and such crystals (i.e., fluorapatite) show lower acid solubility properties that lead to an increased caries preventive effect. The increase of pH (i.e., buffer capacity and pH of saliva, as well as ureolysis in dental plaque) also facilitates crystal precipitation and remineralization (4, 13).

Similarly, supersaturated of saliva with respect to calcium-phosphate salts is the driving force of calculus (i.e., mineralized dental plaque) and salivolith (i.e., salivary duct “stones”) formation. In these cases, negatively charged phospholipids play a crucial role. Ca$^{2+}$ ions bind to the negative charges of such lipids, and inorganic phosphate associates with the bound calcium that forms a Ca-phosphate-phospholipid complex, which is an excellent nucleus of calcium-phosphate deposition. Salivary proteins may also play a role in this process because such complex formation occurs predominantly on lipids that are protein associated. The increase of pH facilitates these processes (13).

Because calcium-phosphate precipitation would lead to a “confluent growth” of tooth surfaces and intensive formation of dental calculus and salivolith, the precipitation must be controlled. For such purposes, calcium and/or hydroxyapatite-binding proteins such as calprotectin, histatins (HRP1), statherin, acidic PRPs, and cystatins (5, 14, SN type) are present in the saliva. All inhibit crystal growth, whereas statherin also inhibits spontaneous unseeded precipitation (nucleation inhibition). Interestingly, dental plaque-bound immunoglobulins also inhibit crystal growth during calculus formation. Mg$^{2+}$ ions also have some nucleation inhibitory effect (4, 13).

Saliva and surface protection

Besides taphant in acquired pellicle formation on tooth (den- ture, implant) surfaces, MUC5B type mucins cover all oral surfaces with a 10-20-μm thick layer. In addition, MUC5B type mucins form a hydrophilic viscoelastic gel (already in low concentration) that causes a high viscosity matrix of saliva. These properties of mucins (MUC5B), together with similar effects of glycosilated PRPs, accomplish the lubricating effect of saliva that defends against physical injuries during chewing (4, 14). Salivary proteins, especially basic PRPs, bicarbonate ions, and phosphate ions may also act as buffers against acids of nourishment and/or bacterial fermentation. PRPs and especially HRP5s are potent precipitators of trinys, which are a widespread phenolic plant compound (flavonoid) of nourishment with unpleasant taste and protein precipitating properties (15). Protease inhibitory effect of saliva (i.e., HRP5s against trypsin-like proteases, cystatins against cysteine proteinases, and SLPI against serine proteinases) may also serve as surface defense by decreasing the proteolytic degradation of surface proteins and salivary defense proteins. Salivary chaperone Hsp70 is also a potent defense protein against cell surface damage; moreover, Hsp70 can repair aggregated and/or denatured salivary proteins (2). Peroxidases also protect host cells that transform H$_2$O$_2$ (produced by microorganisms and during immunoinflammatory reactions) to reactive anion hypohydroxocyanate (OSCN$^-$) that has a stronger antibacterial effect but a smaller cell-damaging effect than H$_2$O$_2$ (16).

The diluting effect of saliva and the oral clearance (i.e., swallowing toward the stomach and/or expectoration) of many proteins, bound or free molecules, and microbes also serve as an effective surface defense mechanism.

Antimicrobial effects of saliva

A network of antimicrobial salivary defense includes numerous salivary proteins. Although some defense molecules are present in a rather low concentration in whole saliva, it should be considered that local concentrations of these proteins nearby the mucosal surfaces (mucosal transudate), periodontal sulcus (gingival crevicular fluid), and oral wounds and ulcers (transudate) may be much greater (2). Furthermore, the effects are additive, synergistic, and in many cases reinforced by immune and/or inflammatory reactions (2, 16, 17).

Some defense proteins are involved primarily in immune activation. Salivary immunoglobulins take part in elimination of bacteria fungi and viruses through specific immune binding and agglutination. Immunoglobulins act via the antibody-induced ozone formation (18). Molecular chaperone Hsp70 acts as a danger signal that leads to a specific immune answer and complement activation and takes part in the antigen presentation (bacterial, micolitic, and viral) (2). Cystatin C has chemonatotic properties, and it plays a role in antigen presentation of dendritic cells present in oral mucosa. Moreover, cystatin S, C, and D show antiviral activity; cystatin C, SA, and SN show antiapoptotic activity; and cystatin S shows antibacterial activity.

Other proteins are responsible for nonimmune elimination of microbes (4, 14, 17). Salivary amylase is proposed to perform inhibitory effect on growth of microorganism. Calprotectin has bactericidal and fungicidal properties. HRP5s show specific antibacterial and antifungal activities, i. actiniferine has bacteriostatic effect. Lysozyme is bactericidal for gram-positive bacteria. Secretory leukocyte proteinase inhibitor shows antibacterial, antifungal and antiviral activity. Defensins possess antimicrobial and cyotoxic properties. Mucins, especially MUC7, are highly affine to microorganisms, entrap and agglutinate bacteria, fungi and viral particles. Peroxidases have antifungal
and bacteriostatic properties through producing reactive anion hypothiocyanate. Acidic PRPs bind bacteria, basic PRPs bind fungi (e.g., Candida albicans), and viruses, whereas glycosylated PRPs bind bacteria and viruses that indicate a role of PRPs in clearance of these microorganisms toward the stomach (4, 16, 17). (Data are summarized in Table 3.)

### Saliva and wound healing

Besides prevention of wound infactions through the above antimicrobial effects, saliva plays other roles in the healing of oral wounds as well. Salivary EGF speeds up the healing process by its angiogenic and cell proliferating effects (19, 20). Other growth factors present in saliva (3) such as transforming growth factor beta, fibroblast growth factor, insulin-like growth factors, and nerve growth factor also contribute to the healing process. Furthermore, saliva contains several blood clotting factors (IXa, VIII, XI) at a level comparable to plasma, and saliva can replace platelets in the thrombin generation (5). This property of saliva is highly important in the oral wound healing because, although saliva dilutes blood-clotting factors of blood origin, blood-clotting can be initiated. A relatively high amount of salivary kallikrein (5) is suggested to play a role in vasodilatation around mucosal injuries to facilitate healing and defense of the injured area.

### Saliva in dental caries

Besides the presumable alterations of bacterial adhesion, plaque formation, and salivary defense mechanisms detailed previously, some more or less-specifically detectable changes of saliva are in connection with caries formation, and it may be used for recognizing risk patients and to maintain prevention. Decreased saliva flow rate, decreased buffer capacity, increased number of S. mutans and Lactobacilli in saliva are usually associated with increased caries prevalence. Similarly, decreased level of certain salivary proteins such as proline-rich proteins (PRP1, PRP3), histatin 1, and statherin is associated with significantly higher caries susceptibility (3, 21).

### Saliva and periodontal disorders

Several important effects of saliva on bacterial adhesion, plaque and calculus formation, and elimination of microorganisms are described previously. Besides these effects and measuring several marker proteins, saliva may be used for periodontal disorder screening. The levels of proteolytic granulocyte enzyme elastase, protease inhibitor alpha1-antitrypsin, and elastase inhibitor alpha-macroglobulin may increase considerably under gingivitis and/or periodontitis. Moreover, the level of alpha-macroglobulin is also a good indicator of an individual's periodontal status (22). Salivary level of 3-hydroxy-fatty acids (lipid constituent of lipopolysacharide endotoxin of several anaerobic bacterial are also good indicators of chronic periodontitis (23). Albumin may also correlate with gingival inflammation (24). Although the periodontal diseases be diagnosed only by dental examination, the latest data on the role of periodontal diseases in cardiovascular and cerebrovascular conditions and also in premature birth may increase the significance of “quick screening” from the saliva (3).

### Saliva and xerostomia

Five main reasons for subjective dry mouth sensation (xerostomia) exist, such as salivary gland disorders, systemic disorders, medication, radiation therapy, and aging. In healthy humans, the resting flow rate is around (or somewhat below) 1 mL/min, although in some conditions, like dehydration, sleeping, relaxation, or altered mental states (i.e., hypnosis, photo-acoustic stimulation) the flow rate may not exceed 0.25 mL/min (25). Under stimulation, the flow rates increase in healthy subjects to the usual value of 1.5–2.3 mL/min, but it may increase to 3.7 mL/min (26). Xerostomia usually appears when resting unstimulated whole saliva flow rate is less than 0.4–0.7 mL/min. In other cases (~25% of patients), the resting flow rate decreases, but the stimulated flow remains normal. In other patients (~22%), both resting and stimulated flow rate is normal (27). In serious cases, saliva demonstrates low pH and buffer capacity, increased total protein albumin and sodium concentration, decreased amylase protein ratio, and high lactobacilli and yeast.
activity and abnormally elevated salivary prostaglandin E2 was
of electrolytes (sodium, chloride, calcium, and phosphorus) and
in the saliva was also found. Cystic fibrosis induces elevation
of phosphate (but not the cystatin C). A degradation of the glycan moiety
protein concentration and decrease the cystatin S concentration
and carbamazepine medications increase the amylase and total
flow rate and pH usually remains normal. Phentoin, valproate,
and carbamazepine medications increase the amylase and total
protein concentration and decrease the cystatin S concentration
(but not the cystatin C). A degradation of the glycan moiety
of salivary mucins and other glycoproteins, and a decreased ef-
ficacy of mucine-induced aggregation of bacteria was also
shown under multiple antiepileptic medications (24). However,
it should also be considered that degradation and decreased bac-
terial aggregation was probably caused by poor oral hygiene in
this group.

Salivary changes under medication
Numerous kinds of medications such as anticholinergics, anti-
pressants, antidepressants, diuretics, benzodiazepines, anihyper-
tensive agents, muscle relaxants, analagetics, and antihistamines
have been reported to induce xerostomia, although some (an-
tipsychotics, benzodiazepines, and antihypertensive drugs) may
also induce sialorrhea (28). Antiepileptic drugs also induce sig-
ificant changes in saliva; however, in this case the level of
flow rate and pH usually remains normal. Phenotoin, valproate,
and carbamazepine medications increase the amylase and total
protein concentration and decrease the cystatin S concentration
(but not the cystatin C). A degradation of the glycan moiety
of salivary mucins and other glycoproteins, and a decreased ef-
ficacy of mucine-induced aggregation of bacteria was also
shown under multiple antiepileptic medications (24). However,
it should also be considered that degradation and decreased bac-
terial aggregation was probably caused by poor oral hygiene in
this group.

Salivary changes in systemic conditions
Anxiety and depression may lead to decrease in salivary flow
rate and consequent xerostomia. A cute stress conditions also
induce significant salivary changes such as a decrease in se-
cretory IgA (29), increase in salivary amylase (25, 30) and
molecular chaperone Hsp70 (25) concentrations, and prompt
changes of bacterial adherence to salivary mucins. In Sjögren’s
syndrome, low level of resting and stimulated flow rate as well
as increased salivary level of sodium, chloride, IgA, IgG, lacto-
ferrin, albumin, P2 microglobulin, lactoferrin, cystatine C, cystatine
S, prostaglandin E2, interleukin-6, soluble interleukin-2 recep-
tor, and kallikrein was reported. A decreased level of phosphate
in the saliva was also found. Cystic fibrosis induces elevation
of electrolytes (sodium, chloride, calcium, and phosphorus) and
lipid levels of submandibular saliva that lead to increased cal-
culus formation. An unusual form of EGF with poor biologic
activity and abnormally elevated salivary prostaglandin E2 was
also found in cystic fibrosis patients (3). Graft-versus-host dis-
 ease causes a mean reduction of 55-90% of salivary flow rate
with elevated concentration of sodium, magnesium, total pro-
tein, albumin, EGF, and IgG in the saliva, whereas the amount of
salivary IgA and IgM decreases, and no change exists in
potassium, calcium, and phosphate concentrations (31). (Data
are summarized in Table 4).

Salivary diagnostics of systemic diseases
In some cases, saliva can be used as a highly effective diag-
nostic tool of systemic conditions. Serum-free hormone levels
in the case of several nonpeptide hormones like cortisol, testos-
terone, estradiol, estradiol, progesterone, aldosterone, androstene-
don, dihydroandostendion, and insulin can be calculated from
salivary hormone levels (3, 32). Saliva levels of small peptide
type neurotransmitters such as met-encephalin, substance-p and
bet-endorphin (33), and metionin (a single amino acid derivative)
may also refer to plasma levels. Salivary levels of epinephrine,
norepinephrine, and dopamine although do not correlate too
much with serum levels, but increase specifically under stress
conditions. Monitoring of the systemic level of several medi-
cations is also possible from saliva. Similarly, medication and
drug abuse and level of active or passive smoking and ethanol
consumption can also be monitored. Screening of virus infec-
tions with detection of specific antibodies against viruses (i.e.,
hepatitis, HIV) in mucosal transudate enriched saliva is also a
simple, well-tolerated, and accurate method (3). Tumor markers
(i.e., c-erbB-e, p53 antigen, CA125) present in the saliva may
be also used for screening and early diagnosis of malignancies
that appear in several regions of the body (i.e., not exclusively
oral tumors) (3). The fact that, in addition to the normal salivary
transcriptome core (180 mRNA), a high amount (≥3,000) of
other mRNA is detectable under several systemic conditions,
and it will be of high diagnostic value in the future (32, 34).
Similarly, oral fluid also provides an available source of micro-
bial or human DNA, although the DNA content is rather low.
This finding is useful for biomarker profiling of oral bacteria,
oral, or systemic diseases and for forensic identification (32).
(Data are summarized in Table 5).

**Chemical Techniques Used in Saliva Analysis**

The methodology of salivary analysis is wide ranging and includes nearly all techniques used commonly in other fields of chemical biology. The methods used most frequently for saliva analysis are summarized briefly below.

**Collection of saliva**

Sample collection should be made at standardized time, according to the diurnal cycle (and the response and recovery time) of the analyte. Subjects should not eat within 60 minutes prior to sample collection. For recovery of salivary glands, alcohol, caffeine, and dairy products should also be avoided. Resting saliva can be collected avoiding any chemical (i.e., acids), physical (i.e., pressure, warm, cold), biologic (i.e., taste, chewing), and psychologic (i.e., imagination of a meal) stimulation. Stimulated saliva is collected most widely with chewing stimulation (i.e., paraffin wax), and/or with taste stimulation (i.e., candy, lemon). Whole saliva can be collected simply by drooling into a vial with forward tilted heads or by allowing the saliva to accumulate in the mouth and then expectorate it into a vial. Isolated parotid saliva may be collected with direct cannulation of the parotid duct or with the use of parotid cap (a plastic container with a pocket that enables some negative pressure for stabilizing the device on the mucosal surface). Mixed saliva of submandibular and sublingual gland may be collected with direct cannulation of submandibular duct. Saliva of minor glands may be collected with pipettes or with small piece of absorbent. A fluid enriched in mucosal transudate and gingival crevicular fluid can be collected placing an absorbent pad between the cheek and the lower gum.

**Handling and storage of saliva**

Saliva is usually homogenized on a vortex mixer for one minute and precleared by centrifugation (i.e., 10,000 × g; 4°C; 10 min.) to remove food rests, bacteria, mucosal cells, and other particles. Saliva may also be cleared by filtration using small (i.e., 0.2 µm) pore size filters, but only small amounts, because the filter pores are blocked by high molecular weight components in saliva. Precleared saliva can be stored on ice (−4°C) without significant changes of enzyme activity (i.e., amylase) or protein degradation only for few hours. Addition of protease inhibitors is advantageous for time consuming analysis procedures. Freezing may lead to significant protein precipitation, even if quick freezing (i.e., liquid nitrogen) is used. Frozen sample can be stored at −20°C without any more damage for a few days only. Somewhat longer storage is possible in liquid nitrogen or at −80°C.

**Detection of ions**

The pH value can be measured with hydrogen-selective electrodes; however, it should be noted that the pH value of the saliva is dependent on the level of dissolved CO₂ thus–for a true pH value to be obtained—saliva must be collected without a loss of CO₂ to avoid measuring a pH value higher than real (5). The free (unbound) form of other ions like sodium and calcium can also be measured with ion selective electrodes. With the use of flame photometry the total amount of sodium, potassium and calcium can be measured in the saliva. With the use of atomic absorption spectrometry the total amount of calcium, magnesium, copper and some other ions (i.e., constituents of dentures like zinc, iron, cobalt, and chrome) is detectable. Photometric (calorimetric) methods can be used for measuring the total amount of chloride, calcium, bicarbonate, and phosphate. In case of calcium and phosphate a high percentage (~50% and up to 20%, respectively) may be bound to proteins and/or lipids (5, 35). Determination of the ratio between free and bound forms of calcium can be performed by comparing the data of flame photometry and electrode measurement. In case of phosphate, an exact discrimination is only possible after a careful isolation of proteins and lipids from saliva fluid.

**Analysis of salivary proteins**

The protein content of the saliva is determined usually with modified biuret reaction (Lowry method [36]). Qualitative protein analysis is carried out most frequently with gel electrophoresis, especially sodium-dodecyl-sulphate polyacrylamide gel electrophoresis, and isoelectric focusing in both cases either in one-dimensional (1-D) or in two dimensional (2-D) forms. Similarly, 1-D and 2-D high performance liquid chromatography (HPLC) is also used widely. These methods are combined frequently with immunologic methods such as Western-blot analysis (in the case of gels) and enzyme linked immunosay (ELISA, EIA) and radio immunosay in the case of whole saliva samples and saliva fractions (i.e., HPLC fractions). Measurements of enzymatic activity with the addition of substrates are common methods for determination of salivary amylase and lysozyme. Newer approaches use in-gel-tryptic-digestion of the separated proteins (7). Digestion is followed by extraction of the resulted peptides and fragmentation with tandem
mass spectrometry (MS/MS) in a predictable fashion that allows computational determination of the peptide sequence (37). The identification of the protein from which the peptide was derived can be reached by protein database searching. In the latest direct analysis of large protein complexes and multidimensional protein identification technologies, trypsin digestion is the first step, followed by chromatography of the peptide fragments (i.e., biphasic or triphasic microcapillary columns and HPLC) and MS/MS analysis (38).

Schizophrenia is a chronic and severely debilitating mental disorder that affects approximately 1% of the world’s population. Although schizophrenia has been recognized for over 100 years, the causes and pathophysiological mechanisms of this illness remained rather elusive until recently. Evidence obtained during the last 3 decades suggests that schizophrenia is a neurodevelopmental disorder that affects the structure and function of distributed brain regions. Multiple neurotransmitter systems have been implicated, as have both gray and white matter abnormalities. These structural alterations result in synaptic miscommunication at local neuronal circuits and long-distance functional disconnectivity, with both genetic and environmental factors contributing to these deficits. This article will discuss our current understanding of the biological and neurochemical bases of schizophrenia and will describe new pharmacological, genetic, and lesion models used for testing the mechanisms that underlie this devastating disease.

Schizophrenia was first identified in 1893 by the German psychiatrist Emil Kraepelin, who termed the disorder dementia praecox because of its early onset and irreversible mental decline. Then, 15 years later, the Swiss psychiatrist Eugen Bleuler recognized that the illness affected both the judgment and emotional state of the patient and referred to this disorder as schizophrenia, from the Greek schiz- to split and phren- mind. Bleuler identified the cardinal symptoms of the illness as loosening of associations, flat affect, social withdrawal, and ambivalence, and these criteria are still used for diagnostic purposes today. The onset of symptoms characteristically occurs during late adolescence and early adulthood. According to the Diagnostic and Statistical Manual IV (American Psychiatric Association, 1994), symptoms are categorized as positive or negative, and patients manifest these symptoms at various degrees during the course of their illness. Positive symptoms are manifestations of psychosis and include unusual behaviors such as paranoid or bizarre delusions, auditory hallucinations, and disorganized speech and thinking. In contrast, negative symptoms represent a loss of normal behaviors such as flat or blunted affect and emotion, poverty of speech (alogia), inability to experience pleasure (anhedonia), and lack of motivation (avolition). In addition, patients exhibit unremitting cognitive deficits. The clinical course and outcome of schizophrenia shows great variability; however, typically, positive symptoms fluctuate and negative symptoms remain more stable over time.

Alterations in Brain Structure and Function
Unlike neurodegenerative disorders such as Alzheimer’s disease and Parkinson’s disease, the brains of patients with schizophrenia reveal neither gross anatomical changes nor the presence of pathological structures such as amyloid plaques or Lewy bodies. Thus, for much of the 1900s, psychiatry textbooks classified schizophrenia as a “functional” psychosis, for example, a condition that had no underlying physical brain disease. The technological advances in the past 25 years made it possible for investigators to re-evaluate the biological bases of schizophrenia systematically and provided evidence of subtle but consistent neuropathological and molecular alterations. Although most of these studies focused on the dorsolateral prefrontal cortex (DLPFC) and hippocampus, other brain regions including the thalamus, cerebellum, and its connecting white matter tracts have been implicated in schizophrenia (Fig. 1).

Prefrontal cortex and anterior cingulate gyrus
Both postmortem tissue and neuroimaging analyses of the brain of patients with schizophrenia show small but reproducible gray matter reductions. In the prefrontal cortex (PFC), these changes were shown to be related to decreases in neuronal cell size and neuropil volume but not to a reduction in cell numbers (1). In
Hippocampus and entorhinal cortex

Convergent evidence from neuroimaging and neuropathological studies indicates that the structure and function of the hippocampus is compromised in schizophrenia. Patients with schizophrenia have decreased hippocampal volume (11, 12) and several cytoarchitectural abnormalities in both the hippocampus proper and entorhinal cortex (13). In addition, neuropathological examination of postmortem hippocampal tissue revealed a decreased number of GABAergic interneurons and several synaptic protein deficits in patients with schizophrenia (14–16). In contrast to the PFC, the levels of GAP-43 protein and the ratio of GAP-43 to synaptophysin mRNAs was decreased in the hippocampus of patients with schizophrenia (16, 17). These changes were correlated with decreased levels of another marker of excitatory synapses, the synaptic protein complexin II (18). Along with these structural and molecular alterations, patients with schizophrenia exhibit reduced activation of the hippocampus during the encoding and retrieval of episodic and relational information, two well-characterized hippocampal dependent tasks (19–21).

Cerebellum and thalamus

Traditionally, most research performed in the field of schizophrenia has focused on brain regions directly implicated in the symptomatology of the disease, namely the PFC and limbic areas. Work by Andreasen et al. (22) first implicated the cerebellum as an affected structure in schizophrenia through the cortico-cerebellar-thalamic-cortical circuit (CCTCC, see arrows in Fig. 1). Dysfunction in one area of this circuit such as the thalamus (23) is thought to affect all other areas of the circuit. As a component of the CCTCC, the lateral hemispheres of the cerebellum have been implicated in cognitive and emotional functioning (24). Retroviral tracing and neuroimaging studies demonstrated cerebellar–prefrontal connections (25), which may contribute to cognitive dysfunction in schizophrenia. Intrinsic to these connections, a forward modeling system of the cerebellum has been proposed in which information from the motor cortex or the PFC is transferred to the cerebellum, and the cerebellum acts as a predictor of the outcome for both motor and cognitive functioning (26). Clinically, patients exhibit cerebellar neurological signs (27), deficits in eyelid conditioning (28), and shortfalls in response timing (29). Neuroimaging studies have shown increases in blood flow and in glucose consumption in the cerebellum of schizophrenic patients relative to that of other brain regions (7, 30–32). In accordance with increased cerebellar activity, a recent study found that the levels of GAP-43 and brain-derived neurotrophic factor (BDNF), which are expressed in cerebellar granule cells in an activity-dependent manner, are upregulated in the patients (33). Additional molecular studies have shown decreased expression of the developmental marker reelin and the GABA synthesizing enzymes GAD65 and GAD67 and increases in the axonal chaperone protein semaphorin 3A (34–37). This finding is interesting considering the fact that GABA dysfunction in the cerebellum may lead to increases in granule cell firing and thus account for the increases seen in blood flow, glucose use, and
Schizophrenia, Biological Mechanisms of

Cortical Layers

Figure 2: Neurochemical and morphological alterations in the prefrontal cortex of patients with schizophrenia. The diagram shows some of the cell types in the layers I–VI of the dorsolateral prefrontal cortex, including glutamatergic pyramidal neurons (light gray) and GABAergic somatostatin-containing neurons, basket/wide arbor neurons and chandelier interneurons (dark gray), along with the changes in cell structure, gene expression, and neurotransmission observed in this region. These changes include decreased mRNA levels for several markers of GABAergic interneurons and reductions in the GAT-1 GABA transporter immunoreactivity in axon cartridges from chandelier cells with increased levels of postsynaptic GABAA receptors in pyramidal cells. Adapted from Ref. 9 and other references in the text.

White matter alterations

As described above and shown in Fig. 1, schizophrenia pathology is not restricted to a single brain region but affects multiple distributed areas. Brain regions considered important in the pathology of schizophrenia, such as the prefrontal cortex and temporal lobe, are linked normally to one another by tracts of dense and reciprocally afferent white matter, which thus suggests that white matter alterations could have a role in schizophrenia pathophysiology. Supporting this idea, white matter volume reductions have been reported in patients with schizophrenia (38–40). Analysis of frontal lobe white matter and corpus callosum of patients with diffusion tensor imaging revealed specific alterations in myelin structure (41). These changes were also observed in children and adolescent with schizophrenia (42), which indicates that white matter abnormalities may be present early in the disease. Postmortem tissue analysis at the light and electron microscopic levels also demonstrated the presence of myelin and oligodendrocyte abnormalities in schizophrenia (43–45). Along with these morphological abnormalities, microarray analysis of PFC tissue from subjects with schizophrenia also demonstrated downregulation of myelin-related and oligodendrocyte-related genes in the patients (46, 47). Finally, recent genetic studies identified polymorphisms in two important regulators of myelination, the transcription factor OLIG2 and the RNA-binding protein QKI, which are associated with increased risk for schizophrenia (48, 49).

Neurodevelopmental Hypothesis of Schizophrenia

As described above, the brains of patients with schizophrenia show alterations in the levels of the developmental markers reelin, GAP-43, and semaphorin 3A. In addition, evidence of disrupted neuronal distribution was found in several cortical areas and the hippocampal formation. These findings together with the absence of neuronal cell loss and concomitant reactive gliosis in these brain regions, both hallmarks of neurodegenerative disorders, led investigators to propose the neurodevelopmental hypothesis of schizophrenia (6, 50), which is still the prevailing theory in this disorder (51, 52). This hypothesis states that the illness is related to abnormal brain development and is supported by several pieces of evidence, including increased frequency of obstetric complications, viral infections, and other developmental stressors in patients with schizophrenia (see the sections below titled “Genetic and Environmental Factors” and “Developmental Models”) and the presence of soft neurological signs, cognitive impairment, and behavioral dysfunction in children long before the first psychotic episode.
Neurotransmitter Systems

As described in the previous sections, neuropathological studies demonstrated alterations in the levels of several synaptic proteins in the PFC, hippocampus, and cerebellum of patients with schizophrenia (13, 15, 53). These observations have led to the hypothesis that the clinical symptoms of schizophrenia are manifestations of abnormal neural circuitry and dysfunctional communication between different brain regions (22, 51). These abnormalities affect multiple neurotransmitter systems. Although dopamine dysfunction in schizophrenia is widely accepted, a growing body of evidence suggests the involvement of glutamate, GABA, and other neurotransmitters in schizophrenia.

Dopamine

The discovery that the first antipsychotic drugs in the early 1950s, such as chlorpromazine, work in vitro by blocking dopamine receptors led to the hypothesis that schizophrenia was the result of excessive dopamnergic neurotransmission (54, 55). Supporting this hypothesis, drugs that enhance dopamine action (e.g., cocaine, amphetamines, and L-DOPA) worsen the symptoms of schizophrenia. However, it is clear that 1) not all patients respond to neuroleptic treatment and 2) not all symptoms are reversed by the medication.

Classical treatments for schizophrenia involve the administration of typical antipsychotics, such as haloperidol and chlorpromazine, which primarily bind to dopamine D2 receptors with high affinity, and atypical antipsychotics, such as clozapine and risperidone, which bind to a broader range of receptors including serotonergic and noradrenergic receptors among others. Although antipsychotics are effective at relieving the positive symptoms via their actions on D2 receptors, they are not effective in ameliorating the negative and cognitive symptoms. Interestingly, recent studies suggest that patients with schizophrenia may have hypofunctional D1 dopamine receptors in the prefrontal cortex (Fig. 2) and that agonists to this subtype of receptor may be effective in treating the working memory deficits associated with this illness (56, 57). In addition to drugs that work on monoamine receptors, new drugs that target glutamate, GABA, and cholinergic receptors are now being tested for ameliorating the cognitive dysfunction in schizophrenia (58, 59).

Glutamate

The glutamate hypothesis of schizophrenia was derived from the fact that drugs that block the N-methyl-D-aspartate (NMDA) subtype of glutamate receptors, such as phencyclidine (PCP) and ketamine, cause schizophrenia-like symptoms in humans and animal models. Furthermore, these drugs mimic not only the positive (psychic) but also the negative and cognitive symptoms of the disease, which suggests that they act on the same basic pathophysiological mechanisms that are affected in schizophrenia.

NMDA receptor dysfunction has been characterized in different brain regions of patients with schizophrenia. Neuropathological studies revealed altered expression of receptor subunits in the prefrontal cortex (60), and single positron emission tomography studies have shown decreased NMDA receptor binding in the hippocampus of patients (61). Studies using NMDA receptor antagonists such as PCP, ketamine, and MK-801 additionally implicate hypofunction of these channels in schizophrenia (62). NMDA receptor antagonists have been shown to block NMDA channels located on GABAergic interneurons selectively (63, 64), which suggests that NMDA receptor dysfunction in a specific subset of these interneurons may be central to schizophrenia (62, 65).

GABA

GABA is the main inhibitory neurotransmitter in the brain, and dysfunction in certain subsets of GABAergic interneurons is one of the most consistent findings in the study of schizophrenia (9, 37, 66-68). Reductions in mRNA and protein levels of the 67 kD form of glutamic acid decarboxylase (GAD67), one of the GABA synthesizing enzymes, have been observed in the prefrontal cortex (69-71), the hippocampus (53, 72), the cerebellum (34, 35, 37), and other brain regions (73). As shown in Fig. 2, chandelier and basket interneurons in the PFC show decreased mRNA levels for the GAT-1 GABA transporter (74) and the calcium-binding protein parvalbumin (70), whereas other subtypes of interneurons have reduced levels of somatostatin (SST) mRNA (73). Posttranslational changes such as increases in GABA, u2 receptor density and GABA receptor radioligand binding in the PFC and anterior cingulate cortex were also observed (75-77). In addition to these findings, single nucleotide polymorphisms in the promoter region of the GAD67 gene were shown to be associated with reductions in gray matter in patients with childhood-onset schizophrenia (78). Considering the role of GABAergic interneurons in the modulation of excitatory output, it can be hypothesized that dysfunction in these cells may mediate some positive, negative, and cognitive symptoms seen in schizophrenia (79).

Other neurotransmitters: acetylcholine

Evidence of the involvement of acetylcholine in the pathophysiology of schizophrenia comes not only from the findings of decreased availability of cholinergic muscarinic receptors in patients (80, 81) but also from genetic studies that link specific polymorphisms in the gene for the alpha 7 nicotinic receptor (CHRNA7) with this illness. The CHRNA7 receptor is one of the ligand-gated ion channels that mediate fast cholinergic transmission at synapses. The CHRNA7 gene is located at chromosome 15q13-14, a locus implicated in the genetic transmission of schizophrenia (82, 83). Specific polymorphisms in CHRNA7 promoter region were shown to correlate with sensory gating alterations in patients with schizophrenia as measured by the P50 inhibition in auditory evoked response (84, 85). Furthermore, a recent study demonstrated that two additional single nucleotide polymorphisms (SNPs) in the CHRNA7 gene correlate with patterns of brain activation in schizophrenia patients during an auditory oddball task (86). The same study also linked an SNP in the gene coding for choline acetyltransferase, the acetylcholine synthesizing enzyme, with these abnormalities.
Genetic and Environmental Factors

Although the etiology of schizophrenia is not completely understood, it is becoming apparent that schizophrenia is a neurodevelopmental disorder that involves both genetic and environmental risk factors. The contribution of genetic factors was demonstrated by twin (87) and adoption studies (88) and by the higher prevalence of schizophrenia-like personality disorders in relatives of patients with schizophrenia (89). Other factors such as season of birth (90) and prenatal or perinatal complications such as ischemia (92) and viral infections (92) have also been identified as risk factors, although to a much lesser degree.

The influence of genetic factors is evidenced by the findings that about 50–75% of monozygotic twins with schizophrenia will have an affected twin and approximately 10% of first-degree relatives are also affected (93). Several genes have been associated with increased vulnerability for schizophrenia, including those encoding proteins associated with NMDA receptor function, synaptic plasticity, mitochondria energy metabolism, oxidative stress, development, and myelination (94, 95).

Recent studies demonstrate that specific polymorphisms in some of these genes correlate with cognitive and neuroimaging abnormalities in patients (96). The best example of these polymorphisms is an SNP coding for the substitution of a valine for a methionine in position 108 of the long form (Val108/158 Met in long form) of the catechol-O-methyltransferase (COMT, Val108/158 Met or SNP) protein. The amino acid substitution results in a protein that has increased stability and, thus, increased rate of dopamine inactivation (97). This polymorphism has been associated with impaired performance in working memory tests and abnormal patterns of prefrontal cortex activation in both patients with schizophrenia and healthy volunteers (98). In addition, polymorphisms in the genes for BDNF and the metabotropic glutamate receptor 3 (GRM3), among others, have been associated with subtle but consistent alterations in PFC and hippocampal structure and function (96).

Animal Models

Schizophrenia is a purely human disease, which makes it hard to model the behavioral manifestations of this illness in animals. Nonetheless, animal models have been shown to reproduce specific aspects of the illness such as its effects on brain structure and function. Currently, several animal models are available to investigators. These animal models can be classified as developmental, pharmacological, genetic, and lesion models. Examples of these animal models are described below, and a complete listing of current animal models can be found in a recent review (99).

Developmental models

Given the evidence of perinatal stressors in some patients with schizophrenia, animal models have been generated to examine the influence of these factors in adult behavior. These studies demonstrated that animals exposed to prenatal viral infections, maternal deprivation, and other stressors exhibit several behavioral abnormalities consistent with schizophrenia, including disrupted prepulse inhibition, enhanced response to amphetamine, and impaired social interactions (100–102). Furthermore, some models show molecular and morphological deficits in the neocortex and hippocampus that mimic the alterations seen in patients with schizophrenia (103).

Pharmacological models

Pharmacological models that exploit the GABA/glutamate system have proven useful in studying the underlying pathophysiology of schizophrenia. These models include the picrotoxin-induced antagonism of GABA receptors in rats (104) and the antagonism of NMDA receptors in both rodents and nonhuman primates (105–109). All these models affect the GABA/glutamate balance in different ways, but only the phenylethylamine model has shown both the GABAergic and NMDA receptor changes seen in patients with schizophrenia (108, 110, 111).

Because PCP administration leads to many symptoms inherent to schizophrenia, studies are now being conducted that administer the compound to rodents and primates to induce a schizophrenic-like phenotype (106, 112). A cute and chronic dosing regimen shows differential and often opposing effects in rodents. Immediately after administration of PCP to rats, neurons of the medial PFC show an initial excitation as seen by activation of early intermediate genes (112). This effect is likely because of the preferential blockade of receptors in GABAergic interneurons by PCP and other NMDA receptor antagonists (64). This initial activation then is followed by a period of cortical depression as described in glucose studies (114), presumably as a compensatory mechanism. A cute PCP administration also produces schizophrenia-like symptoms including social withdrawal (115), impaired sensory motor gating (116), and cognitive dysfunction (105, 107). Chronic intermittent exposure to low dose of PCP in rodents results in decreased metabolic activity in the prefrontal cortex, auditory cortex, hippocampus, and reticular nucleus of the thalamus (109), all regions affected in schizophrenia. Along with this decrease in metabolic function, decreases in parvalbumin expression were also seen (109), which mirror the chandelier and basket cell dysfunction seen in the prefrontal cortex of patients with schizophrenia (70). Taken together, the data suggest that the chronic intermittent PCP exposure model is one of the most functionally and neurochemically relevant animal models of unremitting schizophrenia.

Genetic models

Like the pharmacological model presented above, a genetic model also targets the NMDA receptor. This model was created by knocking down the NR1 subunit of the NMDA receptor, which is obligatory for receptor function, in mice so that only 5% of the protein is expressed (117). These animals, also known as NR1 hypomorphs, show NMDA receptor hypofunction and display several schizophrenia-like behaviors, such as reduced social interactions, increased locomotion, stereotypic movements, and sensorimotor gating deficits (117, 118). Interestingly, treatment of these mice with the atypical antipsychotic...
DISC1 protein exhibits brain and behavioral abnormalities suggestive of normal development (121), and mice that express mutant this chromosome 1q42.1 locus. This protein is known to be critical in schizophrenia (120), which has a balanced translocation in Scottish family with a high incidence of mental illness, including schizophrenia (120), which has a balanced translocation in this chromosome 1q42.1 locus. This protein is known to be critical for normal development (121), and mice that express mutant DISC1 protein exhibit brain and behavioral abnormalities suggestive of schizophrenia, such as impaired learning and memory processes and altered neuronal development (122-125).

Lesion models

Although no clear indication of a brain lesion is found in schizophrenia, developmental lesion models, such as the neonatal ventral hippocampal lesion (NVHL) and the neonatal amygdala data models, have been shown to reproduce several aspects of this illness (126, 127). For example, NVHL rats exhibit increased responses to dopamine agonists and MMDA receptor antagonists, which are manifested only after puberty. These animals also show impaired social interactions, altered sensorimotor gating, and cognitive deficits (128). At the molecular level, these animals show decreased numbers of GAD67 expressing interneurons in the medial PFC, which is similar to the findings observed in patients (71). Overall, this model also reproduces multiple aspects of schizophrenia behavior and pathophysiology.

Concluding Remarks

In summary, the work reviewed in the previous sections suggests that schizophrenia is a neurodevelopmental disorder that affects the structure and function of distributed brain regions and their connecting white matter, with both genetic and environmental factors contributing to these alterations. As shown in Fig. 1, affected regions include frontal lobe and limbic system structures involved in cognition and emotion and areas that participate in sensorimotor integration such as the thalamus and cerebellum. Structural and molecular abnormalities in these regions result in synaptic alterations at local neuronal circuits and long-distance functional disconnectivity. Besides dopamine, multiple neurotransmitter systems have been implicated including glutamate, GABA, and acetylcholine. Based on these findings, drugs targeting specific subtypes of these receptors are now being tested in animal models and patients. It is expected that these new developments will help researchers not only to understand the etiology and basic pathophysiological mechanisms that lead to schizophrenia but also to develop better treatment strategies for this devastating illness.

Systems Approach to Studying Disease

Gregory D. Foltz and Leroy Hood, Institute for Systems Biology, Seattle, Washington
doi: 10.1002/9780470048672.wecb587

The emerging field of systems biology promises to transform our understanding of the molecular basis of human disease. Recent technological advances allow for multiparameter measurements to be integrated across global genomic and proteomic platforms to inform predictive and probabilistic gene and protein regulatory networks. A systems approach to disease is based on the idea that disease-perturbed gene and protein regulatory networks differ from their normal counterparts, and that these differences are predictive of the disease course and response to therapy. The ability to detect disease-related perturbations in individual patients will transform health care over the next decade from our current reactive medicine to a new medical practice that is predictive, personalized, preventive, and participatory (P4 medicine).

The completion of the Human Genome Project fundamentally transformed contemporary approaches to medicine and disease. At the root of this transformation is the concept that biology is an informational science based on a digital code, encoded in the genome, from which all biologic processes are derived. This realization has several important implications for the study of disease. First, the digital code of the human genome is knowable and can be defined, interrogated, and compared in disease and healthy states. A second type of biologic information is that which emerges from the environment to modify the digital genomic readout. Thus, the integration of the digital genomic information and the environmental information across the development of organisms, their physiologic responses to the environment, and their responses to disease is the heart of what has come to be known as systems biology and systems medicine. This field provides a basic blueprint of disease from which hypotheses can be formulated regarding etiologies and possible therapeutic entry points. Second, the digital nature of genomic data, including the complex hierarchy of molecular (biologic) networks, and their dynamical response to environmental stimuli is amenable to modern computational and analytical techniques. Third, because of the parallel advancement of high-throughput genomic and proteomic technologies, the genomic code and its derivative dynamic molecular networks are increasingly accessible and testable at the individual level. Fourth, the digital code and the dynamics of its encoded networks can be compared across model organisms allowing for the targeted manipulation of gene networks implicated in disease states. A key point in the new medicine, then, is the idea that drugs can be designed to reengineer networks (and this will take multiple drugs) to make them behave in a more normal manner—quite a different concept from the idea that one drug should destroy or enhance the activity of one particular target. Finally, unbiased systems analyses result in our understanding of the emergent properties that are not predicted a priori, which leads to new insights into disease states. As a result of these influences, medicine is evolving from an observational, population-based, reactive approach to a more quantitative, predictive, and individualized approach to understanding disease and disease treatment based on rational genomic analysis. This evolution will ultimately transform traditional medicine into a new field of “systems medicine” that will provide personalized, predictive, preventative, and participatory treatment of disease in individual patients.

Systems Biology: An Introduction

Understanding a systems approach to disease first requires an introduction to the emerging field of systems biology. Systems approaches to understanding biologic complexity emerged as a result of several key transformative technological and theoretical advances that created new ways of thinking about biologic analysis and the scientific infrastructure required for integrated experimental models. These advances include 1) the development of high-throughput platforms for the rapid acquisition of global data sets. These platforms, which include high-speed DNA sequencers, DNA microarrays, mass spectrometry-based global proteomic technologies, antibody arrays, and the study of metabolomics with nuclear magnetic resonance (NMR) and mass spectrometry, have fundamentally enabled systems biology. 2) The completion of the Human Genome Project, which
A Systems Biology Approach to Disease

A systems approach to disease is derived from two very simple hypotheses. First, the functions of living organisms are executed by biologic networks of two different types: 1) protein networks (generally protein/protein interactions) that use biological information to carry out functions such as signal transduction, metabolism, development, or physiologic responses, and 2) gene regulatory networks (transcription factors controlling layered networks of other transcription factors) that take input biologic information from, for example, signal transduction networks—integrate and modulate it—and then output it to the protein networks mediating, for example, development of physiologic responses. Second, disease states and (b) to integrate these data to generate predictive mathematical models of disease behavior and response to therapy.

Systems medicine requires the integration of many different types of data into models that have predictive behavior. We discuss below several of the high-throughput platforms that are generating large-scale data for a systems approach to disease.

High-Throughput Platforms for Systems Analysis

Genomics

Complete genome sequencing provided the foundation for systems biology by enabling investigations that could examine specific molecular hypotheses in the context of a completely defined catalog of genes and proteins for humans. The first complete genome of a free-living species, Haemophilus influenzae, was completed in 1995 (1) and was followed quickly by other important human bacterial pathogens (2–4), yeast (5), human (6), mouse (7) and chimpanzee (8). By 2005, only a decade later, more than 1,000 complete genomes have been completed. This massive expansion of sequence data was enabled by
technological improvements in the Sanger sequencing method (9), which allowed for increased automation and throughput (10, 11). Despite these advances, significant infrastructure and cost is required for sequencing even a relatively small genome. As a result, most genome sequencing is still performed at large dedicated genome centers and most completed genomes represent only one or a few sampled organisms (12). Recent developments in microfluidics, image processing, and enzymology promise to increase massively the speed and capacity of DNA sequencing at a significantly reduced cost. Currently, this “next-generation” high-throughput DNA sequencing (from companies such as 454, Solexa, Applied Biosystems, and Helicos) is being used to characterize cancer-associated mutations across extended patient populations (13). Once individual genome sequencing is achieved economically, comprehensive identification of individualized markers of disease susceptibility and treatment response will enable predictive and preventative strategies to treat and prevent disease.

One powerful application that has emerged from large-scale genomic sequencing is the identification and characterization of polymorphisms, either single nucleotide polymorphisms (SNPs) or, more commonly, simple sequence repeats, in genes that identify and predict variations in biologic response, behavior, and predisposition to disease states (by DNA arrays and hybridization or by DNA sequencing of various types). Most common diseases are thought to result from a mixture of genetic and environmental factors. Many factors demonstrate a complex genetic predisposition thought to result from the contribution of small variations in several genes. More than four million putative SNPs have been identified in the human genome. Because they are highly abundant, occurring on average every few hundred base pairs in the genome, and, relatively stable, they provide useful markers for linkage analysis of genes involved in the pathogenesis of complex disease. The development of high-throughput genotyping methods makes genome-wide linkage disequilibrium mapping of SNPs a viable approach to the study of complex disease susceptibility. A nontrivial application of the SNP analysis is the identification of genetic variants that influence a patient’s response to a drug, which usually is used to predict pharmacological efficacy or the likelihood of harmful side effects. An important extension of this application is the identification of SNPs that alter cellular responses to biologic signaling during normal development and function. This largely unexplored area offers vast potential for defining the genetic basis of normal biologic variation in the development of disease.

Transcriptomics

A advance in genome sequencing technology enabled the systematic measurement and comparative analysis of complete transcriptional programs of cells and tissues at various points in time and at any given developmental, pathological, or functional stage. The most widely used methodologies for transcriptome analysis include DNA microarrays, serial analysis of gene expression (SAGE), microarray-based massively parallel signature sequencing (MPSS), and the massively parallel sequencing by synthesis (SBS). DNA microarrays are a powerful tool for high-throughput identification and quantitation of nucleic acids in biologic systems. DNA arrays typically consist of thousands of short gene-specific DNA molecules spatially arranged on a solid surface. Nucleic acid-specific hybridization allows for the precise identification and quantitation of transcript levels in a cellular system at two or more different states. DNA microarrays can either be spotted arrays of oligonucleotides (25-60 bp in length) or cDNA molecules, or they can be oligonucleotide arrays produced by piezoelectric deposition or in situ synthesis. Recently, custom-designed arrays have become available containing up to 400,000 oligonucleotides. This flexibility in array design allows for economical approaches to study specific disease states in systems biology.

In principle, oligonucleotide arrays are more specific than the cDNA array and have the capability to distinguish between single-nucleotide differences. This method has the advantage of distinguishing between transcripts derived from individual members of multigene families and alternatively spliced variants. The widespread acceptance of DNA array technology has led to the development of applications beyond transcriptome analysis that have an impact on the study of disease. DNA array technology has been used in genotyping studies to identify SNPs and to confirm the sequence identity of known regions of DNA. Currently, DNA array applications include promoter analysis, ChiP-on-chip studies of protein-promoter binding site occupancy, mutation analysis, comparative genomic hybridization, and genome resequencing. DNA sequences can also be tagged or labeled in such a way that they can be identified in solution. A powerful new application of sequencing technology, massively parallel signature sequencing (MPS or SBS), combines advances in microfluidics, enzymology, and image processing technologies to allow up to 1,000,000 different sequences of up to 35 residues to be determined simultaneously per sample (14).

Proteomics

Proteomics can be defined as the global characterization of proteins in complex mixtures, including protein identity, abundance, processing, chemical modifications, interactions in protein complexes, and subcellular localization within a cell or tissue. Currently, no proteomics technology approaches the throughput and level of automation of genomic technology. Strategies for protein identification and quantification can be divided into MS-based techniques, designed to provide unbiased global measurements of protein abundance, and antibody-based techniques designed to identify known proteins in a biologic sample. These and other strategies to reduce sample complexity, differentially label protein samples, and improve relative quantitation of proteins by MS analysis and antibody arrays promise to enhance a systems approach to disease.

Proteomics: mass spectrometry techniques

The standard approach to proteome analysis is based on the separation of complex protein samples by two-dimensional gel electrophoresis (2DE) and the subsequent identification of selected separated protein species by one of a variety of mass
specrometric techniques (15). This approach is limited funda-
mentally because specific classes of proteins are not rep-
resented in the gels (e.g., membrane proteins, small proteins, or
very basic proteins) or are undetectable because of their limited
abundance. Furthermore, this method remains labor intensive
despite automation of 2DE gel computerized pattern matching,
protein extraction and digestion, and mass spectrometry-based
analysis. In addition, the enormous dynamic range of protein
abundances found in biologic systems, ranging from 1 to 10^6
copies or greater in cells and up to 1 to 10^{12} in serum, is a
major impediment for detecting low-abundance proteins. Im-
proved throughput is provided by direct analysis using tandem
mass spectrometry (MS/MS) of peptides generated by the di-
gestion of complex, unseparated protein mixtures (16). The key
feature of this method is the ability of a tandem mass spec-
trometer to collect sequence information from a specific pep-
tide, even if numerous other peptides are concurrently present
in the sample. This collection is accomplished in the instru-
ment by the isolation of the peptide ion of interest from other
peptides, fragmentation of the peptide ion in a collision cell
collision-induced dissociation, CID), and the acquisition of the
fragment ion masses in a computer. It is these fragment ion
masses that represent unique identifiers for a peptide and the
sequence of the peptide, and therefore, the identity of a protein
determined by correlating the CID spectrum with the contents
of sequence databases (17). Recently, protein separation tech-
niques have been enhanced by the use of multidimensional liq-
uid chromatography (LC) followed by specific protein/peptide
capture strategies (18).

The development of technologies for global comparative
measurements of proteins or protein moner-metal complexes, the proteome, and their function and structure from cells or tissues of different
states (e.g., healthy vs. Disease) is a fundamental requirement
for a systems approach to disease. Stable isoform labeling of
proteins or proteins enables high-throughput relative quantification of proteins using MS on a scale approaching several thou-
sand per sample. The general strategy involves differentially
labeling proteins or proteolytic peptides with stable isotopes,
mixing of labeled samples at a 1:1 ratio, followed by com-
bined sample processing and subsequent MS analysis. As the labeling reagents possess almost identical chemical properties,
the labeled peptides appear closely paired in the LC and MS
processes. Relative quantification is achieved by comparing ion
signal intensities or peak areas of isotope-encoded peptide pairs
observed in the corresponding mass spectra. Current methods
in current for the isotope encoded tag for relative and absolute quantitation (iTRAQ).

The isotope-coded affinity tag (ICAT) technique involves dif-
ferential labeling of two different protein populations on the side
chain of reduced cysteinyI residues using one of two chem-
ically identical but isotopically different ICAT reagents (19).
By incorporating a biotin affinity tag into the ICAT reagents,
selective isolation and purification of labeled peptides substan-
tially reduces sample complexity. The ICAT approach has been
applied successfully to the systematic identification and quantifi-
cation of proteins contained in the microsomal fraction of cells
(20). It has also been applied, in conjunction with DNA mi-
croarray analysis, to identify differential expression profiles of
hematopoietic progenitor cells (21). A major drawback of ICAT
is that it only labels the fraction of proteins containing cysteine residues. An alternative approach, SILAC, involves
growing two populations of cells, under identical conditions ex-
cept that the culture medium for one population contains 20
essential amino acids in their naturally occurring isotopic forms
(“light” population), whereas the other population is grown
in medium where one or more amino acids are replaced by
heavy isotopic analogs (22). The incorporation of a heavy
amino acid into a peptide, which is referred to as metabolic la-
beling, results in a known mass shift relative to the peptide
that contains the light version of the amino acid. The advan-
tage of using metabolic labeling is that it allows mixing of
labeled and unlabeled cells before the fractionation and purifi-
cation steps and therefore avoids introduction of any errors in
relative quantification in subsequent sample preparation. Fur-
thermore, all peptides within the sample can be analyzed, not
just those containing cysteine residues, increasing confidence in
both identification and quantification.

Isobaric tag for relative and absolute quantitation (iTRAQ) is
a multiplexed approach that allows up to four samples to be ana-
yzed simultaneously by MS in the same experiment (23). Pe-
tides are labeled on the free amine groups at the amino terminus
and on lysine residues. Unlike other isotopic labeling strategies,
the iTRAQ label reagents are designed to provide quantitative
information during peptide fragmentation. This technique mod-
difies peptides by linking a mass balance group (carbonyl group) and
and a reporter group (based on N-methylpiperazine). Designed
to be isobaric (having the same mass), the iTRAQ reagents
are chromatomographically indistinguishable in the LC step, which
causes the ion peak for each of the identical labeled peptides
to be detected simultaneously by the mass spectrometer. When
MS/MS is used for analysis, the reporter group of the iTRAQ
labeled and unlabeled cells before the fractionation and purifi-
cation steps and therefore avoids introduction of any errors in
relative quantification in subsequent sample preparation. Fur-
thermore, all peptides within the sample can be analyzed, not
just those containing cysteine residues, increasing confidence in
both identification and quantification.

Proteonomic reducing complexity
Protein concentrations in biologic systems span 10^{12} orders of
magnitude, whereas the most common available mass spec-
trometry-based methods only allow for the identification of
proteins spanning approximately three orders of magnitude in
concentration from a given sample. Several methods have been
advanced that select for specified fractions of the proteome in
order to reduce the complexity of the sample sufficiently
to identify biologically interesting proteins. Protein glycosyla-
tion, one of the most common posttranslational modifications, is
characteristic of secreted proteins and cell-surface markers but
not found on the predominant serum proteins such as albumin.
Recent approaches selecting for N-linked or O-linked glycosylated peptides using affinity capture techniques or solid-phase extraction followed by stable isotope labeling enrich for these biologically active proteins. Zhang et al. examined glycosylated proteins from several tissues, cells, and plasma and compared the glycoproteins identified in the tissues and cells to those identified in the plasma. A significant overlapping was observed. This study demonstrates that tissue-derived proteins are indeed present and detectable in the plasma via direct MS analysis of captured glycopeptides, proving the feasibility of MS-based approach for plasma protein discovery and analysis. A significant improvement on this technique has been the capture of glycopeptides (rather than glycoproteins) (27).

Multiple reaction monitoring (MRM) is a highly selective, highly sensitive mass spectrometry approach for detecting the presence of particular peptide species in a complex mixture such as plasma (28). A specific tryptic peptide is selected as a stoichiometric representative of the protein from which it is cleaved. This peptide is quantified by MRM against a spiked internal standard (a synthetic stable isotope-labeled version of the peptide) to yield a measure of protein concentration. In principle, such an assay requires only knowledge of the masses of the selected peptide and its fragment ions and an ability to make the stable isotope-labeled version. This method can quantify reliably protein concentrations over a dynamic range of 4.5 orders of magnitude in human plasma using a multiplexed approach. MRM assays coupled with enrichment of proteins by immunodepletion and size exclusion chromatography (29), or enrichment of peptides by antibody capture have also been reported (30). Stable isotope standards and capture by anti-peptide antibodies (SISCA PA) has been shown to extend the sensitivity of a peptide assay by at least two orders of magnitude and with additional development appears capable of extending the MRM method to cover the full known dynamic range of plasma (i.e., to the pg/mL level) (30). In systems approaches to disease, many important bioactive proteins are presumed to be secreted in the blood as key regulators of systems processes. These and other strategies to reduce or overcome the complexity of serum hold great promise for identifying key proteins active in disease states.

Proteomics: antibody-based arrays

An alternative strategy to global proteome analysis using MS is the use of antibody-based array techniques (31-33). A variety of methods have been developed based on antibody binding, all of which are limited by 1) dependence on the affinity and specificity of the antibodies employed for detection, 2) relatively high cost of generating monoclonal antibodies, and 3) potential cross reactivities in complex protein mixtures. Despite these limitations, antibody arrays have the advantage of providing a quantitative and comparative platform for rapid screening of proteomes from different disease states such as lung (34), pancreatic (35), and prostate cancer (36). One emerging approach with tremendous promise is surface plasmon resonance (SPR), which enables real-time, label-free measurement of protein abundance (37). SPR is a physical phenomenon that occurs when electromagnetic waves, such as light, are reflected off a thin metal film at specific incident angles and wavelengths. A fraction of the light energy (either polychromatic, many colors, or monochromatic, one color) interacts with and transfers to the surface plasmons, thus reducing the reflected light intensity at a sharply defined angle or at a specific wavelength. Any modifications on the metal surface, such as occurs with the interaction between antibody and antigen, will affect the SPR condition and can be used to detect and monitor specific molecular interactions. Sensitivity of SPR for low-abundance proteins is estimated to be in the picogram/cenimeter squared range. Current SPR-based chips have 800 unique antibodies arrayed at approximately 4 µm spatial resolution. Significant advantages of this method are that 1) protein abundance can be monitored in real time allowing for assessment of binding dynamics, and 2) slides can be regenerated allowing for cost-effective screens of multiple samples. Another recently developed technique, DNA-encoded antibody libraries (DEALs), is a highly sensitive measurement technique that can detect protein and single-stranded DNA simultaneously on a single chip (38). DNA-encoded antibodies are labeled with single-stranded DNA oligomers. DNA-encoded antibodies and secondary (fluorescently) labeled antibodies are added to the biologic sample containing the protein of interest. The entire complex is then captured by nucleic-acid hybridization onto a spot that was pretreated with the complementary single-stranded DNA oligomer. This approach has been used for the rapid detection of multiple proteins within a single microfluidic channel with a lower detection limit of 10 fM, which is 150 times more sensitive than the analog ELISA.

Computational Approaches

A systems approach to disease requires the integration of vast amounts of quantitative biologic data generated by global genomic and proteomic analyses in order to 1) identify comprehensively key molecular components defining disease and healthy states, and 2) determine how these components interact in biologic networks in a predictable way. Initial efforts primarily integrated and analyzed large databases of gene expression data to identify subsets of genes with predictive value for disease stratification and prognosis. A variety of methods have been applied to disease diagnoses, including approaches based on support vector machines and relative expression reversals, among many others. Application of these methods has led to the discovery of molecular classifiers of varying degrees of accuracy to identify prognostic signatures for breast cancer, ovarian cancer, colon cancer, prostate cancer, and brain cancer (39, 40).

With the development of protein-protein and protein-DNA interaction databases, gene expression data can be mapped onto interaction networks to identify relevant biologic pathways active in specific disease states or experimental perturbations. This type of approach is useful for assigning disease-specific relevance to differentially expressed genes or molecular pathways and has been applied in several human diseases, most notably cancer. Although these interaction networks are very useful tools for visualizing large data sets, they are not computable, predictive network models, which are those that hold
the most promise for predictive medicine and drug development. One approach uses an integrated framework, Pointillist (41), for combining diverse data sets and inferential algorithms to generate model networks, which are incorporated into Cytoscape (42) for visualization and simulation. The integration methodology of Pointillist can handle data of different types and sizes (e.g., interactions, protein expression, or gene expression) to create a higher confidence interaction network than that resulting from a single data set alone. A novel aspect of this methodology is that it does not require a "gold standard" set of data to be used for training nor does it make assumptions about the underlying statistical distributions in the form of parametric models. This process involves designing an efficient deterministic optimization algorithm to minimize the numbers of misses and false positives via an iterative element by element procedure. The methodology is general purpose so that it can be applied to integrate data from any existing and future technologies (43).

Other approaches for inferring genetic regulatory networks include parsimonious linear regression models, probabilistic Boolean networks, and Bayesian networks from expression data (both steady-state and time-course) (44). Probabilistic Boolean networks are robust in the face of biological and measurement uncertainty and offer the ability to characterize and simulate global network dynamics using the inferred model structure (45). It also provides a natural way to determine the influences of particular genes on the global network behavior (46). Thus, the model can be used to predict the effects of perturbations on network dynamics, which is an important goal for understanding disease development and treatment response. These and other predictive models stemming from mathematical descriptions of biochemical reaction networks and statistical influence models are critical for identifying disease-perturbed networks in disease states. Dynamic and predictive network models have been developed for important signaling networks in disease such cancer. Such approaches are now used to predict response to network perturbations in mammalian systems using an algorithm called Reconstruction of Accurate Cellular Networks (ARACNe) (47). These and other computational modeling approaches will play a key role in the identification of disease-perturbed networks, identifying potential therapeutic targets. With the development of comprehensive databases, hypothesis-driven global analysis methods, and predictive network models, systems biology has matured as a predictive science, which is capable of generating testable hypotheses based on network models with predictable behaviors. Applying this systems approach to disease holds great promise for the development of new therapies.

P4 Medicine: Personalized, Predictive, Preventative, and Participatory

Health care will be transformed over the next decade from our current reactive medicine to a new medical practice that is predictive, personalized, preventive, and participatory (P4). Personalized medicine will reflect the fact that each human differs from one another by approximately 6 million DNA bases—and has unique predispositions to differing combinations of diseases. The genome analyses and blood molecular fingerprints will permit each individual to be assessed individually and to be treated individually. Preventive medicine will emerge from the realization that a systems approach to disease will bring deep insights into the disease-perturbed networks and the fact that drugs can be eventually used to reengineer network behavior. Thus, the strategy for choosing drug targets will change in a fundamental manner. In a similar vein—once an individual's DNA has predicted a high likelihood say for brain cancer at the age of 50 or older—one could design drugs to prevent the relevant brain networks from ever becoming perturbed—if the drugs are taken 10 or 20 years before onset—and this would be preventive medicine. Finally, participatory medicine originates from the fact that given more information patients will be able to participate more fully in choosing their own health trajectories. This participation will also require the education of physicians as to the nature of P4 medicine. This transformation, if focused and properly leveraged, can both immensely improve the lives of people and reduce substantially the growing burden of health-care costs in modern countries.

The transformation that is currently on the horizon, from our current reactive medicine to a medicine that is predictive, personalized, preventive, and participatory, will impact much more than medical science. It will affect national economies, social policy, and the spectrum of business relationships, opportunities, and constraints. The science that is driving this change has not yet impacted medicine, but the changes are on the horizon. The changes in the science have been building for the past 20 years, beginning with the human genome project. In coming decades the health-care system will not only generate billions of bits of data for each individual patient but must learn how to use this data effectively—for the individual and for the collective knowledge of medical susceptibilities and response to therapies that will be enabled. This transformation will be driven by new systems strategies for studying disease, powerful new measurement technologies (e.g., nanotechnology), and revolutionary new computational and mathematical tools for dealing with the enormous amounts of information that will be gathered and for converting it into hypotheses about health and disease.

ADME Properties of Drugs
Li Di and Edward H. Kerns, Wyeth Research, Princeton, New Jersey

doi: 10.1002/9780470048672.wecb003

ADME properties have tremendous impact on the success of drug candidates. They are a set of fundamental physico-chemical and biochemical properties of drug molecules that can be affected by physiologic conditions in vivo: solubility, permeability, stability, metabolism, and others. ADME properties can be improved through structural modification by medicinal chemists. They are important both in vitro and in vivo. A successful drug must possess a balance of good potency and drug-like properties. High-throughput ADME assays have been developed and implemented widely in the pharmaceutical industry to reduce the attrition of drug candidates. The data are used to identify potential liabilities, guide structural modification, prioritize lead series, select compounds for in vivo studies, and diagnose in vivo assay results. Studies have demonstrated that early screening of ADME properties is a successful approach to enhance the quality of drug candidates.

Drug discovery typically starts from an unmet medical need (1), followed by target identification-validation, HTS (high-throughput screening) and hit finding, as well as hit-to-lead and lead optimization (Fig. 3). Once an active compound is identified, preclinical development starts. If the compound is efficacious and safe in animals, it will be evaluated in human clinical trials after an IND (investigational new drug) is filed. Phase I clinical trials involve safety and pharmacokinetic studies in a small group of healthy volunteers. Phase II involves efficacy studies in a small group of patients. Phase III continues safety and efficacy studies in a large group of patients. If a compound is safe and efficacious in patients, an NDA (new drug application) is filed for FDA review and approval. Once an NDA is approved, the drug can be marketed. The safety of the drug continues to be monitored in postmarketing studies. Fifty discovery programs, each with hundreds to thousands of compounds prepared, will lead to 10 development candidates and result in one marketed drug (2). The process takes an average of 12 years, costs more than $800 million, and has a success rate of only 10% in the clinic (2, 3). Drug discovery and development is costly and high risk; it takes a long time. A study in the early 1990s showed that many reasons explain why drugs fail in development, such as toxicity, lack of efficacy, or market reasons (Table 1). It was striking to see that, at that time, more than 40% of the drugs failed development because of poor biopharmaceutical properties (3, 4). As a result, a major initiative in the pharmaceutical industry developed to address ADME/TOX (absorption, distribution, metabolism, excretion, and toxicity) issues during drug discovery so that property information can be generated in parallel with activity data and so that successful drugs can be developed with good potency and drug-like properties (Fig. 2) (5). In the same time period, other new technologies also were implemented in drug discovery, such as HTS, combinatorial chemistry, molecular biology, genomics, and proteomics (6, 7). They all have a tremendous impact on the way drug discovery is conducted today. The term ADME originally referred to in vivo processes that govern pharmacokinetics (PK). It has been expanded to include in vitro physico-chemical and biochemical properties that affect in vivo PK. This article discusses various in vitro ADME properties that influence the overall success of a drug candidate in vivo. For detailed discussion of PK and metabolism, please refer to the other articles in this encyclopedia and further reading list. It is important to point out that suitable ADME properties not only are essential for the success of in vivo studies but also critical for the success of in vitro assays (5).

Traditionally, ADME/TOX assays were not high-throughput (8). Each project team only had a few slots per month for ADME/TOX profiling. If a team were making a lot of compounds, they would have to rely solely on potency and selectivity to triage compounds for in vivo studies, and the compound selected potentially could have poor properties and not be worthwhile to pursue. Nowadays, ADME/TOX assays are high throughput. Depending on company philosophy and available

For detailed discussion of PK and metabolism, please refer to the other articles in this encyclopedia and further reading list. It is important to point out that suitable ADME properties not only are essential for the success of in vivo studies but also critical for the success of in vitro assays (5).
Solubility

Solubility impacts every aspect of drug discovery and development. In vivo, an orally administered solid drug has to disintegrate, dissolve, pass through the gastrointestinal membrane into the portal vein, go through the liver, and finally reach systemic circulation. Solubility, along with permeability and metabolism, affects oral absorption and oral bioavailability. For IV dosing, a compound needs to be completely soluble in a dosing vehicle. Thus, good solubility is essential for the success of an IV formulation. Low solubility can cause abnormal PK profiles, such as second peak phenomena, which is caused by precipitation and redissolution. Formulation development for insoluble compounds can be costly and time-consuming, and it can lead to delayed introduction of lifesaving drugs to the market.

Solubility not only affects in vivo assay results, but it also has tremendous impact on in vitro assays (10, 11). Compounds that have poor aqueous solubility can produce erratic assay results, erroneous SAR (Structure-Activity Relationship), discrepancy between assays, and artificially low potency because of the right shift of IC50 curves. They can cause low HTS hit rates, low confirmation of hits from bench-top assays, and underestimation of toxicity. For some compounds, the potency and properties just cannot be measured because of the extremely low concentration. Low solubility can cause a lot of frustration and loss of productivity in drug discovery.

High-throughput kinetic solubility

Several high-throughput solubility methods have been developed and are used widely in the pharmaceutical industry to provide solubility information for thousands of discovery compounds per year. The data are used to provide an early alert for potential solubility issues so that strategies can be developed to address them. High-throughput methods often are used to measure kinetic solubility. In kinetic solubility methods, solid material is not necessarily in equilibrium with the solution. Compounds are dissolved in DM SO, which is added to aqueous buffers. The concentration of the compound in solution is determined by direct UV measurement (13), turbidity (13), nephelometric (14), or flow cytometry (15). Kinetic solubility usually is higher than equilibrium solubility for three reasons: 1) a small amount of DMSO is present in the buffer (~1%), 2) pre-crystallization tends to be amorphous materials, which have a higher solubility than crystalline solid, and 3) equilibrium is not fully established, and the solution is supersaturated. Because compounds are dissolved in DM SO first, the samples do not have memory of the crystal form, so kinetic solubility is not sensitive to crystal form. Kinetic solubility provides an optimistic estimate of the equilibrium solubility and insights for discovery experiments in which compound is first dissolved in DM SO.
Equilibrium solubility

Equilibrium solubility typically is used in late-stage drug discovery and development, when crystal forms of the material are well characterized. However, a recent trend exists to move the assay much earlier in drug discovery to screen compounds in dosing vehicles and to select compounds for in vivo studies. Equilibrium solubility typically is measured by adding a solvent to solid material and shaking for 24 hours. When the solution reaches equilibrium, it is filtered; the filtrate is diluted according to the sample size and analyzed using LC-UV (liquid chromatography-ultraviolet) or LC-MS (liquid chromatography-mass spectrometry). Equilibrium solubility also is used for formulation development and regulatory filing.

Solubility in bioassay medium

Solubility in bioassay medium usually is initiated when a team suspects that bioassay results might be incorrect because of low solubility. The assay is performed by using the exact protocol used in the bioassay, including buffer composition, dilution protocol, incubation time, and temperature. The solution is filtered, and the filtrate is diluted accordingly and quantified using LC-MS. The solubility data are used to guide assay optimization and address questions related to bioassays, such as erratic assay results, erroneous SAR, irreproducible data, and discrepancy between assays (11).

Permeability

Drugs have to go through many biologic barriers before they can reach the therapeutic targets. The barriers can be the gastrointestinal membrane for oral absorption, the blood-brain barrier for brain penetration, and the cell membrane for cell-based assays. Many transport mechanisms exist for absorption (16). Most drugs are absorbed by passive diffusion across the lipid membrane. Certain compounds can be absorbed by active transport. This transport requires the compounds to have certain structural motifs that can be recognized by transporters, such as amino acids, peptides, nucleosides, and so forth. Polar compounds with a small molecular weight (<200 Dalton) can be absorbed by the paracellular route through the junctions between the cells. Endocytosis can enhance uptake of highly lipophilic compounds by forming vesicles that engulf the molecules. Efflux occurs when efflux transporters, such as Pgp, pump the molecules out of cells. Pgp efflux can impair brain penetration. It also affects oral absorption, especially for highly potent compounds, when the low concentration in the gastrointestinal tract is not likely to saturate the efflux transporters.

Strategies to improve permeability include increasing lipophilicity with an optimal Log D value between 1 and 3, reducing hydrogen-bonding capacity, and decreasing polarity and rotatable bonds (5, 8). Prodrugs also are used to enhance the permeability of compounds.

Several software programs are available to predict permeability and absorption. The simple descriptors of Log P and PSA (polar surface area) gave good predictability for oral absorption (17). Several assays described below commonly are used in the pharmaceutical industry to determine the permeability of drug candidates.

PAMPA

PAMPA stands for parallel artificial membrane permeability assay. The assay was developed in 1998 (18). It has been used widely in the industry to measure permeability (13). The assay uses a 96-well filter plate coated with lipids (e.g., 2% phosphatidylinositol in dodecane) as a permeability barrier between two aqueous wells. The donor well contains the test compound in solution, and the acceptor well contains only buffer at the beginning of the assay. Molecules cross the lipid barrier from the donor to the acceptor well, driven by the concentration gradient. After incubation for a period of time, the concentrations in the donor and acceptor wells are determined and the effective permeability is calculated. PAMPA is a single-mechanism assay. It accounts for passive diffusion only. Different variations of the original PAMPA assay have been developed, including a different lipid composition, different filter material and thickness, additives in the donor and acceptor to create "sink" conditions (19), and addition of cosolvent to solubilize compounds that are otherwise insoluble. Specific PAMPA models have been optimized to predict oral absorption [Double Sink PAMPA (19), BAMPA (20), brain penetration (PAMPA-BBB (21)], and skin permeability [PAMPA-Skin (22)]. PAMPA has good correlation with Caco-2 (human colonic adenocarcinoma cell(s) and multi-drug resistant-Madin Darby Canine Kidney) for compounds that predominantly permeate by passive diffusion (23). PAMPA has much higher throughput and lower cost than Caco-2 and MDCK assay. PAMPA is applied widely in drug discovery to predict permeability. Computational Quantitative Structure-Activity Relationship models also have been developed for variations of PAMPA (24).

Caco-2

Caco-2 is a monolayer cell permeability assay. It was designed originally as an oral absorption model, and now it also is used commonly to investigate transporters. Bidirectional transport can be determined from apical to basolateral direction (A→B) and from basolateral to apical direction (B→A). Efflux ratio is the permeability from B to A direction divided by permeability from A to B direction. A high efflux ratio (e.g., > 2.5) is indicative of an efflux substrate. Inhibitors (e.g., verapamil for Pgp) can be added to confirm whether a compound is a substrate for a specific efflux transporter. The system commonly is used to diagnose efflux. Caco-2 not only expresses efflux transporters (Pgp, MRP) but also uptake transporters, such as PEPT1. It is used to screen compounds for substrates of PEPT1 to increase absorption via transporters. Caco-2 is a multiple mechanism assay including passive diffusion, paracellular route, active transport, as well as efflux and metabolism. To increase throughput, a 96-well Caco-2 assay has been developed (25). The Caco-2 assay involves a 21-day cell culture, which takes significant resources. An automated cell seeding and feeding workstation can be used to increase efficiency.
MDCK

MDCK is a monolayer cell transport assay. Similar to Caco-2, bidirectional transport can be determined. MDRI-MDCKII cells are transfected with the human MDRI gene to express human Pgp. The assay is a very sensitive Pgp assay and is used widely in the industry to identify Pgp substrates, especially for CNS (central nervous system) targets (26). MDCK only requires 3 days of cell culture, which significantly reduces resources needed for the assay.

Stability

Drugs encounter many stability challenges after oral dosing. In the gastrointestinal tract, compounds can degrade in different pH environments: acidic pH in the stomach and neutral to basic pHs in the small and large intestine. They can be metabolized in the intestine and liver by various metabolic enzymes. In blood, compounds can be hydrolyzed by hydrolytic enzymes. Physico-chemical and metabolic stability is essential for drug candidates to reach the therapeutic target with an efficacious concentration.

Metabolic stability

Metabolism occurs in two phases. Phase I metabolism oxidizes or reduces the drug molecule or exposes the functional groups to increase water solubility. It involves oxidation, reduction, hydrolysis, hydration, isomerization, and others. CYP450 is a major metabolic enzyme family. Figure 3 shows an example of Phase I metabolism. Phase II metabolism involves synthesis and conjugation reactions, such as glucuronidation, sulfation, methylation, and others. Phase II metabolism increases the water solubility of the compound or detoxifies a reactive species. Examples of Phase II metabolism are shown in Fig. 4.

Metabolism affects clearance and, therefore, half-life and oral bioavailability. It dictates how often and how much (dose regimen) a drug should be dosed (5, 8, 27). In vitro metabolic stability assays can be used to predict in vivo clearance and oral bioavailability, guide structural modification to enhance stability, develop structure–metabolism relationships, and triage compounds for in vivo studies. Strategies to improve Phase I metabolic stability are as follows: 1) Block the labile sites, 2) remove the labile groups, 3) reduce lipophilicity, and 4) introduce polar functional groups. For Phase II metabolism, several approaches can be applied to reduce metabolism: 1) introduce electron-withdrawing groups and steric hindrance, 2) employ isosteric replacement of hydroxyl and carboxylic acid groups, and 3) use prodrugs.

The microsomal stability assay is the most common platform for assessing metabolic liability of a compound. High-throughput assays have been developed to screen large numbers of compounds. Several strategies have been developed to increase throughput and shorten data turnaround time, including the single-time point approach, sample pooling, online extraction, parallel analysis of multiple samples, and the use of a combined ESI–APCI ion source (ESCI) to increase sample coverage. A assay conditions are critical for the success of a microsomal stability assay (28). Substrate concentration cannot be too high (<1 μM), otherwise it can saturate the enzymes. The concentration of DM SO should be kept less than or equal to 0.2%. High DM SO concentration can inhibit the CYP450 enzyme. Microsomal protein concentration needs to be low (0.5 mg/mL) because nonspecific binding can affect assay results. Microsomal batches can vary greatly from batch to batch and from vendor to vendor; therefore, quality control is essential to generate consistent data. Insoluble compounds can produce artificially high stability estimates (29) because of precipitation and nonspecific binding to plasticware. Cosolvent can be used to overcome solubility effects.

Hepatocytes also are used for metabolic studies (30). Other metabolic enzymes are present in hepatocytes, which are not found in microsomes. It was found that hepatocytes give better predictions for Phase II glucuronidation than microsomes, even though both systems underestimated the extent of glucuronidation in vivo (31). Molecules have to permeate hepatocyte cell membrane to be metabolized, which is a closer mimic of in vivo. Hepatocytes are used commonly for studies of metabolic enzyme induction.

Plasma stability

Plasma stability is important for compounds that contain hydrolyzable functional groups, such as esters, amides, carboxylic acids, sulfonamides, lactams, and lactones. It also is used commonly to screen prodrugs and to select antedrugs. Plasma stability is important for compounds that contain hydrolyzable functional groups. They can be hydrolyzed by hydrolytic enzymes. Plasma stability affects clearance and, therefore, half-life and oral bioavailability. It dictates how often and how much (dose regimen) a drug should be dosed (5, 8, 27). In vitro plasma stability assays can be used to predict in vivo clearance and oral bioavailability, guide structural modification to enhance stability, develop structure–metabolism relationships, and triage compounds for in vivo studies. Strategies to improve plasma stability are as follows: 1) Block the labile sites, 2) remove the labile groups, 3) reduce lipophilicity, and 4) introduce polar functional groups. Molecules have to permeate hepatocyte cell membrane to be metabolized, which is a closer mimic of in vivo. Hepatocytes are used commonly for studies of metabolic enzyme induction.
tamin basic amines and they are mostly CNS drugs. About 50% of drugs are metabolized by CYP3A, 10% by CYP2C, and 4% by CYP1A2. For the reasons above, the four most important CYP450 isozymes for drug–drug interaction studies are 3A4, 2D6, 2C9, and 1A2.

PhRMA (Pharmaceutical Research and Manufacturers of America) recently provided general guidelines on in vitro and in vivo drug–drug interaction studies, and leaders in the field are working toward standardization of the assays (36). The current acceptance criteria for CYP450 inhibition is \( \frac{C_{\text{max}}}{K_i} < 0.1 \) or \( I_{50} > 10 \mu M \) for early drug discovery.

Several methodologies have been developed to determine CYP450 inhibition. Some of these methodologies are implemented widely in the pharmaceutical industry (37).

**Fluorescent-based assay**

The fluorescent assay uses singly expressed recombinant human CYP450 isozymes. Substrates are coumarin-based or fluorescein-based compounds that can be metabolized by human CYP450 isozymes to form fluorescent metabolites (38). If a compound is an inhibitor of a CYP enzyme, the metabolic formation will decrease and lead to the reduction of the fluorescent signal, from which percent inhibition is calculated.

The assay is amendable to high throughput. Both the 96- and 384-well format are used commonly in the industry for screening of drug discovery compounds. The assay is used widely in the pharmaceutical industry to assess drug–drug interaction potential. MetaChip (Solidus Biosciences, Inc., Troy, NY) microarray technology has been developed with 11,200 reactions on a single chip and >1000-fold reduction in assay volume (39). The limitation of fluorescent-based assays is that if a test compound is autofluorescent or forms fluorescent metabolites, it can cause false-negative results. As such, fluorescent-based assays are not recommended for FDA submission. If a compound is a fluorescent quencher, false-positive results can be generated.
ADME Properties of Drugs

LC–MS-based assay

LC–MS-based assays use “drug-probes” that are specific substrates for certain isozymes. The formation of metabolites is monitored by using LC–MS–MS. Human liver microsomes are used commonly in the assay. It is important to keep the protein concentration low so that substrate conversion is less than 10% to minimize metabolism and generate relevant kinetic information (40). To increase throughput, a cocktail approach, which uses a mixture of probe substrates for the different isozymes and human liver microsomes, is helpful (41), or the cocktail assay, which uses a mixture of rh-CYP isozymes and a mixture of drug probes, may be used (42, 43). LC–MS–MS-based assay is used typically for regulatory submission or in vivo drug–drug interaction studies (36).

Luminescence-based assay

In the luminescence-based assay, luciferin derivatives are used as substrates and incubated with recombinant human CY P450 isozymes (44). Luciferin is released as a metabolite, which is converted to de-carboxyluciferin with light emission in the presence of luciferase and ATP. The assay is amendable to high-throughput screening of many compounds in 96-, 384-, or 1536-well format. It has the advantages of no fluorescent interference, a large dynamic range, and high sensitivity. Compounds that enhance or inhibit light emission directly can cause false negatives or false positives.

Other ADME/TOX Properties

Several other ADME/TOX properties are profiled commonly in drug discovery, such as uptake and efflux transporters, blood–brain barrier, plasma protein binding, lipophilicity, pKa, and pharmacokinetics. These ADME/TOX properties are discussed in other articles in this encyclopedia and elsewhere (5).

Current therapies for asthma and allergy are aimed at controlling disease symptoms. For most asthmatics, inhaled anti-inflammatory therapy is effective, but a subset of patients remains symptomatic despite optimal treatment creating a clear unmet medical need. Although considered a less-serious condition than asthma, allergic diseases are common and considerably impact on the quality of life of affected individuals. Innovative disease-modifying therapeutics are needed for both allergy and asthma. Biopharmaceutical approaches may identify small molecules that target key cells and mediators that drive the inflammatory responses that underlie the pathogenesis of allergy and asthma.

Asthma and allergy are important conditions whose complex pathology is influenced by both environmental and genetic factors. Although effective anti-inflammatory therapy is available for both conditions, this therapy is used when symptoms develop and is not always effective in all subjects with asthma and/or allergy. Asthma and allergy share some common pathological features including the overexpression of inflammatory mediators that result in leukocyte accumulation and changes in structural cell function. We have considerable knowledge regarding the cells and mediators that control the pathogenic changes in asthma and allergy. This information has informed the identification of small molecules that target aspects of the inflammatory cascade in asthma and allergy. This article will review the background and status of these novel compounds.

Biological Background

Asthma

Asthma is now one of the most common chronic diseases in developed countries and is characterized by reversible airway obstruction, airway hyper reactivity (AHR), and airway inflammation. Key pathological features include infiltration of the airways by activated lymphocytes and eosinophils; damage to, and loss of, the bronchial epithelium; mast cell degranulation; mucous gland hyperplasia; and collagen deposition in the epithelial sub-basement membrane area. Asthma pathology is associated with the release of myriad proinflammatory substances that include lipid mediators, inflammatory peptides, chemokines, cytokines, and growth factors. In addition to infiltrating leukocytes, structural cells in the airways, which include smooth muscle cells, endothelial cells, fibroblasts, and airway epithelial cells, are all important sources of asthma-relevant mediators (1). This complex scenario means that potential targets for therapeutic intervention are many and varied, and the task of successful therapy is challenging.

Anti-inflammatory therapy in asthma is largely reliant on glucocorticoids (GC)—particularly in their inhaled form—with or without the addition of short- or long-acting bronchodilators. The cysteinyl leukotriene-receptor antagonists are also an established part of the asthma armamentarium. Overall, they are less effective than inhaled GC, but some patients show a striking improvement, and a GC-sparing effect has been demonstrated. Although the symptoms of most asthmatics are satisfactorily controlled by regular use of inhaled GC, their use often raises concerns with respect to compliance, particularly in children and adolescents. Increasing evidence shows that long-term use of inhaled GC, especially in high doses, can cause systemic adverse effects, including adrenal suppression, reduced growth and reduced bone–mineral density, as well as local side effects such as dysphonia. Moreover, a significant subgroup of asthmatic patients responds poorly or not at all to high-dose inhaled or systemic GC treatment. As few alternative treatments are available, these patients can be difficult to treat and may require frequent hospitalization (1). Thus, identification of potential targets for therapeutic intervention is an important goal in asthma research.

Allergy

Allergic inflammation is characterized by an immediate immunoglobulin-E-dependent mast cell and basophil degranulation leading to the release of mediators such as histamine that is responsible for most immediate manifestations of allergic disease. Other mediators include platelet-activating factor,
prostaglandins, and cytokines, which include interleukin (IL)-3, IL-4, and tumor necrosis factor-α (TNF-α). Cytokines are particularly important in driving the subsequent late-phase reaction that results in the accumulation of leukocytes at the sites of inflammation. These inflammatory processes lead to various manifestations of allergic disease such as intermittent and persistent allergic rhinitis, conjunctivitis, atopic dermatitis, urticaria, and a degree of airway inflammation observed in allergic (extrinsic) asthma. The burden of allergic disease worldwide is such that it represents a serious public health problem that attracts considerable effort to identify effective and safe therapies.

Histamine has a prominent and diverse role in the pathophysiology of allergic disease. Therapeutic intervention is therefore commonly focused on blocking its interaction with H1 receptors. The H1 histamine receptor is a heptahelical transmembrane molecule that transduces extracellular signals to intracellular second-messenger systems via G proteins. H1 histamines act as inverse agonists that combine with the H1-receptor, which stabilizes it in the inactive form and shifts the equilibrium toward the inactive state (2). Although effective in the treatment of allergic rhinitis first-generation antihistamines, such as chlorpheniramine and promethazine, had a tendency to cross the blood–brain barrier resulting in unwanted side effects, particularly sedation and impaired psychomotor activity (3). In contrast, the second-generation histamine H1 receptor antagonists are highly effective and well-tolerated treatments for allergic disease and are among the most frequently prescribed drugs in the world (4). More recently, several novel anti-histamines, which include fexofenadine, desloratadine, and levocetirizine, have been developed that are either metabolites or active drugs or enantiomers with improved potency, duration, and onset of action, together with increased predictability of active drugs or enantiomers with improved potency, duration, and onset of action, together with increased predictability and safety. Anti-inflammatory effects in vitro and in vivo independent of H1-receptor blockade have been described for most antihistamines, and these may enhance their therapeutic benefit (3). Other treatments available include anticholinergics, decongestants, intranasal corticosteroids, leukotriene receptor antagonists, or desensitization with modified allergens. It is noteworthy that some of these treatments are often used in combination rather than as monotherapy (e.g., combination of an antihistamine with a nasal decongestant or with a leukotriene antagonist).

Small Molecules in Asthma

Interleukin-5

Much inflammation in asthma is thought to be a consequence of the inappropriate accumulation of eosinophils and the subsequent release of their potent proinflammatory arsenal that includes such diverse elements as granule-derived basic proteins, mediators, cytokines, and chemokines (5). Interleukin (IL)-5 is crucial to the development and release of eosinophils from the bone marrow, their enhanced adhesion to endothelial cells that line the postcapillary venules, and their persistence, activation, and secretion in the tissues. Several animal models of asthma including the use of primates have provided good evidence that inhibiting the effects of IL-5 using specific mAb-inhibited eosinophilic inflammation and AHR (6). Given its central role in regulating eosinophil development and function, IL-5 was therefore chosen as a potentially attractive target to prevent or blunt eosinophil-mediated inflammation in patients with asthma.

However, several clinical trials have reported disappointing clinical outcomes after treatment of asthmatic patients with an anti-IL-5 mAb. The first study was designed to validate the safety of the humanized anti-IL-5 mAb mepolizumab (7); it faced criticism of lack of power (8) and the validity of patient selection (9). A later placebo-controlled study (10) found that treatment of mild asthmatic patients with mepolizumab abolished circulating eosinophils and reduced airway and bone marrow eosinophils, but it reported no significant improvement of clinical measures of asthma. Critically, lung biopsy samples from the treatment group contained intact tissue eosinophils together with large quantities of eosinophil granule proteins; these findings likely explain the lack of clinical benefit after mepolizumab treatment. Similar findings were reported with the anti-IL-5 mAb SCH52709 in patients with severe asthma who had not been controlled by inhaled corticosteroid use. These authors reported profound reduction in circulating eosinophils but no significant improvement in either asthma symptoms or lung function (11). Compared with placebo, treatment of mild atopic asthmatics with mepolizumab significantly reduced the expression of the extracellular matrix proteins tenascin, lumican, and procollagen III in the bronchial mucosal reticular basement membrane. In addition, significant reductions were observed in both airway eosinophils that express mRNA for transforming growth factor-beta (TGF-β1) and the concentration of TGF-β1 in bronchoalveolar lavage (BAL) fluid (12). TGF-β1 is implicated in airway remodeling in asthma, and eosinophils are important sources of this growth factor, which thereby contributes to tissue-remodeling processes in asthma by regulating the deposition of ECM proteins. Mepolizumab may prove useful in preventing this. An alternative to the use of humanized anti-IL-5 mAb is the use of molecular modeling of the IL-5 receptor α-chain to develop specific receptor antagonists. Recently, such a compound (YM-90709) has been shown to be a relatively selective inhibitor of the IL-5R (13), and intravenous injection of YM-90709 inhibited infiltration of eosinophils into the BAL fluid of allergen-challenged BDF1 mice (14).

Interleukin-4

Another cytokine important in eosinophil accumulation is IL-4, which together with its close relative IL-13, is important in IgE synthesis by B cells. Both cytokines signal through a shared surface receptor, IL-4Rα, which then activates the transcription factor STAT-6 (15). Studies with soluble IL-4Rα given in a nebulized form demonstrated that the fall in lung function induced by withdrawal of inhaled corticosteroids was prevented in patients with moderately severe asthma (16). However, despite these promising findings subsequent trials have not been as successful; consequently, this treatment is no longer being developed. Other approaches for blocking the IL-4 receptor include administration of antibodies against the receptor and mutant IL-4 proteins. For example, a peptide-based...
vaccine for blocking IL-4 was recently developed by anti-
genic prediction and structure analysis of IL-4 receptor com-
plex. Vaccine construction involved a truncated hepatitis B core antigen as carrier with the peptide inserted using gene engi-
nearing methods. Compared with control animals, immunized allergen-challenged ovalbumin (OVA)-sensitized mice had sig-
nificant reductions in Immunoglobulin-E (IgE), eosinophil accu-
mulation in BAL, goblet-cell hyperplasia, tissue inflammation, and methacholine-induced respiratory responses (17).

Interleukin-13

IL-13 has been found in BAL after allergen provocation of asthmatic subjects, which strongly correlated with the increase in eosinophil numbers. mRNA expression for IL-13 was de-
tected in bronchial biopsies from both allergic and nonaller-
gic asthmatic subjects. In animal models, IL-13 mimics many proinflammatory changes associated with asthma (18). It is therefore another potential therapeutic target for the resolution of
airway inflammation. Two receptors for IL-13 have been described—IL-13 Rα1 and IL-13 Rα2. The latter exists in sol-
uble form, has a high affinity for IL-13, and can thus “mop up” secreted IL-13. In mice, IL-13 Rα2 blocked the actions of
IL-13, which included IgE production, pulmonary eosinophilia, and AHR (19). A humanized IL-13 Rα2 is now in clinical de-
vvelopment as a novel therapy for asthma. A mouse-based study reported that intratracheal administration of human IL-13
induced leukocyte infiltration in the lung, AHR, and goblet-cell metaplasia with allergic eosinophilic inflammation in the esoph-
agus. An anti-human IL-13 IgG4 mAb (CAT-354) significantly reduced many of these parameters. In contrast, another study
using mice sensitized by intranasal application of ovalbumin as a model of asthma/allergy found that the inhibition of the
IL-4/IL-13 system efficiently prevented the development of the
asthmatic phenotype, which includes goblet-cell metaplasia and
airway responsiveness to methacholine, but it had little effect
on established asthma (20). A humanized anti-IL-13 mAb called
IMA638 significantly reduced eosinophils, neutrophils, eotaxin,
and RANTES in BAL fluid from cynomolgus monkeys sensi-
tized to A. Ascaris suum after segmental antigen challenge, com-
pared with levels observed in control animals (21). IMA638
also gave dose-dependent inhibition of the antigen-induced late
responses and airway hyperresponsiveness in a sheep model of
allergic asthma that used animals with natural airway hypersen-
sitivity to A. Ascaris suum antigen (22).

As stated above, IL-4Rs is the signaling component of the
heterodimeric receptor complex shared by both IL-4 and IL-13. Therefore, it represents an attractive target to antagonize the
effects of both cytokines, as this approach may be more effec-
tive than targeting either IL-4 or IL-13 alone (23). Recently,
a recombinant human IL-4 variant pitrakinra (Aerovant) was
developed that competitively inhibits the IL-4 Rα receptor com-
plex to interfere with the actions of both IL-4 and IL-13. In
two independent small-scale parallel-group Phase IIa random-
ized, double-blind, placebo-controlled clinical trials, patients
with asthmatic asthma were treated with pitrakinra or placebo given
either as a single subcutaneous dose or via nebulization twice
daily. Active or placebo treatments were given for 4 weeks be-
fore the patients were given an inhalated inhalation challenge.
Compared with placebos, allergen challenge-induced decreases in
FEV 1 were significantly attenuated after 4 weeks of inhala-
tion of pitrakinra. The frequency of spontaneous asthma attacks
that required rescue medication use was also diminished in the
study in which pitrakinra was given subcutaneously (24). These
important findings support the hypothesis that dual inhibition of
IL-4 and IL-13 can affect the course of the late asthmatic re-
response after experimental allergen challenge. More large-scale
clinical trials on patients with day-to-day asthma are required to
establish fully whether pitrakinra is an effective and safe asthma
treatment.

Interleukin-9

A new TH2 cytokine, IL-9, and its receptor are found in asth-
matic airways in increased levels (25). IL-9 has several proin-
flammatory effects on eosinophils, which includes enhancement of
eosinophil IL-5 receptor expression, differentiation in the
bone marrow, and prolonged survival through inhibition of
apoptosis (26). Transgene expression of IL-9 in the lungs of mice resulted in lymphocytic and eosinophilic infiltration of
the lung, airway epithelial hyperplasia with mucus production,
and mast cell hyperplasia, as well as production of IL-4, IL-5,
and IL-13 (27). Treatment of OVA-challenged mice with an
anti-IL-9 antibody significantly prevented AHR in response to
a methacholine challenge together with reductions in numbers of
eosinophil and levels of IL-4, IL-5, and IL-13 in BAL (28).

Tumor necrosis factor-α

TNF-α is expressed in asthmatic airways and may play a key
role in amplifying airway inflammation through activation of
transcription factors such as NF-κB and AP-1. TNF-α has proin-
flammatory effects on eosinophils, neutrophils, T cells, and
endothelial cells. It is thought to contribute to AHR, airway re-
modeling, and GC resistance in asthma; therefore, it represents
a potential target for therapy. Humanized anti-TNF mAb (in-
fliximab) and soluble TNF receptor blockers (etanercept) have
been developed, and preliminary clinical studies have shown
significant improvements in lung function, airway hyperreactiv-
ity, and exacerbation rate, particularly in patients with severe
asthma refractory to GC treatment. However, some clinical stud-
ies reported negative findings, so heterogeneity seems to exist
in response to TNF-α antagonism. In addition, concerns exist
regarding potential side effects in some subjects treated with
anti-TNF therapy, which include higher rates of solid organ
malignancies or latent TB reactivation (29). Small-molecule
inhibitors of TNFα-converting enzyme have also been synthe-
sized; and these inhibitors may be attractive therapeutic targets
for asthma (30).

Immunoglobulin-E inhibitors

IgE plays a central role in the pathogenesis of diseases associ-
ated with immediate hypersensitivity reactions, which include
allergic asthma. IgE-dependent biological actions are a result of
its binding to high-affinity (FcεRI) receptors on mast cells and ba-
osphils and to low-affinity (FcεRII) receptors on macrophages,
dendritic cells, and B lymphocytes. Allergen molecules then
crosslink adjacent Fab components of IgE on the cell surface, which thereby activates intracellular signal transduction. In mast cells, this action leads to the release of preformed mediators and the rapid synthesis and release of other mediators responsible for bronchoconstriction and airway inflammation. Therefore, blocking the action of IgE using blocking antibodies that do not result in cell activation is an attractive approach.

Omalizumab (rhAb-E25) is a humanized monoclonal antibody directed to the FcRγRII binding domain of human IgE. It inhibited early-phase and late-phase allergen-induced asthmatic reactions and reduces serum-free IgE concentrations to less than 5% of baseline; it has now progressed through clinical development (31). A large Phase II trial studied fortnightly intravenous administration of omalizumab for 20 weeks in 317 patients (32), whereas two Phase III trials, which included over 500 patients each, studied omalizumab given subcutaneously every 2-4 weeks for 12 months (33, 34). Ayres and colleagues (35) examined the effects of Omalizumab in patients with moderate-to-severe allergic asthma whose symptoms were poorly controlled by high doses of inhaled GC. Omalizumab was administered for 12 months and benefited these patients as shown by a 30% reduction in their asthma deterioration-related incidents. A nother study reported that Omalizumab treatment of subjects with both persistent rhinitis and difficult-to-treat asthma resulted in significantly reduced asthma exacerbations and improved quality of life in those patients who received anti-IgE therapy over the 28-week study period (36). Omalizumab has also been shown to be beneficial as an add-on therapy in patients who have inadequately controlled, severe persistent asthma (37). Consistent findings from these trials showed that omalizumab is an effective therapy for patients with symptomatic moderate to severe allergic asthma despite treatment with GC and rescue medication. It reduced the frequency of exacerbations and improved symptom control while allowing a reduction in the use of GC and β2-agonists. It also improved patient quality of life and produced a significant improvement in lung function as measured by PEFR and FEV1. Omalizumab seems to be well tolerated with few side effects reported in these studies with no reports of circulating antibodies against omalizumab. Although more long-term studies are needed to elucidate the benefit and safety of anti-IgE therapy in asthma, its niche may be in the treatment of patients with severe asthma who are dependent on oral corticosteroids.

Eotaxin

Chemokines are a family of small, secreted proteins that control migration of monocytes, lymphocytes, neutrophils, eosinophils, and basophils. Eotaxin is an inducible, secreted chemokine that promotes selective recruitment of eosinophils from the blood into inflammatory tissues. It was first described in 1993 when intranasal injection of naive guinea pigs with BAL fluid from antigen-challenged guinea pigs resulted in the recruitment of eosinophils (38). Uniquely, the major characteristic of eotaxin is its selective ability to act on eosinophils. CCR3, which is a seven-transmembrane-spanning G protein-coupled receptor for eotaxin-1, is highly expressed on eosinophils and mediates the biological effects of other eosinophil chemokines, such as eotaxin-2, eotaxin-3, MCP-3, MCP-4, and RANTES. Furthermore, CCR3 is expressed not only on eosinophils but also on basophils (39), mast cell subpopulations (40), and activated TH2 cells (41), which might explain the coordinated recruitment of these cell types to sites of allergic inflammation. CCR3 is also expressed by airway epithelial cells (42), and although the bronchial epithelium consists of structural nonmigratory cells, expression of the CCR3 receptor may represent an autoregulatory feedback mechanism to monitor chemokine production. Furthermore, eotaxin produced by the epithelium may be sequestered by the CCR3 receptor and presented to infiltrating cells, which thereby enhances their activation; this phenomenon is observed with IL-8 and its receptor. Several clinical studies have suggested a pivotal role for CCR3 ligands/CCR3 receptor in the eosinophilic inflammation characteristic of atopic dermatitis, asthma, and allergic rhinitis; thus, blockade of this receptor may have pronounced beneficial effects in these diseases (43). Several small-molecule CCR3 antagonists have been described. In this regard, N-ureidoalkyl) benzziperidines have been identified as potent CCR3 antagonists, which inhibit eosinophil chemotaxis and calcium mobilization in the micromolar to nanomolar concentration range (44). The small-molecule selective CCR3 antagonist YM-344031 potently inhibited the binding of eotaxin-1 and RANTES to human cells transfected with CCR3, ligand-induced Ca2+ influx, and chemotaxis, together with inhibition of eotaxin-1-induced eosinophil shape change. Furthermore, both immediate and late-phase allergic skin reactions in a mouse model were significantly inhibited by orally administered YM-344031 (45). Another small-molecule selective CCR3 antagonist YM-355179 inhibited eotaxin-induced intracellular Ca2+ influx, chemotaxis, and eosinophil degranulation. It also inhibited eosinophil infiltration into airways of ovalum-challenged guinea pigs and prevented eosinophilic inflammation and airway remodeling. CCR3 antagonist treatment resulted in a marked reduction of eosinophils in the bronchoalveolar lumen and in airway wall tissue, whereas infiltration of lymphocytes or macrophages remained unchanged. Furthermore, antagonizing CCR-3 reduced AHR, goblet-cell hyperplasia, and airway remodeling as defined by subepithelial fibrosis, and it increased accumulation of myofibroblasts in the airway wall of chronically challenged mice. Therefore, antagonizing CCR-3 represents a novel approach and promising asthma or allergy therapy (47). Furthermore, evidence from animal models suggests that IL-5 and eotaxin may work in a synergistic fashion to promote the release of mature eosinophils from the bone marrow (48). Thus, it might be that combination therapies of CCR3 antagonist and humanized anti-IL-5 mAb might prove an effective approach to limit or prevent eosinophilic toxic in the asthmatic lung.
Targeting Inflammatory Cell Accumulation

Asthma pathology is characterized by excessive leukocyte infiltration that leads to tissue injury. Leukocyte extravasation, migration within the interstitium, cellular activation, and tissue retention are controlled by cell-adhesion molecules (i.e., selectins, integrins, and members of the immunoglobulin superfamily). Numerous animal studies have demonstrated essential roles for these cell-adhesion molecules in inflammation, which include L-selectin, P-selectin, and E-selectin, ICAM-1, and VCAM-1, together with many of the β1 and β2 integrins. For example, compared with wild-type mice, inhaled allergen challenge of P-selectin deficient mice resulted in fewer eosinophils in BAL fluid with significant reductions in AHR.

Selectins

Selectins are responsible for the early “rolling” adhesive events between leukocytes and the endothelial cells that line the postcapillary venules. The small-molecule selectin antagonist Bimosiamose (TBC1269) is a synthetic computer-designed selectin antagonist targeted against all three selectins (49). Therefore, these therapies represent potentially important therapeutic targets and these families of adhesion molecules have been under intense investigation by the pharmaceutical industry for the development of novel therapeutics.

Integrins

Selectins are also vital in early adhesive neutrophil interactions in a sheep model of allergic asthma, pretreatment with an L-selectin monoclonal antibody significantly reduced both the early and late airway response and significantly reduced AHR (49). Therefore, these therapies represent potentially important therapeutic targets and these families of adhesion molecules have been under intense investigation by the pharmaceutical industry for the development of novel therapeutics.

Immunotherapy

Asthma and allergy are manifestations of an imbalance in cytokine and signaling pathways that mediate inflammatory and structural changes within the affected tissues. Developing treatments include strategies to alter the cytokine/chemokine balance or to skew the cytokine profile away from T helper 2 (Th2) responses and toward Th1 responses. Immunotherapy may potentially attenuate symptoms by disease modification through the induction of tolerance to common environmental allergens rather than by suppressing inflammation. A major advantage is the potential for a positive effect to remain for several years after the end of the treatment period. The use of allergen-specific immunotherapy is not a new approach to asthma therapy, and until relatively recently the crude nature of the allergen extracts available meant that its use was limited by unwanted side effects, such as anaphylaxis. Strategies to overcome these problems include the use of hypoallergenic isoforms, recombinant allergens, or DNA vaccines (58). For example, in mice with chronic airway inflammation maintained by repeated ovalbumin inhalation, mucosal administration of CpG DNA oligonucleotides significantly reversed airway hyperreactivity together with both acute and chronic markers of inflammation (59). A newer approach is the use of short, synthetic, allergen-derived peptides that induce T cell tolerance but cannot crosslink IgE on mast cells or basophils and induce anaphylaxis. The main effect seems to be a shift from a Th2 to Th1 profile and induction of regulatory cytokines such as IL-10 and TGF-β. One study that used patients with asthmaic reactions to cats demonstrated that treatment with a desensitising vaccine based on many short, overlapping, HLA-binding, T cell peptides derived from Fel d 1 inhibited both early- and late-phase reactions to a subsequent whole-allergen challenge. Changes in immunological parameters included modulation of the proliferation of blood
monocellular cells together with their production of IL-4, IL-10, and IL-13, and of interferon-γ (60). A more recent study from the same group demonstrated that treatment of cat-allergic asthmatics with FeL-derived T-cell peptides significantly improved clinically relevant outcome measurements, which include reductions in late asthmatic reactions to inhaled whole cat dander and significant improvements in asthma-related quality of life (61). Although from these studies are encouraging, we require larger, dose-ranging studies before firm conclusions on clinical efficacy of peptide allergen therapy can be made. Although it is conceivable that targeting T cells may induce Th1-type autoimmune pathology in humans, to date no evidence indicates that this occurs. In addition, nonallergic mechanisms are also likely to be important in the pathogenesis of asthma; thus, it is possible that novel treatments targeted at the allergy fraction of the phenotype may not be as efficacious as hoped.

Integrin signalling
Lead optimization in drug discovery has changed significantly over the past five years and no longer is fragmented into separate hit-to-lead and lead optimization phases. Chemical lead optimization from high-throughput screening (HTS) to clinical candidate identification is now one seamless process that draws on new technologies for accelerated synthesis, purification, and screening of directed, iterative compound libraries. Advances in high-throughput screening technologies allow detection of new allosteric modes of target modulation, which provides new chemotypes and target opportunities. With the incorporation of drug metabolism and pharmacokinetics (DMPK) inputs early in the lead optimization work flow, molecules are not optimized solely for target potency and selectivity. Moreover, "closed-loop" work flows are in place such that synthesis and primary screening operate on a 1-week turnaround for up to 48 compounds/week with DMPK data cycling every other week to guide compound design, which provides expedited timelines for the development of proof-of-concept compounds and clinical candidates with limited human resources.

The competitive drug discovery environment, whether in industry or academia, requires constant innovation and refinement as a prerequisite for success. A combination of market, patient, and regulatory concerns requires that new chemical entities act on truly novel, and therefore not clinically validated, molecular targets. With the high attrition rates and limited human resources, drug discovery efforts must focus on a large and diverse collection of molecular targets and judiciously employ enabling technologies and new paradigms to develop simultaneously multiple early stage programs. Importantly, the goal at the outset of a nascent program is to provide rapid target validation in vivo with a novel small molecule or to deliver a quick kill for the program so that resources can be reassigned. Coupled with these concerns is the need to establish intellectual property early in the development process, as chemical space is shrinking at an alarming rate (1).

Historically, the scope, mission, and technology platforms of lead optimization groups varied considerably across the drug discovery industry, which led to highly variable success rates (2–5). Some organizations had defined “hand-off” criteria and fragmented lead optimization into a hit-to-lead phase and a chemical lead optimization phase. Hit-to-lead focused on optimizing screening hits, usually by library synthesis (solution phase and/or solid phase), for target potency with minimal concern for selectivity, ancillary pharmacology, and pharmacokinetics (PK). Leads that met certain potency criteria and displayed robust structure-activity relationships (SAR) then would be "handed-off" to a second group for the lead optimization phase, wherein more classic medicinal chemistry (single compound synthesis and intense drug metabolism and pharmacokinetics (DMPK) profiling) would occur (2–5). In the past five years, lead optimization in drug discovery has changed significantly and no longer needs to be fragmented into separate hit-to-lead and lead optimization phases (2–5). Major advances have been made in HTS technologies, which have enabled detection of novel modes of target modulation.
Once limited to detection of classic agonists and antagonists by HTS, kinetic imaging plate readers allow for the HTS identification of positive and negative allosteric modulators of both known and novel targets, which offers new chemotypes as well as improved selectivity and safety profiles (6, 7). Chemical lead optimization, from evaluation of screening hits to clinical candidate identification, now can be a seamless process that draws on new technologies for accelerated synthesis, purification, and screening. Directed, iterative compound libraries now are employed throughout the lead optimization continuum with single compound synthesis restricted to an “as needed” basis. With the incorporation of DMPK inputs at the initiation of a lead optimization program, molecules are not optimized solely for target potency and selectivity but also for the optimization of protein binding and pharmacokinetics and for diminishing CYP inhibition (1–11). Moreover, “closed-loop” workflows are in place such that chemical synthesis and primary screening data operate on a 1-week turnaround for hundreds of compounds/week, with DMPK data cycling every other week to guide compound design and to provide expedited timelines for the development of proof-of-concept compounds to validate/kill novel molecular targets and to deliver clinical candidates with limited human resources. To avoid the negative stigma of combinatorial chemistry, both industrial and academic laboratories, this new paradigm for lead optimization is coined “technology-enabled synthesis” or “TES”; however, a more accurate moniker would be “technology-enhanced medicinal chemistry” (12–21).

**Advances in High-Throughput Screening Technologies**

The first step toward a successful lead optimization campaign begins in a state-of-the-art screening facility, which is ideally based on a philosophy that values the ability to automate complex biologic assays to allow screening of difficult-to-screen targets and to detect novel mechanisms of target modulation. Historical HTS paradigms valued the use of automation only to increase throughput; however, the focus now is to execute fully complex tasks with high precision. Modern HTS facilities employ automated screening systems composed of state-of-the-art liquid handling, plate readers, incubators, and other instruments to support a wide variety of cell-free and cell-based assays that range from enzyme assays on purified proteins to phenotypic screens on model organisms like C. elegans and zebrafish embryos (6, 7, 21–24). Advances in analysis software allow for information-rich assay forms, primarily in cell-based or organism-based environments, with read modes based on either parallel acquisition of kinetic data that use instruments like the Hamamatsu FDSS kinetic imaging plate readers (21, 25) or on object-based screening that uses high spatial resolution devices like automated microscopes or the BlueShift Isocyte (21, 26). Both of these read modes yield complex, information-rich data sets. The analysis and storage of such data can be challenging; however, the success of a lead optimization campaign is linked directly to the ability to acquire, synthesize, store, and present compounds as well as to the ability to collect/analyze data from the biologic systems for which we hope to discover proof-of-concept compounds and clinical candidates (6, 7, 21–26).

**A triplicate screen to identify classic and allosteric modes of target modulation**

Miniaturization of assays that employ kinetic imaging plate readers allow for the development of robust high-throughput calcium mobilization-based assays that detect the activation/inhibition of molecular targets through both classic and allosteric modes of target modulation. For instance, we can measure receptor-induced intracellular release of calcium by using an imaging-based plate reader that makes simultaneous measurements of calcium levels in each well of a 384-well plate. In a novel triplicate-screening paradigm (Fig. 1), either vehicle or a test compound was added to cells expressing a G Protein-coupled receptor (GPCR) that has been loaded with a fluorescent dye, Fluo-4. After a 2.5-minute incubation period, an imaging-based plate reader that makes simultaneous measurements of calcium levels in each well of a 384-well plate. In a novel triplicate-screening paradigm (Fig. 1), either vehicle or a test compound was added to cells expressing a G Protein-coupled receptor (GPCR) that has been loaded with a fluorescent dye, Fluo-4. After a 2.5-minute incubation period, a nearly maximal (EC80) concentration of orthosteric agonist was added, followed by a nearly maximal (EC80) concentration added 1 minute later. In this manner, we can screen for and identify classic agonists/antagonists, allosteric potentiators, and antagonists simultaneously, which maximizes the efficiency of each screen and delivers a diverse collection of hits for chemists to optimize. This paradigm affords the medicinal chemists with options, both in terms of a modulatory mechanism for their therapeutic target and in terms of a chemotype, for the lead optimization campaign in a manner previously unavailable (27).

Of course, technology has not advanced only for the screening of GPCRs but also for kinases and ion channels. Kinase screens now employ both low and high concentrations of ATP to identify both ATP-competitive and allosteric inhibitors. Numerous technology platforms recently have appeared for ion channels targets, such as highly automated Ion-Works and Q-patch, which avoid the need for burdensome and slow single patch-clamp experiments (21–27).

**Solution-Phase Parallel Synthesis for Lead Optimization**

The chemical technologies and platforms for chemical lead optimization have undergone a major paradigm shift in the past 10 years. In the 1990s, hit-to-lead efforts were driven by combinatorial chemistry and characterized by large (1000–10,000 member) solid-phase libraries that required months to synthesize and characterize (28). Often, by the time the library was ready for screening, the SAR of the program and/or lead series had moved on, and the value of the library was minimal (28, 29). As a result, most pharmaceutical companies disbanded their combinatorial chemistry groups, and lead optimization relied primarily on single-compound synthesis or small collections...
Figure 1  Triplicate screen to identify allosteric modes of target modulation. (a) Vehicle with an EC20 and EC80 of agonist, (b) waveform profile of an agonist, (c) waveform profile of an antagonist (flowup necessary to distinguish orthosteric versus allosteric antagonist), and (d) waveform profile of a potentiator, aka, positive allosteric modulator. A single screen generates an entire spectrum of hits.

Less than 12 of compounds. Driven to make the lead optimization process more efficient, the concept of solution-phase parallel synthesis began to gain favor, and technologies rapidly began to develop to create this new approach (30–34). In the last five years, major advances were made in the availability of polymer-supported reagents and scavengers and in the advent of precision-controlled, single-mode microwave synthesizers for organic synthesis. Along with the development of robust mass-directed, preparative HPLC purification, platforms have revolutionized and accelerated lead optimization (20, 30–36).

Solution-phase parallel synthesis (SPPS)

Key to the success of SPPS was the development of “scavenging reagents.” Scavenging (quenching) reagents are highly effective tools for the rapid purification and isolation of the desired product(s) from a solution-phase reaction by forming either covalent or ionic bonds with excess reactants and/or reaction by-products. In general terms, scavenging can be considered a “phase-switching” technique wherein a chemo-selective reaction is employed to switch the phase of one product relative to another by virtue of a “tag” attached to the scavenging reagent [30–34]. Three major classes of scavenging reagents are categorized by the nature of the phase-tag: solid-phase polymers, ionizable functional groups, and fluoroalkyl chains [30–34, 37]. In a typical scenario, an excess of reactant B is combined with A to provide product P along with B and other reaction by-products X in a homogeneous solution-phase reaction. Then, B and X are chemo-selectively removed from solution in a subsequent “scavenging” step with a scavenging reactant 1 linked to a phase tag. After separation of the resulting phases, the product, P, is obtained in high purity by simply evaporating the solvent (Fig. 2).

The most commonly used tags are solid-phase polymers, and hence, a wealth of literature centers on the applications of polymer-supported scavenger reagents to transfer a captive species from the organic liquid phase to the solid phase for removal by filtration. Indeed, this approach has gained widespread acceptance because of the commercial availability of a diverse array of electrophilic and nucleophilic polymer-supported scavenging reagents and scavengers can be used simultaneously (30–34).

A rather commonly used tagging strategy involves linking a scavenger to an ionizable functional group, such as a COOH (pKa < 5) or an NR2 (pKa > 10). In this instance, the captured species can be phase transferred selectively by either pH-adjusted liquid/liquid extraction or by solid-phase extraction (SPE) on an ion-exchange cartridge that leaves the desired product either in the organic liquid phase or in the SPE cartridge eluent (34). SPE is a very attractive method for purification because a crude reaction simply is applied to a disposable silica plug and grafted with either a sulfonic acid (SCX—strong cation exchange) or a tertiary amine (SAX—strong anion exchange), and neutral molecules are eluted off with methanol, whereas ionizable functional groups are retained on the SPE cartridge. Unfortunately, this strategy impacts the diversity of a library by limiting the presence of ionizable groups to either neutral or orthogonally charged library members (34).
Lead Optimization in Drug Discovery

Relying on the affinity that fluoroalkyl chains have for each other and the phobia that they exhibit toward both organic molecules/solvents and aqueous solvents, researchers began examining fluorous tags as a means of phase switching (35). Initially, efforts centered on “heavy” fluorous tags (60% or more fluorine content by molecular weight; for example, 18 or more difluoromethylene, CF₂, groups) that used liquid/liquid phase separation to isolate fluorous-tagged molecules from untagged organics. Typically, a three-phase liquid/liquid extraction, which requires an organic layer, an aqueous layer, and a fluorous layer (a perfluorohexane such as FC-72), delivers pure material. More recently, fluorous solid-phase extraction (FSPE) that employs fluorous silica gel (reverse-phase silica gel with a fluorocarbon bonded phase) has been developed to separate effectively both “heavy” fluorous-tagged molecules as well as “light” fluorous-tagged molecules (4 to 10 CF₂ groups) from untagged organics. The FSPE columns, referred to as FluoroFlash (Fluorous Technologies, Pittsburgh, PA) columns, retain the fluorous-tagged material when eluted with a fluorophobic solvent, such as 80/20 MeOH/H₂O, which allows the untagged organic molecule to elute rapidly from the column. Homogeneous reaction kinetics, generally with respect to charged and neutral functional groups and a variety of efficient phase-separation options, have spurred a dramatic increase in the development of fluorous scavenging reagents and protocols (37).

Microwave-assisted organic synthesis (MAOS)

MAOS, fueled by the development of precision-controlled, single-mode microwave reactors, has a profound impact on organic and parallel synthesis. Reaction times typically are cut by orders of magnitude, and it is usual to observe a diminution in side product formation. Moreover, MAOS reactions tend to be general in scope and lend themselves to the synthesis of libraries to develop SAR rapidly. These advantages, easily appreciated when considering established routes with successful reactions, are even more valuable when working out robust conditions for a synthesis. Exploratory reactions can be conducted in minutes to hours instead of days, and speculative, higher-risk ideas can be pursued with minimal time investment. Indeed, MAOS allows any chemistry to be pursued in parallel and allows chemistries that historically were avoided for library synthesis (multicomponent reactions, organometallics, transition-metal catalyzed couplings, etc.) to be completed successfully in minutes (20, 38, 39).

Beyond the speed advantage, two additional merits of MAOS and modern reactors should be highlighted: precision and reaction scope. As has been noted in these pages and elsewhere, the benefits of MAOS have been studied in multimode “kitchen microwaves” for decades; what prevented acceptance in the wider community was irreproducibility because of a lack of pressure and temperature control (Fig. 3). In addition, kitchen microwaves employ multimode resonators that lead to a heterogeneous field and local “hot” spots (Fig. 3a); despite this disadvantage, early work demonstrated the use of MAOS. Modern systems (Fig. 3b) provide a homogeneous field and precise control of temperature and pressure, and they bare little resemblance to kitchen microwaves. Importantly, MAOS relies on dipolar oscillations and ionic conduction, for example, molecular friction, to generate heat and to afford uniform heating of the sample. In contrast, conventional thermal heating relies on heat transfer from the walls of a reaction vessel and affords nonuniform heating of the sample (Fig. 3c). This uniform heating and rapid time to set temperature delivers reproducible results with fewer side products and, as a result, higher chemical yields (20).

Also, MAOS technology significantly has impacted library design and synthesis. For instance, when presented with a small heterocycle as a hit from an HTS, MAOS technology allows one not only to synthesize and evaluate substitutions on the parent heterocyclic scaffold rapidly but also to synthesize and evaluate multiple heterocyclic templates with diverse substituents in parallel (Fig. 4). Therefore, a single library will contain multiple heterocyclic cores with varying degrees of basicity and topology, while broadening the generic scope for a composition of matter patent (38).

Mass-directed preparative HPLC

Despite the purity obtainable by SPPS scavenging (typically >90%) and the high purities obtained by MAOS (also typically >90%), modern lead optimization programs require >95% purity of all compounds that contribute to the development of
SAR and that advance into DMPK assays. For years, many labs employed UV-directed preparative HPLC and often multichannel units to increase throughput. Although this approach worked, purification of a single sample might lead to 30–40 fractions per sample, which then required analysis by analytical Liquid Chromatography/Mass Spectrometer (LCMS) to identify which fractions contained the desired product (34, 40). In 2000, several vendors launched preparative LCMS units that offered mass-directed fractionation. Now, purification of a single crude sample afforded only one or two pure fractions—a significant advance. Additional modifications for library purification included DMSO slugs to bracket sample injections or “at-column dilution” to provide robust chromatography and prevent in-line sample precipitation before the column. These modified systems were capable of purifying, in a single pass, 60 to 80 compounds per day with purity levels exceeding 98%; however, the systems required an expert chromatographer to develop custom gradients for each sample in a library (34, 40).

Recently, several vendors launched an analytical-to-preparative LCMS software package that addressed the need for a dedicated, expert chromatographer to operate each prep LCMS instrument. With analytical-to-preparative software, a file containing the compound ID and exact mass for each sample in a library to be purified is uploaded into the preparative LCMS system, which then electronically accesses the analytical LCMS data and extracts the retention time of the mass of interest from the crude sample chromatograms. The preparative LCMS system analytical-to-preparative software then calculates a customized gradient for each sample in a library and therefore reduces the need for an experienced chromatographer to achieve excellent first-pass purification results. This feature also allows the instrument to run overnight unattended and additionally increases operational efficiency.

Postpurification sample handling and compound characterization

Modern parallel synthesis laboratories, for example, high-throughput medicinal chemistry laboratories, have borrowed a page from the automotive industry and have developed highly efficient assembly lines for postpurification sample handling and compound characterization. Automated weighing systems with bar code readers scan and record weights on unique bar-coded vials into which pure compounds from the preparative LCMS systems are transferred for concentration in a sample evaporator. After the dry-down step, the bar-coded vials with pure, solid sample are transferred to a liquid handling robot. This instrument scans each bar code, weighs the vial, and determines the net weight of the pure product. This data file is merged with a registration file that contains the molecular weight of the compound, and the system software then calculates the volume of DMSO required to dilute the samples to a preset concentration.
Lead Optimization in Drug Discovery

**Lead Optimization in Drug Discovery**

**Expedited Drug Metabolism and Pharmacokinetics**

Lead optimization involves more than just optimizing for target potency. New technology allows early lead optimization campaigns to address multiple parameters and inputs for each round of iterative library synthesis. These inputs allow for the rapid development of potent compounds with drug-like profiles, as opposed to just potent compounds. These data provide “quick kills” to individual leads or series and allow the lead optimization effort to re-direct resources toward more productive leads (1-5).

**High-throughput in vitro drug metabolism assays**

Significant effort has been applied to the miniaturization and DMSO compatibility of in vitro drug metabolism assays. Now, a 48-member library in a 96-well plate of DMSO stock solution can be evaluated rapidly in cytochrome P450 inhibition assays (CYP3A4, 2D6, 2C9), protein binding assays (rat, dog, and human), logP, HERG binding, and other standard assays (8-11, 42, 43). Previously, chemists were forced to choose which compounds to evaluate in these assays, and often only the most potent analogs would be selected; the most potent analogs were not necessarily the ones with the most promise as clinical candidates. Being able to acquire these data for an entire library provides opportunities to pursue leads within a series with the most balanced potency and DMPK profiles. This ability is of critical importance in lead optimization to ensure that drug-like leads are being pursued and additionally refined. Similarly, cassette dosing of compounds in liver microsomes and hepatocytes enables evaluation of an entire library in short order (8-11, 42, 43). This timely evaluation is especially valuable in the lead optimization of a backup clinical candidate wherein the clinical candidate is the positive control and new compounds (typically five to six per cassette) are viewed qualitatively as more or less stable than the first clinical candidate. Once an in vitro/in vivo correlation can be established for a given series, these rapid cassette experiments can drive a lead optimization program and require only intermittent in vivo experiments (8-20, 42, 43).

**Pharmacokinetic cassettes**

Resource and practical constraints prohibit acquiring single rat and dog pharmacokinetics (PK) (i.v. and p.o.) for every member of a library; however, the compound with the best PK may not be the most potent analog in a library, and knowing this data is crucial for lead optimization. In fact, chemical lead optimization programs have been guided solely by optimization of PK. With the success of in vitro cassette paradigms for microsomal and hepatocyte stability, the concept recently was extended to in vivo PK. In rats and dogs (Fig 5) so that an entire library could be evaluated in vivo employing a limited number of animals (8-11). However, some caveats exist. Combinatorial oral dosing to determine oral bioavailability (%F) in cassette format generally proved not very reproducible nor in agreement.
Lead Optimization in Drug Discovery

Figure 5  Pharmacokinetic evaluation of libraries: cassette dosing to evaluate clearance rates relative to a bid control compound.

with single PK experiments. In contrast, intravenous cassette dosing in both rats and dogs proved highly reproducible and
within the error of a single PK experiment and is a valuable tool to determine qualitative rates of clearance between five to
six new compounds and an internal control of known clearance (8-11). PK cassettes employ an overall low dose of test
compounds to minimize potential drug-drug interactions. These rapid cassette experiments prioritize which compounds from a
library then should be studied in single i.v./p.o. single animal PK studies. As shown in Fig. 5, compound 2 has qualitatively
lower intrinsic plasma clearance rate than an internal control compound with known bid (twice daily predicted dosing) PK
(Cl = 12 mL/min/kg), whereas the other four compounds in the cassette have higher clearance and need not be studied more.

Expedited, “Closed-Loop” Work Flow for Lead Optimization

Combining all above-mentioned technologies and paradigms
for synthesis, screening and DMPK evaluation affords an ag-
gressive, expedited process for chemical lead optimization
(1, 12–21). This protocol allows one to two synthetic chemists
to support a chemical lead optimization effort with acceler-
ated timelines that deliver proof-of-concept compounds within 6
months and clinical candidates within 12 months of the initiation
of a lead optimization campaign.

Library design

Independently, the technologies and strategies described herein
provide improvements for chemical lead optimization; however,
when they become closely aligned with screening and DMPK
resources in a “closed-loop” paradigm, the impact on drug
discovery is exponential [Fig. 6]. Starting from an HTS hit,
considerable attention is devoted first to library design, without
question the most important component of a successful lead
optimization effort. Library design changes over the course of
a lead optimization campaign. The initial design strategy is to
explode SAR around a screening hit and to be as diverse as
possible with respect to monomer input and analog synthesis to
rapidly identify productive changes for additional optimization.
In addition, this component of lead optimization is conducted
often in parallel, wherein a single chemist simultaneously will
synthesize diversity libraries around four to six hits to identify
expeditiously the best leads for additional optimization. After
this initial diversity-oriented explosion, library design must
become more focused to impact drug discovery goals: Random
libraries do not accelerate programs. It is important to approach
directed library design from a medicinal chemistry perspective
and to assemble the library as a collection of single compounds
designed to address a particular issue. For example, the design
of a 24-member library should involve careful thought regarding
what four single compounds would be synthesized first to
increase potency, improve PK, and so forth. Then, for each
of the first four analogs synthesized, designers should consider
what the next four analogs should be if the first changes were
productive or nonproductive. This exercise in library design
generates quality data that drive a lead optimization program
toward proof-of-concept compounds and clinical candidates
very quickly (1, 12–21).

Division of labor

A further key feature of the “closed-loop” approach to lead opti-
mization involves division of labor and the transfer of samples
from medicinal chemists to the analytical chemists. In this
paradigm, the medicinal chemists design and synthesize the
compound libraries (24 to 96 compounds) and obtain analyti-
cal LC/MS reports for each member of the library. At this
point, the medicinal chemists transfer the crude samples to the analytical chemists who purify the libraries by mass-directed preparative HPLC to >98% by using analytical-to-preparative software and perform all postpurification sample handling and coordinate submission of samples, in a 96-well plate format, to the biologists and DMPK personnel for screening (vide supra) (12-20). If resources allow, this division of labor affords opportunities for the medicinal chemists to focus on library design, develop and optimize new chemistries, and pursue multiple lead series in parallel (1, 12-21).

Data turnaround

The success of this paradigm hinges on rapid screening and dissemination of data to the medicinal chemists so that the next iteration of library synthesis can be initiated. To facilitate this, the delivery of compounds is coordinated with the biologists and assays are run the same day the compound libraries are delivered. Biologic data then is returned within 24 hours of the receipt of the libraries. This allows lead optimization to operate on a 1 week turnaround between the initiation of chemical synthesis and the generation of primary assay data. Secondary and/or selectivity data typically tail primary data by 1 to 2 days. As these data trigger the need for DMPK information, DMPK data typically follow a week after the initial assay data is obtained. Overall, this expedited process parallels traditional singleton medicinal chemistry work flows but generates data on hundreds of compounds in the time it used to take to evaluate just a few compounds. Moreover, this protocol allows one to two synthetic chemists to support a chemical lead optimization effort with accelerated timelines delivering proof-of-concept compounds within 6 months and clinical candidates within 12 months of the initiation of a lead optimization campaign. It is important to note that this lead optimization paradigm requires collaboration, close and frequent communication with biology and DMPK colleagues, sophisticated databases to store the volumes of data generated, and a major investment in technology (1, 12-20).

The use of metal ions in diagnostic medicine is widespread. Metal complexes and nanoparticles are used clinically in magnetic resonance imaging, nuclear medicine (gamma scintigraphy and positron emission tomography), and X-ray imaging. Preclinically, additional advances are being made in these fields through the creative application of metal complexes and metal-containing nanoparticles. This article briefly describes different clinical imaging modalities and the physico-chemical properties required for imaging agents. Commercial agents are used to illustrate these properties and to describe the clinical state of the art. Selected examples of exciting preclinical imaging agents that have shown efficacy in vivo also are described.

Imaging agents are defined here as compounds that either are required to generate an in vivo image or provide additional contrast to an existing in vivo image. This article describes the use of metal-containing compounds for clinical or preclinical in vivo imaging. This topic covers modalities such as magnetic resonance imaging (MRI), nuclear imaging (gamma scintigraphy, single photon emission computed tomography (SPECT), and positron emission tomography (PET)), X-ray imaging, and computed tomography (CT). Ultrasound contrast agents are used clinically, but these agents do not require a metal ion. For space constraints, cell tracking studies by MRI, reporter gene imaging with PET, and in vitro imaging will not be discussed. The focus will be on compounds used in clinical medicine and those with potential for clinical use. References are limited to 40, so where possible, relevant reviews have been cited. This article aims to provide a sense for the properties (chemical, magnetic, nuclear, etc.) required for an imaging agent, the current clinical practice, and the current promising directions in preclinical research.

Overview of Imaging Agents and Imaging Modalities

General requirements

Imaging agents are used for noninvasive in vivo diagnosis. They generally have found usage where the diagnostic information yielded impacts a life-threatening and/or expensive clinical decision or where the imaging test replaces a more invasive, risky procedure. An example of this use is imaging myocardial perfusion to test for the presence of coronary artery disease. Absence of disease sees the patient sent home, whereas presence of disease results in cardiac catheterization and possible percutaneous or bypass intervention.

For approval, the agent must demonstrate efficacy compared with an accepted gold standard (biopsy, other established imaging modality, or patient outcome). Because imaging agents themselves offer no therapeutic benefit, the safety requirement is quite high. Potential side effects must be minimized, and for nonendogenous metals, such as gadolinium, it is critical that the entire dose be eliminated from the body. The effective concentration range of the agent depends on the technique. For X-ray agents, millimolar tissue concentrations are required to generate contrast. For such highly concentrated agents, it is important to minimize the osmolality of the injected solution to prevent osmotic shock. Nuclear agents are effective at nanomolar or lower concentrations, and toxicity is usually less of an issue; however, receptor-targeted agents should not show any agonist activity.

Metal-essential versus metal-tagged imaging agents

For the compounds described here, the metal is essential for providing image contrast or for creating the image. However, the biologic distribution of the agent can depend primarily on the metal (metal essential) or the distribution can be dependent on a conjugated targeting vector, such as an antibody (metal-tagged) (Fig. 7). In all modalities, metal-essential imaging agents exist. These compounds often have nontargeting and are used to image the blood vessels or organs in an elimination pathway.
nonspecific protein binding. A linker can represent points to alter lipophilicity, charge, and especially with smaller targeting vectors. The complex and the linking radiation, has excellent spatial resolution (routinely 1 mm³ to create CT contrast. MRI does not require ionizing contrast agents are required at very high concentrations to the patient is high, soft tissue contrast is poor, and exogenous contrast is needed. PET imaging can provide quantitative data on receptor occupancy. However, spatial resolution is much worse with these nuclear techniques which enables the imaging of low-concentration targets, like neurotransmitters, with these techniques. PET imaging can provide quantitative data on receptor occupancy. However, spatial resolution is much worse with these nuclear techniques (1-5 mm clinically) than with CT or MRI and the images are susceptible to attenuation and motion artifacts. Nuclear agents typically must be prepared on the day of use because of their short half-lives. These agents also bring a radiation dose to the patient.

Clinical hybrid PET-CT and PET-MRI systems are being developed now. These approaches combine the high-resolution anatomical imaging of CT or MRI with the sensitive molecular targeting of PET.

X-ray or CT Contrast Agents

Planar X-ray imaging is the oldest and most common radiographic technique. CT (formerly, computed axial tomography—CAT scan) is a method in which a series of two-dimensional X-ray images are acquired around an axis of rotation and these images are combined mathematically to generate a three-dimensional image. Contrast in X-ray imaging derives from heavier atoms (Ca, P) and denser tissue (bone) absorbing and scattering the X-rays. Compounds administered to provide additional contrast are termed contrast agents, contrast media, or X-ray dyes. These compounds contain atoms with a large atomic number, Z, such as iodine (Z = 53).

The most common X-ray agents are based on highly soluble tri-iodo aryl derivatives. However, some metal-containing X-ray contrast media exist. The most common is barium sulfate, administered as a suspension to provide contrast in imaging the gastrointestinal tract. Barium (Z = 56) is quite opaque to X-rays, and the sulfate salt is very insoluble, which results in negligible oral bioavailability. The insolubility of BaSO₄ obviates its use for intravenous applications, and soluble Ba(II) complexes are quite labile, releasing the toxic free metal ion.

Gadolinium MRI contrast agents have been used clinically for X-ray contrast (2). These agents have been used mainly with patients known to have an allergy to iodinated contrast. The use of Gd(III) complexes has derived from the excellent safety profile of these agents, the ability to formulate them at the molar concentrations required for injection, the high atomic number of Gd, and the fact that they are available clinically. These compounds are given intravenously or intra-arterially for angiographic imaging.

Animal studies have been reported with other Gd(III) compounds and where the Gd(III) was replaced by other lanthanides, such as Yb(III) or Dy(III). The liver-specific agent [Gd(EOB-DTPA)]²⁻ and its Yb(III) and Dy(III) analogs were evaluated in rat, rabbit, and dog models and could provide good contrast to distinguish liver tumors (2). Recently, bis-methyl sulphide nanoparticles coated with the biocompatible polymer polyvinylpyrrolidone were described (3). Analogous to the iron oxide particles (see below), these nanoparticles were shown to provide contrast in the blood pool and in lymph nodes. Coated gold nanoparticles also have been studied in an animal model (4). Earlier efforts involved metal clusters such as polyoxotungstates; Yu and Watson give an excellent review of metal-based X-ray contrast media up to 1999 (5).

MRI Contrast Agents

Clinical MRI typically involves imaging the hydrogen atoms in water and fat. These molecules are the most abundant molecules in the body, and hydrogen has the highest NMR sensitivity of elements found in the body. A strong magnetic field is required for detection (clinical fields range from 0.3 to 7.0 tesla, most common is 1.5 T). Applied magnetic field gradients provide spatial encoding that allows an image to be reconstructed.

In CT, contrast occurs solely because of the attenuation of the X-ray beam by its interaction with tissue. Contrast in MRI depends on how the image is acquired. Proton density images reflect the different amounts of water content in different tissues. Chemical shift imaging can distinguish water from fat, based on the different chemical shifts of these protons. Contrast also can be altered in other ways: by the exploitation of differences in water diffusion in tissue, by chemical exchange, and by magnetization transfer effects, to name a few. The majority of scans used clinically derive contrast from differences in the relaxation times T₁, T₂, and T₂*.

When nuclei are excited by a radiofrequency (RF) pulse, T₁ is the time constant for the realignment of spins with the static magnetic field (along the z-axis, the longitudinal relaxation). T₁ ranges from about 300 ms for fat to several seconds for cerebrospinal fluid. If the delay between repeated acquisitions is not long enough, then magnetization will not have recovered.
MRI contrast agents provide increased contrast by acting on T1, and TR, different degrees of soft tissue contrast can be obtained. In a spin-echo sequence, an initial 90° pulse is followed by a delay, TE. Then, the dephasing nuclei are refocused because of a 180° pulse and the signal of this spin echo is acquired. Tissue with T2 long compared with TE will produce more signal than tissue with T2 < TE, which gives rise to T2-weighted contrast.

By changing the pulse sequence or the imaging variables TE and TR, different degrees of soft tissue contrast can be obtained. MRI contrast agents provide increased contrast by acting on T1, T2, and T2*. Paramagnetic agents—gadolinium and manganese

The most widely used clinical MRI contrast agents are based on Gd(III). A powerful approach is shown in Fig. 77. These neutral or anionic complexes (as the meglumine or sodium salt) are highly soluble and formulated at 0.25–1.0 M. They consist of a Gd(III) ion sequestered by an octadentate ligand with a water coligand. Gd(III) has seven unpaired electrons and a symmetric 5/2, 6S ground state (M(nll) = 5/2, 5S state). The high spin number and relatively slow electronic relaxation make these complexes potent nuclear magnetic resonance (NMR) contrast agents. The octadentate ligand is required for high thermodynamic stability to prevent the potentially toxic Gd(III) ion from being released in vivo. The ligand also directs the assembly of the complex (metal-essential). The coordinated water is critical for transmitting the relaxation effect. The water ligand is in fast exchange (10−10−12 s−1 at 37°C) with bulk water. Relaxation of this water coupled with fast exchange results in an overall shortening of the bulk water relaxation time, which affects image contrast.

MRI agents are characterized in terms of relaxivity. Relaxivity is defined as the extent to which the contrast agent can change the relaxation rate of solvent water protons normalized to the concentration of the metal ion M (Equation 1)

\[ r_1 = \frac{1}{T_1} - \frac{1}{T'_1} \left[ \frac{M}{[M]} \right] \]  

where T1 is the relaxation time in the absence of contrast agent. Increased relaxivity enables detection at lower concentrations of agents. Gadolinium and manganese complexes shorten both T1 and T2. However, because tissue T1 is usually much longer than T2, these contrast agents affect T1 on a much greater percentage basis and are referred to as T1 agents. T2 agents provide positive (bright signal) contrast.

Some relaxivities of Gd, Mn, and Fe agents are listed in Table 77. For discrete chelates, differences in relaxivity occur mainly because of differences in inner-sphere hydration number (q), in molecular tumbling, and in the rate of water exchange from the inner coordination sphere. Small paramagnetic molecules tumble in solution too fast to frequencies generating a fluctuating magnetic field that can induce nuclear relaxation. However, for imaging studies done at 65 MHz, relaxation is not as efficient as it could be. Compare the relaxivities of Gd(DTPA) and Mn (20 or 64 kHz) because when Mn is bound to albumin it tumbles much more slowly and relaxation is more efficient. Gd(DTPA) does not bind to proteins and has a lower relaxivity. At higher fields, the frequency match of tumbling with Larmor frequency decreases for protein-bound Mn (30 kHz) and relaxivity drops as well. Strategies for slowing molecular tumbling through protein binding, through increased molecular size, or through increased rigidity have proved useful for increasing relaxivity (6).

For fast-tumbling complexes, it is fast motion and not slow water exchange that limits relaxivity. In Table 77, relaxivities for the first four compounds are very similar because they have similar size and molecular weight and tumble in solution at about the same rate, even though they have water exchange rates differing by a factor of 10 (Gd(III) vs. Gd(III)–BMA). When tumbling is slowed, water exchange can be limiting. The water exchange rate also can be adjusted by changing the donor atoms or chelate geometry (7). Amide oxygen donors generally decrease water exchange relative to the carboxylate analog, whereas phosphate donors will increase it. Slow water exchange can limit relaxivity, but it only becomes pronounced when molecular tumbling is slowed.

The hydration number, q, also can be increased, but it may make the complex less stable to dilution (10). Raymond and coworkers (8, 9) have described a series of 2 or 3 complexes with fast water exchange that are resistant to transmetallation and/or anion binding. Increasing q also should be coupled with slowed tumbling to achieve very high relaxivity. Alme et al. (10) recently have demonstrated this with a novel 3–2 complex bound to albumin.

A more common approach is to assemble multiple chelates either covalently (11) (oligomer, polymer, and dendrimer) or non-covalently (12, 13) (micelle, liposome, and emulsion). These approaches all yield higher molecular relaxivities because of the assembly, but the per-ion relaxivity also is increased because motion is slowed. Fast internal motions can limit these relaxivity gains, but this limitation can be overcome by rigidifying the structure in some way (14). The iron oxide nanoparticles (MION) is used. USPIO and SPION are superparamagnetic, which means that they become magnetic in the presence of an applied field but revert to being nonmagnetic.
when taken out of the field. USPIO have a single Fe₃O₄ core about 4–5 nm in diameter, and it is coated to make the particle biocompatible. SPIO have more than one crystal of iron oxide and are larger than USPIO but still submicron. The small size allows SPIO and USPIO to be formulated as suspensions and administered intravenously. Large particles have been used for GI tract imaging after oral administration.

No inner space water molecules in iron particles exist, and the relaxation of water derives from the water molecules diffusing near the particle. Some generalities exist about relaxivity in these particles. For the USPIO, longitudinal relaxivity \( r_1 \) can be quite high, and these can function as effective \( T_1 \) agents, especially at low fields. The \( r_{1\beta} \) ratio for USPIO is significantly larger than for gadolinium complexes, and \( r_{2\beta} \) increases with increasing magnetic field. When an aggregation of crystals exists, which is the case in SPIO, \( r_1 \) decreases while \( r_2 \) increases. Thus, both for the particles themselves as well as for aggregates of particles, the ratio of \( r_{2\beta} \) typically increases as the size of the particles or aggregates increases, although the \( T_2 \)-relaxivity as a function of particle size can be quite complicated.

These agents are used mainly as \( T_2 \)-agents where they provide negative image contrast (destroy signal) wherever they localize. The mechanism is predominantly through altering the local magnetic susceptibility. \( T_1^* \). Gadolinium agents need to interact directly with water to cause relaxation. The \( T_2^* \) effect of iron oxides is a through space effect and means that even if the agent is compartmentalized in a small space, it still can provide significant contrast. A good example of this effect is in brain perfusion imaging. Even though the blood vessels represent only about 3% of the brain, the \( T_2^* \) effect of the contrast agent extends well beyond the vessels and yields robust contrast. Lanthanides have been coated with different biocompatible reagents, such as dextran and citrate. The coating and particle size both impact biodistribution. Recent efforts (16, 17) have focused on using chemically functionalizable coatings.

**Clinical applications**

The first generation of gadolinium-based agents are tracers of extracellular fluid (ECF) agents. The various ECF agents are almost indistinguishable from an efficacy perspective and, as a result, often are referred to by physicians as “gadog” or “gadolinium.” They are used to detect or rule out lesions in the brain because of the disrupted blood-brain barrier in the presence of tumor. They are used to generate blood vessel images immediately when injection (dynamic first-pass angiography) occurs as well as for assessment of cerebral, myocardial, and renal perfusion. Although nonspecific, the ECF agents are used widely in clinical practice and are by far the most commonly used MRI contrast agents.

The ECF agents are eliminated almost exclusively via the kidneys. The next generation of contrast agents were designed for liver imaging (18). Three different approaches are seen in approved agents. SPIO such as AMI-25 (ferumoxides, Feridex, Bayer Healthcare, USA and Endorem, Guerbet, France) and SHU-555A (ferucarbotran and Resovist, Bayer-Schering, Germany) are recognized by the reticuloendothelial system and transported to Kupffer cells in the liver. The SPIO make the normal-functioning liver appear dark. Tumors and fibrotic lesions do not take up the particles and appear bright on a \( T_2 \)-weighted image (Fig. ??). The Gd-based agents Gd–EOB–DTPA and Gd–BOPTA have mixed renal and hepatobiliary clearance. The complexes are taken up by hepatocytes and transported through the liver and gall bladder. Here, the healthy liver appears bright on a \( T_1 \)-weighted image, while lesions are not enhanced. The manganese compound Mn–DPDP (mangafodipir and Teslascan) is unstable with respect to transmetalation (19). The complex partially dissociates in plasma. Both the complex and free Mn²⁺ are taken up rapidly by the liver. In hepatocytes, the manganese ion binds to cellular proteins, which results in increased relaxivity. Like the Gd-based liver agents, the normal liver appears bright on a \( T_1 \)-weighted scan.

Although ECF agents are used for blood vessel imaging, the imaging must be done immediately after injection (so-called dynamic MRA). The blood concentration drops quickly with time as the agent both distributes outside the vessels into the interstitial space and is cleared via the kidney. There was a push to develop “blood pool” agents (20) that are present only in the vascular space to maximize blood-tissue contrast and that provide persistent contrast in the blood such that slightly longer, higher resolution scans can be used (the rapid imaging required with ECF agents sacrifices spatial resolution). Three approaches have been employed resulting in compounds that have progressed to the clinic or to clinical trials:

1. **Serum albumin targeting:** MS-325 was designed to bind reversibly to serum albumin. Albumin binding serves to localize the agent in the vascular space; it increases the relaxivity of the protein-bound complex, and the unbound fraction is available for renal clearance. MS-325 is approved for use in the EU and other countries. The bile acid–GdDTPA conjugate gadodocoletic acid (a.k.a. B22956, Fig. ??) being developed by Bracco functions similarly; Phase II clinical trials have demonstrated its efficacy.

2. **Increased size, Fig. ??:** A different approach was taken with the compound Gadomer (also called Gadomer-17, Bayer Schering Pharma). Gadomer is a dendrimer with 24 gadolinium DO3A-monomamide chelates on the periphery of the dendrimer. Its size is large enough to restrict the dendrimer to the vascular compartment and to increase relaxivity relative to ECF agents, but it is still small enough to be renally eliminated. A related approach was taken by Guerbet with the compound P792 (gadomelitol, Vistarem, Guerbet, France). P792 is retained in the vascular space because of its size; the relaxivity is high because the gadolinium sits at the center of the molecule, which gives it a long correlation time.

3. **USPIO:** The ultrasmall iron oxide particles have good \( T_2 \) relaxation properties, especially at lower fields (1.5 T). Their small size and coating enables them to evade the RES and remain in the blood pool; they are too large to extravasate. The dextran-coated formulation NC100150 was evaluated in multicenter trials and found to be effective, but ultimately, it...
was abandoned. The citrate-coated V50P particle has entered Phase II trials.

The USPIO AMI-227 (ferumoxtran, Combidex, Advanced Magnetics, USA or Sinerem, Guerbet, France) has undergone clinical trials for lymph node imaging. In addition to being useful for angiography, these particles are trafficked slowly to the lymph nodes. A day after injection, normal-functioning lymph nodes appear dark on a T2-weighted image. If a tumor is present in the node, then it appears brighter because the cancer cells do not take up the iron particle. These particles also are taken up by macrophages and may prove useful as a marker of inflammatory response.

EP-2104R is a peptide-based agent that targets fibrin. Fibrin is an abundant component of blood clots (thrombi). The fibrin-specific peptide is conjugated to several gadolinium chelates to create a high-relaxivity, thrombus-specific contrast agent that worked well in animal models (21) of coronary, cardiac, and pulmonary thrombosis. Figure 77 shows an EP-2104R-enhanced image of a right atrial thrombus in a porcine model and highlights the difference between positive, T1-weighted contrast agents and negative, T2-weighted contrast agents (e.g., Fig. ??). Recently, this compound has entered clinical trials.

Newer agents

A part from EP-2104R, the compounds described above rely on distribution and passive targeting for their imaging efficacy. Newer contrast agents are targeted actively. Some examples that have been studied in animal models are described below and shown in cartoon form in Fig. ??.

The Westerdal group (16, 17) have developed a platform technology based on iron oxide particles called cross-linked iron oxides (CLIO). These particles have amine groups on the surface that can be used to attach multiple targeting vectors as well as fluorochromes for multimodality (MRI, near IR) imaging. Examples from this group include particles targeted to vascular cell adhesion molecule (VCAM) or for atherosclerotic plaque detection, particles targeted to E-selectin in cancer, particulates targeted to mucin-1 expression (MUC-1) in cancer, and derivatized particles with annexin V for imaging apoptosis. Iron oxides usually provide higher sensitivity than gadolinium-based agents and, as mentioned above, extend their contrast-enhancing effect through space.

The Wickline/Lanza group (22) uses a perfluorocarbon emulsion as a contrast agent platform. Gadolinium chelates with lipophilic tails can incorporate into the emulsion such that thousands of Gd(III) ions per particle exist. Targeting is achieved by derivatizing a targeting vector (antibody, small molecule, peptide, etc.) with a lipid chain to incorporate into the emulsion. They have demonstrated targeting to thrombus and also to angiogenesis by targeting the integrin αvβ3.

Considerable effort has been expended for imaging atherosclerosis using a variety of approaches (12, 23), in addition to those described above: gadolinium chelates noncovalently associated with high density lipoprotein (HDL); immunomicelles containing gadolinium chelates targeted to the macrophage scavenger receptor, and micelles formed from gadolinium chelates with perfluorocarbon chains.

Another approach has been to make the contrast agent responsive to its environment. The molecular parameters affecting relaxivity (hydration, tumbling time, and water exchange) can be altered by an enzymatic transformation, by pH change, or when binding an analyte (e.g., Ca or glucose). For instance, Meade and coworkers (24) developed a gadolinium complex that changed its relaxivity in the presence of the enzyme beta-galactosidase (Fig. ??). The complex has a galactose residue conjugated to it that blocks the access of water into the inner coordination sphere of the gadolinium. When the sugar is cleaved by the enzyme, relaxivity is enhanced and can be detected by MRI. Querol and Bogdanov (25) recently reviewed these amplification strategies.

Radiopharmaceuticals

A radiopharmaceutical is a pharmaceutical with a radioactive element incorporated in it. Radiopharmaceuticals that emit gamma rays are used for imaging, whereas those that emit alpha particles, beta particles, or Auger electrons are used for therapeutic purposes, mainly in cancer. Because most of the periodic table consists of metals, it is not surprising that many radionuclides with useful imaging or therapy properties are metallic. Therapeutic radiopharmaceuticals are outside the scope of this article but will be discussed where imaging is used to guide the therapy. The nuclear imaging agents described will be split into gamma emitters, such as 99mTc, and positron emitters, such as 64Cu.

Gamma ray (γ-ray) emitters

The most widely used metal-based imaging agent is based on the metastable isotope technetium-99m. The hexakis(sodium) 99mTc haloferrate(V) complex, Tc-99mHMPAO (Cardiolite, sestamibi) (Fig. ??), is used routinely for myocardial perfusion imaging to evaluate coronary artery disease. Imaging is done either in two dimensions or in three. Planar imaging with a gamma camera is a 2-D projection of the gamma rays emitted from a 3-D source (the patient) and is analogous to planar X-ray imaging. SPECT generates 3-D images by using a gamma camera to acquire multiple 2-D images from different angles and by reconstructing the image.

For gamma imaging, the ideal agent should have a half-life for decay on the order of the examination, and it should be eliminated from the body with a half-life on the order of the examination. This minimizes the radiation exposure to the patient. The isotope should be readily available for widespread use and should only emit γ-rays. The emission energy should be high enough (>50 keV) to penetrate tissue but low enough (<30 keV) that it is efficiently detectable by the camera. The agent should be easily prepared and on administration should be rapidly taken up by the area of interest with quick background clearance. 99mTc is the best isotope for γ-imaging based on its physical properties and availability; 64Cu is the...
using a Tc-tagged bombesin peptide fragment.

A generator provides a readily available on-site source of 99mTc. A complex is used to label white blood cells for infection imaging. Illustrates tumor-targeted planar γ-emission imaging in a mouse model. An active research effort into Tc-tagged imaging agents is underway (26-29). For tissue penetration and detection, 141 keV. 99mTc is a decay product of 99Mo (t1/2 = 66h). The technetium generator consists of reactor-produced 99Mo that is immobilized on an anion exchange column encased in lead. Each day pertechnetate, 99mTcO4-, is produced, which can be eluted off the column. The generator provides a readily available on-site source of 99mTc to hospital radiopharmacies.

Applications of nuclear medicine imaging agents

The most common nuclear medicine procedure is myocardial perfusion imaging. Here, the imaging agent is administered while the patient is exercising (treadmill or bicycle) or given a drug to increase blood flow. The imaging agent is taken up rapidly by the heart muscle and retained there. Imaging is performed later, and the image reflects blood flow during exercise. Areas of reduced flow are indicative of coronary artery disease. Originally, the tracer used was the thallous ion as the chloride salt, 201Tl. 201Tl+ enters myocytes through potassium ion channels. Thallium still is used, but the majority of exams are done with Tc agents, the most common being 99mTc-sestamibi and 99mTc-tetrofosmin (Moyvane, GE Healthcare, USA) (Fig. 7). Figure 7 also shows approved brain and kidney perfusion agents. Bone imaging is done routinely to search for metastases. Bone-seeking agents are structurally ill-defined 99mTc complexes of pyrophosphate (PYP, also useful in imaging myocardial infarction), methylenediphosphonate (MDP), or hydroxymethylenediphosphonate (HDP). The 99mTc complex of DTPA is used in perfusion imaging. 99mTc also is co-ordinated directly to micron-sized aggregated particles of serum albumin for lung perfusion studies. 111In forms a lipophilic insoluble complex with β-hydroxyurea (linoleic acid), and this complex is used to label white blood cells for infection imaging. Ga either as the citrate or nitrate behaves as a mimic of Fe2+ and has been used in imaging inflammation and tumors.

Initially, imaging agents were discrete metal-essential complexes. Increasingly, the metal is complexed by a bifunctional (prelabeling technique). This process avoids exposing a potentially sensitive moiety to harsh reduction/chelation conditions and may be useful for proof-of-concept studies. However, for clinical use, usually it is preferred to conjugate the ligand first to the targeting group and to react this purified product with the Tc(V) complex and then couple to the targeting group (postlabeling technique). This process avoids exposing a potentially sensitive moiety to harsh reduction/chelation conditions and may be useful for proof-of-concept studies. However, for clinical use, usually it is preferred to conjugate the ligand first to the targeting group and to react this purified product with technetium for ease of use in the hospital setting.

Another widely used approach to targeting 99mTc is through the hydrazinonicotinic (HY-NIC) technique (28). This approach

Receptor-targeted radiotherapy is a growing field. Imaging plays a key role in the efficacy of these therapeutic radiopharmaceuticals (30). Not all tumors express a given receptor, and in those that do, receptor density can vary in time and as a response to treatment. Imaging tumor uptake with a diagnostic analog can select patients for therapy and be used to monitor treatment. Imaging also can help with dosimetry because it is critical to deliver enough radiation to kill the tumor while minimizing damage to other organs or nearby bone marrow. 90Y is a pure γ-emitter used in therapy. The chemistry of Y4+ and in3+ is similar enough that 111In often is incorporated for imaging studies. 177Lu is another isotope used in therapy, and it also emits a gamma with suitable energy for imaging.

Bioconjugate approaches for Tc and In labeling

The bioconjugate chemistry of technetium is more specialized (26-28) because of how the isotope is produced and because of the rich redox chemistry of technetium (oxidation states from −1 to +7). Pertechnetate eluted from the generator sometimes must be reduced and chelated. For clinical applications, a kit can be used to stabilize a given oxidation state (Fig. 7) gives a flavor. Many permutations exist of the co-ligands used, reducing agents, and methods for conjugation to the targeting vector; these are the subject of excellent review articles (26-29). For conciseness, the three most common bifunctional approaches are described.

The oxotechnetium core, [Tc=O]3+, in Tc(V) is readily accessible from stannous chloride reduction of pertechnetate. The Tc(V) oxidation state can be stabilized by thiolate, amide N, and amine N donors. As a result, many examples exist of 𝑁3,𝑁,𝑁 ligands (see, e.g., Figs. 7 and 7) that form the base of square pyramidal complexes with Tc(V) where the oxo group is the pyramid apex. As Tc(V) is capable of deprotonating an amine N-H and coordinating to the amide nitrogen, amino acids may make useful building blocks for N,N,N,N-ligands. The MAG3 ligand in Fig. 7 is assembled from mercaptoacetate coupled to three glycines. The resultant [Tc(O)(MAG3)] complex has a pendant carboxylate group that can be activated and coupled to the amine of a targeting vector. One can appreciate that ligands assembled from other amino acids would generate functionalizable side chains for coupled to the Tc(V)-deprotonate shown in Fig. 7. In principle, one can form the Tc(V) complex and then couple to the targeting group (prelabeling technique). This process avoids exposing a potentially sensitive moiety to harsh reduction/chelation conditions and may be useful for proof-of-concept studies. However, for clinical use, usually it is preferred to conjugate the ligand first to the targeting group and to react this purified product with technetium for ease of use in the hospital setting.

Another widely used approach to targeting 99mTc is through the hydrazinonicotinic (HY-NIC) technique (28). This approach

Metallic Medicine, Imaging Agents

The most common nuclear medicine procedure is myocardial perfusion imaging. Here, the imaging agent is administered while the patient is exercising (treadmill or bicycle) or given a drug to increase blood flow. The imaging agent is taken up rapidly by the heart muscle and retained there. Imaging is performed later, and the image reflects blood flow during exercise. Areas of reduced flow are indicative of coronary artery disease. Originally, the tracer used was the thallous ion as the chloride salt, 201Tl, which enters myocytes through potassium ion channels. Thallium still is used, but the majority of exams are done with Tc agents, the most common being 99mTc-sestamibi and 99mTc-tetrofosmin (Moyvane, GE Healthcare, USA) (Fig. 7). Figure 7 also shows approved brain and kidney perfusion agents. Bone imaging is done routinely to search for metastases. Bone-seeking agents are structurally ill-defined 99mTc complexes of pyrophosphate (PYP, also useful in imaging myocardial infarction), methylenediphosphonate (MDP), or hydroxymethylenediphosphonate (HDP). The 99mTc complex of DTPA is used in perfusion imaging. 99mTc also is co-ordinated directly to micron-sized aggregated particles of serum albumin for lung perfusion studies. 111In forms a lipophilic insoluble complex with β-hydroxyurea (linoleic acid), and this complex is used to label white blood cells for infection imaging. Ga either as the citrate or nitrate behaves as a mimic of Fe2+ and has been used in imaging inflammation and tumors.

Initially, imaging agents were discrete metal-essential complexes. Increasingly, the metal is complexed by a bifunctional chelator that is tagged to a small molecule, peptide, or antibody-targeting group. Clinical examples include 99mTc-Acibromab, a Fab’ monoclonal antibody fragment directed toward the carcinoembryonic antigen (CEA) expressed on most colorectal cancers; 111In-DTPA labeled capromab antibody for imaging of prostate cancer and prostate metastases; 111In-DTPA conjugated to a synthetic peptide analog of somatostatin (111In-pentetreotide, Octreoscan, Covidien, USA) is used for the detection of cancers overexpressing the somatostatin receptor; 99mTc-P829 (NeoTect, Bayer Healthcare, USA), is a peptide-based analog of somatostatin with the 99mTc chelator built into the peptide (Fig 7). An active research effort into Tc-tagged imaging agents is underway (26-29); Figure 7 illustrates tumor-targeted planar γ-imaging in a mouse model using a Tc-tagged bombesin peptide fragment.

Receptor-targeted radiotherapy is a growing field. Imaging plays a key role in the efficacy of these therapeutic radiopharmaceuticals (30). Not all tumors express a given receptor, and in those that do, receptor density can vary in time and as a response to treatment. Imaging tumor uptake with a diagnostic analog can select patients for therapy and be used to monitor treatment. Imaging also can help with dosimetry because it is critical to deliver enough radiation to kill the tumor while minimizing damage to other organs or nearby bone marrow. 90Y is a pure γ-emitter used in therapy. The chemistry of Y4+ and in3+ is similar enough that 111In often is incorporated for imaging studies. 177Lu is another isotope used in therapy, and it also emits a gamma with suitable energy for imaging.

Bioconjugate approaches for Tc and In labeling

The bioconjugate chemistry of technetium is more specialized (26-28) because of how the isotope is produced and because of the rich redox chemistry of technetium (oxidation states from −1 to +7). Pertechnetate eluted from the generator sometimes must be reduced and chelated. For clinical applications, a kit can be used to stabilize a given oxidation state (Fig. 7) gives a flavor. Many permutations exist of the co-ligands used, reducing agents, and methods for conjugation to the targeting vector; these are the subject of excellent review articles (26-29). For conciseness, the three most common bifunctional approaches are described.

The oxotechnetium core, [Tc=O]3+, in Tc(V) is readily accessible from stannous chloride reduction of pertechnetate. The Tc(V) oxidation state can be stabilized by thiolate, amide N, and amine N donors. As a result, many examples exist of 𝑁3,𝑁,𝑁 ligands (see, e.g., Figs. 7 and 7) that form the base of square pyramidal complexes with Tc(V) where the oxo group is the pyramid apex. As Tc(V) is capable of deprotonating an amine N-H and coordinating to the amide nitrogen, amino acids may make useful building blocks for N,N,N,N-ligands. The MAG3 ligand in Fig. 7 is assembled from mercaptoacetate coupled to three glycines. The resultant [Tc(O)(MAG3)] complex has a pendant carboxylate group that can be activated and coupled to the amine of a targeting vector. One can appreciate that ligands assembled from other amino acids would generate functionalizable side chains for coupled to the Tc(V)-deprotonate shown in Fig. 7. In principle, one can form the Tc(V) complex and then couple to the targeting group (prelabeling technique). This process avoids exposing a potentially sensitive moiety to harsh reduction/chelation conditions and may be useful for proof-of-concept studies. However, for clinical use, usually it is preferred to conjugate the ligand first to the targeting group and to react this purified product with technetium for ease of use in the hospital setting.

Another widely used approach to targeting 99mTc is through the hydrazinonicotinic (HY-NIC) technique (28). This approach
Involves reacting an activated ester of HYNIC acid with an amine group of the targeting moiety (peptide or protein) and purifying it. A Tc(V) oxo complex is prepared by reduction of TcO$_4$$_{-}^-$. In the presence of a coligand such as ticine, mannitol, or glucophosphate. Sometimes triphenylsulfonic acid/phosphine is used as a reducing agent and coligand. The HYNIC derivative then is reacted with this Tc(V) complex and the hydrazine group coordinates to the Tc$_3$ oxidation state. The complex is water-soluble and, subsequently, tridentate ligands have been employed. The single amino acid chelator found to be less stable in vivo and, subsequently, tridentate ligands have been employed. The single amino acid chelator (SAAC) approach (34) involves a protected unnatural amino acid that contains a tridentate chelator as shown in Fig. ?? The SAAC can be incorporated into the targeting peptide at any point using solid-phase peptide synthesis and represents a small perturbation to the peptide compared with the N-terminus of the peptide or coligand. The HYNIC derivative then is reacted with this conjugate (35). Often a DOTA derivative is used to chelate the Cu$^{+}$ ions and the hexadentate NOTA ligand ($\text{Cu}^{+}$)$_2$ has been reported that involve bifunctional 64Cu compounds that cause the complex to fall apart, and the copper is trapped inside the cell. The redox potential of Cu$^{+}$ATSM is lower than that of Cu$^{+}$TSM, and this redox potential is believed to be the root of the selectivity of Cu$^{+}$ATSM for hypoxic tissue. Copper complexes also are used as bifunctional chelators (37), however, transmetallation remains an issue. The Cu$^{+}$DOTA complex is known to lose copper in vivo. Increasing the macrocycle size by two carbons (cyclocyclam) to give TETA results in a more stable/inert complex. Cross-bridged macrocycles also have been used to give more inert complexes. However, it is important to have facile incorporation of the copper into the chelate, and some ligands giving more stable complexes do not exhibit efficient/mild labeling kinetics. The coordination chemistry here still is evolving (37). Several in vivo studies have been reported that involve bifunctional $^{64}$Cu compounds that are targeted, for example, to vascular endothelial growth factor (VEGF) receptor (38), to malignant melanoma (39), or to the $\alpha$V$\beta$3 integrin (40) for tumor detection or for monitoring cancer therapy.

Positron emission tomography (PET)

Radioisotopes that decay by positron emission also are detectable with a gamma camera. The positron undergoes an annihilation reaction with an electron in tissue resulting in two gamma rays (511 keV) being emitted at 180° apart. PET scanning involves acquiring a series of 2-D images at different orientations and reconstructing them to give a 3-D image. PET imaging has the benefit of higher resolution than SPECT and also offers the potential for getting quantitative data. This quantitative aspect has been exploited in obtaining absolute measures of blood perfusion as well as in determining receptor occupancy numbers. A resurgence of PET has occurred in recent years mainly because of the success of $^{18}$F-fluorodeoxyglucose (FDG) in oncology and the development of the combined PET/CT scanner. PET/CT provides a high resolution CT anatomical image onto which the lower resolution molecular image of the PET tracer is superimposed.

The majority of PET research involves $^{18}$F ($t_{1/2} = 110$ min) and $^{11}$C ($t_{1/2} = 20$ min). With considerable effort, these isotopes can be incorporated into organic molecules such as hormones or drugs. The benefit is that the tracer does not alter the pharmacokinetics of the molecule being labeled in the same way that the conjugation of a metal complex will. Nevertheless, applications of metallic PET tracers exist. Rubidium-82 ($t_{1/2} = 1.27$ min) has a very short half-life but is easily obtained from a strontium-82 generator. The rubidium ion is a potassium analog, and $^{82}$Rb$^+$ is used in myocardial perfusion studies.

Although useful, rubidium is limited in half-life and chemistry. The other more studied PET metal isotopes are $^{68}$Ga ($t_{1/2} = 68$ minutes) and $^{64}$Cu ($t_{1/2} = 12.7$ hours). $^{68}$Ga can be produced on site by a generator. $^{64}$Cu production requires a cyclotron, but its relatively long half-life allows it to be shipped from a central source. Most in vivo work with $^{68}$Ga has involved targeting the somatostatin receptor with a peptide–gallium conjugate (33). Often a DOTA derivative is used to chelate the $^{68}$Ga, but the hexadentate NOTA ligand (Fig. ??) also offers high stability.

The bisomocarbazol bismethoxytrifluorophosphine $^{64}$CuTFSM and $^{64}$CuU$^{+}$TSM, Fig. ??, have been used to image perfusion and hypoxia, respectively (36). It is believed that these compounds freely diffuse into cells. Reduction from Cu$^{(II)}$ to Cu$^{(I)}$ inside the cell causes the complex to fall apart, and the copper is trapped inside the cell. The redox potential of Cu$^{(II)}$TFSM is lower than that of Cu$^{(II)}$TSM, and this redox potential is believed to be the root of the selectivity of Cu$^{(II)}$TSM for hypoxic tissue. Copper complexes also are used as bifunctional chelators (37), however, transmetalation remains an issue. The Cu$^{(II)}$DOTA complex is known to lose copper in vivo. Increasing the macrocycle size by two carbons (cyclocyclam) to give TETA results in a more stable/inert complex. Cross-bridged macrocycles also have been used to give more inert complexes. However, it is important to have facile incorporation of the copper into the chelate, and some ligands giving more stable complexes do not exhibit efficient/mild labeling kinetics. The coordination chemistry here still is evolving (37). Several in vivo studies have been reported that involve bifunctional $^{64}$Cu compounds that are targeted, for example, to vascular endothelial growth factor (VEGF) receptor (38), to malignant melanoma (39), or to the $\alpha$V$\beta$3 integrin (40) for tumor detection or for monitoring cancer therapy.
Conclusions

Metal-based imaging agents comprise a broad and growing field with compounds ranging from simple aqua ions to small molecules to supramolecular assemblies and nanoparticles. The imaging modality and chemical approach to the agent are best chosen based on the question that needs to be addressed by imaging. The imaging field continues to embrace advances in chemical biology to meet the challenges of in vivo imaging: the diagnosis and etiology of disease, the characterization of the disease at the molecular level, understanding the metabolic pathways, and monitoring the response to therapy.

Natural Products as Anticancer Agents

David G. I. Kingston, Department of Chemistry, Virginia Polytechnic Institute and State University, Blacksburg, Virginia
David J. Newman, Natural Products Branch, Developmental Therapeutics Program, Division of Cancer Treatment and Diagnosis, National Cancer Institute, Frederick, Maryland
doi: 10.1002/9780470048672.wecb369

Natural products have provided some of the most effective drugs for the treatment of cancer, including such well-known drugs as paclitaxel (Taxol™; Bristol-Myers Squibb) adriamycin, vinblastine, and vincristine. Natural products have also provided many compounds that have led to the discovery of new biochemical mechanisms. This review summarizes the major natural products in clinical use today and introduces several new ones on the cusp of entering clinical practice. The review is organized by mechanism of action, with compounds that interact with proteins discussed first, followed by compounds that interact with RNA or DNA.

Natural products were the original source of almost all the drugs used by mankind before 1900, and they continue to be a major source of new drugs and drug leads (1, 2). The reasons for the continued importance of natural products are not hard to discover. In the first place, a high correlation exists between the properties of drugs and those of natural products (3, 4). In addition, natural products usually have built-in chirality, and they are thus uniquely suited to bind to complex proteins and other biologic receptors. Finally, natural products have been enormously successful as drugs and drug leads, not only in the anticancer area but also in many other pharmaceutical areas (5). It is thus unsurprising that several authors have gone on record as advocating an increase in the drug discovery effort assigned to natural products (4, 6, 7).

This review summarizes the contributions of natural products to the discovery and development of anticancer agents. It includes information on many natural products and natural product analogs that are in clinical use as anticancer drugs, and it describes some natural product drugs in late-stage clinical trials. Because of space limitations, it is does not provide a comprehensive listing of all natural product and natural product-derived anticancer agents; readers interested in such a listing should consult a recent review (8).

Overview of Natural Products as Anticancer Agents

As of the time of writing, 178 drugs are approved worldwide for the treatment of cancer in all of its manifestations, and 172 of these are listed together with their classifications as to source in a recent review (8). Of the 178 approved antitumor agents, 25 (14%) are natural products, 48 (27%) are modified natural products, and 20 (11%) are synthetic compounds derived from a natural product pharmacophore. Natural products have thus led to 52% of the approved drugs against the collection of diseases that go by the collective name of cancer. Another 20 drugs (11%) are biologics, with the remainder being synthetic compounds. The highly significant contribution of natural products to anticancer drug discovery is clear from these figures.

The term "natural product" describes a broad class of anticancer agents, which range from complex compounds like paclitaxel and vinblastine to relatively simple compounds such as combretastatin-A4. A associated with these different structures are several different mechanisms of action, some of which were only discovered when the corresponding natural product was investigated. The following sections are divided on the basis of the mechanism of action of the drugs rather than their source, and consequently, any given section may include plant, microbial, or marine-derived agents. The broadest division is between those compounds that act by targeting proteins in some way and those compounds that act by direct interactions with DNA or RNA. Thus, these two broad areas provide the two major sections of this review.

Compounds that Target Proteins

The mammalian cell cycle is a complex and carefully regulated biologic process that leads to cell division, and faulty regulation...
of this cycle is one feature of most cancers. The cell cycle thus offers several targets for therapeutic intervention, and several of the proteins involved either directly or indirectly in controlling this cycle are the targets of some important anticancer agents. The most important targets, in terms of the number of drugs that target them, are the proteins tubulin, topoisomerase I, and topoisomerase II, but other proteins such as the checkpoint kinases chk1 and chk2 and the heat shock protein Hsp90 are also the targets of some drugs.

The protein tubulin is an interesting and important target. It exists in both α and β forms, and during a normal cell cycle, these two monomeric proteins polymerize into microtubules by noncovalent interaction; these microtubules are then involved in the reorganization of the chromosomes into the nuclei of the mother and daughter cells. After mitosis, the microtubules dissociate to α and β tubulin monomers. This process is dynamic, and even very small perturbations in assembly and/or disassembly of the monomers dimers may lead to cell death, either by inhibition of the assembly of tubulin monomers into microtubules or by inhibition of the dissociation of microtubules to α and β tubulin monomers. These two monomeric proteins polymerize into microtubules by interaction with the proteasome.

Compounds that inhibit tubulin assembly

The vinca alkaloids

The antitumor alkaloids vinblastine (1) and vincristine (2) were the first natural products to be used on a large scale as anticancer agents, and they thus blazed the trail for others that came afterward. Vinblastine (as vincaloloblastine) was isolated from Catharanthus roseus (L.) G. Don, which was formerly known as Vinca rosea L., by two independent teams during the 1950s (9, 10), and vincristine (as leurocristine) was isolated and structurally characterized by Svoboda (11) and Neuss et al. (10) in 1961 and early 1962, respectively. These alkaloids inhibit the polymerization of tubulin into microtubules. Vinblastine is used in combination with other agents for treatment of Hodgkin's disease and bladder and breast cancers, whereas vincristine is used for treatment of acute lymphocytic leukemias and lymphomas.

The semisynthetic analogs vindesine (3) and vinorelbine (4) have been developed more recently. Vindesine, which was first developed in the 1970s, is in clinical use; it seems to be more active than vincristine against non-small-cell lung cancer, but it also has a higher hematological toxicity than vincristine, so its utility is still being evaluated (12). Vinorelbine has been approved for treatment of non-small-cell lung cancer, and the fluorinated analog vinflunine (structure not shown) has entered clinical trials (13). For a recent general review of the vinca alkaloids and their analogs, see Reference 14.

Combretastatin

The first member of this class of compounds, (-)-combretastatin (5), was isolated from Combretum caffrum in 1982 (15). Subsequent studies led to the isolation of many additional combrestatins, including combretastatins A1 (6) and A2 (7), which are two of the most active members of this class, with potent activity as inhibitors of tubulin assembly. Additional development by the Petit group led to the design of combretastatin A4 phosphate (CA4-P) (8) as a promising drug candidate. This compound is actually a prodrug, which only functions as an inhibitor of tubulin assembly after hydrolysis of the phosphate group to yield the active compound (9). It was subsequently found to be an important member of a new class of compounds known as tumor-specific vascular targeting agents. CA4-P operates by binding to endothelial cell tubulin and causing changes in the morphology of the endothelial cells lining the microvessels feeding the tumors. This process causes disruption of the blood flow, which makes the microvessels unable to deliver oxygen to the tumor and leads ultimately to tumor necrosis. It received orphan drug approval by the Food and Drug Administration (FDA) in 2003 for thyroid cancer, and the FDA has approved it for a “fast track” Phase II clinical trial against anaplastic thyroid cancer (16).

Eribulin (E7389)

The natural product analog E7389 is not yet in clinical use, but it is in Phase III clinical trials and hopefully will enter
Natural Products as Anticancer Agents

Clinical use within the next few years. The natural product on which it is based, halichondrin B (9), is a member of a relatively large family of congeners with a polycyclic macrolide structure, which is reminiscent of ionophores. Many years of synthetic work by Kishi’s group at Harvard and a group at the Eisai Research Institute in the United States led to the selection of the two lead compounds E7389 (10) and E7390 (11) (17). These compounds were compared in both in vitro and in vivo assays at the National Cancer Institute (NCI) with the natural product obtained by deep-water dredging of a producing sponge. In an example of the skill of synthetic chemists when given what initially seemed to be an almost impossible task, E7389 was prepared in large quantity and entered clinical trials in 2001 as an inhibitor of tubulin assembly. It has a mechanism of action different from that of other tubulin interactive agents; it inhibits microtubule growth, but not shortening, and sequesters tubulin into aggregates (18). It showed good activity against refractory breast carcinoma in Phase II studies and entered Phase III studies for the same indication in late August 2006. Very recently, Hamel’s group at NCI have reported additional investigations on the mechanism of binding of both halichondrin B and E7389 to tubulin, which indicates that these agents may well form small, highly unstable aberrant tubulin polymers rather than the conventional massive stable structures found with vinca alkaloids and the antimitotic peptides (19).

Dolastatin

The dolastatins are a class of bioactive peptides isolated by the Pettit group from the Indian Ocean nudibranch, Dolabella auricularia. A total of 18 compounds were isolated over a 20-year period, with structures varying from relatively simple linear peptides to cyclic peptidolactones with nonpeptide components. Dolastatin 10 (12) was the most potent compound, with cytotoxicity in the subnanomolar range. It was shown to be a potent antimitotic agent, binding strongly to the β-subunit of tubulin (20), but it could not be isolated in sufficient quantity because of the scarcity of the source and of the low levels of secondary metabolites in the nudibranch. Pettit and colleagues thus devised many synthetic schemes, which led to the production of enough dolastatin 10 to go into human clinical trials as a tubulin interactive agent. Although it progressed to Phase II, it did not continue further because of a lack of activity and toxicity. However, the base structure led to the synthesis and biologic evaluation by various groups of a large number of related compounds, and synthadotin (also known as tasidotin, 13) emerged as a lead compound (21, 22). Synthadotin is an orally available synthetic derivative of dolastatin 15, and it is in Phase II trials as a tubulin interactive agent. Its discovery provides another example of the skill of synthetic chemists and the potential of novel natural products to be developed into drugs.

Compounds that promote tubulin assembly

Paclitaxel (Taxol)

Paclitaxel (Taxol™; Bristol Myers Squibb 14) and its semisynthetic analog docetaxel (15) are two of the most important anticancer agents of the last 25 years. Paclitaxel was isolated originally by Wall and Wani from Taxus brevifolia (23) and named taxol; this name was later trademarked by Bristol-Myers Squibb. Paclitaxel (Taxol™) is a water-soluble polyether that forms nanometer-sized aggregates in aqueous solution. These aggregates then bind to tubulin, which results in the formation of microtubules that are resistant to depolymerization. Paclitaxel is approved for the treatment of ovarian cancer, breast cancer, and non-small-cell lung cancer.

Docetaxel (Taxotere®)

Docetaxel (Taxotere®; Sanofi-Aventis 15) is a semisynthetic derivative of paclitaxel. It is approved for the treatment of breast cancer, non-small-cell lung cancer, and prostate cancer.

Other tubulin interactive agents

Other tubulin interactive agents include vincristine, vinblastine, and colchicine, which are all derived from the vinca alkaloids. These agents inhibit microtubule formation and cause the depolymerization of microtubules, leading to纺丝 segregations and cell death.

References

taxel on tubulin have been proposed, but recent REDOR NMR studies have established T-Taxol as the most probable conformation (36). The synthesis of the highly active bridged analog britaxel-5 (36), which is constrained to a T-Taxol conformation, confirmed this hypothesis (37).

Epothilones

The epothilones A-D were isolated from the myxobacterium Sorangium cellulosum as antifungal agents (38), but they were found subsequently to have the same mechanism of action as paclitaxel, which promotes the assembly of tubulin into microtubules (39). The epothilones are thus of great interest as potential antitumor agents because of their mechanism of action and because they are also active against some paclitaxel-resistant cell lines. At first glance, they would seem to have a very different shape from paclitaxel, but molecular modeling has shown that some significant common structural features exist in the two base molecules (40). Originally, the epothilones were difficult to obtain in large quantity, and a significant amount of work was performed in academia and industry to synthesize both epothilones A and B and their more active precursors, epothilones C and D (42). However, by using genetic manipulation, Frykman et al. (41) cloned and expressed the polyketide gene cluster that produces epothilones A and B. Subsequent removal of the terminal gene for the P450 enzyme and transfer to a different host enabled them to produce crystalline epothilone D from a large-scale fermentation.

The aza-analog of epothilone B (ixabepilone, 21), which is constrained to a T-Taxol conformation, is in Phase III trials. Epothilone D (KOS-862, 20) and ZK-EPO (23) are in Phase II clinical trials, and the synthetic analog fludelone (22) looks very promising in animal trials (43). However, an evaluation of the epothilones as a class has been limited to taxane-sensitive tumor types (prostate cancer and breast cancer) and does not seem to be distinctly different to the activity of taxanes. Epothilones should certainly not be considered as alternative taxanes, but
whether epothilones are here to stay or will fade away has yet to be determined." (44).

Compounds that inhibit Topoisomerase I

Camptothecin analogs

Camptothecin (24) was isolated from Camptotheca acuminata in 1966 by Wall et al. (45). It had potent anticancer activity in preliminary in vitro and animal assays, but its development was hampered by its extreme insolubility in water. It eventually entered clinical trials in the 1970s as the sodium salt of the carboxylic acid formed by opening the lactone ring, but this proved to have no efficacy and it was dropped from development. Interest in camptothecin was rekindled by the discovery that its primary cellular target was inhibition of topoisomerase I (46). Extensive medicinal chemical studies then led to the development of the two water-soluble derivatives topotecan (Hycamtin; GlaxoSmithKline, Brentford, Middlesex, United Kingdom, 25 and irinotecan (Camptosar; Pfizer, New York, NY, 26). The camptothecins are unique pharmacologically in having topoisomerase I as their only target, and in being able to penetrate mammalian cells readily, and several analogs are in clinical trials (47). Hycamptin and Camptosar are in clinical use for second-line treatment of metastatic ovarian cancer and small-cell lung cancer (topotecan) and for treatment of metastatic colorectal cancer in combination with 5FU/leucovorin (irinotecan) (47, 48).

Rebeccamycin

Rebeccamycin is an indolocarbazole; a comprehensive review of this class has appeared recently (49). Compounds related to rebeccamycin (27) are extremely interesting from a mechanistic standpoint, because relatively simple modifications of the indolocarbazole skeleton generate molecules with enhanced topoisomerase I activity. Thus, active agents can be made by modification of the rebeccamycin skeleton using fluorine substitution, which gives rise to BMS-250749 (28); this compound is headed for Phase I trials as a topoisomerase I inhibitor (47, 50). Second, modification of the base skeleton to include other heterocyclic and carbocyclic rings extends the compounds into previously unexplored chemical space. An example is demonstrated by asymmetric phenyl substitution, which produces compounds such as 29 with significant cytotoxic activity in cell lines, blocking at G2/M or S phase in the cell cycle (51).

Compounds that inhibit Topoisomerase II

Podophyllotoxins

Podophyllotoxin is a major constituent of the rhizome of the American May apple, Podophyllum peltatum. It was shown as early as 1947 to inhibit formation of the mitotic spindle, and its structure (30) was elucidated in 1951 (52). Podophyllotoxin is too toxic for use as an anticancer agent, but medicinal chemical studies led to the development of etoposide (31) and teniposide (32) as podophyllotoxin analogs. They differ chemically from podophyllotoxin in their stereochemistry and glycosylation at C4 as well as being demethylated at C4', but their most significant difference is in their mechanism of action. Unlike the parent compound, etoposide and teniposide act as inhibitors of topoisomerase II rather than as inhibitors of tubulin polymerization. Clinically etoposide (31) is used in combination with cisplatin against small-cell cancer, and it is also effective for the treatment of testicular cancer and non-small-cell lung cancer. Teniposide (32) is used in combination with cisplatin against neuroblastoma, with ara-C against acute lymphoblastic leukemia, and with carboplatin against small-cell
lack of water solubility, and the soluble compound Etopophos (Bristol Myers Squibb 33) was developed to circumvent this problem. It can be administered intravenously and is then rapidly converted to etoposide by plasma phosphatase. For a recent general review of the podophyllotoxins, see Reference 53.

Anthracyclines

From the perspective of the number of patients treated, one of the most important classes of topoisomerase II inhibitors is that of the anthracyclines, with daunorubicin (34) and its derivative doxorubicin (adriamycin) (35) being the best known of these agents currently in clinical use. Adriamycin is still a major component of the treatment regimen for breast cancer, despite its known cardiotoxicity (54). The mechanism of action of these molecules is now known to be inhibition of topoisomerase II (55), although they are also effective DNA binders (56). Both drugs are used for the treatment of acute non-lymphocytic leukemia, Hodgkin and non-Hodgkin lymphomas, and sarcomas, in addition to breast cancer. Derivatives of doxorubicin, such as epirubicin, idarubicin, pirirubicin, and valrubicin, have also been approved for clinical use, and the expansion of the efficacy of doxorubicin is being explored through targeted delivery techniques, including both liposomally encapsulated and monoclonal-linked derivatives.

Compounds that interact with other proteins

Geldanamycin

The first signal transduction modulator to enter clinical trials, other than a formal cyclin-dependent kinase or protein kinase C inhibitor, was the microbial product 17-allylamino-geldanamycin (17-AAG, 36). This modulator entered Phase I trials in 2001 and is currently in Phase II trials in a variety of cancers. Geldanamycin and its derivatives bind at the major ATP-binding site of the protein chaperone Hsp-90. The protein chaperones are emerging as attractive targets for cancer chemotherapy, and the reader is referred to three recent reviews for additional information (57–59).

Staurosporine

The indolocarboxazoles first came into prominence with the identification of staurosporine (37) and its simple derivative UCN-01 (38) as inhibitors of components of the eukaryotic cell cycle and of protein kinase C. Although these compounds are related structurally to rebeccamycin, they have very different mechanisms of action, in that they are highly potent but entirely nonselective inhibitors of protein kinases. UCN-01 has entered Phase I/II clinical trials against a variety of cancers, including leukemias, lymphomas, various solid tumors, melanoma, and small-cell lung cancer. Its clinical development
has been hampered by its high binding to human plasma proteins (60, 61).

Salinosporamide

The marine bacterial metabolite salinosporamide A (39) was isolated from the totally new genus Salinispora that mapped to the Micromonosporaceae, which are found in marine sediments across the tropics. It demonstrated activity as a cytotoxic proteasome inhibitor (62) similar to that observed for the structurally related compound omuralide (40) (63, 64), which resulted from a spontaneous rearrangement of the microbial metabolite lacystin in neutral aqueous media. Salinosporamide has been synthesized (65, 66) and has been fermented in saline media on a large scale under cGMP conditions. It entered Phase I clinical trials in May 2006.

Compounds that target DNA or RNA

The second major class of anticancer agents consists of compounds that act directly on DNA or RNA, either by intercalation, by alkylation, or by cleavage

Actinomycin D

The first microbial-derived agent in clinical use for cancer was actinomycin D (42) (which was systematically named as 9-D-actinomycin C1 and generically named daclomycin) that was introduced in the early 1960s. Despite extensive research into the preparation of analogs, no derivatives have progressed beyond clinical trials (67). Its mechanism of action is inhibition of DNA-dependent RNA synthesis, which in turn depends on the strong intercalation of actinomycin into double-helical DNA (68, 69). It is used clinically in the treatment of trophoblastic tumors in females, in metastatic carcinoma of the testis, and in Wilms’s tumor in children (67). In recent years there have been reports that actinomycin D may also act on the signal transduction cascade(s) at the level of transcription factor(s), and it will be interesting to see whether these activities rejuvenate interest in this class of molecules (70).

Bleomycins

A rather important class is the family of glycopeptolide antibiotics known as bleomycins (e.g., bleomycin A2 and Blenoxane; Nippon Kayaku Co., Ltd., Tokyo, Japan) (42); the bleomycins are structurally related to the plasmodiomics (71, 72). Bleomycin was originally thought to act through DNA cleavage, because it cleaves both DNA and RNA in an oxidative, sequence-selective, metal-dependent fashion in the presence of oxygen. Recent studies, however, suggest that an alternative mechanism of action may be inhibition of t-RNA from experiments reported recently by the Hecht group (73). Bleomycins are used clinically in combination therapy for the treatment of squamous cell carcinoma and malignant lymphomas.

Mitomycins

The mitomycins (mitosanes) were discovered in the late 1950s, and mitomycin C (43) was approved for clinical use in Japan in the 1960s and in the United States in 1974. Its serious bone marrow toxicity has led to extensive synthetic studies aimed at developing a less toxic analog but without significant success; it remains the only clinically used member of this class. It alkylates DNA only after undergoing a one-electron reduction. The current model postulates that mitomycin C alkylates and cross-links DNA by three competing pathways (74). Clinically it is used primarily in combination with other drugs for the treatment of gastric and pancreatic carcinomas (75).

Calicheamicin

Calicheamicin (44) is a member of a large group of antitumor emedine antibiotics. It was isolated from Micromonospora echinospora ssp. calichensis by workers at Lederle Laboratories (Pearl River, NY, now Wyeth) (76, 77); the structures of the related esperamicins were published simultaneously (78, 79). Calicheamicin is one of the most potent biologically active natural products ever discovered. It causes single-stranded and double-stranded DNA cleavage through a unique mechanism that involves reductive cleavage of the trisulfide “trigger” followed by Bergman cyclization to a diradical. It proved to be too potent and too toxic for direct clinical use, but it has been used as the “warhead” in the antibody-targeted chemotherapeutic agent Mylotarg (Wyeth Laboratories, Collegeville, PA), which was approved by the FDA in 2000 for clinical use for the treatment of acute myelogenous leukemia (80). Mylotarg is
Ecteinascidin

Currently, no approved antitumor drugs directly are derived from marine sources, but ecteinascidin (Yondelis; PharmaMar, Madrid, Spain) was submitted to the EMEA in early August 2006 for approval as an antisarcoma agent and was recommended for approval by the EMEA advisory committee in July 2007 (entered in proof) approved in September 2007 for Sarcoma. This compound was isolated originally from the Caribbean tunicate, Ecteinascidia turbinata (81, 82). The original supplies for preclinical studies came from a combination of wild harvesting and aquaculture both in sea and on land. The supply problem was finally overcome by the Spanish company, PharmaMar, which developed a 21-step semisynthetic route from the bacterial product cyanosafacin B (46) that could be carried out under cGMP conditions (83). This route provided an adequate source for advanced clinical trials and an assured supply if the drug is approved for clinical use.

Ecteinascidin 743 has a novel mechanism of action, binding to the DNA minor groove and alkylating the N2 position of guanine. This process strongly inhibits the transcription of specific genes. Ultimately it causes a p53-independent cell-cycle block, which leads to apoptosis. It has shown a clinical benefit rate close to 40% in Phase II studies on sarcomas (84).

Other agents

Mitomycin (47) is an antitumor antibiotic isolated from Streptomyces plicatus. It currently is used to a limited extent for the treatment of embryonal cell carcinoma of the testes and of cancer-related hypercalcemia (85). It is reported to be a specific inhibitor of the Sp1 transcription factor in hematopoietic cells (86).

Streptozotocin (48) is an N-nitroso urea isolated from Streptomyces achromogenes. It acts as a DNA-alkylating agent (87), and it is recommended for use in combination with doxorubicin (35) as the drug of choice for the chemotherapy for patients with malignant neuroendocrine pancreatic tumors (88).

Conclusions

As noted in the Introduction, natural products have served historically as the major source of drugs and lead compounds for the treatment of cancer, and the examples provided in this short review indicate that important discoveries in this area are still being made. Despite this impressive track record,
Natural Products as Anticancer Agents

Figure 13 Structures of ecteinascidin and cyanosafracin B.

Figure 14 Structures of mithramycin and streptozotocin.

many pharmaceutical companies have deemphasized natural product–based drug discovery efforts in favor of approaches such as combinatorial chemistry. Sadly de novo combinatorial chemistry, which was expected to be a panacea for the discovery of small-molecule drug leads over the last 15 or so years, has so far yielded only one drug for antitumor therapy. This drug is the orally active multikinase inhibitor, Sorafenib from Bayer AG (Leverkusen, Germany), which was approved in 2005 (89). The comments of Ortholand and Ganesan (4) are appropriate here.

The early years of combinatorial chemistry suffered from an excess of hype, and a major victim was natural-product screening. Many organizations went through an irreversible shift in policy, and prematurely discontinued their efforts in this area. We are now seeing the backlash from this knee-jerk reaction. The early combinatorial strategies were flawed and unproven, and have yet to deliver any blockbuster drugs. Meanwhile, we have lost the uniqueness of screening natural-product space as a complement to synthetic compounds. If past indicators are any guide, there are undoubtedly many more unique and potent biologically active natural products waiting to be discovered.

The data in this review support this statement and show clearly that natural products continue to provide both tools to probe biologic mechanisms and skeletons upon which to “improve” on the properties of the natural product. Scientists are still discovering or rediscovering the truth that natural products are the best lead structures from which to begin a search for novel mechanisms and novel treatments for a multitude of diseases, not just cancer.

Catalytic reactions provide the opportunity to perform more environmentally friendly reactions. As the pharmaceutical industry produces a large amount of waste for a relatively small amount of drug product manufactured, the use of catalytic reactions is becoming more important. Catalysts can be biological or chemical in nature and can be used to effect a wide variety of transformations.

The pharmaceutical industry employs a wide variety of chemical transformations to prepare the active components of drugs. Cost and environmental pressures encourage the use of catalytic reactions for both bond-forming reactions and the creation of stereogenic centers. As the pharmaceutical industry generates a large amount of waste in the preparation of a relatively small amount of drug product, catalytic reactions will only increase in importance in this industrial sector (1). The E-factor, which is the amount of waste produced (Kg) to make a Kg of product, is high for the fine chemical and pharmaceutical industries. The use of catalytic methods, rather than stoichiometric ones, can help reduce waste (2). The development of a “green” process, however, has to be weighed against the speed of developing the process to the target molecule.

The purpose of this article is to provide an overview of the different types of chemical and biological catalysis currently available to the pharmaceutical industry in the process area. In other words, these transformations can be performed at scale. The types of catalysts that have been used are given together with systems that show potential for future application. The chemocatalytic area has addressed the synthesis of aromatic and heterocyclic compounds, which are common classes in pharmaceutically active compounds, whereas biocatalyst applications tend to be aimed toward the production of chiral molecules.

The uses of catalysts for asymmetric pharmaceutical synthesis have been reviewed by others (see the Further Reading section).

Types of Catalysts

Catalysts can be classified in many ways. A summary of the methods discussed in this article is given in Table 1. For enzyme catalysts, the recommendations of the Nomenclature Committee of the International Union of Biochemistry and Molecular Biology (IUBMB) have been followed (3). Enzymes are classified into six general groups, and the first digit of the enzyme commission number corresponds to the following general categories: 1) oxidoreductases, 2) transferases, 3) hydrolases, 4) lyases, 5) isomerases, and 6) ligases. The number of large-scale applications differs significantly among these enzyme types. Most commercial applications use hydrolases or oxidoreductases, which can be attributed to the broad range of enzymes available in these two classes (4).

Biological Catalysts

In a few cases, biocatalysts have the advantage that no chemo-catalytic alternative exists. It usually occurs when the exquisite stereoselection of a biocatalyst is used to distinguish between two equally reactive groups within a molecule based on stereoechemistry; the stereoselective oxidations of steroids and aromatic compounds are examples (5). A further instance in which biocatalysts are very powerful and no chemocatalyst equivalent is available is for glycosylation reactions and the stereoc-trolled synthesis of polysaccharides. In many areas, however, biological and chemical catalysts compete; examples of this competition include the reduction of ketones (vide infra) and the desymmetrization of cyclic anhydrides (6, 7). In these cases, the choice of which catalyst system to use will depend on accessibility and on process performance in such areas as selectivity, activity, and consumption, as well as cost. These parameters are highly product specific and often are difficult or impossible to predict. For the development of syntheses of new products, the fast screening of highly diverse libraries, be they biocatalytic

or chemocatalytic, is, therefore, an important tool to determine the best choice of a catalytic system (8, 9). The use of molecular biological methodologies do allow for highly selective and efficient biocatalysts to be developed in a relatively short period of time (7). Without precedence, the development of a chemocatalyst is a long-term option.

**Enzymes**

Enzymes can be used in different formulations, immobilized or soluble, and with different degrees of purity, such as cell preparations and crude or enriched isolates. Isolation to a purified form takes time and effort and is usually avoided unless absolutely necessary. In many cases, molecular biology allows for an enzyme to be highly enriched (overproduced) in an organism, which reduces the need for purification (10). Such recombinant cells are, therefore, often used as cell preparations except if the cell needs to be treated to make the substrate accessible to the biocatalyst. More than 50 different enzyme subclasses are commercially available and can be used to prepare chiral molecules. A summary (11-14) of the most often used classes of enzymes that have been used in chemical synthesis is given in Table 2 (16-45). Reactions do not have to be performed in totally aqueous media as some enzymes can tolerate organic solvents (15). 

Enzymatic processes are now being applied to a wide range of pharmaceutical product syntheses (46). Examples are given for the preparation of cyanohydrins, which can then be used to prepare α-hydroxy acids and α-amino acids. Cyanohydrins are a very useful class of compounds as they can be transformed into a wide variety of compounds while retaining the stereogenic center (32, 35). Hydroxy nitrilases are available from natural sources (13), which can give access to either enantiomer of the product cyanohydrin (Fig. 1) (47).

Figure 1  Cyanohydrin formation with hydroxy nitrilases.

Figure 2  Synthesis of L-methionine.

An example of an acylase to perform a resolution is provided by the Degussa process to L-methionine (1). The racemic acetyl methylthionine (2) is prepared by a chemical synthesis. The acylase hydrolyses only the L-isomer (Fig. 2). The D-isomer is racemized by base and put back into the process stream (48).

The most powerful approaches, which can be used with several different enzyme systems, lead to a single enantiomer as the product in high yield and do not rely on a classic resolution approach in which the unwanted enantiomer is discarded. These approaches include dynamic kinetic resolutions, deracemizations, and asymmetric and desymmetrization reactions (49, 50). In some cases, a chemical catalyst may be available to "recycle" the unwanted isomer in the same reactor (vide infra). It is sometimes possible to racemize the unwanted isomer of the substrate and then to perform the reaction again (51).

Whole cells

When chemical transformations were performed by whole cells, such as the reduction of carbonyl compounds by baker's yeast, low asymmetric induction could result as two enzymes are present in the organism that provide the antipodes of the product (52). This result has now been circumvented by the use of genetically modified microorganisms so that the desired enzyme is overproduced (53, 54).

The use of a whole cell allows for a required enzyme cofactor to be regenerated. In other cases, it allows for several enzymes to work in parallel and to perform many complex transformations. An example is provided by the synthesis of D-amino acids from hydantoins (Fig. 3). The carbomylase drives the reaction to completion as carbon dioxide and ammonia are evolved. The same approach has been used with the L-versions of the enzymes to synthesize L-amino acids (14, 42, 55).

Several complex antibiotics are prepared by whole-cell fermentations. Examples are the penicillin antibiotics in which the side chain can be removed and replaced with a synthetic one to enhance activity or stability. Other examples include the macrolide antibiotics, such as avermectin (56) and erythromycin (57), in which the organism uses an enzyme "cassette" to build up the seco-chain before cyclization.

Figure 3  Synthesis of D-amino acids from hydantoins.
In some instances, metabolic engineering of an organism can provide the desired compound. As an example, shikimic acid is used as the starting material in the synthesis of Tamiflu (Roche Laboratories, Inc., Nutley, N.J.), which is an antiviral drug. Bacteria produce shikimic acid as an intermediate on the biosynthetic route to chorismic acid, itself an intermediate for several essential products such as phenylalanine, tyrosine, and ubiquinone that the cell needs to function (58). By knocking out or controlling the genes that develop the enzymes that use shikimic acid as the substrate, the organism can be persuaded to overproduce this valuable starting material (Fig. 4).

Chemists have also taken lessons from nature and often use biomimetic syntheses or approaches to complex molecules; here, reactions used in an organism are mimicked in the laboratory (59, 60). In addition, catalytic transformations can be coupled, and it could be two chemocatalysts (vide infra) (61, 62).

**Chemical Catalysts**

**Transition metal**
Transition metal-based catalysts perform a wide variety of reactions. Many useful reactions can be used to build the carbon–carbon framework of the target molecule or to introduce functional groups into complex molecules. Many achiral methods exist; they often are named after the person who discovered or popularized them (see Table 3 (64-170)). In some instances, the achiral reaction has been adapted to provide an asymmetric method; the latter examples are included in Table 4 (93, 118, 120, 124, 142, 149–202). The use of metal catalysts that act as Lewis acids or bases have been omitted as numerous examples can be described (63).

When implementing a transition metal-catalyzed step at scale, many factors have to be considered, some of which also relate to biological and organocatalytic reactions. The one factor that does not overlap with these other types of systems is the price of the metal. Although cheaper metals such as iron, nickel, and copper can be used for some transformations, often the metal required is precious, such as palladium, platinum, rhodium, iridium, or ruthenium. The use of gold catalysis has recently become an area of intense research (141). These precious metals are expensive; usage needs to be minimal, and they must be recycled either for reuse in the reaction or through recovery. Refining has to be a topic of considerable economic concern.

For some reactions, especially asymmetric transformations, the ligands needed to perform the reaction may be more expensive than the metal! Here, the catalyst has to be extremely efficient to achieve the required cost benefits. The economics of the

transformation not only depend on the cost of the catalyst and how much is used (usually defined by turnover number, which is the number of times the catalyst goes round the catalytic cycle), but also the duration of the reaction. The turnover frequency is the number of times the catalyst completes a catalytic cycle per hour. Reactor time can be expensive, and time needs to be minimized but not at the cost of making the reaction so fast that it becomes unsafe or reagents, such as hydrogen, cannot be delivered at an appropriate rate.

An example of a metal-catalyzed reaction to form a biaryl product is the Suzuki reaction. The coupling can be performed without any phosphorus ligands for the metal and with only a small amount of the metal (0.05 mol %) (Fig. 5). A reaction that has become popular is the preparation of aromatic

![Figure 5](image_url)
amines by a palladium-catalyzed coupling reaction (Fig. 6). This methodology is general (89).

In addition to carbon–carbon bond formation, transition metal catalysts can also generate a stereogenic center. The first reaction of this type in which useful amounts of asymmetric induction were observed was an asymmetric hydrogenation to make phenylalanine and the method has been used for many years to synthesize the anti-Parkinsons drug, l-Dopa (3) (Fig. 7) (142, 143).

This transformation was important as it showed that a chemical catalyst could perform with similar asymmetric integrity to that of a biological system. Today, literally thousands of ligands and catalysts can be used to perform asymmetric hydrogenations as well as other reactions; see Table 4.

Many aspects must be considered in finding a catalyst to perform a step in the synthesis of a drug. The main aspect is the time required to find suitable catalyst systems. If a closely analogous reaction has been reported in the literature, then it may not be a large problem or concern. In most instances, however, this is not the case. In addition to enantioselectivity or diastereoselectivity, the factors necessary to find an efficient achiral catalyst must also be fulfilled.

Stereogenic centers can also be prepared by carbon–carbon bond-forming reactions or reductions of functional groups other than alkenes. Some reactions are also summarized in Table 4 (144). For a comprehensive work on asymmetric catalysts, see Reference 145. In some cases, two stereogenic centers can be created. This result can be achieved either in a single step as
with the asymmetric reduction of a tetrasubstituted alkene, or by coupling two reactions together as with a conjugate addition followed by trapping the resultant enolate with an electrophile (146, 147). An illustration of this strategy is the synthesis of the bicyclic ketone 4 (Fig. 8) (147, 148). The allyl group is a good electrophile and is then converted to the analogous ketone by a Wacker oxidation.

An example of an asymmetric hydrogenation used in the preparation of a pharmaceutical intermediate is provided by a synthesis to carbapenems (5) (178). Reduction of the \( \beta \)-keto ester occurs under equilibrating conditions so that the erythro-product is formed in high yield and selectivity (203). Another catalytic step with ruthenium is used to introduce the acetoxy group (Fig. 9) (153).

An asymmetric oxidation is used in the synthesis of esomeprazole (6), a proton pump inhibitor, which has therapeutic advantages over the racemic mixture omeprazole (Fig. 10) (204).

Chemocatalysts sometimes have an advantage over biological systems. Often the antipode of a ligand is accessible, although if a natural product is used as the source of the stereogenicity, then it may be less abundant and more expensive. As a last resort, and as ligands are relatively small molecules, an achiral synthesis and resolution might be used. This latter option is not available with a biological catalyst.

One of the main concerns of using a transition or heavy metal catalyst, especially toward the end of the synthetic sequence, is the removal of the metal. A wide variety of methods is known

Organocatalysts

This class of catalysts covers chemocatalysts that do not contain a transition metal. The class has been known for many years, but it is relatively recently that the term "organocatalyst" has been used (209). A wide variety of transformations can be performed, which is currently an area of intense research (209-218). Table 5 (220-252) summarizes some key transformations in which organocatalysis can be useful. Reactions range from the asymmetric epoxidation of alkenes, which need not be conjugated to another functional group, to aldol reactions and other carbon-carbon forming transformations. Some progress has also been made to couple two reactions together (219).

\( \alpha \)-Proline catalyzes the aldol reaction. This approach has been applied to the synthesis of carbohydrate derivatives as illustrated by the glucose derivative 7 (Fig. 11) (237). The three-component Mannich reaction can be used to prepare \( \beta \)-amino and \( \beta \)-amino \( \alpha \)-hydroxy carbonyl compounds in a single step (Fig. 12) (233). As with other types of catalysts, organocatalysts can be immobilized to aid recovery (253).

Systems with Biocatalysis and Chemocatalysis

As enzymes usually only accept one enantiomer or isomer as substrate, many enzymatic reactions are resolutions; the
unaffected isomer is waste. One way to circumvent this problem, which can have significant economical consequences, is to include a racemization or isomerization step with a second catalyst so that the substrate for the desired transformation can be accepted as the correct isomer (254, 255). This method allows dynamic kinetic resolutions to be performed with the desired product isomer being produced in high yield rather than with the 50% maximum available from a classic resolution approach (256).

A chemical catalyst can be used to racemize an alcohol, whereas an enzyme is used to prepare an ester of one of the enantiomers of that alcohol. In this example, reduced pressure was used to remove the isopropanol by-product and drive the reaction to completion whereas the Shvo catalyst was used to racemize the alcohol (Fig. 13) (257).

Future Outlook

Both biological and chemical-based catalysts are useful for a wide variety of reactions that range from carbon-carbon bond formation to the generation of a new stereogenic center. With the increasing awareness of green chemistry and the need to reduce waste in the pharmaceutical industry where this problem has been particularly bad, the use of catalytic reactions will surely continue to increase.

Biocatalysts are being applied widely in the industry, including the preparation of carbon-carbon bonds. Stereoselective oxidation with biocatalysts is an area where chemistry will find it hard to compete. A need still exists for new catalysts to replace stoichiometric reagents, as in the reduction of an amide to an amine, amide formation, and substitution of an alcohol (Mitsunobu reaction) (258). In both arenas of catalysis, the overall goal for green chemistry and stereoselectivity must be carbon-hydrogen bond activation.

Recent Progress in Drug Discovery Based on Plant-Derived Natural Products Research

Kuo-Hsiung Lee, Hideji Itokawa, Toshiyuki Akiyama and Susan L. Morris-Natschke, Natural Products Research Laboratories, School of Pharmacy, University of North Carolina, Chapel Hill, North Carolina
doi: 10.1002/9780470048672.wecb373

Numerous important bioactive compounds have been, and continue to be, isolated worldwide from natural sources. These compounds include both primary and secondary metabolites isolated mainly from plants, as well as from the animal and mineral kingdoms. The recent development of new bioassay methods has facilitated progress in the BDH (bioactivity-directed fractionation and isolation) of many useful bioactive compounds from natural sources (1). These active principles could be developed or additionally modified to enhance the biologic profiles as clinical trials candidates. Many natural pure compounds have become medicines, dietary supplements, and other useful commercial products. This article summarizes research on many different useful compounds isolated or developed from plants with an emphasis on those discovered recently by the laboratories of the authors as antitumor and anti-HIV clinical trial candidates.

From ancient times, many crude herbs have been used as remedies for various diseases. In Asia, these therapies include traditional Chinese medicine (TCM), Japanese-Chinese medicine (Kampo), Korean-Chinese medicine, Jamu (Indonesia), and Ayurvedic medicine (India). In Europe, phytotherapy and homeopathy have found medicinal use. These herbal therapies generally are classified as “alternative medicines” in America. Alternative medicine, which comes mainly from the aforementioned traditional and folk medicines used worldwide, also is being combined with conventional medicine (Western medicine), which results in integrative medicine. In TCM, crude herbal drugs formerly were divided into three categories: upper-, middle-, and lower-class medicines. Upper-class medicines usually are not toxic, have moderate physiologic effects, and often are used to maintain good health. Thus, they sometimes are called therapeutic drugs. Both upper- and middle-class medicines are used as therapeutic drugs, but the former medicines are not as toxic as the latter. Lower-class medicines can contain very toxic substances, which can be used judiciously as medicines. TCM prescriptions usually mix herbs that belong to these three categories, according to a unique principle (2). The experience gained by using TCM for centuries provides a rich source of information for modern research in drug discovery.

Anticancer and Antitumor Compounds

Suffness and Douros (3) suggested the following definitions to avoid confusion of terminology. Cytotoxicity is used when compounds or extracts show in vitro (in cells) activity against tumor cell lines. Antitumor or antineoplastic indicates that the materials are effective in vivo (in animals) in experimental systems. Anticancer refers to compounds that are active clinically against human cancer.

The development of novel, clinically useful anticancer agents is highly dependent on the bio assay screening systems, as well as the sample sources. Two bioassay types have been used: cell-based and mechanism of action (MOA)-based. Initially, cell-based assays used primarily L1210, P388, and nasopharyngeal (KB) cells in preliminary screening for antitumor activity. Screening against a panel of human cancer cell
lines was implemented to discover agents active against different types of cancer. For active agents, the in vitro studies are followed by in vivo xenograft studies to ensure efficacy. New MOA-based bioassay systems aimed at particular molecular targets also have revolutionized the discovery of potential drug candidates. Important anticancer drug targets include tubulin, DNA topoisomerases I and II (topo I and topo II), cyclin-dependent kinases (CDKs), growth and transcription factors, and so forth.

Higher plants have yielded many effective, clinically useful anticancer drugs, including those derived from Catharanthus alkaloids, Taxus diterpenes, Camptotheca alkaloids, and Podophyllum lignans. Research in this area has been reviewed extensively (3–13).

The seminal discoveries of taxol (tubulin-interactive) and camptothecin (topo I-interactive) by Wall and Wani (14–16) represent how natural products have influenced the additional development of natural product-derived and synthetic entities. The following discussion of the discovery and development of current important antineoplastic compounds will be organized by plant species.

**Catharanthus species**

Catharanthus alkaloids, particularly vinblastine (A1) and vincristine (A2), are well-known anticancer drugs, which are used clinically to treat Hodgkin’s lymphoma and acute childhood lymphoblastic leukemia, respectively. These alkaloids interact with tubulin, a protein necessary for cell division, and are inhibitors of mitosis (the process of cell division).

Originally, these compounds were isolated from *Catharanthus roseus* (L.) G. Don [formerly known as *Vinca rosea* (Apocynaceae family)], which is used as folk medicine in Madagascar to inhibit milk secretion and as a hypotensive agent, astringent, and emetic. Moreover, native people in England and the West Indies have used this species to lower blood sugar.

Numerous synthetic analogs have been designed to have activity against other tumor types or to have fewer side effects. Among them, navelbine (vinorelbine) (A3) was developed by Burroughs Wellcome (17) and is used against non-small cell lung and advanced breast cancers. This synthetic analog of A1 has an eight-membered, rather than a nine-membered, C ring, and a dehydrated D ring (18). Eldisine (vindesine) (A4)
Recent Progress in Drug Discovery Based on Plant-Derived Natural Products Research

**Figure 2** Structures of natural and synthetic taxoids.

is another structurally modified analog, which is used against acute lymphoblastic leukemia, breast cancer, and malignant melanoma.

EC145 (A5), a folic acid conjugate of desacetyl vinblastine monohydrate, represents a new generation of receptor specific targeted chemotherapy and is undergoing Phase I anticancer clinical trials (19). Phase II trials for bladder and kidney cancers are underway with vinflunine (A6), a bifluorinated vinorelbine derivative (20, 21).

**Taxus species**

Taxol (paclitaxel) (B1), a taxane diterpene isolated from the bark of the Pacific yew tree Taxus brevifolia Nutt. (Taxaceae family), is used extensively in patients with advanced and metastatic ovarian and breast tumors, particularly tumors that are refractory to standard chemotherapy. Initially, supply problems severely limited the full exploration of its antineoplastic potential. However, the semisynthesis of B1 from 10-deacetylbaccatin III (B2), which is isolated from needles of the European yew tree, Taxus baccata L., provided an alternative renewable resource to resolve the supply problems.

Wall and Wani (22) are the pioneers in taxol discovery. To date, around 400 taxoids have been isolated from the Taxus species. Taxus alkaloids were reviewed recently in the book Taxus, genus Taxus edited by Ikokawa and Lee (23). Biologic
activity and the chemistry of taxoids from the Japanese yew also have been reviewed (24).

\[ B_1 \] interacts with cellular tubulin via promotion of microtubule assembly and inhibits mitosis. It is active against breast, brain, tongue, endometrial, and ovarian, as well as other, cancers (25, 26). The clinically used analog docetaxel (taxotere) (\[ B_3 \]) is synthesized from the more readily available \[ B_2 \]. Taxotere is used particularly against non-small cell lung cancers.

Extensive structure-activity relationship (SAR) studies have led to many related antineoplastic taxane analogs, including ortataxel (\[ B_4 \]), an orally administered taxoid in Phase II clinical trials (27). SAR studies of ring C-seco-taxoids were published recently (28).

In addition, conjugates between taxol and various other compounds, such as 3,17β-estradiol (29), various fatty acids (30), or a biodegradable polymer (poly-L-glutamic acid, paclitaxel polyglumex) (31, 32), seek to improve drug targeting or tissue distribution. The laboratories of the authors have conjugated taxoids with other anticancer agents, including epipodophyllotoxins (\[ B_5 \]) (33) and camptothecin (\[ B_6 \]) (34). A recent review

---

**Figure 3** Structures of natural and synthetic camptothecins.
provides an overview of novel formulations of taxanes, including many in clinical trials, developed to overcome the solubility issues with B1 and B3 (35).

**Camptotheca species**

Camptothecin (CPT, C1) is a potent antitumor pentacyclic alkaloid isolated from Camptotheca acuminata Decne. (Nyssaceae family) and originating in China (36, 37). Interest in CPT was sparked by the discovery that its primary cellular target is DNA topo I (38). 10-Hydroxycamptothecin (C2), which also occurs naturally, has a better therapeutic index and is used in China for treating many cancers.

Poor water solubility of the natural products led to the development of the semisynthetic, more water-soluble analogs topotecan (Hycamptin, C3) and irinotecan (Camptosar, C4), which are used primarily for the treatment of advanced ovarian and metastatic colorectal cancers, respectively (39). Some CPT analogs, such as C5 synthesized in the laboratories of the authors showed greater topo I inhibition than CPT (40). Additional CPT analogs also are of interest in combination regimens as radiation sensitizers (41). Two epipodophyllotoxin-camptothecin conjugates, C6 and C7, from the laboratories of the authors exhibit dual mechanisms of action, being both topoisomerase I/II-inhibitory (42). They have improved in vitro anticancer profiles (42) and are active against etoposide- and camptothecin-resistant KB cells (KB7D and KB/CPT100, respectively).

Clinical application and perspectives on the CPTs have been discussed in several excellent reviews (43–45). New CPT
analogs in anticancer clinical trials include DB-67 (a silatecan or 7-silylcamptothecan, C8 (46) and rubitecan (9-nitrocamptothecin, C9 (47)).

**Podophyllum species**

The genus Podophyllum (Berberidaceae family), including the American *P. peltatum* L. (American mayapple) and Indian or Tibetan *P. emodi* Wall (syn. *P. hexandrum* Royle), has been used for centuries for its medicinal properties. Podophyllin, a resin obtained from an alcoholic extract of Podophyllum rhizome, has been used for a long time as a remedy for warts and was listed in the U.S. Pharmacopoeia from 1820 to 1942, when it was removed because of undesirable toxicity (48).

Podophyllotoxin (D1) is an aryltetralinlactone cyclolignan with a flat, rigid five-ring skeleton; it was isolated in 1880 from rhizomes of *P. peltatum*. It was found to show antineoplastic

**Figure 6** Structures of colchicine and related compounds.

**Figure 7** Structures of tanshinlactones and neo-tanshinlactone.
activity, but it is highly toxic and failed the U.S. National Cancer Institute (NCI) Phase I clinical trials as an antitumor drug in the 1970s. Chemical modification of D1 led to successful development of the clinically useful antitumor drugs etoposide (D2) and teniposide (D3). These compounds inhibit cellular DNA topo II and are used to treat small cell lung and testicular cancers and lymphomas/leukemias. Etoposide (etoposide phosphate, D4) is a clinically used, water-soluble phosphate ester of etoposide. It lessens the chance of precipitation of the drug during intraavenous administration.

Limitations of D2, including myelosuppression, drug resistance development, and poor water solubility, prompted extensive SAR studies. Using drug improvement principles, several series of 4-alkylamino and 4-arylamino epipodophyllotoxin analogs were synthesized and showed increased inhibition of DNA topo II activity and increased cytotoxicity in D2-resistant cell lines (49–51). From the preclinical development in the laboratories of the authors, GL-331 (D5) (52), which contains a p-nitroanilino moiety at the 4-position of D2, emerged as a clinical trials candidate. Compared with D2, GL-331 has advantages of better water solubility, easier manufacturability, and fewer side effects. It also shows cytotoxic activity against D2-resistant cancer cell lines. GL-331 progressed to Phase IIa clinical trials as an anticancer drug (53).

The rational design of improved D2 analogs has made use of several new computational strategies (52, 54–56). In 2004, Goralda et al. (57) reviewed the distribution, sources, application, and new cytotoxic derivatives of D2. More recently, Lee and X Lao (58) also have reviewed podophyllotoxins and related analogs, including GL-331, to demonstrate how plant natural products can lead to successful preclinical drug candidates.

Cephalotaxus species

The genus Cephalotaxus (Cephalotaxaceae family) contains coniferous evergreen trees and shrubs that are indigenous to Asia. Historically, the bark has long been used in TCM for various indications. Powell et al. (59–61) originally isolated the antitumor alkaloids homoharringtonine (E1) and harringtonine (E2). Subsequently, Chinese investigators discovered that alkaloids from C. fortunei Hook. F possess antitumor activity (62). Consequently, E1 was obtained from the Chinese evergreen tree C. harringtonia K. Koch var. harringtonia (63), and other active alkaloids were isolated from various Cephalotaxus species (64, 65). Interestingly, the parent compound, cephalotaxine (E3), is devoid of antitumor activity. E3 has been investigated in anticancer clinical trials at the U.S. National Cancer Institute (NCI), particularly for the treatment of myeloid leukemia (66, 67). However, its side effects still remain an issue. Thus, the authors have continued to study new natural constituents of Cephalotaxus species and to develop new analogs on the basis of SAR studies, as presented in a review by Itokawa et al. (68).

Colchicine species

The alkaloid colchicine (F1) isolated from the medicinal plant Colchicum autumnale L. (Liliaceae family) still is used to treat gout and familial Mediterranean fever. F1 and thiocolchicines (F2) (SCH, rather than OCH3 at C-10), which is more stable and more potent but slightly more toxic, are mitotic inhibitors that inhibit polymerization of tubulin (69). Although they show antileukemic activity, they are too toxic to use as anticancer agents, which prompts the synthesis of new, less toxic analogs. Replacing the C-7 acetamide group on the B ring with various oxygen-containing groups (ketone (F3), thiocolchicoline, hydroxyl (F4), and ester (F5–F6)) led to compounds that were equally or more active in vitro than F2. The C-ring contracted colchinol-7-one bismethyl ether or allo-ketone (F7) was equipotent with the seven-membered ring natural product F1. Three-related, ring-contracted colchinicinoids (F8–F10) showed excellent activity in drug-sensitive and drug-resistant K562 cell lines (71).

The above synthetic colchicinoids have three methylated phenolic groups in the A ring, which are needed for full potency as tubulin/mitotic inhibitors. Removing one or two of the methyl groups reduces potency, and trimethylated colchicines and thiocholicchines (F11–F14) no longer interact with tubulin but rather are a new class of DNA topo II inhibitory agents (72). They show in vitro activity against bone and breast cancers (73).

Salvia species

Salvia officinalis L. (Labiatae family) is native to Europe and America, but the roots and rhizome of S. miltiorrhiza Bunge (called Tanshen) have been used widely in China for treating various cardiac (heart) and vascular (blood vessel) disorders, such as atherosclerosis or blood-clotting abnormalities. This plant exhibits hypotensive effects, causes coronary artery vasodilation, and inhibits platelet aggregation. Accordingly, it should not be used in combination with warfarin. Tanshen also has been applied for hemorrhage, dysmenorrhea, miscarriage, swelling, inflammation, chronic hepatitis, and insomnia (74, 75). Clinically available preparations of a S. miltiorrhiza / Oliberia odorifera mixture may have potential as an anti-anginal drug (76).

Tanshinone diterpenoids, including tanshineone I (G1) and tanshineone IIa (G2), are bioactive compounds from S. miltiorrhiza (77). Sodium tanshinone sulfate (G3) is a water-soluble derivative of G2, used clinically to treat angina pectoris and myocardial infarction, and exhibits strong membrane-stabilizing effects on red blood corpuscles. In addition, novel seco-

Figure 8 Structure of sinococuline.
Other studies have shown that S. miltiorrhiza exerts clear cytotoxic effects and strongly inhibits the proliferation of liver cancer cells (79). Various tanshinones were tested in SAR studies against several human tumor cells, namely nasopharyngeal (KB), cervical (Hela), colon (Colon 205), and laryngeal (Hep-2) cell systems (74, 75). Neo-tanshinlactone (G4), also originally isolated from Tan-shen, has a unique and different structure compared with other compounds from S. miltiorrhiza Bunge. Preliminary studies of this compound showed unique specific activity against the...
in vivo from the stems and rhizomes (82). It also has analgesic, and anti-inflammatory crude drug. Mountains of east Asia, has folkloric uses as a diuretic, an in vitro activity of this compound type (81). The major pigment in Curcuma species (Zingiberaceae family) is the yellow phenolic diarylheptanoid curcumin (J1). Curcumin and its analogs have potent antioxidant and anti-inflammatory effects, cytotoxicity against tumor cells, and antitumor-promoting activity (96). The biologic effects and targets of curcumin, as well as its possible roles in cancer prevention and therapy, have been reviewed recently (97, 98).

Cocculus species

Cocculus trilobus DC. (Menispermaceae family), found in the mountains of east Asia, has folkloric uses as a diuretic, an analgesic, and an anti-inflammatory crude drug. Smicosoline (H1) was isolated as an anti-tumor principle from the stems and rhizomes (82). It also has in vivo activity against P388 leukemia. H2 likely is a general cytotoxic rather than a cell-specific agent (83).

Maytenus species

Maytenus ilicifolia Mart. ex R. E. F. (Celastraceae family), more commonly known as "Cangora," is found in South America where it is used for its analgesic, antipyretic, anti-septic, and anticancer properties and for birth control, particularly in Paraguay. Bioactivity-directed fractionation and isolation by various research groups has led to the isolation of various active principles. Kupchan et al. (84, 85) first identified antileukemic maytansinoids, for example, maytansine (I1), from the African plant Maytenus ovata (later renamed M. serrata (Hochst. ex A. Rich.) R. Wilczek). Although it advanced to Phase II clinical trials, testing then was suspended because of neurotoxicity. The related maytansine (I2), isolated from M. diversifolia (Maxim.) Ding Hou, has been investigated for growth-inhibiting and apoptosis-inducing activities in K562 leukemia cells (86). Cyclotoxic monoterpene indoles include pristimerin (I3) and isolignostane H (I4) from M. ilicifolia (87), as well as the triterpene dimers dihydroisocangorosin A (I5) and cangorosin B (I6) (88, 89). The authors also have identified cytotoxic sesquiterpene pyridine alkaloids, including emargatinones B (I7) and F (I8), from M. emarginata (Willd.) Ding Hou (90, 91).

Recently, new triterpenes were isolated from M. chuchu-huasca R. Hamet and Colas (92), along with sesquiterpenes from the same plant (93). New compounds also were reported from M. cuzzoinea Loes. (95). The major pigment in Curcuma species (Zingiberaceae family) is the yellow phenolic diarylheptanoid curcumin (J1). Curcumin and its analogs have potent antioxidant and anti-inflammatory effects, cytotoxicity against tumor cells, and antitumor-promoting activity (96). The biologic effects and targets of curcumin, as well as its possible roles in cancer prevention and therapy, have been reviewed recently (97, 98).

Several synthetic curcumin analogs, including J2, showed potent antiandrogenic activities against two human prostate cancer cell lines, PC-3 and DU-145 (99). In expanded in vitro testing, these synthetic curcumin derivatives showed antiprostate cancer activity superior to that of hydroxyflutamide, the currently available and preferred anti-androgen for treating prostate cancer (100). In continuing work in the laboratories of the authors, dimethoxy-4-ethoxycarbonylethyl-curcumin (J3) showed potent anti-androgenic activity and therefore is

Euphorbia species

Euphorbia kansui Liou (Euphorbiaceae family) is distributed widely in northwest China. The dried roots of the plant are known as “kansui” and classified as a lower-class medicine. It is used as an herbal remedy for ascites (abdominal fluid accumulation) and cancer in China. Ingenol diterpenoids are among the bioactive chemical constituents. Kansuiphorins A–D (K1–K4) were isolated as cytotoxic principles of E. kansui by the laboratories of the authors (105, 106). In particular, K1 and K2 demonstrated potent antileukemic activity against P-388 leukemia in mice (105). A related ingenol-type diterpene (DBDI), K5 showed unique suppression of mast cell activation, a process that occurs during inflammation, and thus, might have the potential to treat allergic diseases (107). In other pharmacological studies, two isolated ingenols from an immunoenhancing E. kansui extract increased immune activity in a dose-dependent manner (108).

Three new cytotoxic diterpenoids, Yuexiandajisus D (K6), E (K7), and F (K8), were isolated from the species E. ebracteolata Hayata. (109). In additional studies, K6 showed moderate cytotoxicity against additional (HCT-8 and Bel-7402) cell lines (110).

Anti-HIV Compounds

Acquired immunodeficiency syndrome (AIDS), a degenerative disease of the immune system, is caused by the human immunodeficiency virus (HIV) and results in life-threatening opportunistic infections and malignancies. Antiviral and immunomodulating natural products have been investigated as treatments for AIDS (111).

Lomatium suksdorfii (coumarin derivatives)

DCP

L5

Figure 12 Structures of anti-HIV coumarins.

BDFI (112). Substitution of two camphanoyl esters for the acetate and isovaleroyl groups in the natural product lead to the extremely potent lead compound 3',4',R-di-O-(-)-camphanoyl-khellactone (DCK) (L2) (113). After additional synthetic modification to improve potency, 4-methyl DCK (L3) and then 3-hydroxymethyl-4-methyl DCK (L4) were found. The latter compound was selected as a clinical trial candidate (114).

Furthermore, a positional isomer of DCK, 3',4',R-di-O-(-)-camphanoyl-2',2'dimethylidydropyranoc2,3'-fichrsimeone (DCP) (L5) is even more promising because most DCP analogs are active against drug-resistant HIV strains, although DCK analogs are not. Adding an ethyl group at the 2-position of DCP decreased toxicity to cells compared with DCP, so, to date, the most likely clinical trials candidate in the DCP series is 2-ethyl DCP (L6) (114, 115).

The DCK and DCP compounds exert their antiviral activity by blocking the HIV reverse transcriptase (RT), however, at a later step than that affected by the clinically approved RT inhibitors, such as AZT. Thus, these compounds have a novel mechanism of action compared with current drugs. DCK and DCP compounds could be useful in the treatment of AIDS, although additional investigation is merited and needed (116).

Syzigium claviflorum (triterpene betulinic acid derivatives)

Triterpenes represent a structurally varied class of natural products existing in many plant species. Thousands of triterpenes have been reported with hundreds of new derivatives described each year. Some naturally occurring triterpenes exhibit moderate anti-HIV-1 activity and, therefore, provide good leads for additional drug development because of their unique mode of action and chemical structures. Research has identified anti-HIV triterpenes that block HIV entry, including absorption (glycyrrhizin) and membrane fusion (RPR103611); inhibit viral reverse transcriptase (RT) (minuscopic acid) and protease (ganoderiol, geumonoid); and act during viral maturation (DSB, see more description below) (117).

Two lupane triterpenes, betulinic acid (M3) and platanic acid (M2), from Syzigium claviflorum Wall. (Myrtaceae family) were reported first to reduce HIV IIIB reproduction by 50% in H9 lymphocytes (118). Afterwards, many derivatives were...

synthesized and studied for anti-HIV activity. Dimethyl succinyl betulinic acid (DSB, M3) was found to be the most useful candidate as an anti-HIV agent (119, 120).

DSB was discovered originally by the Natural Products Research Laboratories (NPRL), University of North Carolina, directed by the author (K.H.L.) (119), and then licensed to Panacos Pharmaceuticals, Inc. (Watertown, MA) for development. Panacos has named the compound Bevirimat and lists it as the lead antiviral product of the company.

During 2004, two Phase I studies and a Phase I/II study of M3 were completed. In the Phase I studies, the drug was well tolerated and showed good anti-HIV levels in the body. In the Phase I/II study, M3 showed activity in HIV-infected patients and significantly reduced viral blood levels (known as viral (load) (122, 123). A nther 2004 milestone was that the U.S. Food and Drug Administration (FDA) granted Fast Track Status for M3.

The Phase IIa study demonstrated the antiviral potency of M3 following once-daily oral dosing for 10 days in HIV-infected subjects not on other antiretroviral therapy. Viral load was reduced significantly compared with placebo. On day 11, following complete dosing, the median reduction at the 200-mg dose was a 91% decrease. In the Phase IIa trial, M3 was well tolerated, all adverse experiences were mild or moderate, and no dose-limiting toxicity was identified (122, 123).

Subsequently, studies have shown that M3 can be administered successfully in a tablet form rather than by an oral solution. A lbis, two drug interaction clinical trials of M3, in combination with the approved HIV drugs ritonavir and atazanavir,

have been completed and showed little likelihood of significant adverse drug-drug interactions when used in combination therapy (124).

In summary, M3 shows potent viral load reduction, a strong safety profile (with no evidence of organ toxicity or clinical intolerance), no evidence of clinically significant drug interactions, and, quite importantly, no evidence of rapid resistance development, which is a primary cause for antiretroviral treatment failure (125-127).

Phase II clinical trials began in 2006 and are still ongoing. One of the trial goals will be to determine an optimal dose of M3. These trials will involve HIV-infected patients who are failing current therapy and will be randomized, blinded, and placebo-controlled (124).

In Phase III clinical trials targeted for 2007/2008, combination therapy studies will be performed in a total of 300 to 500 patients at a commercial dose. The target for New Drug Application (NDA) is 2008/2009 (124). The efficient clinical trials progress of M3 continues to mark it as a leading new treatment for AIDS.

Active Compounds Isolated from Well-Known Folkloric Medicine

In addition to anticancer and anti-HIV agents, various types of active compounds that are active against other diseases and disorders (e.g., malaria, inflammation, and so forth) also have been isolated from natural sources, especially well-known folkloric medicine. These compounds and their plant sources are described below.

**Artemisia annua (qinghao, artemisinin derivatives)**

Qinghao (Sweet Wormwood) is the dried aerial parts of the herb *Artemisia annua* L. (Asteraceae family), which has been used in China for centuries to treat fever and malaria. Artemisinin ($\text{N}_1$) (Qing Hao Su) (128), the active principle, directly kills *Plasmodium falciparum* (malaria parasites) with little toxicity to animals and humans. Thus, it is a clinically effective, safe, and rapid antimalarial agent (129, 130). The novel endo-peroxide link is essential for the antimalarial activity.

Artemether ($\text{N}_2$) and arteether ($\text{N}_3$) are the most well-studied analogs among many synthetic derivatives and are used in malaria-prone regions, particularly India (131). Artemether and sodium artesunate (a hemisuccinate derivative of dihydroartemisinin) ($\text{N}_4$) have been added by the World Health Organization to its Model List of Essential Medicines (132).

The laboratory of the authors has synthesized analogs related to artemisinin (133). Recently, an antimalarial synthetic trioxolane drug development candidate called OZ-277 ($\text{N}_5$, also known as RBx11160) (134) has sparked great interest and has progressed to Phase II clinical trials in India, Thailand, and

Africa. Modification and pharmacological studies are ongoing (135–137). A recent review discusses artemisinin and related antimalarials (138).

Ginsengs: Asian, American, Sanchi, and Siberian

Ginseng is the root of *Panax ginseng* C.A. Meyer (Asian ginseng) (Araliaceae family). In Oriental medicine, it has enjoyed a strong reputation since ancient times for being tonic, regenerating, and rejuvenating. The genus name *Panax* is formed from the Greek pan (all) and akos (remedy). This panacea (panakeia) was believed to be the universal remedy. Wild ginseng is scarce and has been replaced by cultivated ginseng or "true" ginseng. Species include American ginseng (*P. quinquefolium*) L., cultivated in North America; Japanese ginseng (*P. japonicus* (Harms.) C.A. Meyer), widely distributed in Japan; San-chi ginseng (*P. notoginseng* (Burk.) F.H. Chen), reputed as a tonic and hemostatic in China; and Siberian ginseng (*Eleutherococcus senticosus* Maxim.).

Asian ginseng (*Panax ginseng* C.A. Meyer) Many compounds have been isolated from the root of Asian ginseng: polysaccharides, glycopeptides (panaxanes), vitamins, sterols, amino acids and peptides, essential oil, and polyalkynes (139–141). About 30 saponins (called ginsenosides) isolated from the root are dammarane triterpenoids, which generally contain three or four hydroxyl (OH) groups (a 3*β*,12*β*,20(S) trihydroxylated-type (protopanaxadiol-type) and a 3α,6α,12β,20(S) tetrahydroxylated-type (protopanaxatriol-type), which are attached to various sugars. The individual saponins (e.g., ginsenosides Rb1, Rc, Rg1, and Rh2) differ in the mono-, di-, or tri-saccharide nature of the two sugars attached at the C-3 or C-6 and C-20 hydroxy groups. In some cases, the C-20 hydroxy group is absent (e.g., in ginsenoside Rg5) or the C-12 hydroxy group also is attached to a sugar.

Traditionally, ginseng is used to restore normal pulse and remedy collapse, to benefit the spleen and liver, to promote production of body fluid, to calm nerves, and to treat diabetes and cancer. Regarding the last two effects, ginsenoside Rh2 has been found to lower plasma blood glucose in streptozotocin-induced diabetic rats (142), and recently, ginseng and its constituents have been studied for cancer prevention and anticarcinogenic effects against chemical carcinogens. Ginsenoside Rg3 and Rg5 were found to reduce significantly lung tumor incidence, and Rh2, Rg3, and Rh2 showed active anticarcinogenic activity (143). In addition, effects of ginseng on quality of life have been discussed (144).
American ginseng (Panax quinquefolium L.)
American ginseng contains almost the same components as Panax ginseng (139). Thus, it could be used for the same medical conditions as Asian ginseng. However, in Chinese theory, some differences exist: American ginseng is “cool” and is used mainly to reduce the internal heat and promote the secretion of body fluids, whereas Asian ginseng is “warm.” Correspondingly, differences in biologic activity also exist (140): American ginseng stimulates the production of human lymphocytes, whereas Asian ginseng does not have a significant effect, and Siberian ginseng enhances production.

The main chemical difference between Asian and American ginseng is in the presence or absence of ginsenoside Rf (146) and 24(R)-pseudoginsenoside F₁₁ (148). Ginsenoside Rf is found in Asian ginseng but not in American ginseng, and although 24(R)-pseudoginsenoside F₁₁ is abundant in American ginseng, only trace amounts are present in Asian ginseng (141, 145–147).

Sanchi ginseng [Panax notoginseng (Burk.) F.H. Chen]
This ginseng exerts a major effect on the cardiovascular system. It dilates the coronary vessels and reduces vascular resistance, which results in increased coronary flow and decreased blood pressure. Chinese traditional medicine used this ginseng to arrest bleeding, reduce blood stasis, and relieve pain. Recent studies have shown that, in the treatment of angina pectoris, this herb can produce a 95.5% improvement in symptoms. The herb usually can stop bleeding in cases of respiratory bleeding or vomiting of blood.

P. notoginseng contains saponins similar to those found in P. ginseng, both ginsenosides and notoginsenosides. Certain saponins of both types, including notoginsenosides K, R₁, and U (144, 145), showed immunological adjuvant activity (stimulated immune response against antigens) (148, 149). Another important bioactive constituent of P. notoginseng is the non-protein amino acid dencichine (146), which can increase platelets and stop bleeding (150).

Siberian ginseng (Eleutherococcus senticosus maxim.)
Siberian ginseng is harvested from its natural habitat in Russia and northeast China and has been used in China for over 2000 years. It is not a true ginseng like Panax ginseng or P. quinquefolia, but it does belong to the same Araliaceous family. Siberian ginseng has its own bioactive ingredients with unique and proven medicinal values. It possesses significant adaptogenic action (antistress and antifatigue) and is recommended as a general tonic. Because of its nontropic mechanisms of action, Siberian ginseng has a broad range of clinical applications. The root contains polysaccharides, phenolics (coumarins, lignans, and phenylpropanoids), and glycosides. Some members (e.g., eleutheroside K, O₁₃) of the latter group are specifically triterpenoid in nature, whereas others, including isofraxoside (eleutheroside B₁, O₂₀), glycosides of syringaresinol (e.g., eleutheroside E₁, O₂₀), and the ethyl ether of galactose (eleutheroside C, O₂₁), belong in a miscellaneous series. Eleutherosides E (O₂₀) and B (O₂₂, also called syringin) are two major glycosides and typically are used as marker...

Figure 19 Structures of Ganoderma triterpenes.

compounds associated with bioactivity, particularly antifatigue action (151). A new lignan glycoside eleutheroside E₂ (O23) was isolated recently from E. senticosus (152).

Ganoderma lucidum (fungus)

Chinese people consider *Ganoderma lucidum* (Polyporaceae family) as the “Miraculous King of Herbs.” It is highly regarded for its medicinal properties, which include promoting the healing ability of the human body, strengthening the immune system, and increasing longevity. Accordingly, *Ganoderma* works in the treatment of cancer because it helps cleanse the body from toxins and strengthen the immune system. It also enhances liver detoxification, thus improving liver function and stimulating the regeneration of liver cells.

The chemical composition includes polysaccharides and lanosteroid triterpenes. In the former class, many polysaccharides have been linked to immune-stimulating effects (153–155). The latter class contains over 130 different triterpenoids with diverse pharmacological activities (156). Examples of the polyoxygenated triterpene structures are ganoderic acids B (P1), C₁ (P2), and D (P3), as well as ganoderiol F (P4), ganodermanon- diol (P5), and ganodermanontriol (P6).

Because of its widespread use as a health food as well as for medicinal purposes, the quality control of *G. lucidum* is quite important, and modern analytical methods are being established for the quantitative determination of major triterpenoids, including P₁–P₃ as marker compounds (157).

Cordyceps sinensis (Tung Chung Hsia Tsao)

Vegetable caterpillars are called “Tung Chung Hsia Tsao” in Chinese, which translates as “winter worm and summer grass.” They result from the infection of large underground caterpillars by a fungus. An entomopathogenic fungus grows in the larva of the sphinx moth in autumn. Although the larva hibernates underground through the winter, the fungus kills the infected host and grows throughout the cadaver. In summer, a rod-like stroma of the fungus grows out from the mummified shell of the dead host, looking like a sprouting, dark blue to black grass. The mycelia of *Cordyceps sinensis* (Berk.) Saccar. (Clavicipitaceae family) that colonize the larvae of *Hepialus armoricans* (Hepialidae family) are representative vegetable caterpillars and are highly valued in the Chinese traditional medicinal system.
Initial records of using vegetable caterpillars as medicine date back to the Ming dynasty in China and appear in "Pen-Tsao-Kang-Mu" (Compilation of Materia Medica) in 1596. This fungus is regarded as a popular and effective medicine for treating numerous illnesses, promoting longevity, relieving exhaustion, and increasing athletic power. More recently, their physiologic activities, including immunostimulating and antitumor effects, have encouraged their medicinal use.

In traditional medicinal practices, wild-harvested mycelia are considered to have higher therapeutic benefits and, therefore, command higher prices than cultivated fungus. Native occurrence of the fungus is confined to the highlands of the Himalayan region, in addition to some provinces of China with cold, arid environments. Several mycelial formation products grown in artificial media are available commercially as health food supplements in the United States and Canada.

A comprehensive review (158) recently discussed the chemical constituents and pharmacological actions of the Cordyceps species. Chemical constituents include cordycepin (Q1), 3′-deoxyadenosine and other adenosine analogs, ergosterol derivatives (Q2–Q4), and peptides, including cyclic peptides such as cordycepeptide A (Q5), and other adenosine analogs, ergosterol derivatives (Q2–Q4), and peptides, including cyclic peptides such as cordycepeptide A (Q5), and other adenosine analogs, ergosterol derivatives (Q2–Q4), and peptides, including cyclic peptides such as cordycepeptide A (Q5), and other adenosine analogs, ergosterol derivatives (Q2–Q4), and peptides, including cyclic peptides such as cordycepeptide A (Q5). These compounds likely contribute to the antitumor, antibacterial, antifungal, and anti-inflammatory activities. Regarding the latter activity, Q1 has been found to inhibit platelet aggregation (160). C. sinensis also contains polysaccharides, which account for anti-inflammatory, antioxidant, antitumor, antinflammatory, immunomodulatory, hypoglycemic, and hypolipidemic effects (158, 159). New diphenyl ethers (cordyols A–C, Q6–Q8) were discovered recently in Cordyceps (161). Q6 was associated with significant anti-HSV (herpes simplex virus) activity (161).

Conclusion

Based on the above successful examples, new drugs derived from natural product leads will be discovered continuously, and modern medicinal chemistry-based molecular modification will play an important role in developing the new leads into useful drug candidates. Highly efficient bioactivity-directed fractionation and isolation, characterization, analog synthesis, and mechanistic studies are prerequisites for the development of new plant-derived compounds as clinical candidates for world-class new medicines. Drug discovery also will benefit from the development of new biological targets and the continual improvement of bioassay technology (162–169). The development of new, effective, and safe world-class drugs from medicinal plants, which have been appreciated for centuries for treating illness, will be long lasting, as they are the best and most effective source for generating new medicines by use of modern scientific technology.

In the past, studies into the distribution of platinum anti-cancer agents inside cancer cells were experimentally challenging because of a lack of readily available and sensitive platinum mapping techniques. Recent advancements in the area of platinum mapping in cells have meant that the biologic fate of cisplatin and its derivatives can be studied in several new ways. In particular, electron microscopy, fluorescence microscopy, and synchrotron radiation induced X-ray emission have made significant contributions in the study of cisplatin in vitro. The applications of these three techniques and the insights they provide into the intracellular distributions and interactions platinum complexes are reviewed here. The strengths and weaknesses of each technique and their potentials for additional use in this field of research have been evaluated.

Introduction

Platinum-based anticancer drugs including cisplatin, carboplatin, and oxaliplatin are the most widely used and effective chemotherapeutic agents in the current arsenal (1, 2). They are believed to exert their action by binding to nuclear DNA that leads ultimately to the affected cell undergoing apoptosis (3). To reach the nucleus, the complex must traverse the cell membrane, the cytoplasm, and the nuclear membrane to avoid the detoxification mechanisms of the cell along the way. Less than 1% of the platinum that enters the cell successfully makes this journey and, consequently, the great bulk of the platinum suffers other fates (4, 5). Determining how the cell deals with platinum is important for understanding and for overcoming unwanted toxicities and inherent and acquired resistance, but is experimentally challenging.

Biologic Background

Although the cytotoxicity of cisplatin (and its derivatives) is accepted widely to be a result of its interactions with DNA, much is still unknown about the interactions of cisplatin on a cellular level. To begin with, the intracellular uptake of cisplatin is still the subject of much debate. Some studies have suggested that cisplatin diffuses into cells passively, as uptake has been observed to be not saturable, not dependent on pH, and not inhibited by coadministration of structural analogs (6, 7). Other studies have argued that some component of cisplatin uptake is carrier mediated, as cisplatin accumulation is modulated by ATP, membrane potential, ion concentrations, and several transportomes, which includes the copper influx transporter CTR1 and the ATP dependent copper efflux transporter ATP7B (8–15). Indeed, it has been observed that cisplatin accumulation is reduced in many cisplatin-resistant cell lines (16–18). Hence, the mode of platinum influx and efflux in cells plays an important part in drug resistance, and it needs to be understood better.

Another area that requires additional understanding is the role of cytoplasmic organelles in the fate of platinum drugs. Platinum has been shown to be localized within the Golgi apparatus, endoplasmic reticulum, mitochondria, and lysosomes, the cytosol, and the nucleus. However, only the consequences of nuclear localization have been defined satisfactorily (19–21). It has been observed that the Golgi apparatus and the endoplasmic reticulum change in morphology after cisplatin treatment. One explanation for this change is that protein translation has been inhibited after cisplatin localization in these organelles (22, 23). Another suggestion is that these organelles contain enzymes and proteins that are linked directly to mechanisms of cisplatin induced resistance, including glutathione-S-transferase and metallothins (21, 24, 25). Hence, the changes observed in these organelles may be caused by the participation of these enzymes in the deactivation of cisplatin.

It is well documented that the aquated form of cisplatin localizes within the mitochondria, and that the inhibition of respiration and spontaneous release of calcium ions into the...
Reduced X-ray emission. Through the use of three important imaging techniques: electron view and evaluate recent developments in the study of the fate of resistance, with several alterations that have been identified in cisplatin-resistant cell lines. These alterations include a decrease in the expression of proteins involved in the mechanisms of drug-resistance. In a study by Yang et al. (26), the morphology of the mitochondria was found to be changed significantly after one hour incubations with 50 µM cisplatin, suggesting that the damage done to the mitochondria is subsequent to lysosomal and nuclear localization, which suggests that this organelle has only a secondary role in cisplatin-mediated cytotoxicity (23, 26–30). The involvement of lysosomes in the action of cisplatin is also of interest. Cells that have been treated with cisplatin have an increased number and size of lysosomes, suggesting that they may play an important role in detoxification of the drug (8). In other studies, this organelle has been implicated in the mechanisms of resistance, with several alterations that have been identified in cisplatin-resistant cell lines. These alterations include a decreased number of the organelles, a more alkaline lumen, and altered recycling of the luminal contents between the endosomal and lysosomal compartments (31, 32). Interestingly, lysosomes have also been implicated as a potential site of induced cytotoxicity. Endogenous and/or exogenous stress can cause the membrane of the lysosome to permeabilize and release hydrolases. If this release is uncontrolled, it can lead to necrosis and selective release of two classes of hydrolases (sphingolipidases and cathepsins) that can trigger the so-called “extrinsic” pathway to apoptosis. A hallmark in lysosomal cathepsins (found in many cancer types) can degrade the extracellular matrix of the cell and lead to tumor metastasis (33–37).

Thus, the mode of platinum entry into cells and its subsequent intracellular pathways and interactions with subcellular organelles are defined poorly. Addressing where and how platinum drugs are processed in cells could greatly help elucidate the cause of unwanted toxicities as well. The phenomena of drug-resistance, ultimately improving drug design. In the past several techniques such as cell fractionation, atomic absorption spectroscopy, and light and electron microscopy were employed to study the distribution of cisplatin in vitro (8, 19, 21, 30). A lack of readily available, accurate, and sensitive platinum-imaging techniques limited the research in this area. In the past decade, new and improved techniques have emerged for the detection of platinum in cells. Here, we review and evaluate recent developments in the study of the fate and distribution of platinum complexes in cancer cells, achieved through the use of three important imaging techniques: electron microscopy, fluorescence imaging, and synchrotron radiation-induced X-ray emission.

Platinum Imaging Techniques

Transmission electron microscopy

Transmission electron microscopy (TEM) has been used extensively in biology for direct visualization of ultrastructural details and platinum deposits in cells. The underlying physics behind TEM is similar to that of ordinary light microscopy; however, the resolutions achieved by TEM can be some 400-fold greater than that of light microscopy (38). Briefly, the mechanics behind TEM involves an illuminating source, the electron gun, that sends a beam of electrons through a vacuum and onto the specimen of interest. An image is formed according to the differential absorption of electrons by various parts of the specimen; this image is amplified via a series of electromagnetic or electrostatic lenses and is projected onto a fluorescent screen. All manufactured transmission electron microscopes guarantee a resolution of 0.344 nm, TEM is particularly useful in cellular biology, where resolutions of around 2 nm (the width of one third of a mitochondrial membrane) are needed (38, 39).

The preparation of biologic samples for TEM involves several steps. First, the sample is fixed, usually chemically, to preserve the structural integrity and the spatial information of the cells while simultaneously terminating any biologic activity. After fixation, the sample is dehydrated and embedded in an epoxy resin, then sectioned into thin slices (that range from 80 to 800 nm) and stationed onto a grid, ready for examination by the electron microscope. For specific staining of cellular components, immunolabeling can be employed; the contrast between cellular components or the background can be heightened by staining with heavy metal salts, such as those of uranium, lead, and osmium, all of which have sufficient mass and electron density to scatter the electron beam (40).

The high resolution attainable by TEM has led to its use in biologic platinum studies in two ways; to reveal ultrastructural morphologic changes in drug treated biological samples and to map directly the platinum moieties in cells. Several studies have used TEM to examine morphologic features of organ tissues, sarcoma, and tumour cells, before and after cisplatin treatment to gain insights into its toxicity and mode of action (41, 42). Among the more recent findings from these fine-structure studies was the observation that the morphology of rat kidney tissue changes after cisplatin treatment in vivo (8). It was observed that cisplatin induced a large increase in the number and the size of lysosomes in the cells of the kidney, which suggests that lysosomal sequestration is a mechanism used by the kidney for the removal of platinum and other heavy metals (8, 43). Other similar fine-structure studies revealed significant changes in mouse kidney morphology after cisplatin incubation, with observed features such as necrotic proximal tubules, damaged tubular basement membrane, and short, irregular microvilli (44).

In in vivo studies, Yang et al. (26) found that the morphology of the mitochondria to be changed significantly after one and 4 hour incubations with 50 µM cisplatin on the head and neck squamous cell carcinoma cell line (HNSCC). The mitochondria showed swelling, distortion of the cristae as well as the inner and outer membranes, whereas the nucleus and nucleoli remained unchanged. This finding led to the authors to challenge the notion that the site of action of cisplatin is solely with nuclear DNA, which suggests that cisplatin could act directly on the mitochondria to cause the release of cytochrome c trigger in the apoptotic cascade (26). In another study conducted by Mejra et al. (45) on human small cell lung carcinoma cancer cells (GLC-C), a high nuclear to cytoplasmic ratio was observed after 4 hour incubations with 333 µM cisplatin. Furthermore, similar cisplatin treatments on the cisplatin resistant sub-line, GLC-CDDP, were shown to cause swelling of the Golgi apparatus and an increase in the numbers of mitochondria (45).
Early attempts to map the distribution of the electron-rich platinum moieties inside cells employing TEM have met with some success, with platinum(II)-pyrimidine complexes being amongst the first platinum species to be mapped (46). In this study, it was observed that cells stained with platinum(II)-thymineuracil complexes, prepared as 1% solutions, showed platinum staining in the chromatin, nucleolus, and ribosomes with high selectivity. However, it should be noted that the concentration present in a 1% platinum complex solution is much greater than those in normal experimental dosages. In a separate study by Kh and Sadler (47), gray electron dense areas were also observed to be localized primarily within the nucleus and nucleolus of human epithelial carcinoma (HeLa) cells after 4 hour incubations with high concentrations of cisplatin (200 µM). These gray areas were later confirmed by electron-probe X-ray analysis to contain platinum (47).

In later TEM studies by Ghadially et al. (48), a lower concentration of cisplatin (30 µM) was incubated in HeLa and human lymphoblastoid (RPMI 6410) cells for periods that ranged from 1 hour to 4 days. No intracellular platinum was detected in either cell line. However, similar incubations with platinum(II)-uracil resulted in development of lysosome-like bodies in the cytosol, which are referred to as "platinosomes," that contain electron dense species identified by X-ray analysis as platinum (48). In a related study, similar concentrations of cisplatin were injected into rabbit knee joints and incubated for 30 minutes and observed electron dense spots, identified by the employment of a GPt antibody stain. This stain could be performed by counting the gold labels per cm² of area of interest on the images of three or more individual cells. It was found that the distribution of Pt-DNA adducts was the same for both GLC4 and GLC4-CDDP cell lines, with adducts detected in the nucleus (preferentially at loci with high-density chromatin), and in the mitochondria DNA. Platinations were found to be high-est in apoptotic and dividing cells (45). It should be noted that again, high cisplatin incubation concentrations were required to acquire accurate quantitative Pt-adduct formation data.

Overall, TEM has proven to be a valuable tool for biologic platinum studies. It can provide qualitative information, with excellent resolution, regarding the intracellular sites of platinum interactions and accumulations. Quantitative information regarding certain structures, such as Pt-adducts, can now be acquired. Despite these advantages, limitations exist in the use of TEM as a mapping technique for platinum. TEM cannot attain visual information of living samples, and the process of fixation, dehydration, and resin embedding can significantly affect the distribution of the platinum species inside cells. Furthermore, TEM lacks the sensitivity to detect single platinum moieties accurately, mainly because of the damage caused to the ultrastructural sample sections by the high-energy beams (53). Hence, TEM is limited to the detection of clusters or deposits of platinum metals; sparse distributions of platinum remain undetected. Additionally, the cisplatin incubation concentrations required for the detection of platinum deposits and Pt-adducts in cells are much greater than normal experimental dosages. This finding could produce misleading results in relation to the intracellular distribution of platinum.

Fluorescence imaging

Currently, fluorescence microscopy is one of the most useful techniques for the examination of drug localization in fixed and live cells. However, to use this technique, the drug must be fluorescent, or labeled with a fluorescent tag. Two forms of fluorescence microscopy are observed in the literature: wide-field epifluorescence microscopy and later scanning confocal microscopy. Briefly, the mechanics behind both techniques involves irradiation of the sample with high-energy photons, which excite appropriate fluorophores to high-energy states. After excitation, the fluorophores undergo relaxation in the forms of nonradiative transitions between excited states, and this energy can be lost as heat to the solvent. Fluorescence results as the fluorophore relaxes even more back to its ground state that emits a photon with a longer wavelength than the original excitation photon. In both techniques, this process is performed on a light microscope platform. The two fluorescent techniques differ in how the resultant fluorescence is collected and initially excited. In wide-field epifluorescence microscopy, the sample is illuminated using a high-energy light source, such as a Hg or Xe lamp, and the emitting photons are collected and amplified using a charged coupled device camera. The resulting images can be in "red color;" however, this technique collects emitted fluorescence across a large depth of field, including light outside the focal plane, which limits axial resolution to ~1 µm. In confocal microscopy, the sample is excited by scanning with a laser, and the emitting photons are collected and amplified using photon multiplier tubes. The resulting images are in "gray scale;" however, the additional employment of a pinhole positioned before the detector eliminates out of focus light, which enables resolutions of around 0.1–0.2 µm in the XY plane. This method allows the sample to be "optically sectioned" without
physical sectioning, which enables three-dimensional images to be created (52, 53).

Several advantages exist in using fluorescence microscopy in drug distribution studies. Unlike TEM, fluorescence microscopy is a noninvasive technique that can acquire three-dimensional images of living cells in real time with minimal preparation. Additionally, the spatial distribution of fluorescence within cells can be detected with high sensitivity and signal specificity; hence, both qualitative and quantitative data can be acquired at relatively low drug incubation concentrations. Furthermore, intracellular organelles can be labeled with fluorescent organelle-specific stains to identify the sites of drug accumulation in co-localization experiments (52, 54).

Recently, platinum agents have been labeled with various fluorescent tags for fluorescence microscopy studies. The earliest work of this kind was conducted by Molenaar et al. (55), who tagged a cisplatin derivative with a carboxyfluorescein diacetate (CFDA) moiety. The CFDA ligand is a nonfluorescent derivative of fluorescein and the CFDA-Pt complex becomes fluorescent following cellular uptake and acetate hydrolysis. In this study, human osteosarcoma cells (U2-OS) were incubated for 30 minutes in 10 µM CFDA-Pt. Using wide-field epifluorescence microscopy, the complex was observed to distribute initially throughout the entire cell, and then accumulate in the nucleus to form fine granular patterns at 3 hours after incubation. After 8 and 72-hour incubations with the complex, colocalization experiments employing a Golgi fluorescent probe. After 24 hours, no significant fluorescence was observed in the nuclei of the cells, which suggests that the fluorophore had undergone efflux from the cell and the Golgi. The fluorescence distribution of the free CFDA fluorophore proved to be very different from the complex, which suggests that the platinum complex is not mimicking the behavior of the fluorophore (55). A later study by the same group (56) found that the treatment of biologically active dinuclear platinum complexes labeled with the same CFDA moiety in U2-OS cell lines shows very similar localization to the mononuclear CFDA-Pt complex (56). Therefore, fluorescence microscopy has allowed for the intracellular pathway of CFDA tagged platinum complexes to be deduced and subsequently identified as a significant role in the cellular processing of these types of complexes.

In a similar study, Safaei et al. (57) studied the distribution of a fluorescein-labeled cisplatin analog (FDDP) using epifluorescence microscopy in fixed human ovarian carcinoma cells (2008). This study showed the complex was localized within the cytoplasm after a 5 minute incubation with 2 µM F--DDP. After 10 to 30 minutes, fluorescence was observed in the nuclear regions. Like the Pt-CFDA complex, F-DDP also displayed fine granular patterns in the nucleus, and it was distributed in discrete vesicular structures, not localized diffusely throughout the cytoplasm. Staining with organelle-specific markers revealed that F-DDP was sequestered into the lysosomes, Golgi, and secretory compartments of the cells. The roles of these subcellular organelles in the processing of the complex were investigated by the use of various pathway inhibitors. These biologic tools in conjunction with fluorescence microscopy revealed that the secretory pathways, involving the Golgi and lysosomes played an important role in intracellular trafficking of these tagged complexes, particularly with regard to drug efflux (57).

In another fluorescence microscopy study, the trafficking pathways of a fluorescently tagged Alexa Fluor-platinum complex in a cisplatin-sensitive human KB epidermoid carcinoma cell line (KB-3-1) and its cisplatin-resistant subline (KB-CP-r) were compared. During the first 30 minutes of the incubation, the fluorescence from the complex moved from the membrane and into the Golgi apparatus; after 2 hours, the complex was distributed throughout the cell, including nuclear compartments. Internalization of the fluorescent complexes was very different in the cisplatin resistant subline, where the overall accumulation of the complex was lower, as determined by decrease of cellular fluorescence by flow cytometry. Only punctate cytoplasmic staining was observed after incubations, with little fluorescence in the cell nucleus. The altered distribution suggests that cellular resistance could be caused by modified trafficking, possibly involving the failure of cell membrane proteins that bind cisplatin (58).

From these studies, it can be observed that fluorescence microscopy can indeed be a powerful technique for studies into the biologic fate of platinum anticancer agents. It not only provides qualitative and quantitative distribution data, but also offers the option of real-time imaging, which reveals cellular processes in action. Despite the usefulness of fluorescence imaging in distribution studies, inherent disadvantages exist with this technique. For example, it is difficult to ascertain whether the fluorescence observed is from the fluorophore-platinum complex or the fluorophore alone (should cleavage occur in the cell and the distribution will differ from the properties of the platinum complex alone, which affects such factors as cellular uptake (59, 60). Furthermore, a highly conjugated, aromatic fluorophore may act as an intercalator, which generates different reaction profiles with DNA. Hence, caution should be used when evaluating the distributions of fluorescence in cells.

The disadvantage associated with altered distribution because of the fluorescence tag does not apply when the drugs concerned are intrinsically fluorescent platinum species, such as those of the platinum-anthraquinone complexes. Platinum-anthraquinone complexes were designed to increase the DNA affinity of the platinum moiety by its chemical linkage to a bio-carrier, in this case an intrinsically fluorescent DNA intercalator (61, 62). In a series of time-lapse fluorescence microscopy studies conducted by Reedsjö et al. (63, 64), the cellular distribution of a group of dinuclear cationic platinum-anthraquinone complexes was observed in live parental A2780 cells. At the low incubation concentration of 3 µM, the complexes were observed to enter the cells slowly, with fluorescence predominantly being localized within the cytosol after 2 hours. After 24 hours, the complexes were localized in the lysosomes whereas the free ligand was found to be additionally localized in the nucleus. In contrast, studies using the same complexes in the cisplatin resistant A2780 subline show that the complexes were encapsulated by the lysosomes at the beginning of their incubation.
which suggests that lysosomal sequestration plays an important role in the resistance profile of A2780 cells. However, additional DNA titration studies found that the fluorescence of the anthraquinone was quenched in the presence of DNA; hence, any nuclear localization of the drug may not have been detected (63, 64).

Additional studies using the same complexes in both cisplatin sensitive and resistant forms of U2-OS cells also showed differences in the cellular processing of the drugs; both the free ligands and platinum complexes were rapidly found to accumulate in the nucleus, after uptake into the Golgi, which was hypothesized to be involved in transport of the platinum complexes out of the cells (56). In this set of studies, fluorescence imaging helped to illustrate the differences in the intracellular interactions of dinuclear platinum-anthraquinone complexes in different cell lines and in the different resistance profiles of A2780 and U2-OS resistant sub lines.

In a separate fluorescence microscopy study, the distribution of a mononuclear neutral platinum-anthraquinone complex, Pt1C3 (1), was examined in human colon adenocarcinoma cells (DLD-1) and A2780 cells (see Fig. 1). In both cell lines, fluorescence was observed to be predominantly localized within lysosomes after 1-, 4-, and 24-hour incubations with the complex, with no colocalization with mitochondrial and nucleic acid fluorescent probes. These results were in conflict with the high cytotoxicity profile observed for the platinum complex and cellular uptake studies that showed high platinum content within the nucleus after 4 hour incubations (65). Several possible reasons exist for the lack of fluorescence detected in the nucleus.
The amount of DNA binding may be too low to detect by confocal techniques. Alternatively, the platinum cytotoxin could be cleaved from the fluorescent anthraquinone part of the complex and is still entering the nucleus. Last, quenching of the molecules fluorescence could have occurred through reaction with an endogenous molecule such as DNA. Hence, although the bio-distribution of these intrinsically fluorescent drugs will not be altered because fluorescence tagging is unnecessary, limitations still exist in the application of fluorescence imaging in the mapping of these intrinsically fluorescent platinum complexes in cells.

X-ray fluorescence microscopy

A recently embraced technique in the monitoring of platinum in cells is that of synchrotron radiation induced X-ray emission (SRIXE). SRIXE is essentially synchrotron-based X-ray fluorescence microscopy and allows for the accurate two-dimensional analysis of elemental distribution within biologic samples (provided that the element is heavier than fluorine). The high intensity of X-rays derived from third generation synchrotron sources gives rise to the high sensitivity of platinum detection, with detection possible down to 5–10 ppm, and the high spatial resolution of about 0.15 × 0.15 µm² (66–68). At this level of elemental sensitivity, SRIXE has advantages over electron microscopy because the detection of platinum is possible at much lower drug concentrations. Furthermore, the location of the unmodified platinum complex can be monitored directly using SRIXE, and it is not merely inferred indirectly by the imaging of chemically modified analogs of the drug as done in fluorescence microscopy studies. Additionally, it is not necessary to fix or to section samples for SRIXE because of the highly penetrating nature of hard X-rays (photons with energy > 1 keV), and the samples can be studied relatively close to their natural hydrated state (with some cryogenic treatments) (69).

Briefly, the principle behind SRIXE involves the focusing of a beam of hard X-rays from a synchrotron source to a submicron area section on a sample. When absorbed by core electrons of the elements in the sample, these photons result in ejection of these electrons. Electrons from a higher energy orbital move down to fill the vacancies left, which results in the release of photons with energy that is equivalent to the difference in the binding energies of the two shells. This X-ray fluorescence is detected and converted into an X-ray spectrum, conveying characteristic peaks (see Fig. 2) (66). The identity of the elements can be deduced from the energies of the peaks, and the integration of the peaks correlates to the quantities of the elements present. By this method, many elements can be identified concurrently, which allows maps of the distribution of these elements to be generated at submicron resolution (66–68).

So far, studies that use SRIXE to map the distribution of platinum inside cells have been limited, and all studies have been conducted at low resolution. The first of these studies was conducted by Ilinski et al. (68), who used SRIXE to compare the uptake of platinum(II) complexes in the cisplatin-sensitive 2008 cell line and its cisplatin-resistant subline. In this study, incident X-ray energy of 11.7 keV (just above the platinum 2p3/2 absorption edge) was used, and Lβ fluorescence lines were collected with resolutions of 1 × 0.2 µm². It was observed that cisplatin accumulation in the cisplatin-resistant subline was half that of the cisplatin-sensitive cell line after 24-hour incubation with 10 µM cisplatin. In contrast, Pt103, a cisplatin derivative that displayed high activity against cisplatin-resistant tumors, showed a higher accumulation after the same incubation period. This suggests that increase of Pt103 cellular uptake was responsible for its bypass of cisplatin resistance mechanisms in cisplatin-resistant 2008 cells. However, the accuracy of this experiment was compromised because of the overlap of the fluorescence peaks between Pt Lα and ZnKβ when 11.7 keV is used as the incident energy (68). Regardless, the potential of SRIXE to map the distribution of platinum quantitatively within individual cells was demonstrated.
Following this, Hall et al. (60, 70) used SRIXE to examine elemental distribution within A2780 cells that had been treated with cisplatin and platinum(IV) complexes. This study employed incident energy of 12.6 keV (above the Zn Kα absorption edge), and emissions from both Kα and Lα fluorescence were collected at a resolution of 0.3 × 0.3 µm². It was observed that cisplatin and the platinum(IV) analogs accumulated in the nucleus of the cells after 24-hour incubations with 20 µM solutions (note that zinc elemental maps were used to identify the cell nucleus; see Fig. 3). This finding suggests that most platinum(IV) species had been reduced, and it was confirmed qualitatively by collecting micro-XANES spectra at points of high platinum concentration within the cells. The observation was also confirmed quantitatively by obtaining XANES spectra of bulk cell samples and quantifying the percentage of remaining platinum(IV) (60, 70). Hence, this study confirmed that SRIXE can be used for qualitative and quantitative studies of platinum accumulation inside cells, and it showed that the coupling of SRIXE with XANES affords a powerful technique in which both the distribution and oxidation state of a drug within a biologic system can be determined.

In later studies, Hall et al. (71) employed the same method as above to study the intracellular distribution of platinum complexes that carry bromine labels (2, 3) or anthraquinones (1). Again, after 24 hours, all complexes were found to be localized within the nucleus, with little platinum being in the cytosol. In the case of the platinum(II)-3-bromopyridine complex (2), the bromine was also observed to colocalize with the platinum. This finding is consistent with the amine moieties that remain bound to platinum(II) complexes inside cells. In another case of the platinum(IV)-bromacetate complex (3), the distribution of the bromine was much more diffuse when compared with that of the platinum, which is consistent with the reduction of the platinum(IV) complex. However, whether the reduction occurred before or after cell entry is still unclear (see Fig. 4) (71). Hence, by this method of labeling, the bio-transformation of platinum(IV) agents can be monitored via SRIXE.

SRIXE has also been recently employed to investigate cisplatin resistance. Shimura et al. (72) has measured the quantitative difference in cisplatin accumulation between lung carcinoma cells (PC-9) and its cisplatin-resistant subline. Using an incident energy of 15 keV and a resolution of 1.5 × 0.75 µm, it was found that at 12 hour incubations using 1 µM cisplatin, the intensity of platinum in the resistant subline was 2.6 fold less than observed for the sensitive cell line (72). By using the same method as Ilinski et al. (67), Chen et al. (73) mapped the distribution of cisplatin in intrinsically cisplatin-resistant human melanoma cells (MNT-1) and in human epidermoid carcinoma cells (KB-3-1). This study found that cisplatin was sequestered into the melanosomes, and nuclear accumulation was reduced.

Although SRIXE is relatively new to cellular platinum studies, it has proven to be an excellent and reliable technique for the detection of platinum drugs in cells. Currently, success of elemental distribution studies using SRIXE is limited by the comparatively poor resolution. In the above studies, organelles, such as mitochondria, Golgi, endoplasmic reticulum, and lysosomes were not resolved because many of these subcellular organelles and structures are smaller than 0.1 µm (52). Hence, SRIXE in platinum studies currently lacks the high resolution found in TEM and fluorescence microscopy studies.

**Conclusion and Future Applications**

Advancements in imaging techniques, as illustrated above, has facilitated the significant progress made by studies of the intracellular distribution of platinum anticancer agents, providing deeper insight into the cellular fate of these drugs. All techniques mentioned have the potential to make even more valuable contributions biologic studies of platinum complexes. In terms of imaging, TEM provides the highest level of two-dimensional morphologic spatial resolutions. Additional developments into immunoelectron microscopy may allow for the intracellular mapping of more platinum–protein structures.
Figure 4  SRIXE maps showing the distribution of Br (left column) and Pt (right column) in A2780 whole cancer cells treated with cis-(PtCl2(3-Brpyr)(NH3)) (top row) or cis, trans, cis-(PtCl2(OAcBr)2(NH3)2) (bottom row). Figure reproduced with permission from Reference 71 with kind permission from Springer Science and Business Media.

Fluorescence microscopy uniquely allows for real time, three-dimensional tracking of drugs in live cells at low incubation concentrations. When employed in conjunction with tools such as pathway inhibitors, this technique can elucidate drug trafficking pathways and reveal the roles of intracellular components in the drug action.

SRIXE is a powerful technique that can map the distribution of platinum with very high sensitivity and at low incubation concentrations of the unmodified platinum drug. With future improvements to its resolving power, this technique has the potential to obtain unprecedented information on the distribution of both endogenous and exogenous elements at a sub-cellular level.

In addition to the advancement of the mentioned techniques, the future of the imaging of cellular platinum may also benefit from alternative techniques, such as that of secondary-ion mass spectrometry and autoradiography. However, these techniques have yet to be used in investigations of the in vitro distributions of platinum complexes.

Platinum Anticancer Drugs. Chemical Biology of

Programmed Cell Death as a Therapeutic Approach

Kurt Deshayes, Genentech, Inc., Department of Protein Engineering, South San Francisco, California
doi: 10.1002/9780470048672.wecb472

Although turnover rate varies greatly with cell type, the survival of multicellular organisms requires the constant renewal of healthy cells and the removal of pathogen-infected or damaged cells. A critical component of homeostasis is the proper regulation of programmed cell death or apoptosis. Both oversensitivity of crucial cells and resistance of malfunctioning cells to apoptotic stimuli threaten survival. A lack of death response permits mutant cells to survive normal death stimuli and potentially proliferate. Conversely, excess apoptosis removes cells required for organism survival. Restoring homeostasis by controlling apoptosis is a potentially powerful technique for alleviating disease.

Biologic Background

Programmed cell death allows the removal of overpopulated cells, pathogen-infected cells, malformed cells, or cells that have sustained genetic damage (1). Several disease states are linked either to a lack of apoptotic response or to unwanted cell death (2) (see Table 1).

When activated by cellular stress (e.g., hypoxia, DNA damage, or nutrient withdrawal), programmed cell suicide is initiated by the intrinsic apoptotic pathway (Fig. 1). A key step, the release of cytochrome c through changes in the mitochondrial outer membrane permeabilization, is regulated by the Bcl-2 protein family (3). Cytochrome c in combination with the Apaf-1 protein catalyzes the processing of procaspase-9 (cysteinyl, aspartate-specific protease) within the apoptosome (4). Caspase-9 initiates hydrolysis of zymogen procaspase-3 and procaspase-7, which, when activated, lead to the degradation of cellular targets and eventual cellular suicide (5). Caspase activity is regulated by Inhibitor of apoptosis (IAP) proteins, which are negative (prosurvival) apoptosis regulators (6). Conversely, the IAP proteins are antagonized by a second mitochondrial activator of caspases (Smac) protein and released from the mitochondria alongside cytochrome c, which serves as a positive (proapoptotic) apoptosis regulator (7).

Another important mechanism for promoting programmed cell death is the binding of ligands to the death receptors, which occurs in the extrinsic pathway (8) (Fig. 1). The death receptors recruit and activate caspase-8, which in turn regulates effector caspase-3 and caspase-7. Caspase-8 processes the Bcl-2 family member Bid, which collaborates with other members of the Bcl-2 family to induce cytochrome c release from the mitochondria and thereby activates the downstream intrinsic pathway (9).

Changes in the balance between the proapoptotic and prosurvival signals modulate the response to apoptotic stimuli. Cancer cells are a prominent example of how overexpression of prosurvival factors leads to a harmful repression of programmed cell death. In contrast, neurodegenerative disorders (Parkinson’s and Alzheimer’s diseases) have been suggested to result from excess cell death in slowly regenerating neurons, which leads to a loss of function (2).

Presumably, targeting the apoptotic pathway can be a means to treat cancer by antagonizing the prosurvival components or by agonizing the proapoptotic components. Recent positive results with agents that target the apoptosis pathway have increased interest in cancer therapies directed at this pathway. It is quite possible that antagonizing selected proteins within the apoptosis pathways may not be sufficient always for broadly applicable therapy. However, the connectivity between the pathways can be exploited by the judicious application of multiple agents that act in concert, perhaps synergistically, on the different components of the pathway to give broad therapeutic benefit.

When thinking about proapoptotic therapies, agents can be designed that trigger a cascade of enzymes, such that once the proteins have been activated the process will continue without the help of the therapeutic agent. This is strikingly different from a therapy that relies on enzyme inhibition for their therapeutic effect. The latter often requires chronic dosing to maintain continued enzyme inhibition. Apoptosis-inducing reagents may require only doses sufficient to overcome initial apoptotic roadblocks. Furthermore, fast-growing solid tumors often are hypoxic and nutrient-starved, conditions that would lead a normal cell into apoptosis. To avoid programmed cell death, cancer cells keep apoptosis in check through the overexpression of prosurvival factors. The studies discussed in the following sections

suggest that cancer cells are primed for programmed cell death and, therefore, are more sensitive to the induction of apoptosis.

Targeting the Bcl-2 Family of Proteins

It was first observed in type 2 B-cell lymphoma that the translocation of the Bcl-2 gene leads to radical overexpression of Bcl-2 (10). The overproduction of Bcl-2 has been shown to be transforming (10). Members of the Bcl-2 protein family contain as many as four characteristically helical Bcl-2 homology motifs (BH1–BH4). Bcl-2 proteins are divided into classes, as pro-survival proteins (Bcl-2, Bcl-xL, Mcl-1, A-1, and Bcl-w), proapoptotic proteins (Bak and Bax), and proapoptotic proteins that contain only the BH3 motif (Bim, Bid, Puma, and Noxa) (3, 11). The manner in which the different Bcl-2 family members interact and the mechanisms by which cytochrome c release is initiated are unclear, but the central role of the Bcl-2 family in apoptosis, and the therapeutic potential of regulating these proteins, is well established.

Changes in the ratio of prosurvival to proapoptotic Bcl-2 proteins regulate cellular response to apoptotic stimuli. For example, decreasing the production of prosurvival proteins will sensitize cells to apoptosis (12). Genta, Inc. (Berkeley Heights, NJ) is investigating this method as a potential cancer therapy.

Another potential therapeutic approach is to mimic the proapoptotic BH3 only proteins with small molecules that bind to the prosurvival members of the Bcl-2 family and promote apoptosis. This interaction involves a large hydrophobic interface, which is a challenging target for a small-molecule antagonist. Nonetheless, progress in the development of Bcl-2 antagonists has been reported. For example, a natural product, Gossypol, isolated from cottonseed oil, was shown to have spermicidal activity, and tested originally as a potential male contraceptive (15). Gossypol is believed to bind to the prosurvival Bcl-2 proteins (16) (see Fig. 2). The cytotoxic effects of Gossypol have been redirected as a potential anticancer therapeutic. Ascenta (San Diego, CA) has moved the R enantiomer of Gossypol, AT-101, into phase II human clinical trials. In these trials, the pan-specific Bcl-2 inhibitor has been combined with Rituxan (Genentech, Inc., South San Francisco, CA) in the treatment of relapsed CLL (chronic lymphocytic leukemia) (17). Recent results with MEFs (mouse embryo fibroblasts) that express neither Bax nor Bak show that Gossypol can kill cells independent of the proapoptotic Bcl-2 family proteins, which suggests that another mechanism is responsible for Gossypol-induced cell killing (18).

Other potential therapeutic approaches involve the use of small-molecule BH3 mimetics. Such agents are believed to antagonize the prosurvival Bcl-2 members by mimicking the action of the BH3 domain. The Abbott small molecule (ABT-737) was developed using the SAR (structure activity relationship) by NMR (nuclear magnetic resonance) method of Dr. Stephen Fesik (19). This molecule binds with subnanomolar potency to members of the prosurvival Bcl-2 family, Bcl-2, Bcl-xL, and Bcl-w, but does not bind to the other widely expressed member of the family, Mcl-1. In vitro and in vivo studies show ABT-737 has excellent...
Programmed Cell Death as a Therapeutic Approach

Figure 1  The extrinsic apoptotic pathway is triggered when death receptors are engaged by their cognate ligands, which results in recruitment of the adaptor protein FADD and the apical caspase, caspase-8. This recruitment leads to the activation of caspase-8 and subsequent activation of the effector caspases 3 and caspase-7. The intrinsic apoptotic pathway is triggered by stimuli, such as irradiation, chemotherapeutic agents, or growth factor withdrawal. Activation of proapoptotic Bcl-2 family members by the p53 pathway neutralizes the antiapoptotic proteins Bcl-2, Bcl-xL, and Mcl-1, which leads to the disruption of the mitochondrial membrane potential and to the release of cytochrome c and Smac into the cytoplasm. These events result in Apaf-1-mediated activation of caspase-9 and subsequent activation of the effector caspase 3 and caspase-7 and then culminate in cell suicide. XIAP is the last line of defense against cellular suicide and acts by inhibiting caspases. Other IAP proteins (ML-IAP, cIAP1, and cIAP2) do not inhibit caspases directly but sequester the proapoptotic molecule Smac, which prevents it from blocking the action of XIAP. Smac mimetics bind to IAP proteins and block their inhibitory activity by antagonizing the critical IAP–caspase and IAP–Smac interactions.

Targeting the Inhibitor of Apoptosis Proteins

IAP proteins prevent cell death through interactions between their BIR (baculoviral IAP repeat) domains and the proteases that are critical for the initiation and execution of apoptosis, caspase-3, caspase-7 and/or caspase-9 (23). X-chromosome-linked IAP (XIAP) is a ubiquitously expressed IAP protein and a potent inhibitor of caspases that plays a critical role in resistance to chemotherapeutic agents and other proapoptotic stimuli. Although no direct genetic mutation defines XIAP as an oncogene, XIAP overexpression is common in cancer and has been linked to poor patient prognosis (24). In another class of IAP proteins, c-IAP1 and c-IAP2 are unique among IAP proteins for their ability to interact with TRAF1 and 2 (tumor necrosis factor receptor-associated factors 1 and 2) (25, 26). Importantly, c-IAP1 and c-IAP2 are also targets of genetic amplification, which correlates with resistance to chemotherapy and radiotherapy (27). The (melanoma inhibitor of apoptosis protein) (ML-IAP) is upregulated in melanomas but not expressed in most normal adult tissues (28). Changes in IAP expression modulate apoptotic response to cellular stress. For example, an antisense oligonucleotide developed by Aegera Therapeutics, Inc. (Montreal, Quebec, Canada), AEG35156, reduces expression of XIAP. Treatment with AEG3516 increases apoptosis in studies with myeloid leukemia cells, and the antisense approach currently is in phase I/II clinical trials for refractory AML (acute myeloid leukemia) in combination with chemotherapy (29). The strategy of up-regulating IAP action to inhibit apoptosis has been validated...

by transfection of a gene-encoding XIAP in a rat glaucoma model (30).

The Smac protein promotes apoptosis by neutralizing the IAP proteins through interactions of the Smac N-terminal region with the BIR domains of the IAP (31, 32). The interaction between Smac and IAP proteins disrupts the IAP inhibition of caspases, which allows caspase activation and eventual cell suicide. In vivo and in vitro studies reveal that cell killing via either the intrinsic or the extrinsic pathways can be enhanced by Smac mimetics (33–36). Collectively, these results suggest that Smac mimetics that bind to the BIR domains of the IAPs extricate the caspases in a manner analogous to Smac. Significantly, interactions between Smac and the BIR3 domain of XIAP are localized to the four N-terminal residues of mature processed Smac (31, 32), suggesting that a small-molecule mimetic might be sensible. The immediate challenge in developing a small-molecule Smac mimic is rescaffolding the key binding determinants of the tetrapeptide onto a platform that exhibits drug-like properties. This rescaffolding has become an active area of research with several groups producing nonpeptide Smac mimics. Examples of small-molecule Smac mimetics under preclinical investigation are shown in Fig. 3, with significant progress reported by groups from Abbott (37), University of Michigan (38), Genentech (39), Novartis (Basel, Switzerland) (40), Princeton University (Princeton, NJ) (41), and Texas Southwestern Medical Center (Dallas, TX) (25). Based on these reports, it seems that an effective Smac mimic will require a free amino group and a small hydrophobic amino acid at the
N-terminus, a proline derivative in the third position, and an aromatic group at the fourth position. The studies mentioned above demonstrate Smac mimetics are effectors of both the extrinsic and the intrinsic apoptosis pathways.

Targeting the P53 Pathway

The transcription factor p53 responds to cellular stress by promoting the production of growth suppressors and proapoptotic factors that lead to cell cycle arrest, senescence, or apoptosis (42). Activation of the p53 pathway is known to target more than 16 genes that regulate apoptosis (43). Significantly, when detecting DNA damage, p53 initiates the expression of proapoptotic BH3-only proteins Puma (p53-upregulated modulator of apoptosis) and Noxa (43) (see the “Targeting the Bcl-2 Family of Proteins” section above). Approximately 50% of cancers show mutations or deletions in the p53 gene, which silences a critical mechanism for limiting the propagation of damaged cells. Most alterations that lead to loss of p53 function consist of single amino acid mutations that destabilize the protein core (44). Function has been rescued in these mutants by binding of peptides derived from the C-terminal domain (44) or small molecules (45). Activity of C-terminal peptides is believed to be at least partially caused by antagonizing the binding of the p53C-terminus to the DNA-binding motif of p53. The small-molecule activators developed by Pfizer (New York, NY) shown in Fig. 4, CP-31398 and CP-257042, restore p53 function by stabilizing the protein core (45). The potency of these molecules requires a hydrophobic group within a fixed distance from an ionizable group, which suggests a specific interaction with the protein. Studies with CP-31398 show inhibition of tumor growth in melanoma and colon cancer xenograft models.

Regulation of p53 activity is complex, including numerous posttranslational modifications. One such modification is ubiquitination by the E3 ligase MDM2 (murine double minute 2); the interaction between MDM2 and p53 has been identified as a potential target for therapeutic intervention. MDM2 binds to p53 in the transcription activation domain, blocking p53 function...

while simultaneously targeting p53 for ubiquitination and degradation. Cancers with functional p53 often silence p53 by the overexpression of MDM2 (46). Studies that use either blocking antibodies and peptides or reduction of MDM2 levels employing antisense oligonucleotides demonstrate that disruption of the p53–MDM2 interaction activates the p53 pathway, which blocks proliferation and promotes apoptosis (47, 48). Examination of a crystal structure of a p53-derived peptide bound to MDM2 reveals that three amino acids (Phe19, Trp23, and Leu26) project deep into a hydrophobic-binding pocket on the MDM2 surface (46, 49). The localized nature of the interface suggests MDM2 as a potential small-molecule target. The Hamilton group used an approach analogous to the Bcl-2 work mentioned above to obtain a helix mimic that binds to MDM2 (50). By screening for molecules that only show activity in cells with wild-type p53, researchers at the Karonlinska Institutet (Stockholm, Sweden) discovered a small molecule they named RITA, which shows in vivo p53-dependent antitumor activity (51) (see Fig. 4). A major advance in this area is the work reported by the Hoffman-La Roche team (Nutley, NJ) in their development of a series of potent MDM2 antagonists they named the nutlins (Fig. 4). This class of MDM2-binding molecules was identified initially in a high-throughput screen and followed by extensive structural optimization that yielded potency in the 100–300-nM range (52). Studies using an osteosarcoma SJS/A-1 xenograft tumor model demonstrated that a 20-day course of treatment with racemic nutlin-3 resulted in a 90% inhibition of tumor growth as compared with vehicle treatment. Resolution of the racemate to give the active nutlin-3 enantiomer increased potency two fold, and studies with enantiomerically pure compound evidenced 100% growth inhibition in the SJS/A-1 model as well as in an LNCaP prostate xenograft model. Both models showed significant tumor regression, which suggests that the disruption of the MDM2–p53 interaction is antiproliferative and proapoptotic and that antagonizing MDM2 suppression of p53 is a promising therapeutic approach for cancers that retain wild-type p53 function (49).

Targeting the Death Receptors

One of the most promising advances in apoptosis-cancer therapies is the activation of the extrinsic pathway through the death receptors (53). This is an extremely active area of biology research, but with little potential for a small-molecule approach. An attractive feature of the extrinsic pathway is that its unique activation mechanism provides an avenue for promoting cell death in cancers that resist current therapies (8). Another feature of the extrinsic pathway is that many cancer cells highly express death receptors but do not express the decoy receptors that are found on normal cells, which increases the susceptibility of cancer cells to death receptor activation (54). As mentioned earlier, the potential for agents that target multiple components of apoptosis holds promise for effective treatment of resistant cancers. An exciting example of this potential is illustrated in a study in which a ligand that activates death receptors, Apo2L/TRAIL, was combined with a Smac-derived peptide (36); complete regression was observed in a mouse glioma model, one of the most difficult cancers to treat and one for which no current viable therapy exists. This result suggests that activation of the extrinsic pathway in combination with apoptosis-sensitizing agents is an effective strategy for treating cancers resistant to conventional therapies.

Discovery of the RNA interference (RNAi) pathway has been revolutionary to biology and biologically based therapeutics. The messenger RNA (mRNA) targets once believed to be “undruggable” by conventional methods are now being enthusiastically pursued with RNAi-based therapeutics. Fundamental research into the RNAi pathway and biotechnological research on the application of RNAi may one day make a new class of drugs a reality by targeting the mRNA of disease-causing or disease-promoting genes directly. The whole process begins with the design and validation of short-interference RNA (siRNA) using bioinformatics and cell culture systems. siRNA that has high specificity and potency (knockdown efficiency) then could be applied to animal models of human diseases for more evaluation, with the ultimate hope of advancing to clinical trials.

Numerous chemical modifications of siRNA are currently being investigated in an effort to enhance their stability, to extend their stay in the body, and, perhaps, to avoid immune stimulation. Different delivery methods are developed depending on the diseases, tissues, or organs being targeted. In short, this relatively new biotechnology is advancing quickly as we learn from its failures and successes. In the current article, we will explore the background and current state of research as well as discuss some hurdles and future directions in the application of RNAi to treat human diseases.

In 1998, Andrew Fire and Craig Mello (1) published their seminal work on RNA interference (RNAi) with their discovery of double-stranded RNA (dsRNA) as the trigger of posttranscriptional silencing in Caenorhabditis elegans. The phenomenon of posttranscriptional gene silencing was first observed in plants (2–5). In the two decades since, many components in the RNAi pathway have been identified and characterized (see also RNA Interference, Mechanisms and Proteins Involved in). Another phenomenon of posttranscriptional silencing comes from microRNA (miRNA). In 1993, Lee et al. (6) cloned a short noncoding RNA (later referred to collectively as microRNA), lin-4. In 2000, Reinhart et al. (7) cloned another miRNA called let-7 that functions similarly to lin-4. Both lin-4 and let-7 regulate translation via partially complementary sequences in the 3′ untranslated region (UTR) of mRNA they target. Advances in research eventually merged the RNAi pathway with the miRNA pathway by showing that they closely share core components (see also RNA Interference, Mechanisms and Proteins Involved in).

In principle, dsRNA and short-hairpin RNA (shRNA) are cut by Dicer and its associated proteins, such as TRBP, into ∼21-nucleotide (nt) short interference RNA (siRNA) or mature miRNA. One strand (the guide strand) will be integrated into the RNA-induced silencing complex (RISC), which has AGO2 as its core component, whereas the other strand (the passenger strand) will be either degraded (siRNA) or released (miRNA). In the current model, siRNA, by perfect complementarity with the targeted mRNA, triggers the degradation of mRNA in the RISC, whereas miRNA generally suppresses the translation of the target mRNA by incomplete complementarity with the 3′ UTR region (see also RNA Interference, Mechanisms and Proteins Involved in). The discovery that dsRNA, particularly siRNA, can be introduced exogenously into mammalian cells to knock down target mRNAs in a sequence-specific manner generated much enthusiasm for exploring siRNA duplexes as gene-specific therapeutics (8). The subsequent development of siRNAs as drugs has been rapid. Currently, three Phase I studies...

without unacceptable toxicity are already complete (Table 1) (9-45).

RNAi-based therapeutics begin with the design and identification of siRNAs that show high specificity and knockdown potency in the lab. Once several siRNAs have been selected, they are applied to animal models with the diseases of interest. Before delivery, siRNA may also be modified to enhance its stability. siRNA duplexes can be delivered via different routes and even with different strategies. We will now summarize and discuss the entire process, from the initial design of a siRNA duplex to its application in clinical trials.

Design and Evaluation of siRNA

Currently, two methods are available for the endogenous RNAi pathway for therapeutic purposes: either by introducing a viral vector to express shRNA that mimics a miRNA precursor, which then would be processed by Dicer into siRNA, or by delivering siRNA that mimics a Dicer cleavage product into the cytoplasm. Because siRNA has to be processed into siRNA in vivo to be functional, the design of a shRNA vector follows the same rules as for siRNA. For either method, the first consideration is to ensure that the siRNA specifically targets the mRNA of interest (specificity), at the same time, the siRNA
should have a minimum desirable (if not the highest possible) knockdown efficiency (potency).

**Specificity**

The initial siRNA design starts with a bioinformatics-aided search for "targetable" sequences —21 nt long in the mRNA of interest (46). Because a perfect complement with the targeted mRNA triggers degradation and an imperfect complement triggers translational suppression, the chances of generating a 21-nt siRNA with an off-target effect is high, without careful attention to design (47, 48). The principle here is to avoid sequences in the siRNA "seed region" complementary to untranslated mRNAs (Fig. 1). The "seed region" is at positions 2-7 or 2-8 of the guide strand of the miRNA or siRNA duplex. For miRNA function, the seed region usually complements the 3′ UTR of the target mRNA perfectly. Off-targeting of siRNA is found to be associated with perfect complementarity between the seed region and the 3′ UTR of unwanted mRNA (49). It is highly possible that targeting to the coding region of nontranslated mRNA would also contribute to off-target effects. Several software and Internet search programs can be helpful in the selection of siRNA sequences to minimize off-target effects (50, 51). These effects should also be checked with a microarray assay in cell culture systems because currently no ideal strategy to design (47, 48). The principle here is to avoid sequences in the siRNA "seed region" complementary to untranslated mRNAs (Fig. 1). The "seed region" is at positions 2-7 or 2-8 of the guide strand of the miRNA or siRNA duplex. For miRNA function, the seed region usually complements the 3′ UTR of the target mRNA perfectly. Off-targeting of siRNA is found to be associated with perfect complementarity between the seed region and the 3′ UTR of unwanted mRNA (49). It is highly possible that targeting to the coding region of nontranslated mRNA would also contribute to off-target effects. Several software and Internet search programs can be helpful in the selection of siRNA sequences to minimize off-target effects (50, 51). These effects should also be checked with a microarray assay in cell culture systems because currently no ideal strategy completely eliminates off-target effects.

**Potency**

Although our current understanding of RNAi activity cannot provide us with a precise prediction of individual siRNA potency, algorithms based on common features of empirically tested high-potency siRNAs are available (46, 52). Once the bioinformatic part is complete, a candidate siRNA can be synthesized and tested in cell culture systems for knockdown efficiency. Knockdown efficiency is commonly assessed with real-time polymerase chain reaction (PCR) to check for changes in the mRNA level and with western blot to check for decreases in the protein level. The final goal of this stage is to identify several siRNAs that show high knockdown efficiency and minimal off-target effects at nanomolar or lower concentrations. To be prepared for possible underachievers at any point in the long process from the bench to the bedside, it is better to have more than one siRNA to begin with.

Theoretically, an alternative method is available for selecting siRNA with high specificity and potency: A library of tiling siRNAs covering the whole mRNA sequence of a disease-causing or relevant gene of interest can be screened with cell culture systems, and individual siRNAs with stringent specificity and high efficacy then can be identified from this library. Drawbacks of this method are that it is more expensive and more labor intensive, although the knowledge gained from this approach can assist in the future design of therapeutic siRNAs.

When considering specificity and potency, it is helpful to bear in mind sequence conservation across species as well. Therapeutic siRNAs usually have to undergo tests that involve nonhuman cell cultures and animal disease models, so it is more reasonable to start with siRNAs that target conserved sequences in disease-related mRNA. One should remember that homologs in different organisms may function differently, and each siRNA could show different knockdown efficiency in different organisms.

Several practices could enhance the specificity and potency of siRNA once its sequence is decided. For example, because the loading of siRNA into RISC is asymmetric (53, 54), the first nucleotide of the 5′ end of the guide strand is efficient at suppressing off-targeting (57).

**Chemical Modification of siRNA**

Some chemical modifications can enhance the specificity of siRNA even more. Chemical modifications of riboses in the guide strand have been found to suppress off-target effects without affecting potency (55, 56). In fact, 2′-O-methyl modification at nucleotide 2 of the guide strand is efficient at suppressing off-targeting (57).

**Chemical modification to increase siRNA stability**

The main purpose of modifying siRNA chemically is to increase its stability so that it remains active in the animal and human body. Unmodified siRNA gets degraded quickly in human plasma, with a half-life of only minutes (58, 59). To convert siRNA into drugs, several ways of modifying siRNA to prolong its half-life have been investigated (Fig. 1). Knowledge of...
how to avoid nucleic degradation has come to us from previous therapeutics research that use antisense oligonucleotides and aptamers, and this knowledge has been beneficial in the chemical modification of siRNA. Nuclease degradation is prevented mainly via two types of modification.

The first type is phosphodiester modification: Replacing one of the two nonbridging oxygen atoms with a sulfur atom (P-S) or an isophosphorane borane (BH3) moiety is found to protect siRNA from exonuclease degradation (58-62; Fig. 1). Whereas moderate P-S modifications are well tolerated in terms of knockdown potency and toxicity, extensive P-S modifications should be avoided because of increased binding of the modified siRNA duplex to serum proteins, which may result in cytotoxic knockdown. Although BH3 modification has not been investigated extensively, current research shows it has some advantages over P-S modification (65); however, one situation to avoid is having a BH3 modification at the center of the guide strand, which could reduce the efficacy of the siRNA.

The second type is 2'-sugar modifications: Modifications at the 2'-position of the ribose ring protect siRNA from endonuclease degradation. These modifications mainly include 2'-O-methyl (2'-OMe), 2'-deoxy-2'-fluoro (2'-F) modifications, and locked nucleic acid (LNA) (57, 60, 66-68; Fig. 1). A proprietary 2'-OMe modifications not only increase plasma stability but also ameliorate off-target effects and enhance the in vivo potency of siRNA (55, 57). One important point to remember is that 2'-OMe modifications could impair the cleavage of passenger strand and target mRNA, so it is crucial to keep this modification away from the cleavage site in the passenger strand (69, 70). 2'-F modifications dramatically increase the stability of siRNA in human plasma without adverse effects on specificity and potency; these modifications do not enhance the performance of siRNA, unlike 2'-OMe modifications (58). The most commonly used LNA in the siRNA duplex contains a methylene bridge to connect the 2'-oxygen with the 4'-carbon of the ribose ring (Fig. 1). Besides increasing stability, LNA modifications may also help to reduce off-target effects and enhance potency. Moderate LNA is generally well tolerated in siRNA, with several notable exceptions. LNA modification should be avoided at the 5'-end of the passenger strand because this may affect the asymmetric loading of the guide strand (71). Both extensive LNA and LNA at certain locations (depending on the specific siRNA) may block the RNAi activity of the modified siRNA (72).

### Chemical modification to avoid innate immune response

Nucleic acids can trigger innate immune responses (73). dsRNA longer than 30 base pairs (bp) can efficiently trigger serine/threonine protein kinase (PKR). Although siRNA is smaller, at higher concentrations it may trigger this pathway, which leads to global blockade of translation and ultimately cell death (74, 75). Another issue of perhaps greater concern in RNAi therapeutics is that siRNA could activate Toll-like receptors (TLRs), especially the dsRNA receptor TLR7 in plasmacytoid dendritic cells, which triggers the production of type I interferons and proinflammatory cytokines and thus induces nuclear factor-B activation (76). Some siRNAs have a greater tendency to activate TLRs, and, for this reason, they should properly be called immunostimulatory RNA (isRNA) (72, 77). 3’ blunt ends and GU-rich sequences are strong stimulants to PKR; therefore, they should be avoided when designing the siRNA (78). It is important to investigate whether a siRNA duplex is an siRNA using in vitro plasmacytoid dendritic cell culture before in vivo application to animal models (72). Chemical modifications at the 2’-sugar can be beneficial because they help avoid immunostimulation (Table 2).

Different chemical modifications may be used in combination to attain the accumulated benefits of each individual modification, although research in this area has not been exhaustive.

#### In Vivo Delivery

siRNA duplexes have to be delivered effectively to treat diseases. Efficient and cell type-specific delivery may be the biggest obstacle to the development of RNAi therapeutics. For use in animal models and clinical trials, different delivery strategies have been developed to meet the requirements for different diseases and target tissues (or organs).

#### Direct application of naked siRNA

This delivery method applies siRNA dissolved in saline or 5% dextrose (D5 W) directly to the targeted tissues, with many successes reported. Most siRNA-saline solutions target specific organs, such as the eye (intravitreal injection), lung (intranasal or intratracheal instillation), or central nervous system (intraventricular, thecal, or parenchymal infusion) (Table 1). Because these organs allow direct administration of siRNA, they were a natural focus of initial RNAi therapeutics. Certain cell types can take up naked siRNA efficiently via unknown mechanisms, whereas many other cell types are refractory to naked siRNA. For this reason, siRNA duplexes have to be conjugated or formulated for efficient delivery in most cases.

#### Delivery via liposomes and lipoplexes

Liposomes are vesicles enclosed by a phospholipid bilayer, which can fuse with a cell membrane and deliver the enclosed contents into the cytoplasm (Fig. 2). Liposomes have already delivered many drugs with decreased toxicity and increased pharmacokinetics. In particular, stable nucleic acid lipid particles (SNALPs) that consist of a mixture of cationic and fusogenic lipid bilayers were used for intravenous and intraportal delivery (29, 79). These SNALPs can be coated with a diffusible poly(ethylene glycol)-lipid (PEGylated lipid) conjugate, which stabilizes the liposomes during formation and prevents rapid systemic clearance from the circulating blood. Liposomes have successfully delivered siRNA that target liver diseases like hepatitis B virus (HBV) infection (79, 80; Table 1). siRNAs are commonly transfected into cultured cells with reagents such as Lipofectamine 2000 (Invitrogen Corporation, Carlsbad, CA) or TransIT-TKO (Mirus Bio Corporation, Madison, WI). Complexes formed by siRNA and most commercial

Figure 2 Examples of therapeutic siRNA delivery strategies. a. RNA aptamer conjugation. b. Cholesterol conjugation. c. PEG-liposome. d. Antibody-protamine conjugation. Different chemical modifications and delivery strategies can also be used in combination.
transfection reagents are called lipoplexes. Lipoplexes are relatively easy to form, and they have been widely used for siRNA delivery. Successful applications have been reported via almost all the delivery routes, including subconjunctival, intrathecal, intracranial, intratumoral, intraperitoneal, intravenous, intravaginal, and intraretinal administration (Table 1).

### Chemical conjugation to small molecules

The idea of conjugating cationically small molecules, such as cholesterol and siRNA, was borrowed from previous research based on antisense oligonucleotide therapeutics (81). Both the 5′ and 3′ ends of the passenger strand tolerate conjugations well. 5′-end cholesterol conjugation of the passenger strand has been shown to efficiently deliver siRNA intravenously for targeting the ApoB gene in the liver and jejunum (82).

RNA aptamers can also be conjugated to siRNA for the purpose of cell-specific delivery. Aptamers are artificial DNA or RNA molecules that bind to specific molecular targets (83). Theoretically, RNA aptamer binding to cell-specific receptors or antigens can be linked to siRNA for the purpose of cell type-specific RNAi. One report using a siRNA conjugated with an RNA aptamer that has a high affinity for prostate-specific membrane receptors showed that it silenced survival genes in prostate cancer cells with a high cell specificity and efficacy (18).

#### Conjugation with peptides and antibodies

When it comes to cell-specific delivery, peptides or antibodies can also be conjugated noncovalently with siRNA. The extreme specificity of an antibody to recognize and bind to a cell-specific antigen makes antibody conjugation a very attractive approach for delivering siRNA. A fusion protein with a specific antibody and a protamine fragment, which is arginine-rich and thus positively charged, can bind to siRNA (negatively charged) for delivery. Some successful in vitro and in vivo applications include the delivery of siRNA to B16 melanoma expressing HIV envelope protein or HIV-infected primary CD4+ T cells using a fusion protein of protamine and Fab fragment of antibody to HIV envelope protein (Tables 1 and 3).

The simplest peptide conjugation uses cholesterol oligo-D-arginine (Chol-R9, chosen because of the positive charge of arginines). Noncovariant formation of a complex of siRNA with Chol-R9 efficiently delivered siRNA targeting VEGF into cells. Moreover, in a mouse model bearing a subcutaneous tumor, this complex led to regression of the tumor (12). Other peptides that have been investigated include MPG, derived from the fusion peptide domain of HIV-1 gp41 protein and the nuclear localization sequence (NLS) of SV40 large T antigen. To be used for siRNA delivery, a mutation that affects the NLS of MPG was generated to prevent the nuclear entry of siRNA. In cell culture, the peptide enables rapid delivery of the siRNA into the cytoplasm, which results in robust downregulation of target mRNA (84). Similar to MPG, Penetratin (Qbiogene Inc., Irvine, CA), which is a peptide derived from the homeodomain of the Drosophila protein Antennapedia, is known to deliver cargo into cells. Indeed, Penetratin 1 can be conjugated to siRNA for rapid and efficient delivery into cultured primary mammalian hippocampal and sympathetic neurons (85). For all these peptides, only one report of successful in vivo delivery has been made to date, in an animal model with chol-R9.

Some peptides can be recognized by cell-specific receptors and thus can be conjugated with siRNA for cell-specific delivery. Recently, a 29-amino-acid peptide derived from rabies virus glycoprotein (RVG) was shown to be capable of delivering conjugated siRNA (via a nonamer arginine fusion, RVG-R9) transvascularly to the brain, which resulted in efficient gene silencing. This peptide was found to bind specifically to the acetylcholine receptor expressed by neuronal cells (82).

#### Delivery with nanopolymers

Nanotechnology involves the manipulation of atoms and molecules to construct structures on the nanometer scale (often 100 nm or smaller). Liposomal vesicles, lipoplexes, as well as antibody- and some peptide-conjugated siRNA complexes discussed above are actually nanoparticles. Nanoscale technologies are changing the foundations of therapeutics; in fact, this branch of medicine is now referred to as "nanomedicine" by the National Institutes of Health. Nanoparticles have special advantages in drug delivery. First, therapeutic agents can be encapsulated and hence protected from degradation, clearance, and nonspecific binding. Second, the release speed and location (tissue or even subcellular localization) of drugs can be well controlled by manipulating the composition of nanoparticles. And finally, the pharmacokinetics of the drugs can be optimized (98).

Currently, the most widely used nanoparticles for siRNA delivery are nanopolymers formed with polyethyleneimine (PEI). PEI polymers are synthetic, are highly cationic charged, and can be used directly to form complexes with siRNA duplexes. The resulting PEI-siRNA polyplexes are thought to enter cells via endosomes, in which PEI disrupts the low endosomal pH, leading to the eventual release of PEI-siRNA complexes into the cytoplasm. Several reports using PEI polymers demonstrated efficient siRNA delivery in animal models of influenza, Ebola virus infection, and tumors (Table 1). Components such as peptides and small compounds (e.g., folate) for cell-specific delivery can also be added into the PEI-siRNA polyplexes. For example, arginine-glycine-aspartic acid-(RGD)-peptide, which is known to bind to both tumors and tumor-endothelial cells in vivo (87), has been successfully used to deliver PEI-siRNA into tumor tissues (14). One drawback of PEI has been its extreme toxicity at high concentrations. Its methylene backbone (-CH(2)CH(2)N(3)-) and high charge density make for poor biodegradability and high toxicity to cells. Much effort has been expended to optimize the PEI structure to expand its safety margin (88-91).

Another material of current interest is chitosan. Chitosan is produced commercially by the deacetylation of chitin, which is the structural element in the exoskeleton of crustaceans. Chitosan is positively charged and is bioadhesive to negatively charged molecules, such as nuclear acids, and surfaces, such as mucosal membranes. Chitosan enhances the transport of polar drugs across epithelial surfaces and is biocompatible and biodegradable. Previously, it was used for DNA delivery in other contexts. However, for siRNA delivery, chitosan appears to have particular advantageous properties. For example, siRNAs are delivered to mammalian hippocampal and sympathetic neurons (85). For all these peptides, only one report of successful in vivo delivery has been made to date, in an animal model with chol-R9.

Some peptides can be recognized by cell-specific receptors and thus can be conjugated with siRNA for cell-specific delivery. Recently, a 29-amino-acid peptide derived from rabies virus glycoprotein (RVG) was shown to be capable of delivering conjugated siRNA (via a nonamer arginine fusion, RVG-R9) transvascularly to the brain, which resulted in efficient gene silencing. This peptide was found to bind specifically to the acetylcholine receptor expressed by neuronal cells (82).

Disease Models and Clinical Trials

Current RNAi therapeutics are focused on infectious diseases caused by viruses, neurological diseases, and cancers or other overgrowth-related diseases (summary in Table 1).

Infectious diseases caused by viruses

Current viral diseases under consideration for RNAi therapeutics include those that infect the respiratory system, such as respiratory syncytial virus (RSV), parainfluenza virus (PIV), severe acute respiratory syndrome-associated coronavirus (SARS-
RNA interference to Treat Human Diseases, Applications of

Cov5), and influenza viruses; those that infect the central nervous system, such as Japanese encephalitis virus (JEV); viruses that infect the liver, such as HBV and Ebola virus; and those that infect other organs or are tumorigenic, such as herpes simplexes viruses types 2 (HSV-2) and human papillomaviruses (HPV). From these efforts, one Phase I clinical trial has been completed without untoward toxicity for siRNA-based therapeutics for RSV through intranasal administration of naked or lipoplex complexes. Notably, RSV infections are the leading cause of pediatric hospitalization in the United States today.

Tumors and other overgrowth-related diseases

The most investigated target for RNAi therapeutics to treat tumors and overgrowth-related diseases is vascular endothelial growth factor (VEGF) or its receptor VEGFR. siRNAs that target to VEGFR for age-related macular degeneration (AMD) have passed Phase I clinical trials. VEGF is overproduced in AMD, which resulted in the overgrowth of choroidal blood vessels into the subretinal space. AMD is a leading cause of blindness. Choroidal neovascularization (CNV) is the advanced stage of AMD and accounts for ~80% of the vision loss in AMD. Mouse or rat models of laser-induced CNV have been used to test the efficacy, potency, and delivery of siVEGFR1 (Table 1).

Most RNAi therapeutics use subcutaneous tumor xenograft mouse models. siRNA targeting overgrowth-related genes, such as VEGF, VEGFR, HER2, c-Myc, gliotoxin, and RhoA, have been tested with different delivery methods and demonstrated varying degrees of success (Table 1).

Dominant diseases

Hopes of applying RNAi-based therapeutics to treat dominant inheritable diseases continue. siRNA can distinguish a single-nucleotide difference between wild-type and mutant alleles when well designed (53, 94). A nother strategy for applying RNAi therapy to dominant diseases was initiated by Kiang et al. (95) and validated by O'Reilly et al. (96). Their strategy comprises two elements: gene suppression in conjunction with gene replacement. This strategy was tested in a model of retinitis pigmentosa, which is caused by single-site, dominant mutations in the rhodopsin gene. Using recombinant adeno-associated virus (AAV), researchers delivered a siRNA targeting a site independent of the mutation for both mutant and wild-type alleles while they applied in conjunction a codon-modified replacement gene refractory to that siRNA. The strategy proved successful both in vitro and in vivo.

Other diseases

The first report of efficient in vivo RNAi therapeutics involved a mouse model of fulminant hepatitis (acute liver failure) (97). Here, intravenous injection of Fas (also known as Tnfrsf6) siRNA protected hepatocytes from apoptosis. Some chronic diseases, such as dyslipidemias, arthritis, and colitis, are also under investigation for RNAi therapeutics. siNF (for arthritis and colitis) and siApoB (for dyslipidemias) have already been developed in animal models. Diseases of the nervous system are another category of special interest. siRNAs that target neurotransmitters, such as dopamine transporter (hyperlocomotor response), serotonin transporter (behavior response), P2X3 (chronic neuropathic pain), DOR (DELT-induced nociception), AGRP (metabolic alterations), and NR2B (formalin-induced nociception), are among those tested with animal models (Table 1).

RNAi-based therapeutics also holds out new hope for the treatment of neurodegenerative diseases, such as spinocerebellar ataxia, amyotrophic lateral sclerosis, Huntington’s disease, Alzheimer’s disease, and prion diseases (98–100; Table 1). Some neurodegenerative and other inheritable diseases are mediated by dominant alleles with trinucleotide repeats; allele-specific RNAi was developed for this kind of disease, including Huntington’s disease and myotonic dystrophy (101–103). Among preclinical research that is not related to trinucleotide repeats, Pfeifer et al. (44) used lentivectors to deliver PpIC-specific siRNA to both cell cultures and a mouse model of scrapie infection. They achieved efficient and stable suppression of PpIC accumulation in cultured neurons and a significant extension of survival in the mouse model. Hong et al. (104) generated replication-defective herpes simplex virus vectors for Aβ-specific siRNA and neprilysin-specific shRNA. These viral vectors inhibited Aβeta accumulation, both in vitro and in vivo.

Current Hurdles and Future Promises

With three Phase I clinical trials having passed to date, the area of RNAi therapeutics has moved rapidly from the first demonstration of efficient gene knockdown using siRNA duplex in mammalian cell culture in 2001 to many reports of the successful application of siRNA in animal disease models by 2003 (Table 1). More recently, John et al. (105) demonstrated that long-term systemic administration of siRNAs effectively silenced hepatocyte gene expression in rodents and primates, without significant changes in the levels of three hepatocyte-expressed miRNAs (miR-122, miR-16, and let-7a) or any effect on miRNA activity.

Many negative concerns that once surrounded RNAi therapeutics have been eliminated or at least addressed. Side effects that could be caused by off-target effects and immunostimulation from siRNA can now be reduced to acceptable levels through improvements in design, modification, and delivery strategies, and all these have greatly improved in vivo knockdown efficiency.

Despite all the progress, every aspect of RNAi-based therapeutics bears improvement. Algorithms for siRNA design are still far from ideal. In many cases, the required dosage is still high, in the range of 100 micrograms per administration in mice. Chemical modifications and delivery strategies remain to be optimized, with the goal of tissue-specific delivery and high knockdown efficiency.

A nother strategy for RNAi therapeutics, in parallel with siRNA, is shRNA delivered with recombinant viral vectors,
development advance, we are optimistic about the miraculous emergence of the RNAi pathway itself and as techniques and strategies that allow us to function and therefore may cause hazardous mutations, which have already hindered the use of retrovirus in gene therapy. Grimm et al. (107) investigated adenovirus-associated virus type B (AAV8) as a viral vector for shRNA expression in liver. lethality was found to be widespread at higher viral titers because of overexpression of the endogenous miRNA pathway. Thus, the application of adenovirus for RNAi therapy requires caution in optimizing the viral dosage and sequence of the encoded siRNA.

Dramatic changes in the expression of specific miRNAs are found in a variety of diseases, especially cancers (108). Some of these changes contribute to the etiology of certain diseases. It has been proposed that miRNA-based therapeutics could be developed by delivery of either miRNA duplexes to compensate for decreased levels or antisense oligos to block the effect of elevated levels of specific miRNA (109). For example, miR-21 levels were found to be elevated in gliomas, and their knockdown is associated with increased apoptotic activity (45, 110). Recently, Corsten et al. (45) showed that application of (LNA)-anti-miR-21 oligonucleotides has a synergistic effect in vitro and decreasing cell viability in human glioma cells (111). Given the potential to control the level of any miRNA through the RNAi pathway, RNAi therapies hold great promise for the treatment of virtually any disease with an etiology or pathology associated with an elevated or bad mRNA. As a treatment of virtually any disease with an etiology or pathology associated with an elevated or bad mRNA, RNAi therapy holds great promise for patients.

Given the potential to control the level of any miRNA through the RNAi pathway, RNAi therapies hold great promise for the treatment of virtually any disease with an etiology or pathology associated with an elevated or bad mRNA. As a phenomenon that biologists just began to uncover at the end of the last century, RNAi has generated enormous interest among scientists in both basic and medical research. As the secrets of the RNAi pathway itself emerge, and as techniques and strategy development advance, we are optimistic about the miraculous emergence of the RNAi pathway itself and as techniques and strategies that allow us to function and therefore may cause hazardous mutations, which have already hindered the use of retrovirus in gene therapy. Grimm et al. (107) investigated adenovirus-associated virus type B (AAV8) as a viral vector for shRNA expression in liver. lethality was found to be widespread at higher viral titers because of overexpression of the endogenous miRNA pathway. Aberrant transcription patterns are associated with most human diseases. Therefore, enormous interest exists in the development of designer molecules that can be used to regulate directly the transcription of predetermined genes for the ultimate treatment of a wide range of disease states. One emerging strategy is to identify molecules that reconstitute one or more functions of the endogenous proteins that upregulate transcription, transcriptional activators. In doing so, they function as either inhibitors or activators of transcription. Using this approach, a variety of protein- and small molecule-based transcriptional regulators have been developed, and at least one has reached clinical trials.

Diseased cells possess different transcription profiles relative to their normal counterparts; therefore, considerable interest exists in the discovery of molecules that correct errant transcription patterns for use as mechanistic tools and as therapeutic agents. One emerging mechanism for accomplishing this task is the use of molecules that mimic key functions of the endogenous proteins that upregulate transcription: transcriptional activators. By doing so, they either inhibit or activate the expression of specifically targeted genes (1). As illustrated in Table 1, exogenous agents that can upregulate or downregulate transcription are being developed for the eventual treatment of such ailments as cancer, inflammation, viral infections, metabolic disorders, and genetic disorders. For example, one method by which apoptosis can be induced in cancer cells is via the modification of the aberrant expression levels of those proteins that regulate cell growth and survival. A molecule that upregulates the proapoptotic bax gene directly could induce apoptosis when introduced into p53-deficient osteosarcoma cells (3). Conversely, a molecule that inhibits transcription of the survivin gene (an inhibitor of apoptosis protein) could induce apoptosis when introduced into lung carcinoma cells (9). In this article, we describe the structure and the function of natural transcriptional activators and outline the most common strategies for designing exogenous molecules that affect their function directly. References for more detailed treatments of the individual topics are provided at the end of the article.

Biological Background

As their name implies, eukaryotic transcriptional activators are responsible for initiating gene-specific transcription. To accomplish this task, activators localize at specific DNA sequences in a signal-responsive manner and facilitate the assembly of the eukaryotic transcriptional machinery (RNA polymerase II and associated factors) (1, 21). This process requires activators to participate in many protein-protein and protein-DNA interactions yet can be accomplished with a fairly simple architecture. Activators are composed minimally of a DNA binding domain (DBD) and a transcriptional activation domain (TAD). The primary function of the DBD is to localize the transcriptional activator to specific sites within genomic DNA. The DBD thus imparts much of the gene-targeting specificity of the activator. In contrast, the TAD participates in many protein-protein interactions that are critical for transcription initiation. By doing so, it dictates the timing and extent of gene activation. The two domains can, in general, function independently. In other words, if the DBD of transcriptional activator A is attached to the TAD of activator B, the new chimeric activator will upregulate transcription of gene A.

The modular character of transcriptional activators facilitates the design and the implementation of non-natural molecules that can affect gene transcription. Designer replacements of each of the two domains can be used individually to inhibit transcription by preventing either activator-DNA interactions or activator-transcriptional machinery interactions (Fig. 1). In contrast, linking a DBD and a TAD either covalently or noncovalently is a common strategy used to create activator artificial transcription factors (ATFs), which are molecules that seek out

Transcription-Based Therapeutics

Inhibitors of activator-coactivator interactions: handful of small molecules

Inhibitors of activator-DNA interactions: polyamides, PNA TFOs, small molecules (natural & unnatural products)

Activator ATFs: minimally a DNA binding domain (DBD) coupled to a transcriptional activation domain (TAD)

Figure 1. Strategies for designing molecules that regulate transcriptional activators. Transcriptional activators initiate transcription by binding to DNA sequence specifically and stimulating the assembly of the transcriptional machinery through one or more protein interactions. Molecules that prevent either the DNA binding of the activator or the interaction of activators with their binding partners within the transcriptional machinery can be used to inhibit transcription. Alternatively, gene-specific transcription can be initiated by a molecule that mimics both key functions of an activator, which is an activator artificial transcription factor (activator ATF).

and upregulate the transcription of specific genes (22). The design of inhibitor and activator molecules relies on understanding the structure and the mechanism of the DBD and the TAD of the natural proteins. As illustrated in the subsequent sections, the DBD is more understood than the TAD; therefore, the development of artificial DBDs is far more advanced than TAD replacements.

Activator ATFs

As described above, the function of a transcriptional activator can be reconstituted minimally by an activator ATF that contains a DNA-binding domain and a transcriptional activation domain. The earliest artificial activators were composed of DBDs and TADs taken from naturally occurring proteins (1). Although these activator ATFs are powerful mechanistic tools, their application scope is narrow because they can only target genes that contain the DNA binding sites of the endogenous protein DBDs. In addition, controlling the delivery and the stability of the constructs in vivo can be challenging. The development of non-natural replacements for each of the two key activator ATF domains has been an important goal to address these fundamental limitations.

DBDs

Much work has been done to develop artificial DBDs that can bind with high specificity and affinity to predetermined DNA sequences (22). This binding has been achieved, for example, by mutating amino acids on natural protein scaffolds to recognize novel sequences (zinc fingers), using the hydrogen bonding properties of nucleic acid-like molecules [triplex-forming oligonucleotides (TFOs), peptide-nucleic acids (PNAs)], or tailoring the DNA-binding properties of natural products (polyamides, for example). This section describes only the properties of zinc fingers and polyamides, because TFOs and PNAs are described in depth in related articles. Table 1 summarizes many of the applications of these molecules.

Zinc fingers (ZF)

Protein DNA-binding domains offer several attractive features for activator ATF design; the most important of which is the high affinity and specificity with which they typically recognize their cognate DNA sequence. The Cys2His2 ZF fold has proven to be enormously versatile as a DNA-targeting entity. It is composed of ~30 amino acids folded into a ββα structure that is stabilized by hydrophobic interactions and by the coordination of a zinc ion by two conserved cysteine residues in the antiparallel β sheet and two histidine residues in the α helix. The solid-state structure of the 3-finger protein Zif268 in complex with DNA illustrates that each finger makes its primary sidechain–base interactions to three adjacent nucleotides in the sense strand of the DNA duplex (Fig. 2a). It does so by inserting its α helix into the major groove of DNA, on which amino acids at positions −1, 3, and 6 of the helix contact the 3′, middle, and 5′-nucleotides of the 3-bp subsite, respectively (23). Also, in some ZFs an aspartic acid at position 2 of the helix interacts with a cytosine or adenine base in the antisense strand of the adjacent triplet, which makes these domains seem to recognize a 4-bp subsite instead (23, 24).

One simple method for creating a ZF protein capable of binding to a predetermined DNA sequence is through the “modular assembly” approach. In this approach, pre-existing, single-finger ‘modules’ with known specificities are assembled into a multifinger array. To facilitate this, three archives of known zinc finger modules have been created by the Barbas laboratory, Sangamo BioSciences Inc., Richmond, CA and ToolGen Inc. Seoul National University, South Korea. The Barbas modules were developed using a combination of phage display and rational design methods under the assumption that ZF domains...
function with position independence. They are capable of recognizing all GNN triplets, most ANN and CNN triplets, and a few TNN triplets (N = any base). The Sangamo modules were also developed by phage display but under the assumption of position dependence, and are capable of recognizing all GNN triplets and a smaller number of non-GNN triplets. And finally, the ToolGen modules are naturally occurring human zinc fingers whose nucleotide triplet sequences were identified through a yeast one-hybrid assay. And in collaboration with the Zinc Finger Consortium, these archives are now available through a web-based server called ZiFiT (Zinc Finger Targeter) that facilitates the design of multifinger arrays that bind to your desired DNA sequence (24).

In practice, ZF proteins composed of 3–6 fingers with apparent dissociation constants in the picomolar to nanomolar range have been attached to proteinaceous transcriptional activation domains and used successfully to upregulate endogenous genes in mammalian cell culture (Table 1). One such activator ATF that contains a six-finger DBD that binds within the \( \gamma \)-globin promoter can increase fetal hemoglobin levels 7–16 fold in human erythroleukemia cells (2). Additionally, ZF-based activator ATFs that target the VEGF-A (vascular endothelial growth factor) gene have even been shown to function in animal models (4, 5); despite this success, stable delivery remains a challenge because they must be administered by viral vectors (23).

Polyamides

Small molecule DBDs represent an attractive choice for activator ATF construction because they may circumvent the delivery limitations of proteins. Toward this end, considerable progress has occurred in developing programmable small molecules that can be designed readily to target a wide range of DNA sequences (22). In particular, the polyamide class of DBDs has been used successfully for the construction of several activator ATFs (25). The inspiration for the polyamides developed from the minor groove-binding natural products distamycin and netropsin, which exhibit greatly enhanced DNA binding affinities relative to distamycin and netropsin, with dissociation constants in the picomolar to nanomolar range, and they have been shown in several applications to traffic to the nucleus and to interact with their cognate DNA sites. Enhancing their use even more, Dervan et al. (25) have developed a set of “pairing rules” that can be used to design molecules to target specific DNA sequences. In addition, the molecules can be prepared by solid phase synthesis, which makes them accessible to many users.

Polyamides have been used as the basis for several different activator ATF constructs that function in cell-free and in cellular systems. In contrast to protein DBDs, they are synthesized easily to contain both peptidic and nonpeptidic TADs (19–20, 26). However, they often require special modifications to enhance cellular permeability and typically target shorter DNA sequences (6-8 base pairs) relative to proteins (27).

TADs

The most common TADs used in the construction of activator ATFs are derived from the activation domains of natural proteins. For example, sequences taken from the amphipathic class of activators are composed of aromatic amino acids linked through amide bonds; they bind to A/T-rich tracts of DNA in the minor groove with moderate affinity through a combination of hydrogen bonds between the amide bonds and the minor groove functional groups, hydrophobic contacts, and electrostatic interactions with the phosphate backbone. Polyamides consist not only of pyrrole amino acids, but also of imidazole, pyrrole, and other heterocyclic amino acids that enable recognition of A•T, T•A, C•G, and G•C base pairs through the formation of specific hydrogen bonds with minor groove functionality, although overall specificity varies with sequence context (Fig. 2b). Although several different polyamide structural motifs exist, the hairpin polyamide in which a flexible amino acid tether connects two polyamide arms is used most commonly. As the name suggests, this molecule folds into a hairpin-like structure in the minor groove such that the arms are side-by-side, which maximizes hydrophobic interactions with the walls of the minor groove and facilitates the formation of polyamide-DNA hydrogen bonds. The molecules exhibit greatly enhanced DNA binding affinities relative to distamycin and netropsin, with dissociation constants in the picomolar to nanomolar range, and they have been shown in several applications to traffic to the nucleus and to interact with their cognate DNA sites. Enhancing their use even more, Dervan et al. (25) have developed a set of “pairing rules” that can be used to design molecules to target specific DNA sequences. In addition, the molecules can be prepared by solid phase synthesis, which makes them accessible to many users.
Transcription-Based Therapeutics

Interspersed with polar ones and typically possess robust activity across organisms (1, 22). For example, activating sequences from the viral protein VP16, the yeast activator Gal4, and the p65 subunit of the human activator NF-κB have all been attached to ZF proteins and function as activator ATFs in mammalian cell culture (2–4, 6). However, activator ATFs that contain nonprotein DBDs typically use much smaller sequences to minimize the overall size of the construct. For instance, a monomeric or dimeric repeat of eight residues of VP16 (VP1 and VP2) could upregulate a reporter gene in vitro using yeast nuclear extracts when attached to a polyamide (18), whereas a monomeric or dimeric repeat of an 11 residue sequence taken from VP16 (ATF14 and ATF29, respectively) could upregulate a reporter gene in mammalian cell culture when attached to a TFO (10).

Several strategies have been employed to develop novel peptidic TADs that function similarly to natural TADs. For example, a 20 amino acid peptide sequence designed rationally to form an amphipathic helix (AH) (Fig. 3a) was successful in upregulating a reporter gene in yeast when fused to the Gal4 DBD (28), as well as in vitro with yeast nuclear extracts when fused to a polyamide DBD (18). In addition, another successful approach has been to use phage display peptide libraries to select against the protein targets of natural TADs. For instance, a selection performed against the KIX domain of the mammalian coactivator p300/CBP yielded an 8-amino acid peptide named KBP 2.20 that is capable of upregulating a reporter gene 40-fold in mammalian cells when attached to the Gal4 DBD (29). Additionally, a selection performed against the masking protein (Gal80) of the yeast activator Gal4 yielded a 20-amino acid peptide named G80BP-A that is capable of activating transcription of a reporter gene in both yeast (30) and mammalian (15) cell culture when attached to the Gal4 DBD. This TAD functioned only weakly when a PNA was used as a DBD, however, because of the distortion of the promoter on binding (15).

Finally, nonpeptidic TADs have been developed recently that possess the advantage of increased stability toward proteolytic degradation. Often, these molecules are considerably smaller than protein-derived TADs and thus may exhibit advantageous cell permeability properties. The first small molecule TAD to be reported was an amphipathic isoxazolidine 1 (Fig. 3b). Its ability to upregulate transcription was demonstrated initially in a cell-free assay where it proved to be as active as a larger peptidic activator (MW 290 vs 1674) (31). This amphipathic isoxazolidine also functions in mammalian cell culture in a dose-dependent manner with up to 80-fold activation at 1µM and an EC_{50} of 31 nM (32). In addition, a hydrophobic molecule named wrenchnool designed originally as an inhibitor of the ESX-Sur2 interaction is also capable of functioning as an activation domain on localization to DNA. When conjugated to a polyamide, this molecule upregulated transcription in a cell-free system 3.5-fold over background. This synthetic activator ATP was, however, inactive in mammalian cell culture, which was possibly caused by limited nuclear localization (19). Finally, peptoids (oligo-N-substituted glycines) are emerging as an effective alternative to peptidic TADs. KBP02, which is a peptoid that was identified from a library screen against the KIX domain of CBP, is capable of activating robustly (up to 1000-fold) transcription of a reporter gene in mammalian cells.
DNA–protein interactions

One method by which transcription can be modulated passively is by targeting the promoter of a gene with artificial DBDs. Using this method, inhibition of transcription can be achieved by competing for the binding sites of endogenous transcriptional activators (22). For example, TFOs designed to target a sequence that encompasses the Ets-1 and AML-1 sites in the hypoxic response element (HRE) in the VEGF promoter can block RNA polymerase II during elongation. For example, a PNA that was designed to target a region encompassing a point mutation in codon 12 of the K-RAS proto-oncogene showed a concentration-dependent ability to downregulate expression of the mutant allele over the wild type in pancreatic cancer cells (12). In part because of their lower binding affinities, polyamides must be conjugated to DNA-modifying agents to arrest a transcribing polymerase. For example, a polyamide conjugated to the DNA alkylation chlorambucil exhibited cytostatic activity in colon carcinoma cells; this effect was attributed to the downregulation of the H4c gene—2-fold, most likely because of the alkylation of a G residue located two bases downstream of a target site present in its coding region. This alkylating polyamide was even effective at suppressing tumor growth in a dose-dependent manner in a mouse model with no obvious toxicity (38). On the other hand, unconjugated polyamides have been used successfully to alleviate blockage of an elongating RNA polymerase by targeted expanded intronic repeat sequences and by preventing formation of non-B DNA structures (39). Finally, in addition to inhibiting elongation, PNA s also can block RNA polymerase II at the initiation step of transcription. This action can be achieved by targeting ssDNA sequences in the open complex located at the transcription start site, and it has been applied successfully with PNA s to downregulate expression of the human progesterone receptor (hPR) isofoms A and B in breast cancer cells (33).

Protein–protein interactions

Another method by which transcription can be modulated passively is by inhibiting the interaction of natural activators with their protein targets (Fig. 4). Transcriptional inhibition can be achieved by blocking activator-coactivator interactions. For example, the histone acetyltransferase CBP/p300 is a global coactivator capable of binding to a diverse group of activators including CREB, c-Myb, Jun, and HIF-1α (40). To identify a molecule that can disrupt the interaction of HIF-1α with p300, a high-throughput competition binding screen was performed against the minimal protein complex, and a small-molecule fungal metabolite named chetomin was identified (Fig. 4). Chetomin not only reduced endogenous HIF-1α/p300 complex formation in cells, as demonstrated by coimmunoprecipitation experiments, but also reduced the activation of hypoxia-responsive reporter genes both in cell culture and in vivo. On probing the specificity of this inhibitor against other p300-dependent activators such as RAR, SREBP2, SRC-1, and STAT2, only the activity of STAT2 was significantly attenuated, and this is most likely because it is the only one that, along with HIF-1α, targets the CH1 domain on p300 (41). Overall, this example illustrates the challenges of inhibiting activator function selectively by this mechanism. For instance, although the molecule KG-561, which inhibits the IKK/NF-κB interaction within the CREB/CBP complex, could inhibit significantly transcription of CREB-dependent genes in human cells, preliminary studies indicate that it also impedes activation by another CBP-dependent activator NF-κB (42). In addition, although inhibiting complex formation between the coactivator p300 and the activator Tcf4 with the fungal metabolites PKF113-584 and CP949091 leads to antiproliferative effects in colon cancer...
Inhibitors of activator–coactivator and activator–masking protein interactions. Structures of small molecules that compete effectively with transcriptional activators for binding sites within coactivators and within masking proteins.

Cells, these molecules also can prevent complex formation between β-catenin and the tumor suppressor protein APC, which impacts their effectiveness (43). Taken together, these results demonstrate that inhibitors of activator–coactivator interactions have enormous potential and are in need of additional evaluation.

Inhibiting protein interactions can also lead to the activation of transcription. Activators are often regulated by masking proteins that bind to the TAD, which prevents it from contacting the transcriptional machinery until upregulation is required. Typically, TAD-masking proteins are of higher affinity and specificity than TAD-transcriptional machinery interactions and are therefore more straightforward to target with small molecules.

For example, the p53 TAD binds as a helix to a relatively deep hydrophobic cleft in the protein MDM2, and a small molecule library screen for inhibitors of this interaction yielded a series of cis-imidazoline analogs termed Nutlins. The active enantiomer of Nutlin-3 inhibits recombinant p53/MDM2 complex formation in vitro with an IC50 value of 0.09 µM, and activates p53 (thereby inducing apoptosis) in cancer cells that contain wild-type p53. When evaluated in vivo, Nutlin-3 treatment of osteosarcoma xenografts established in nude mice results in a 90% inhibition of tumor growth (44). In addition to the Nutlins, many other inhibitors of the p53/MDM2 interaction that exhibit biologic activities have been reported (40). Terphenyl 2 increases p53 activity by 10-fold in colon cancer cells at a concentration of 40 nM (45). In tumor cells that overexpress MDM2, sulfonamide 3 (IC50 value of 32 µM) increases p53 activity by 20% (46). Benzodiazepine 4 binds to MDM2 with an IC50 value of 30 nM (47). Finally, an isindolinone with an IC50 value of 5 µM (5) induces p53-dependent transcription in a dose-dependent manner in MDM2 overexpressing human sarcoma cells (48).

Other Approaches

Additional strategies are available to alter gene expression patterns for therapeutic purposes, many of which are discussed in other articles of this volume. In most cases, these approaches target processes that are upstream or downstream of transcription and can thus influence a wide array of genes both positively and negatively. One strategy involves targeting the...
ligand-dependent class of transcription factors known as nuclear receptors with small molecule agonists or antagonists to promote their interaction with coactivator or corepressor proteins, respectively. For example, metabolic disorders caused by malfunctioning PPAR nuclear receptors can be alleviated by targeting the γ isoform with an agonist class of molecules called thiazolidinediones for the treatment of diabetes (49). Another strategy involves targeting protein kinases with small molecule inhibitors to intervene at some stage in the signaling cascade that precedes the process of transcription. For instance, in the treatment of inflammation, one pathway by which the non-steroidal anti-inflammatory drug aspirin and sodium salicylate exert their effects is by inhibiting the binding of ATP to the kinase IKK-γ, which in turn prevents the phosphorylation (and ultimately the degradation) of the cytoplasmic sequencin protein of the transcription factors NF-κB (50). And finally, the HDAC inhibitor SAHA was approved by the FDA in October 2006 for the treatment of cutaneous T-cell lymphoma, and at least 10 more compounds are currently in clinical trials in hopes of finding inhibitors for market against every major tumor type (51).

Targeting the transcript of a particular gene using the related methods of RNAi and antisense is another powerful strategy for manipulating expression. Currently, two siRNAs that target the VEGF transcript are in clinical trials for the treatment of macular degeneration, as well as one for the treatment of respiratory syncytial virus infection. Although many antisense oligonucleotides are in various phases of clinical trials, to date only fomiviren has been approved for the treatment of cytomegalovirus retinitis (52). One disadvantage of this strategy is that by targeting the transcript rather than a sequence within the genome, these methods usually require higher concentrations to produce an efficient outcome (23).

Future Directions

Tremendous progress has been made toward developing activa
tor ATFs as therapeutic agents for the treatment of a variety of disorders. Indeed, ZF-based ATFs are currently in clinical tri-
als (http://www.sangamo.com/index.php) and a purely synthetic activator that upregulates the transcript levels of endogenous genes in cell culture has been developed. The next frontier is the incorporation of additional functionality into activator ATFs that would confer properties such as temporal control and tissue specificity analogous to endogenous activators. The three-hybrid approach in which the TAD and the DBD associate noncova-
sently only in the presence of a small molecule was the first demonstration that temporal control could be engineered in an ATF, and this pioneering approach has been used in a variety of contexts (53). For entirely synthetic ATFs, one recently reported strategy exploits conformational entropy to create protein-DNA dimers that are inactivated at elevated temperatures but func-
tion well at a lowered temperature (54). In all examples, delivery of the molecules to the appropriate tissues and to the nuclei of those tissues remains an open challenge. Creation of a fully functional activator ATF will thus stimulate advances on a va-
riety of scientific fronts.

Chemistry of Neoglycoproteins

Yuan C. Lee, Biology Department, Johns Hopkins University, Baltimore, Maryland
doi: 10.1002/9780470048672.wecb379

Natural glycoproteins often contain heterogeneous oligosaccharide chains, which make it difficult to elucidate the structure–activity relationship of the carbohydrates of these glycoproteins. Neoglycoproteins were developed to overcome such a problem. Neoglycoproteins are proteins modified with carbohydrates of defined structures. The modification can be random or specific and can use chemical or enzymatic methods. The protein functional groups most often used are $\alpha/\epsilon$-amino groups, $\beta/\gamma$-carboxyl groups, $\gamma$-carboxylamides, sulfhydrils, and phenols. In some cases, existing glycans on glycoproteins can be modified to make the glycan structures homogeneous. Alternatively, glycopeptides or glycoproteins can be synthesized totally de novo, without using any natural proteins, peptides, or oligosaccharides. In addition to providing homogeneous carbohydrate structures on a single protein, neoglycoproteins also provide a multivalency effect (glycoside clustering effect). The use of neoglycoproteins greatly promoted the understanding of the roles of carbohydrates in biologic systems, which led to some clinically important development.

Glycosylation is one of the most complex posttranslational modification of proteins (1). It is well known that glycans attached to glycoproteins are heterogeneous, even at a single glycosylation site of a glycoprotein from a single type of cells. Two reasons for this heterogeneity are that multiple possibilities of linking two monomeric units of carbohydrates exist and that carbohydrates have the ability to form branched structure routinely. Branched structures are especially pervasive on the cell surface glycoconjugates. These factors cause great difficulties in elucidating the biologic roles of carbohydrates in glycoproteins and have hampered considerably the progress in this area of research in comparison with proteins and nucleic acids. To partially alleviate such a problem, neoglycoproteins (2) were devised. In neoglycoproteins, carbohydrates attached to proteins are of a known structure and the level of attachment can be varied more broadly than that found in natural glycoproteins. The latter aspect actually is very important in manifesting the "cluster effect" (multivalency effect) (3, 4), for example, a linear increase in valency that produces logarithmically increasing effects. Production of neoglycoproteins needs not start from natural proteins or glycoproteins but can be designed totally de novo. The de novo approach often is used to attain the desired "cluster effect" more precisely than the random attachment of sugars to proteins. Most of methodologies for the preparation of neoglycoproteins are chemical, but incorporation of enzymatic and molecular biologic methods increasingly are gaining popularity. In this article, the emphasis is placed primarily on protein derivatives (neoglycopeptides), but some examples of peptide derivatives and microarrays also are included.

Historical Background

The first neoglycoproteins (without being referred to as such) were prepared by Avery and Goebel, who used sugar-derivatized proteins to raise antibodies directed toward carbohydrates (5, 6). Typically, carbohydrates by themselves are poor antigens. Avery and Goebel demonstrated that by conjugating carbohydrates to proteins, antibodies against carbohydrates can be raised more efficiently than by carbohydrates alone. Avery and Goebel used diazoated $p$-aminophenyl or $p$-aminobenzyl derivatives of sugars for conjugation to tyrosyl side chains of protein (diazo-coupling). Using a similar approach, Monsigny and colleagues (7, 8) prepared (GlcNAc)$_n$–BSA to determine the binding specificity of wheat germ agglutinin. Iyer and Goldstein (9) also used the diazo-coupling technique, but Buss and Goldstein (10) improved the coupling efficiency by first converting the anilino-group of the glycoside aglycon into the isothiocyanate group by reacting it with thiophosgene so that the sugar derivatives will react with the amino groups of proteins rather than with the phenolic groups of proteins. Lee and colleagues (11-14) used thioglycosides that contained various functional groups to conjugate to proteins, and the term "neoglycoprotein" was introduced at this time. Thioglycosides were chosen...
NaCNBH₃ preferentially reduces the Schiff base (aldimine) to 
amiceric amination (15–17). Contrary to sodium borohydride,
principles of various conjugation methods is shown in either 
nonglycosylated or glycosylated. A summary of chemical
Aminophenyl glycosides had been used in a similar fashion to hydrate to conjugate to Tyr groups of globulins and albumins.

tyrosyl groups of proteins
Most neoglycoproteins are prepared using natural proteins—
From Natural Proteins
Preparation of Neoglycoprotein From Natural Proteins
Most neoglycoproteins are prepared using natural proteins—
either nonglycosylated or glycosylated. A summary of chemical principles of various conjugation methods is shown in Fig. 1.

Via tyrosyl groups of proteins
The classic method of Avery and Goebel (5, 6) and Tillett et al. (10) used diazotized aminobenzyl derivatives of carbohydrate to conjugate to Tyr groups of globulins and albumins. Aminophenyl glycosides had been used in a similar fashion to prepare BSA derivatives as mentioned above (8). Such products can be very colorful because of the highly conjugated bonding system. However, usually only a limited number of Tyr groups exist in typical proteins, and the diaco coupling is not totally specific to phenolic side chains. Moreover, the chemical stability of products also is a problem. It should be noted that the modification of Tyr often results in the inactivation of enzymes and other biologically active proteins. The introduction of an aromatic ring for each glycosylation site also considerably increases the hydrophobicity of the product, which results in decreased solubility and increased undesirable nonspecific interaction.

A unique approach of carbohydrate-protein conjugation was reported in the case of chitosan. The target protein first is oxidized with tyrosinase to yield o-quinone groups, which can be conjugated readily to chitosan (22). This approach should be applicable to amino-terminated glycosides also.

Via amino groups of proteins
This approach is by far the most popular approach for the preparation of neoglycoproteins because of the ready surface availability of the ε-aminogroup of Lys side chains and the higher reactivity of ε-amino-groups in most proteins.

Reducing oligosaccharides can be conjugated directly to the amino groups by the reductive alkylation (or reductive amination) method (13) between the carbonyl group of sugars and the amino groups of proteins if a prolonged reaction time is no objection. The slow reaction rate in the reductive amination is because of the extremely low concentration of the acyclic form of sugars in solution that provides the reactive aldehydic group. In the case of oligosaccharides, a compounding effect is a decrease in reactivity as the molecular weight increases. This problem can be overcome by providing the ω-aldehyde group in the alkyron (13, 18), which allows the completion of the reactive alkylation overnight. Another alternative is to reduce the reducing terminus and then use mild periodate oxidation to generate aldehyde group(s) from the acyclic sugar. When oligosaccharide lactones (prepared from bromine oxidation of the reducing oligosaccharides) were used to conjugate to BSA, many days also were required to complete the reaction (22).

Many other reactive derivatives of mono- or oligosaccharides for reactions other than reductive alkylation have been described (Fig. 1). For example, isothiocarbamates was derived from p-aminophenyl glycosides (10). Glycinate was used to conjugate to the amino groups of proteins (23). For more complex reactions, methyl imidate (derived from cyanomethyl thioglycosides), for example, would react with amino groups to form an amindia link, which has an even higher pKa than the ε-aminogroup (12). Various activated form of ω-carboxyl thyglycosides have been used (24–26) to modify amino groups. It should be noted that although amidation converts the amino group into a neutral amide group, reductive alkylation and amidation retain the positive charge of the original amino group, and the protein integrity is better preserved. When the number of amino groups is high (such as in BSA), it is possible to attach a greater number of glycan chains than normally observed in natural glycoproteins.

Via sulfhydryl groups
If a protein contains a surface-oriented free side chain of cysteine, ω-haloacetyl that contains glycoside or glycopeptide can be reacted to form theimide (27). ω-Haloacetylated glycosides or maleimidated glycopeptides (28) also can be used in the same way. However, a free surface-oriented SH in natural proteins/glycosides is rather rare in number, and hence the scope of this type of neoglycoprotein preparation also is limited. If glycosylation is desired at a specific site and if a Cys can be introduced in the peptide sequence by genetic engineering, it may allow a custom-designed neoglycoprotein with site-specific glycosylation. It also is possible to modify the amino groups in protein with haloacetyl or maleimide groups.
that then can react with thiolated carbohydrate derivatives (e.g., 1-thio-oligosaccharides) to form a thioether link. In this case, the number of glycan attachments (on the amino groups) can be far greater compared with the naturally available number of SH side chains.

An alternative to thioether formation is to form a disulfide bond between thioglycoside and the Cys–SH group of protein (29) or by disulfide exchange between disulfide glycoside and Cys–SH (30). The glycan attached via the disulfide bond, however, has a real risk of being detached by a reductive/oxidative cleavage or a sulfide exchange in biologic systems and, thus, is less desirable.

Via special affinity

Chen and Wold (31, 32) used the unique affinity of avidin/streptavidin for biotin to prepare neoglycoproteins. Glycosides that contain a biotin terminus could be bound so tightly to avidin (Kd < 10^{-13} M) that they could be considered virtually covalently bound. The limitation of this method, however, is that the maximum number of glycan attachments is dependent on the valency of avidin, which is four, and the attached glycans face diverse directions. Interestingly, the fourth binding site of avidin turned out to be very difficult to fulfill. The model of biotinylated glycan and avidin also was used to study glycosylation processing (33). It should be noted that avidin itself is a glycoprotein that contains heterogeneous oligosaccharides and that its nonglycosylated recombinant version (NeutralLite) (34) is more suitable for the preparation of definitive neoglycoproteins.

Via enzymatic action

A transglutaminase reaction was found to be useful in the preparation of neoglycoproteins. For example, ω-amino glycosides were used as a substrate for transglutaminase for the addition of carbohydrates to glutamine side chains (35, 36). The success of this reaction, however, seems somewhat unpredictable.

Some endo-β-hexosaminidase were found to be useful in neoglycoprotein preparation. Although the normal function of these enzymes is to cleave the bond between the two GlcNAc residues next to asparagines of the N-glycan attachment site, they can perform an en block transfer of oligosaccharides (e.g., Man9–GlcNAc) to a GlcNAc-terminated acceptor quite effectively under certain conditions (Fig. 2). Endo-A and endo-M have been used to transfer Man9–GlcNAc (endo-A) or a biantennary complex-type oligosaccharide (endo-M) to the GlcNAc–Asn site of glycoproteins, which can be generated by the hydrolytic action of the endo-β-hexosaminidase (37-39). Whereas endo-A is active only on high-mannose-type glycans, endo-M accepts complex-type glycans as a substrate as well, more effectively for biantennary than triantennary structures. Endo-M has been used for modification of eel calcitonin effectively (38, 39). In either case, the acceptor GlcNAc need not be attached to the Asn. GlcNAc itself and its glycosides are known good acceptors.

A very interesting and useful application of endo-A was reported recently by Wang and coworkers (40, 41). Based on the knowledge that some endo-glycosidase effectively can transfer oxazoline derivatives of GlcNAc-oligosaccharides, Wang and coworkers used endo-A on the oxazoline derivative of...

De Novo or Semisynthetic Preparation of Neoglycoprotein

The advancement in the techniques of the chemical synthesis of oligosaccharides and peptides (including molecular engineering) elevated the neoglycoprotein preparation to the *de novo* synthesis level, which opened a wide range of application possibilities.

Via incorporated Cys in the peptide

When a Cys can be incorporated into the peptide sequence by means of bioengineering, thioaldooses can be attached via a disulfide bond with the newly introduced SH group in the protein. In a recent example (29), asparagine (N-297) of IgG–Fc was replaced with Cys and its SH group was used to form a disulfide bond with thio-oligosaccharide (29). When 3-thio-derivative of Man₉GlcNAc₂ was attached to the thio-modified IgG by such a scheme, the Fc-mediated IgG potency increased several fold over that of the IgG that contains the natural Fc. The distance of glycan to the peptide backbone attached by this method is approximately the same distance as in the natural N-glycan.

Via native chemical ligation

The technique of native chemical ligation (NCL) or expressed protein ligation (EPL) (42) tremendously expanded the scope of peptid/protein synthesis. This approach also has been adopted for the construction of neoglycoproteins. For complete synthetic approaches to the preparation of defined glycoproteins, several excellent reviews (19, 42, 44) exist. The basic principle of NCL is illustrated in Fig. 3 (45). In this article, only a few examples are mentioned. Macmillan and Bertozzi (46) used *Escherichia coli*-expressed peptides and chemically synthesized glycopeptides to construct GlyCAM-1, a natural ligand for L-selectin. Similarly, Tolbert et al. reported chemical ligation of synthetic glycopeptides with *E. coli* expressed and TEV protease-cleaved peptides (19).
Chemical synthesis

One prototypic example of chemoenzymatic synthesis is the preparation of “glycotentacles” (36). First, cyclic peptides that contain several glutamine residues were synthesized. Gal-terminated glycan chains were attached to the glutamine residues by transglutaminase reaction, which then was sialylated enzymatically with sialyltransferase to obtain NeuAcα2,3Gal-terminated glycans. This approach provides flexibility in the size of the cyclic peptide and the choice of glycan structures. As mentioned earlier, the transglycosylation by endo-A was facilitated greatly when the reducing terminal GlcNAc was converted chemically to its oxazoline derivative first (41, 47). A synthetic mucin based on a poly (ω-L-glutamic acid) backbone decorated with p-aminophenyl-glycoside of LacNAc followed by sialylation with sialyl transferase was prepared as an anti-influenza agent (48).

Although the use of glycosyltransferases requires more expensive sugar nucleotides, the exquisite specificities offered by these enzymes sometimes override the cost concerns. Glycosylation often are used in terminal modifications such as sialylation and fucosylation.

Other techniques and reagents

The ease of “click chemistry” (49) has attracted many applications in the area of neoglycoconjugates. The principle of “click chemistry” is illustrated in Fig. 4. The conjugation based on click chemistry can be performed between either the ω-alkyn group on a protein or vice versa (50). The popularity of “click chemistry” resides in its ease of operation, its indifference to reaction conditions (solvent, pH), and its high yields. A traceless Staudinger ligation was reported for its high yields. A traceless Staudinger ligation was reported for (47).

A related reaction using the Diels–Adler cycloaddition of a diene-containing glycoside and a maleimide-equipped protein gives neoglycoproteins at ambient temperature in good yield (51). Preparation of “diene” glycosides may be the limiting step in this application. Squaric acid esters (52) sometimes are used to link glycans to proteins. N-Acetyl-chito-oligosaccharides were linked to silk fibroin by reacting solubilized silk fibroin with cyanuric chloride-activated oligosaccharides (Fig. 5a). One prototypic example of chemoenzymatic synthesis is the preparation of “glycotentacles” (36). First, cyclic peptides that contain several glutamine residues were synthesized. Gal-terminated glycan chains were attached to the glutamine residues by transglutaminase reaction, which then was sialylated enzymatically with sialyltransferase to obtain NeuAcα2,3Gal-terminated glycans. This approach provides flexibility in the size of the cyclic peptide and the choice of glycan structures. As mentioned earlier, the transglycosylation by endo-A was facilitated greatly when the reducing terminal GlcNAc was converted chemically to its oxazoline derivative first (41, 47). A synthetic mucin based on a poly (ω-L-glutamic acid) backbone decorated with p-aminophenyl-glycoside of LacNAc followed by sialylation with sialyl transferase was prepared as an anti-influenza agent (48).

Although the use of glycosyltransferases require more expensive sugar nucleotides, the exquisite specificities offered by these enzymes sometimes override the cost concerns. Glycosylation often are used in terminal modifications such as sialylation and fucosylation.

Cluster effect (or multivalency effect)

In addition to providing structurally well-defined glycans on a protein carrier, neoglycoproteins offer a platform for presenting multiple copies of glycans in a limited confine. The first indication of the effectiveness of the clustering of sugars on neoglycoprotein was observed in the study of neoglycoproteins binding by rabbit liver membrane (11). The binding of BSA-based neoglycoproteins that carry several different sugars by rabbit liver membrane revealed that Gal-BSA was bound very effectively but neoglycoproteins of other sugars (GlcNAc, Man, L-Fuc) were totally ineffective, which indicates that the sugar binding is specific for Gal. The more astounding finding was that when the number of Gal on BSA increased linearly, the binding affinity increased logarithmically, which resulted in a subnanomolar binding affinity (as KI) at the Gal content of about 40 residues per molecule of BSA. The monomeric Gal derivative had an affinity of only ca. mM in KI. This effect was demonstrated more dramatically by the synthetic oligosaccharide mimetics of natural Gal-terminated N-glycans of mono-, di-, and tri-antennary structures (58), in which a 2- and 3-fold increase in valency brought about a ca. 1000-fold increase, respectively, in the binding affinity. Other examples of cluster effect are binding intricately synthesized pentamic and decameric clusters of galabiose (Gal–Gal)–containing structures to Shiga-like toxin (59) and Man-containing dendritic...
Chemistry of Neoglycoproteins

Figure 5 Squaric acid (52) and cyanuric acid (53) as linkers in neoglycoproteins.

Figure 6 Preparation of glycoconjugate by one-pot reaction (57).

Vaccines
Avery and Goebel (5, 6) and Tillett et al. (20) constructed their neoglycoproteins for raising vaccines against carbohydrate groups. The attachment of carbohydrates to proteins apparently made the carbohydrates more antigenic. The preparation and the use of neoglycoproteins for antibody generation is a very important endeavor (64). In fact, many vaccines currently in use (Hemophilus b conjugate, meningococcal 4-valent conjugate, and pneumococcal 7-valent conjugate) are neoglycoproteins in one form or another (65, 66). The antigenicity of dextran-chicken serum albumin was studied with respect to glycan size and density (67).
Lectin specificity and glycosyltransferase substrates

The groups of Monsigny and colleagues (7, 8) and Iyer and Goldstein (9) prepared neoglycoproteins for specificity studies of plant lectins (7, 8). The specificity studies later were extended to animal lectins (4, 68–70) with excellent results. Neoglycoproteins also can serve as substrates for glycosyltransferases in the chemo-enzymatic preparation of more complex glycan structures. In addition, neoglycoproteins are useful as substrates in the assay for glycosyltransferases. Examples are β-1,4-galactosyltransferases (71, 72) and α-fucosyltransferase (73).

Isolation Media and Probes

Many animal lectins have been isolated and purified using neoglycoprotein conjugated to agarose beads. C-type lectins are especially amenable to purification using neoglycoprotein-affinity gel because of the ease of elution simply by using EDTA-containing buffers. The examples include the use of GlcNAc-c-BSA-Sepharose for chicken hepatic lectin (74) and Man-BSA-Sepharose for alligator hepatic lectin (70). Neoglycoproteins also are useful as probes for sugar-binding proteins. Fucose-specific adsorptions on gel tubes of Candida albicans were demonstrated with fluorescence-labeled BSA derivatives bearing different sugars (75). More recent and elegant application was the use of de novo-designed glycoproteins to study the ER-quality control process as related to the activity of glycosyltransferase (76). T-antigen bearing neoglycoprotein was found to be useful as probes for breast carcinoma (77).

Glycoarrays

Microarrays of glycans (glycoarrays), which can be regarded as a special form of neoconjugates, are proving to be a powerful tool for glycomic analysis (78–81). Many above-mentioned conjugation methods and some other methods have been used in the construction of glycoarrays (82). For example, amino-terminated glycosides were reacted with carboxyl derivatives on a glass slide (amide formation) (83, 84) and reducing oligosaccharides were conjugated to 1,2-dihexadecylglycerol-3-phosphoethanolamine (DHPE) and the resulting NGL was adsorbed directly on a solid surface (86). A modified version of NGL uses amine derivatives of DHPE (87). In a recent report, sulfation specificities of glycosaminoglycan interactions with growth factors and chemotactic proteins were probed with microarrays (88).

Glycopeptides and Glycoproteins, Synthesis of
Mammalian glycosylation, the process by which a cellular complement of glycans of dazzling complexity is produced, involves a minimum of 1% of the genome (in humans) and is the dominant postsynthetic modification of both proteins and lipids endowing these molecules with an extended range of structure and function. This article provides a brief outline of the metabolic process by which monosaccharides—the raw material for the construction of complex oligosaccharides—are converted into high energy nucleotide sugar “building blocks” that are in turn assembled into four major classes of mammalian carbohydrates: glycoproteins, glycolipids, GPI anchored structures, and polysaccharides. Finally, the article concludes with a brief discussion of modern methods for manipulating glycans in living cells and in animals—using synthetic, molecular biology, and “chemical biology” approaches—as early steps toward developing sugar-based medicines.

As more information is uncovered regarding the human genome and proteome, it becomes increasingly clear that a deeper level of information resides in the great variety of signaling, receptor, and structural molecules that comprise the human body than is predicted from a strict examination of the genetic code. The answer to this apparent disparity lies in the posttranslational modification of proteins that endows the unexpectedly modest number of genes with great product diversity. Although dozens of posttranslational modifications occur, glycosylation—the addition of one or more sugar residues to a protein or lipid to convey additional information, structure, or function—is arguably the most common (1). In recent years, major strides in the development of sensitive and reliable methods of detection and functional analysis for complex carbohydrates have revealed just how significant these posttranslational glycosylation modifications are; yet, many of these structures remain elusive as large-scale sugar-specific technologies have lagged the rapid rate of discovery for genes and proteins. Now, information gleaned from glycomics is accelerating the study of glycosylation (2, 3) and has generated claims that 220–250 genes, roughly 1% of the human genome, are involved in glycan production and modification (4), and that a minimum of 50% of proteins are glycosylated (5). This article outlines the biosynthetic process of mammalian glycans by first examining the basic monosaccharide building blocks and the ways they combine to form oligosaccharide and polysaccharide structures (Fig. 1). An inspection of the various glycoprotein, glycolipid, GPI anchor, and independently functional polysaccharide linkages is then provided along with a brief description of the structure and function of the various classes of enzymes in the respective biochemical pathways. The article concludes with examples of current research efforts in synthetic chemistry, biologic, and “chemical biology” strategies that seek to exploit the flurry of recent advances in understanding mammalian glycans to develop novel sugar-based therapies for human disease.

Monosaccharides—The Building Blocks for Glycosylation

Monosaccharides are obtained from the diet and transported into cells

In mammals, the primary source for the monosaccharides used for glycan biosynthesis is the diet, but many cell types also scavenge sugars released into the bloodstream by other tissues and organs. A typical mammalian diet containing polysaccharides and starches will result in a rich supply of simple sugars after digestion in the gastrointestinal tract (the full names, abbreviations, and chemical structures of mammalian monosaccharides are given in Fig. 2). These sugars, as well as several less abundant monosaccharides such as galactose (Gal), mannose (Man), or glucosamine (GlcN), are absorbed into the bloodstream and taken up by cells throughout the body via transporters located in the plasma membrane.
Glycan Biosynthesis in Mammals

Figure 1 - Overview of mammalian glycan biosynthesis. Monosaccharides, most commonly glucose (shown), are imported into a cell by membrane transporters of the GLUT or SGLT families. Imported sugars can undergo extensive processing in the cytosol, as exemplified by ManNAc conversion to sialic acid (see Fig. 7), or be directly phosphorylated and converted to high energy nucleotide sugars (an NDP-monosaccharide is shown, where N is a nucleoside). Nucleotide sugars may be used in the cytosol to synthesize lipid-linked precursors of N-linked glycans (see Fig. 3), or they may be transported into the lumen of the ER or Golgi by nucleotide sugar transporters (NST) and therein used as donors for oligosaccharide biosynthesis catalyzed by glycosyltransferases (GTs). The NDP released by GT action is converted to NMP by pyrophosphatase (PPase). Upon further processing and transport, glycans are displayed on the cell surface (shown) or exported from the cell (not shown) where they have diverse functions ranging from signaling and metabolic regulation (e.g., glycoprotein hormones) to a structural role (e.g., polysaccharides that are major ECM constituents).

Characterization of the function and structure of monosaccharide transporters found in the plasma membrane led to the identification of the SGLT (sodium-dependent co-transporters from the gene SLC5A) and GLUT (sodium-independent facilitative transporters from the gene SLC2A) families (6, 7). Various members of these two transporter families are localized to different tissue types. For example, GLUT1 is found in erythrocytes; GLUT4, GLUT5, and GLUT12 predominate in skeletal muscle tissue although other transporters are also expressed at lower numbers in this metabolically voracious tissue (8); and GLUT14 is specifically expressed as the predominant transporter in two alternative splice forms of the human (but not mouse) testis (9). Another feature of these proteins is overlapping substrate specificity with many family members capable of transporting multiple monosaccharides, albeit with differing efficiencies (10).

De novo synthesis of high-energy nucleotide sugars

After monosaccharides are delivered into cells, they are subjected to a series of chemical conversions, including epimerization, acetylation, condensation, and phosphorylation reactions, to produce the spectrum of building blocks required for glycan biosynthesis. The intracellular metabolic network is capable of the de novo synthesis of sufficient amounts of glucosamine (GlcN), fructose (Fru), mannose (Man), fucose (Fuc), N-acetyleneuraminic acid (sialic acid, Neu5Ac or Sia), galactose (Gal), N-acetylgalactosamine (GalNAc), N-acetylgalactosamine (GalNAc), xylose (Xyl), and glucuronic acid (GlcA), all of which exist in the α-conformation except for α-fucose. Mammals other than humans also produce the N-glycolylneuraminic acid (Neu5Gc) form of sialic acid (11).

In the cytosol, these monosaccharides can be phosphorylated and subsequently coupled with nucleotides such as uridine diphosphate (e.g., UDP-GlcNAc), guanosine diphosphate (e.g., GDP-mannose), or cytosine monophosphate in the case of sialic acids (Fig. 2b) to create a set of high energy "building blocks" for glycan assembly. In some cases, such as for the initial steps...
Figure 2  Mammalian monosaccharides and nucleotide sugars. (A) Chemical structures, common names, and abbreviations of the 11 monosaccharides found in mammalian glycans as well as ManNAc, the precursor for sialic acids. (B) Examples of the three classes of nucleotide sugars are provided by UDP-GlcNAc (Glc, GlcA, Gal, GalNAc, and Xyl also use UDP), GDP-Man (Fuc also is linked to GDP), and CMP-Neu5Ac/Gc (IdoA is produced by postsynthetic epimerization of GlcA and therefore does not require a nucleotide sugar).
in the synthesis of the dolichol-linked 14-mer used in N-linked glycan biosynthesis (discussed below) or for O-GlcNAc protein modification (12), nucleotide sugars are used in the cytosol; more often they are transported into the lumens of the Golgi apparatus and endoplasmic reticulum (ER) where the bulk of oligosaccharide assembly and processing occurs. In either case, the release of the monosaccharide from its bonded nucleotide phosphate provides the energy currency for the formation of glycosidic bonds found in glycolipids and glycoproteins.

Transport of nucleotide sugars into ER/golgi

The transport of high energy nucleotide sugars from the cytosol into the ER and Golgi lumens occurs by highly specific
membrane proteins of the SLC35 nucleotide sugar transporter family. This class of proteins has at least 17 members, some of which can accept multiple substrates; at the same time, certain nucleotide sugars can be accepted by multiple transporters. These transporters are organellar specific; typically nucleotide sugars are only transported into an organellar compartment endowed with the corresponding glycosyltransferases (13). For example, CMP-Sia, GDP-Fuc, and UDP-Gal are transported solely into the Golgi; UDP-GalNAc, UDP-GlcNAc, UDP-Glc, and UDP-Xyl are transported twice as rapidly into vesicles of Golgi as ER; conversely, UDP-Glc is transported into ER vesicles much more rapidly than into the Golgi (10).

Regulation of the assembly of complex carbohydrates from nucleotide sugars, which is an extremely complex and still poorly understood process, is accomplished by several means, including compartmentalization of glycosyltransferases, the activities of these enzymes, nucleotide sugar-transport rates, and the available concentration of substrates (14). By influencing the latter two parameters, nucleotide sugar transporters play a major role in determining the outcome of glycan structure and significant efforts have been expended to understand the transport mechanism. Briefly, these proteins are anti-porters that exchange the nucleotide sugar for a corresponding nucleotide monophosphate in an equimolar fashion (15). For example, a nucleotide monophosphate (NMP) may be exported from the ER in exchange for the importation of a nucleotide sugar (Fig. 1). It is worth noting that NMP is not a product of the glycosylation process within these organelles; instead NMP is produced by enzymatic dephosphorylation of NDP generated during the glycosyltransferase-catalyzed attachment of a monosaccharide residue to a growing oligosaccharide chain. Consequently, both the specific transporter and the corresponding nucleotide diphosphatase are required within the lumen of a specific organelle for successful transport, and evidence suggests that the transport of these nucleotide sugars into the ER or Golgi apparatus regulates which macromolecules will undergo glycosylation (16). Transport is competitively inhibited by corresponding nucleoside monophosphate or diphosphate in the cytosol, but not by the free sugars, and it does not require an energy source such as ATP. Finally, after glycan assembly, the many posttranslational modifications that glycans undergo (phosphorylation, acetylation, and sulfation) also require active transport of necessary materials into the ER and Golgi; for example, PAPS (3′-phosphoadenosine 5′-phosphosulfate) required for sulfation is imported by the PAPST1 gene product (17).

Glycoconjugate Assembly

Once the required high energy nucleotide sugars and other building blocks have been translocated to the appropriate cellular compartments, the glycosylation of newly synthesized proteins and lipids can begin. In this section we examine the production of the major classes of prevalent mammalian glycan structures; a more thorough discussion, including low abundance glycans not discussed here, can be found in review articles (see the Further Reading list).

Glycoproteins

In proteins there are two major glycan classes, N-linked (Fig. 4) and O-linked (Fig. 5), based on the atom (nitrogen or oxygen) of the specific amino acid residue to which the glycan is tethered. Glycans are also distinguished from one another by significant differences in biosynthesis, structure, and function.

N-linked glycosylation

N-Linked glycosylation is one of the most prevalent protein modifications and serves many invaluable functions, including stabilization of structure, enhanced solubility, immunomodulation, mediation of pathogen interaction, serum clearance rate, protein half-life, and proper folding (18). Dysfunctional N-glycosylation can result in serious detriment to the cells and organism as a whole as exemplified by congenital disorders of glycosylation (CDGs) (19) and adult diseases such as cancer (20).

The term “N-linked” refers to the chemical linkage of the glycan moiety to the nitrogen of the amido group of an asparagine (Asn) residue in the host protein. N-linked glycosylation is a multicompartmental affair, which involves the cytosol and both the ER and the Golgi complexes (Fig. 3). Biosynthesis of glycoproteins begins on the cytosolic face of the ER by the formation of a 95-105 carbon polysaccharide lipid, dolichol phosphate (Dol-P), which acts as a carrier for the nascent glycan structure. Assembly of the core glycan on this carrier begins by addition of a GlcNAc-P (from UDP-GlcNAc) onto Dol-P, forming GlcNAc-P-glycosylphosphoryl dolichol (GlcNAc-P-Dol) through the action of the GlcNAc-1-phosphotransferase DPAGT1. This reaction exemplifies the use of monosaccharide transferases that occur throughout the assembly of the core structure as well as in subsequent elaboration processes. A second GlcNAc and five Man residues are added (from UDP-GlcNAc and GDP-Man, respectively) in sequence to form Man9GlcNAc2-P-Dol, which is then flipped to the luminal side of the ER (A in Fig. 3) (21). Additional Man and Glc residues are added in the lumen of the ER via donors Dol-P-Man and Dol-P-Glc, which results in the primary core structure Glc3Man9GlcNAc2-P-Dol (B in Fig. 3). The terminal α-1,2-linked Glc residue is required for recognition by the oligosaccharide transferase (OST) that attaches this core glycan structure on block to the host protein (C in Fig. 3).

N-Linked glycosylation is considered to be a cotranslational rather than a posttranslational modification because OST searches unfolded polyopeptides emerging from the ER during translation for a universal Asn-X-Ser/Thr consensus sequence, where X is any residue except proline. Proline is disallowed because its rigidity prevents the consensus sequence from forming a loop structure wherein the hydroxyl group of Ser/Thr interacts with the amido group of Asn, thereby making it more nucleophilic and enhancing the installation of the glycan moiety (23). OST binds to Glc3Man9GlcNAc2-P-Dol and catalytically cleaves the phosphoglycosidic bond in the GlcNAc-P moiety, thereby releasing Dol-P during the transfer of Glc3Man9GlcNAc2 to the targeted Asn residue (B in Fig. 3) (24).

Once the transfer of the core Glc3Man9GlcNAc2 14-mer to protein is complete, the terminal Glc residues are removed in...
Figure 4: Overview of mucin-type O-glycan biosynthesis. The production of the eight core structures found in O-glycans is shown along with the enzymes and nucleotide sugars that are involved in each step. Additional information on the enzymes shown can be found in the KEGG databases (see the legend for Fig. 3).
sequence by glucosidase I (the terminal α1-2-linked Glc) and glucosidase II (the α1-3-linked Glc residue). Glcα1-ManGlcNAc2 targets the nascent glycoprotein for entry into the calnexin/calicretin cycle within the ER, which is a major component of the quality control system that assists glycoproteins to fold properly and to achieve their ideal conformation (C in Fig. 3). After folding is completed, the final Glc residue is removed by glucosidase II, and a terminal α1-2-linked Man residue is removed from either of the two other arms of the oligosaccharide by ER mannosidase I or II. The remaining Manα1-GlcNAc2 oligosaccharide structure is transported along with the newly formed protein to the cis-Golgi for further modification (D in Fig. 3). Golgi mannosidases IA and IB subsequently remove three additional α1-2-linked Man residues to form an intermediate Manα1-ManGlcNAc2 glycan structure that is subsequently built into the high-Man, complex, and hybrid subclasses of N-linked glycans. The formation of complex N-linked glycans begins in the medial-Golgi with the addition of a GlcNAc residue by mannosyl-α1-3-glycoprotein-α1-2-N-acetylglucosaminyltransferase (MAGT1) onto the α1-3-linked Man residue of Manα1-GlcNAc2 (26). Manosidase II removes the two remaining terminal Man residues from Manα1-GlcNAc2 and mannosyl-α1-3-glycoprotein-α1-2-N-acetylglucosaminyltransferase (MAGT2) adds a GlcNAc residue to the final remaining terminal Man residue (27). Additional modifications, such as the addition of a Fuc to the proximal GlcNAc, addition of a β1-6-GlcNAc to the α1-6-linked Man residue that already bears β1-2-GlcNAc, or capping with terminal sialic acids, generate a wide variety of diverse structures within the complex N-linked glycan class (10). Biosynthesis of hybrid N-linked glycans begins with the addition of β1-2-GlcNAc to the α1-2-linked Man residue of the intermediate Manα1-GlcNAc2 glycan structure; the removal of the two remaining Man residues by mannosidase II, as occurs in complex N-linked glycan biosynthesis, is prevented by the addition of a β1-4-GlcNAc to the proximal β1-4-Man residue (28). This mannosidase II-protected structure is translocated to the trans-Golgi where additional modifications to the oligosaccharide structure occur, which once again generates a vast array of structures.

O-linked glycosylation

O-Linked glycosylation is a posttranslational modification where the glycan moiety is attached to the hydroxyl group of a serine or threonine amino acid residue of a protein, often in dense clusters of carbohydrate that force the peptide chain into a highly extended, poorly folded conformation. There are several potential O-glycans, including O-linked Fuc and O-glycan linkages to hydroxylsine (in the collagen sequence Gly-X-Hyp-Gly) and hydroxyproline (in plants, but by far the most common form of O-glycosylation is the addition of α1-N-acetylgalactosamine to form O-linked Galα1-3Ser/Thr (known as mucin-type O-glycosylation) to which many subsequent oligosaccharides can be added for varying functionality. Aberrations in O-linked glycosylation are often found in various disease states, including blood disorders, cancer, and diabetes.

Unlike N-glycosylation that always begins with an N-linked Glcα1-ManGlcNAc2 14-mer core structure, mucin-type O-glycosylation begins in the Golgi apparatus with the addition of a single monosaccharide, typically GalNAc, onto a Ser or Thr residue of a protein that has already completed the folding process (Fig. 4). The production of the initial O-linked Galα1-3Ser/Thr structure, known as the Tn-antigen, is facilitated by an enzyme, O-GalNAc transferase, which forms a complex with the protein. Often, this simple glycan moiety is translocated to the trans-Golgi for elongation through the stepwise addition of Gal, GalNAc, or GlcNAc residues that form the basis of eight core structures. These structures can be further modified by sialylation, sulfation, acetylation, fucosylation, or polylactosamine extension (10). Although there is not a specifically defined consensus sequence for mucin-type O-linkages (29), statistical analysis has yielded a rule set to predict sites of O-GalNAc modification. For instance, there are inherent differences in site specificity between tissue types based on different GalNAc transferase expression patterns between cells. Moreover, because O-glycosylation occurs on fully folded proteins, only surface-exposed Ser and Thr residues will be accessible for O-glycosylation. The density patterns of O-linked glycans also suggest that nearby residues can influence transferase activity (29).

A iso of interest in a discussion of O-linked glycans is the addition of a single GlcNAc to Ser or Thr to form a class of cytosolic and nuclear glycosylated proteins (30). O-GalNAc is very common in nuclear and cytosolic proteins, including nuclear pore proteins, transcription factors, and cytoskeletal elements (31). O-GalNAc modification is likened more to phosphorylation than to the other forms of glycosylation because of its transient nature and frequent yin-yang status with phosphorylation at the same sites, particularly during different cell-cycle stages and in development (32).

Glycolipids

A glycolipid is any compound containing one or more monosaccharide residues bound by a glycosidic linkage to a hydrophobic moiety such as an acylglycerol, a sphingoid, or a prenol phosphatide. In mammalian, most glycolipids are glycosphingolipids (GSLs), which is a large and widely varying family of amphipathic lipids based on the ceramide N-acylsphingoid lipid moiety (Fig. 5). GSLs reside in cellular membranes, typically in the plasma membrane where the glycan is almost always oriented outward, exposed to the extracellular space. These molecules play a role in the protective glycocalyx covering of a cell and participate in raft assemblies such as the “glycosynapse” (33). GSLs participate in cell–cell recognition, cell–matrix interactions, and cell surface reception and messaging. GSLs are required for proper development. Biopsythetetic or catabolic defects result in pathologies ranging from liver disease to insulin-resistant diabetes, multiple sclerosis, Tay–Sachs, and Gaucher’s disease.

Glycolipid synthesis begins on the cytosolic face of the ER (34) with the condensation of a serine residue and a palmityl-CoA to form 3-dehydrophosphoinositol, which is hydroxylated at the 4-oxygen, acylated, and unsaturated between C4 and C5 in a trans-fashion to form ceramide (Cer)
Figure 5  Overview of glycolipid biosynthesis. Mammalian glycosphingolipids (GSLs) are synthesized from Cer after the addition of Gal, to form the small GalCer-series, or after the addition of Glc and Gal to form the ubiquitous LacCer class, which is subdivided into gangliosides, globosides, and the neo-lacto-series. Additional information on the enzymes and specific GSLs shown can be found in the KEGG databases (see the Legend for Fig. 3).
Glycan biosynthesis in Mammals

Glycolipids; most commonly, Cer is conjugated with a Gal or one of several modifications that lead to different classes of monosaccharides and phosphoethanolamine linked to the C-terminus of a protein.

Ceramide then crosses the ER membrane and undergoes modifications, whereas the GlcCer core can experience extensive differences; a prime example is 9-O-acetylation of the terminal residue of GD3 that endows this potent inducer of apoptosis with anti-apoptotic properties (38). The N-terminal domains of the promiscuous glycosyltransferases responsible for the construction of the gangliosides specify the distribution of these enzymes within the Golgi stacks, which results in a differential expression pattern (37). A salvage pathway also exists for resynthesizing gangliosides, recycling them from their endosomal breakdown through the Golgi; this recycling pathway dominates in slowly dividing cells, whereas de novo synthesis dominates in highly mitotic cells.

GPI anchors

The discovery that phospholipase C could release alkaline phosphatase from lipid-linked structures on cellular surfaces (39) led to the identification of the glycophasphatidylinositol (GPI) membrane component (40). GPI structures are a synthetic tour de force of nature, combining lipids, carbohydrates, and proteins into a single macromolecule. Certain proteins require GPI anchoring to be functional; for example, L-64E-mediated T-cell activation is critically dependent on its GPI anchor (41), and folate uptake functions efficiently only when its receptors are GPI anchored (42).

The basic structure of the GPI-anchor (Fig. 6) maintained across all species studied thus far) begins with phosphatidylinositol (PS, consisting of diphosphateinositol, which is attached to an inositol via a phosphodiester. An oligosaccharide chain, which is attached to the inositol, consists of GlcN (donated by Dol-P-Man donors), three linear Man residues (provided by Dol-P-Man donors). Finally, phosphoethanolamine (P-EtN) is linked to the terminal Man residue (43).

The GPI anchor is synthesized in the ER lumen and trafficked into the Golgi where it can be modified further by sulfation or additional glycosylation before cell-surface presentation. Unlike GalCer-derived GSLs, structures based on GlcCer are ubiquitous. This GSL forms at the cis-Golgi and is translocated to the lumen of the Golgi via the Golgi stack trafficking process (37) to become a substrate for various glycosyltransferase enzymes and complexes. The addition of a Gal residue to GlcCer results in LacCer, which is the foundation for three additional classes of GSLs. First, the (neo-)lacto-series, or blood group series, begins with the addition of a β1-3-GlcNAc. Next, the Globo series is distinguished by the addition of an α1-4-Gal (also known as the Pk antigen). Third are the gangliosides, which are glycolipids that feature one or more sialic acid residues; membership in this group does not preclude inclusion in the lacto- or globo series. Gangliosides are present in nearly all animal cells, but they are particularly prevalent in the plasma membranes of cells in the central nervous system (37).

Because of the importance of gangliosides in a variety of disease states and the volume of research devoted to them, the biosynthetic processes of this class of GSLs are described briefly. All gangliosides begin as LacCer except for GM4 (α2,3-GalCer). From LacCer, non-GM4 ganglioside biosynthesis continues down one of two branches: the α1-2-Gal (also called the α-pathway) through addition of a GalNAc residue, or into the “ganglioside proper” pathways (a-, b-, and c-pathways) through the addition of one or more sialic acid residues. GalNAc and Gal residues can be added as side chains that may be capped with additional sialic acids. Sialic acids appended to gangliosides can have subtle differences in structure that can result in drastic functional differences; a prime example is 9-O-acetylation of the terminal residue of GD3 that endows this potent inducer of apoptosis with anti-apoptotic properties (38). The N-terminal domains of the promiscuous glycosyltransferases responsible for the construction of the gangliosides specify the distribution of these enzymes within the Golgi stacks, which results in a differential expression pattern (37). A salvage pathway also exists for resynthesizing gangliosides, recycling them from their endosomal breakdown through the Golgi; this recycling pathway dominates in slowly dividing cells, whereas de novo synthesis dominates in highly mitotic cells.

GPI anchors

The discovery that phospholipase C could release alkaline phosphatase from lipid-linked structures on cellular surfaces (39) led to the identification of the glycophasphatidylinositol (GPI) membrane component (40). GPI structures are a synthetic tour de force of nature, combining lipids, carbohydrates, and proteins into a single macromolecule. Certain proteins require GPI anchoring to be functional; for example, L-64E-mediated T-cell activation is critically dependent on its GPI anchor (41), and folate uptake functions efficiently only when its receptors are GPI anchored (42).

The basic structure of the GPI-anchor (Fig. 6) is maintained across all species studied thus far) begins with phosphatidylinositol (PI), which spans the external ER membrane linked to an inositol via a phosphodiester. An oligosaccharide chain, which is attached to the inositol, consists of GlcN (donated by Dol-P-Man donors), three linear Man residues (provided by Dol-P-Man donors). Finally, phosphoethanolamine (P-EtN) is linked to the terminal Man residue (43).

The GPI anchor is synthesized in the ER lumen and trafficked into the Golgi where it can be modified further by sulfation or additional glycosylation before cell-surface presentation. Unlike GalCer-derived GSLs, structures based on GlcCer are ubiquitous. This GSL forms at the cis-Golgi and is translocated to the lumen of the Golgi via the Golgi stack trafficking process (37) to become a substrate for various glycosyltransferase enzymes and complexes. The addition of a Gal residue to GlcCer results in LacCer, which is the foundation for three additional classes of GSLs. First, the (neo-)lacto-series, or blood group series, begins with the addition of a β1-3-GlcNAc. Next, the Globo series is distinguished by the addition of an α1-4-Gal (also known as the Pk antigen). Third are the gangliosides, which are glycolipids that feature one or more sialic acid residues; membership in this group does not preclude inclusion in the lacto- or globo series. Gangliosides are present in nearly all animal cells, but they are particularly prevalent in the plasma membranes of cells in the central nervous system (37).

Because of the importance of gangliosides in a variety of disease states and the volume of research devoted to them, the biosynthetic processes of this class of GSLs are described briefly. All gangliosides begin as LacCer except for GM4 (α2,3-GalCer). From LacCer, non-GM4 ganglioside biosynthesis continues down one of two branches: the α1-2-Gal (also called the α-pathway) through addition of a GalNAc residue, or into the “ganglioside proper” pathways (a-, b-, and c-pathways) through the addition of one or more sialic acid residues. GalNAc and Gal residues can be added as side chains that may be capped with additional sialic acids. Sialic acids appended to gangliosides can have subtle differences in structure that can result in drastic functional differences; a prime example is 9-O-acetylation of the terminal residue of GD3 that endows this potent inducer of apoptosis with anti-apoptotic properties (38). The N-terminal domains of the promiscuous glycosyltransferases responsible for the construction of the gangliosides specify the distribution of these enzymes within the Golgi stacks, which results in a differential expression pattern (37). A salvage pathway also exists for resynthesizing gangliosides, recycling them from their endosomal breakdown through the Golgi; this recycling pathway dominates in slowly dividing cells, whereas de novo synthesis dominates in highly mitotic cells.
Glycan Biosynthesis in Mammals

Figure 7 Metabolic oligosaccharide engineering of sialic acid. Exogenously supplied analogs of ManNAc or sialic acid can intercept the sialic acid biosynthetic pathway (at different points) and be displayed on the cell surface in place of the natural sialic acids Neu5Ac and Neu5Gc. The sampling of non-natural "R" groups shown here was selected from References 84, 92, 93 and 97–101 (note that not all "mix-and-match" permutations of the indicated groups have been reported). Additional information on the enzymes shown can be found in the KEGG databases (see the Legend for Fig. 3).
Hyaluronan
Hyaluronan, or hyaluronic acid, is synthesized at the plasma membrane (rather than in the ER or Golgi apparatus) by one of three distinct hyaluronan synthases, which allows it to be easily secreted directly to the ECM (47). Hyaluronan is the simplest GAG, consisting of the repeating unit \(-\text{GlcA-\beta-1,3-GlcNAc-\beta-1,4-}\); this GAG forgoes postsynthetic modification and remains unbound to surface proteins.

Heparin/heparan sulfate and chondroitin/dermatan sulfate
Heparin/heparan sulfate GAGs (HSGAGs) and chondroitin/dermatan sulfate GAGs (CSGAGs) share a common synthetic origin, with both being linked to a core protein through a specific uronic acid. HSGAGs differ from other GAGs in two major respects. Keratan sulfate differs from other uronic acids in its disaccharide repeat. The first GlcNAc or GlcNAc residue determines whether the GAG will belong to the heparan sulfate or condroitin sulfate family, respectively. HSGAGs consist of the repeating unit \(-\text{GlcNAc-\beta-1,4-Glc} \alpha-N\text{-Acetylglucosamine transferase I and II) and a GlcNAc (by glucosamine acid transferase I) are attached sequentially to complete the tetramer.} \]

Synthesis of the polysaccharide portion of these GAGs begins with the addition of GalNAc (or GlcNAc) and GlcA residues to the O-linked tetramer in an alternating fashion by multidomain glycosyltransferases (48). The addition of the first GlcNAc or GalNAc residue determines whether the GAG will belong to the heparan sulfate or condroitin sulfate family, respectively. HSGAGs consist of the repeating unit \(-\text{GlcNAc-\beta-1,4-GlcA-\alpha-1-3-}, \)-which contains GlcA rather than GlcNAc and employs 1-3- rather than 1-4-glycosidic linkages between the repeating disaccharides; despite the differences in the monosaccharide building blocks used, CSGAGs are also constructed from genes in the EXT family (48). When the HSGAG or CSGAG chain has grown to an appropriate length, it is acted upon by additional enzymes that impart structural uniqueness. 2-0, 3-0, and 6-O-sulfotransferases add sulfate groups at appropriate locations (50). N-deacetylase N-sulfotransferase can exchange the amine groups of GlcNAc, and C5 epoxytransferase converts a portion of GaNAc residues to IdoA. This epimerization results in the distinction between condroitin sulfate and dermatan sulfate (51).

Keratan Sulfate
Keratan sulfate differs from other GAGs in two major respects. First, it can be either N- or O-linked to the core protein (52). Second, its repeating disaccharide unit contains a Gal rather than one of the uronic acids in its disaccharide repeat. The basic repeating unit is \(-\text{Gal-\beta-1,3-GalNAc-\alpha-1,4-}\), assembled by \(\beta\)-1,4-galactosyltransferase (B4GALT1) and a \(\beta\)-1,3-GalNAc transferase (B3GALT1 or B3GALT2). Three classes of keratan sulfate are distinct in their protein linkage. KSI members are N-linked to an Asn of the protein; they are found primarily in the cornea and can be terminated with sialic acids, Gal, or GlcNAc. KSI members are O-linked to a Ser/Thr residue of the core protein; they are primarily found in cartilage, are highly sulfated, and are terminated by sialic acids. KSIIs are found in brain tissue and have a unique linker between the keratan sulfate chain and the protein: a Man O-linked to a Ser of the protein.

Manipulating Mammalian Glycans—Early Steps Toward Sugar-Based Medicines
Although many aspects of glycans remain mysterious, mammalian glycosylation has now been elucidated well enough to provide a basic understanding of glycan biosynthesis, structure, and function that, combined with the realization that many disease states result from glycan abnormalities, have spurred efforts to develop sugar-based medicines. As modern medical research looks for ways to exploit the knowledge that has been gained regarding glycan biosynthesis to create new therapeutics, several challenges inherent in modifying glycosylation in living cells and tissues must be overcome (53). A particular obstacle to biologic intervention is the lack of template for carbohydrate structures akin to the DNA sequence that specifies primary amino acid sequences of proteins that motivates gene therapies. Similarly, the expense of de novo synthesis of complex oligosaccharides coupled with their notoriously poor pharmacologic properties make them nonideal drug candidates and hinders conventional synthetic approaches to drug development. Nonetheless, these limitations, both biology- and chemistry-based approaches remain enticing; moreover, merging these two disciplines into innovative “chemical biology” strategies seems particularly promising. This article concludes by discussing each of these topics briefly, after providing a short synopsis of the contributions of rapidly coalescing glycomics efforts to the study of mammalian glycosylation and development of human therapeutics.

Advances in technology and bioinformatics ease characterization
Efforts to manipulate glycans for medical purposes rely on knowing what oligosaccharide structures exist in health and disease, the biosynthetic machinery that builds these sugars, and specific molecular changes rendered by therapeutic intervention. In the past, the difficulty of characterizing glycans has made tackling even one of these tasks formidable. Now, however, bioinformatics has combined technological advances in carbohydrate analysis with the concept of global characterization found in genomics and proteomics to create the field of “glycomics”—the study of all the glycan structures produced by the cell. Modern methods using mass spectrometry, chromatography, nuclear magnetic resonance, and capillary electrophoresis have identified many carbohydrate structures (3, 54, 55). These techniques, along with high throughput arrays using lectins and other glycan-binding proteins (56), have resulted in a significant amount of information available in databases such as the Online glycan database (http://www.glycanbank.org).
as those available online from the German Cancer Research Center (http://www.glycosciences.de), the Consortium for Functional Glycomics (http://www.functionalglycomics.org), and the AFB-CNR of the University of Provence and the University of the Mediterranea (http://www.cazy.org). These resources complement automated methods for predicting function, structure, and localization of newly discovered glycans and glycan-related enzymes alongside their arrays of references, composition and spatial structures, and gathered NMR shift data (4). These developments are critical both for the glycobiology specialist undertaking further study of the intricacies of glycosylation and well as for the non-specialist, such as a physician, who seeks to apply glyobiology-based technologies in the clinic.

Biological approaches

Genetic approaches

Fascinating findings that viruses alter the glycome by regulating expression of host glycosyltransferases or by expressing their own glycosyltransferases (37) and forward genetics approaches that have identified glycan defects associated with specific genetic abnormalities (58) have motivated efforts to exploit modern genetic tools to manipulate glycosylation. Unfortunately, tools such as knockout mice to eliminate a specific biosynthetic enzyme often have manifold and severe effects such as early lethality (59). By contrast, in other situations, including the “goat” knockout pig created to supply organs for xenotransplantation (60), the removal of a glycosyltransferase did not abolish production of the targeted oligosaccharide epitope. Notwithstanding these difficulties, the compelling links between defects in specific glycosylation enzymes and disease currently refractory to treatment, such as cancer (20), have ensured the continuation of research efforts to develop genetic methods to manipulate glycans.

Molecular biology approaches

In addition to upregulation or knock-down of biosynthetic elements, modern molecular biology offers techniques for more subtle manipulation of the glycosylation process. The biosynthesis of glycan structures relies on precisely localized enzymes for proper construction, for example, the localization of glycosylation enzymes within the ER and Golgi cisternae in the same sequence in which they act to modify oligosaccharide substrates (61). One way that this localization is achieved is based on the thickness of the membranes, which increases from the ER to the cis-, medial-, and trans-Golgi compartments; glycosyltransferase enzymes possess transmembrane domains of a length optimal to anchor them to a specific location in a cell’s secretory organelles (62). It is therefore possible to relocate an enzyme involved in glycosylation by swapping that enzyme’s native transmembrane region with a transmembrane domain of a different length and thereby changing substrate preference (63). Additionally, the stem region, located between the transmembrane and catalytic domains, can also be swapped to tune the activity of a glycosyltransferase (64). Although currently largely laboratory research tools, these studies point the way to a future where fine control over glycosylation may be possible by mix-and-matching the membrane, stem, and catalytic domains of glycan processing enzymes.

Synthetic approaches

Modern synthetic chemistry has been able to reproduce several glycan structures of considerable complexity and biomedical relevance. The pioneering example is the use of synthetic sialyl Lewis X for the treatment of reperfusion injury (65). For the past decade, much effort, which has been facilitated by automated synthesis (66), has focused on the creation of carbohydrate-based vaccines. It is possible to use synthetic carbohydrate analogs of viral and microbial surface polysaccharides as vaccines to elicit an immune response against the microorganism. In fact, because an “artificial” polysaccharide can be carefully designed through precise synthesis, this type of vaccine may be both safer and more effective at lower dosage [i.e., through multivalency (67, 68)] than a naturally derived vaccine such as that of a live or killed microbe that contains a mixture of glycoforms, some of which may be immunogenic (69). Synthetic polysaccharide vaccines have been recently developed for several targets, including Haemophilus influenzae type b (70), human immunodeficiency virus (71), and various cancers (72, 73). In the future, as synthetic strategies are streamlined to become both technically and cost-effective, the possibilities of using carbohydrates to positively impact human health are numerous; for example, human breast milk contains a multitude of oligosaccharides that are distinct from other species such as the cow. Human-specific milk sugars are both developmentally important and have activity against pathogens (74), and the ability to supplement infant formula with these sugars would be valuable especially in the third world nations where malnutrition is endemic and infectious diseases are prevalent.

Chemical biology approaches

Combined chemical–biological synthesis

Combining tried-and-true synthetic methods with emerging chemoselective ligand methodology (75) and chemoenzymatic transformations that use the suite of enzymes cells employ for glycosylation (76) has led to the production of a multitude of carbohydrate structures. These hybrid approaches, exploiting biologic tools for programmable one-pot strategies (77), have several attractive features, including the ability to not only make a carbohydrate moiety but rather an entire glycoprotein (78) or glycolipid (79). Another important aspect of a synthetic strategy is that chemically distinct glycan structures can be produced allowing evaluation of the biological response of an individual glycoform, rather than an averaged response obtained when testing a mixture of the profusion of glycoforms found in nature. To illustrate, prion proteins from diseased and healthy cells have different glycan profiles that are proposed to be critical for disease progression (80), but this hypothesis is difficult to verify without the synthetic ability, which is afforded by the methods described herein, of producing testable quantities of individual prion glycoforms.
Small-molecule switches for controlling glycosylation

The emerging use of small molecules to control the activity of glycans processing enzymes (81) and direct biosynthetic traffic in the Golgi (82) constitutes an intriguing approach for modulating glycan synthesis. These efforts build on the modular nature of glycosyltransferases, where the membrane, stem, and catalytic domains can be swapped without loss of function. In particular, fusion proteins were created that combined the catalytic or localization domain of fusosyltransferase 1 (FUT1) with the rapamycin-binding proteins FRP or FRB. Then, by exploiting rapamycin-mediated heterodimerization of these elements to control Golgi localization of both domains and thereby reconstitute FUT1 activity, Koliher and Bertozzi showed that cell-surface glycosylation could be altered (83). In the future, bringing a rich complement of biologic and chemical tools into play, as exemplified by this approach, will continue to drive progress toward glycanc-based therapies.

Metabolic oligosaccharide engineering

“Metabolic oligosaccharide engineering” is an attractive alternative to the synthetic strategies outlined above not only because of its basic simplicity but also because it provides one of the few ways to alter glycosylation in living systems. This methodology, pioneered by the Reutter laboratory for sialic acid (84) (Fig. 7) and now extended to GaINac (85, 86) and GlcNAc (87), is based on the remarkable ability of certain non-natural monosaccharide analogs to be metabolically incorporated into glycosylation pathways and to replace the corresponding sugar residue in the oligosaccharide complement of a cell.

The opportunity provided by metabolic oligosaccharide engineering is divided into two essential classes. First, the intrinsic “on/off” switch that nature has to fine-tune function and structure (88), and thereby endow glycans with antiviral properties (89), enhance immunogenicity (90), modulate cell adhesion (91), or confer stem cell fate (92). Alternatively, when the analog bears a chemical functional group unique to the cell surface, such as a ketone (93) or an azide (94), such sugars can act as “tags” for the delivery of genes (95), toxins (96), or imaging agents (97) by exploiting chemoselective ligation chemistry that has been developed to be compatible with physiologic conditions (75).

Eukaryotic cell glycosphingolipids (GSLs) are central components of membrane lipid microdomains that function as trans plasmamembrane signaling foci. GSLs serve as important receptors and coreceptors, primarily to mediate host/microbial pathogen interactions, and undergo unique intracellular trafficking pathways. As such, their chemical modification can generate interventive therapeutic strategies and biologic probes. The process of achieving such goals via chemistry of the carbohydrate is in its infancy, but substitution within the lipid moiety has been used extensively. A consideration of the importance of the lipid moiety in GSL function has led to novel chemical approaches that attempt to retain this property.

Glycosphingolipids (GSLs) are sugar–lipid conjugates expressed on the outer bilayer leaflet of the plasma membrane of all eukaryotic cells. The linear and branched chain carbohydrate structure is determined by a series of Golgi-lumen-located glycosyl transferases that add single sugars from nucleotide sugar donors transported into the Golgi lumen. The acceptor specificity and intraGolgi location of these glycosyl transferases determine the carbohydrate sequence of the GSLs eventually expressed on the plasma membrane. However, there still remains considerable uncertainty as to the mechanism of their sorting via the vesicular secretory pathway and their recycling from the cell surface. Differential sorting of GSLs to the apical and basolateral plasma membrane of polarized cells has been attributed to a combination of carbohydrate and lipid moieties in relation to the domain organization within the membrane (1, 2).

Glycosphingolipid Structure and Metabolism

A typical GSL, globotriaosyl ceramide galactose 1-4 galactose 1-4 glucosyl ceramide (Gb3), is shown in Fig. 1. The sugar sequence of membrane-embedded GSLs can adopt several conformational energy minima because of a restriction around the glucosyl anomeric link as a function of the relative plane of the membrane in which the GSL is contained (3). Molecular modeling of glucosyl ceramide defined nine thermodynamic minima of which the three most favorable are shown for Gb3. Modeling of blood group A GSLs showed that the internal sugar sequence greatly can affect the presentation of the A-epitope from perpendicular to parallel to the cell surface (4). Membrane parallel orientation of GSLs may be limited for longer sugar chains because a calculation of the phi/psi angles of tetra- and pentasaccharide globoseries GSLs showed that these termini can clash with the membrane for some conformers (5). These restrictions are dependent on the relative plane of the plasma membrane in relation to the glucose anomeric link. This relative plane, in turn, is defined by the composition of the ceramide moiety and the phospholipid bilayer. These are distinct in the liquid ordered vs the liquid crystalline phase so it is very likely that the partitioning of GSLs in and out of lipid microdomains significantly affects the conformation of the oligosaccharide.

Ceramide

The synthesis of the ceramide lipid moiety of GSLs is initiated in the endoplasmic reticulum (ER) (6) via the condensation of serine and palmitoylCoA. This enzyme has been cloned (7). The product is 3-keto-sphinganine that then is reduced to sphinganine and acylated by ceramide synthase with a long-chain fatty acid to form dihydroceramide, which is converted to ceramide by ceramide desaturase, which inserts the 4,5-trans double bond. GSLs are highly heterogeneous in terms of fatty acid composition. Fatty acid chain lengths vary from C16 to C24 and can be monounsaturated or 2′hydroxylated in mammalian systems. The functional importance of the heterogeneity has not been defined but may relate to the receptor function of GSLs and their intracellular trafficking (8). Such trafficking, in turn, is related to the membrane organization of GSLs in terms of their ordered or disordered domain structure (9). This membrane organization is itself a property of the GSL lipid moiety. The fatty acid heterogeneity was thought to be a function of the availability and the lack of specificity of the anabolic enzyme, but recently a family of ceramide synthases has been identified (Lass1-6) (10, 11) with a restricted and, in some cases, unique fatty acid
glycosphinoglycans.

Neutral GSLs

Greater than 90% of the GSLs are based on the transfer of glucose to ceramide to give glucosyl ceramide. Dihydroceramide also can serve as a substrate (23). Glucosyl ceramide then is extended by lactosyltransferase to give lactosyl ceramide. Lactosyl ceramide is the precursor of all the major GSL series. Unlike all other glycosyltransferases involved in GSL biosynthesis, glucosyl ceramide synthesis is a cytosolic enzyme (26-28). Except for this initial enzyme reaction, glycolipid biosynthesis occurs within lumen of the Golgi (29). Glucosyl ceramide synthase transfers glucose from UDP-glucose to ceramides to form glucosyl ceramide on the outer cytosolic surface of the Golgi vesicles. Glucosyl ceramide needs to flip into the Golgi lumen to provide the precursor for the majority of GSL biosynthesis. This translocation is achieved, at least in the majority of cells, by the ABC transporter, MDR1. MDR1 (or P-glycoprotein) was discovered first because of its ability to mediate cytotoxic drug efflux in drug-resistant cells. The up-regulation of Pgp has been shown subsequently to be a major mechanism for drug resistance in cancer cells (30), and MDR1 inhibitors commonly are used therapeutically (31).

MDR1 is a member of a family of ATP-dependent drug efflux pumps (32). Several of these pumps, including MDR1, have been shown to mediate lipid translocation and phospholipid bilayers (33). This translocation activity has been implicated in part as the mechanism for drug efflux by which the hydrophobic cytotoxic drug is translocated from the cytosolic to the external leaflet of the plasma membrane bilayer. MDR1 first was shown to translocate glucosyl ceramide analogs from the cytosolic to the external leaflet of the plasma membrane (33). However, the major glucosyl ceramide translocation activity of MDR1 later
was shown to occur in Golgi vesicles (34). The transfection of cells with MDR1 resulted in a major increase in glycolipid biosynthesis that was prevented by MDR1 inhibition (35). In a cell-free microsomal system, exogenous glucosyl ceramide was incorporated exclusively into more complex GSLs in an MDR1-dependent manner (34). In most cells, MDR1 inhibition prevents neutral, but not acidic, GSL synthesis (34), which suggests that the lactosyl ceramide first made from the pool of glucosyl ceramide translocated into the Golgi lumen by MDR1 is unavailable for immediate ganglioside synthesis. The inhibition of MDR1 therefore represents a means to regulate selectively the neutral GSL biosynthesis (36). This regulation, however, raises a problem for the synthesis of gangliosides. Some GlcCer has been shown to be translocated directly to the cell surface without the involvement of transGolgi traffic (37,38). Recently, LacCer and GlcCer generated by cell-surface sialidase-mediated plasma membrane GM3 turnover was found to be incorporated exclusively into gangliosides (39). Thus, potentially, gangliosides could be made from cell-surface GlcCer, derived either by direct transit from the Golgi lumen by MDR1 or by degradation of other plasma membrane GSLs at the cell surface (or lysosomes).

Lactosyl ceramide synthase is a β-1,4 galactosyl transferase (40). Lactosyl ceramide is the only glycosylconjugate that contains lactose (as opposed to lactosamine). Lactosyl ceramide is the substrate for several glycosyl transferases that then define a core sequence of glycosphingolipids. The Globo series is defined by an α-1,4 galactosyl transferase activity (41,42) to make initially globo triosyl ceramide (also defined as the α series) and GD77 (43) and is the substrate for Gb4 synthase (a β-1,3 GalNAc transferase) (44). Gb4 is the major neutral glycolipid of most cells, including human red blood cells. Gb4 (also termed the P antigen (45)) is the precursor of the Forssman antigen formed by the action of an α-1,3 GalNAc transferase (46,47). Ganglio series glycolipids are made by the action of a β-1,3 GalNAc transferase (48) on lactosyl ceramide to give gangliotetraosyl ceramide, which then is the substrate of α-1,4 Gal transferase (type 2 chain); Lacto series glycolipids are made by the action of β-1,3 GalNAc transferase (49) and β-1,4 Gal transferase (type 2 chain). Lacto series GSLs are defined by the action of β-1,3 GalNAc transferase (49) and β-1,4 Gal transferase (type 2 chain) (51).

Gangliosides

Gangliosides are the major acidic GSLs and are derived primarily from the α-2,3 sialylation of lactosyl ceramide to give the simplest monosialylated GSLs, GlcCer (52). The sialic acid of GlcCer can be α-2,8 sialylated further to give GD3 (53), which can be sialylated further to form GT3. GlcCer, GD3, and GT3 all can serve as substrates (in addition to lactosyl ceramide) for the gangliosides of glycosyl transferases to form the “α”, “β”, and “γ” series of gangliosides, respectively (Fig. 3).

The sialic acid (N-acetylneuraminic acid) of gangliosides and sialylglycoproteins can be N-glycolyl or N-acetyl, and particularly in the context of the lectins that bind such glycoconjugates, this reality is of evolutionary significance (54). Many modifications of sialic acid (primarily 0-acetylation at the 7,8,9
Figure 3. Structure of the major acidic GSLs (gangliosides). Lactosylceramide, GM3, GD3, and GT3 are substrates for the same series of glycosyl transferases reactions, namely, GalNac transferase, galactosyl transferase II, and sialyl transferase V. Positions (α2-3 or α2-6) have been described (55) that are primarily α2-3 linked to galactose within sialoconjugates. The total synthesis of the most common gangliosides has been described (56-59). Gangliosides are abundant in neuronal tissue, and mouse knockout studies indicate a stabilizing function in axons in white matter (60). Gangliosides provide the receptors for myelin-associated glycoprotein (MAG) inhibition of neurite outgrowth (61-63), and their mimics may be of therapeutic value in neuronal injury (54).

Gangliosides within lipid rafts also can modulate growth factor receptor- and src kinase-mediated tyrosine phosphorylation signaling cascades (66). This modulation can be a carbohydrate—carbohydrate-based interaction (67). Although the molecular basis of such flexible sugar-sugar binding is not known, a series of selective interactions have been defined (68) within the context of a “glycosignaling domain” (69, 70) or a “glycosynapse” (71). GM3 inhibits phosphorylation in such domains, but deacetylation of the sialic acid results in the promotion of signaling (72), which indicates the central importance of the sialic acid. Indeed, sialyl-sphingosine was found to be the minimum structure to block signaling (73). Ganglioside signal modification plays an important role in distinguishing motile metastatic tumor cells from sessile “normal” cells (74, 75).

Galactosyl ceramide-based GSLs

A few GSLs are based on galactosyl ceramide rather than glucosyl ceramide. Galactosyl ceramide synthase, unlike glucosyl...
Inhibitors of glycosphingolipid biosynthesis

L-cycloheximide is an inhibitor of serine palmityltransferase (85), the first committed step in GSL biosynthesis. However, because this inhibitor prevents the synthesis of the highly bioactive ceramide, an interpretation of GSL depletion is equivocal.

Fumonisin B1 (Fig. 4) is a fungal inhibitor of ceramide synthase because of structural similarity to sphingamine (86). This inhibition also depletes ceramide levels, however. Moreover, the identified fatty acid selective ceramide synthases have proven to be fumonisin resistant (10, 11). From the structure, it is evident that fatty acid chain length-specific ceramide synthases might have a binding site that is too restricted to accommodate the branched terminus of this inhibitor. Sensitive to fumonisin also is present in the sphingolipid base because acylation of sphingosine rather than sphinganine in vitro is nonexistent to fumonisin (87), which is consistent with the saturated alkyl chain of this amino alcohol.

The natural form of ceramide is the D-erythro isomer, and this form is the substrate for glucosyl ceramide synthase, which forms the precursor to the majority of GSLs. The imino glucopyranosyl analog, butyl deoxynojirimycin (DNJ), is a potent inhibitor of glucosyl ceramide synthase and thereby prevents the synthesis of the majority of GSLs. This inhibitor has been used as a substrate reduction approach to several GSL storages. However, DNJ also inhibits glucose oxidase and thereby affects intracellular glucopyranose carbohydrate processing (90) and glucose storage (91), therefore, more selective inhibitors have been developed. An inhibitor of glucosyl ceramide synthase was designed to mimic the product of this reaction structurally. S-Phenyl-2-decanoylamino-3-morpholino-1-propanol (PDMP) (Fig. 5) is a membrane permeable and has been used extensively to examine the role of glucosyl ceramide-based GSLs in a variety of physiologic processes (92). However, PDMP was found to have additional inhibitory activities (93), for example, on other enzymes for which ceramide is a substrate such as ceramide acyltransferase. Several generations of derivatives of PDMP have been designed subsequently with improved specific activity for glucosyl ceramide synthase. The first was to lengthen the hydrocarbon chain from 10 to 16 carbons (84) (PPMP) and then to replace the morpholino ring with a pyrrolidino ring (P4) (95). Later substitutions within the phenyl ring were examined (96) and the 4-hydroxy derivative was found to be the most potent inhibitor (IC50 for the GC synthase is 90 nM).

Although the use of these inhibitors has been highly informative, the functional aspects of GSLs in plasma membranes have been difficult to define. Changes in growth status, differentiation, and malignancy are associated with altered GSL profiles (97). Ganglioside modification of growth factor receptor kinase activity (a coreceptor function) may relate to these changes (98). This difficulty in defining the functional aspects of GSLs in plasma membranes is largely because of the lack of methodologies for varying the expression of any specific GSL.

The overall importance of GSLs to cell physiology has been demonstrated clearly by using molecular biology techniques. Many glycosyltransferases involved in their synthesis have been cloned. As indicated above, the glucosyl ceramide synthase is the first committed step in the synthesis of most GSLs. This enzyme has been knocked out in mice and shown to be embryonic lethal (99). Interestingly, cultured cells survive well without this enzyme (100), which indicates that GSLs are required for the more differentiated functions in embryogenesis. Other enzymes involved in ganglioside biosynthesis, for example, GM3 synthase and GM2 synthase (60), have provided a more selective approach to reduce ganglioside biosynthesis, and knockout mice that lack these enzymes have been shown to have a less severe phenotype, primarily confined to CNS defects in long-term neuronal cell function. Knocking out the galactosyl ceramide synthase gene in mice results in the formation of dysfunctional and unstable myelin (78). A similar phenotype was observed for the 3′sulfotransferase knockout mouse, which indicates that SGC is the major species responsible for these defects (84). Several previous studies had shown the importance of SGC and its glycerol-based analog, sulfoglucosylceramide in spermatogenesis (83) and fertilization (101). Similarly, the sulfation of galactosyl ceramide in the brain is a function of myelination (102). The calcium-mediated interaction between galactosyl ceramide and SGC demonstrated to occur in vitro (103) is implicated strongly in myelin compaction. Ganglioside binding to myelin-associated glycoprotein (MAG) has been shown to be responsible for some negative signals that prevent neuronal cell regeneration (61).

GSL carbohydrate binding complementarity has been proposed as a mechanism for signal transduction, primarily by Hakomori (71), who has shown the binding interaction between GM3 ganglioside and gangliotriosyl ceramide lactosylceramide, SSEA3 and Gb4. These in vitro binding selectivities correlate with cellular adhesion between cells that express high levels of these GSLs (68). Nevertheless, the mechanism by which the flexible GSL carbohydrate chain can interact specifically with another flexible carbohydrate chain in these GSLs is unknown. The Hakomori group also has shown that gangliosides can modulate the growth factor receptor function and has proposed a cis-interaction between the receptor and the...

ganglioside within the plane of the plasma membrane (75). Sim- lar lateral interactions between receptors and GSLs have been proposed for the α2-interferon receptor (104, 105) and CO19 (106) with globotriaosyl ceramide. Both these transmembrane protein receptors contain an extracellular N-terminal sequence with similarity to the sequence within the receptor binding domain of the verotoxin (Shiga toxin) B subunit (107). Interest ingly, α2-interferon receptor signaling has been compared with that of γ-interferon. Both these receptors are internalized by clathrin-coated pits, but only α2-interferon signaling is pre- vented by the inhibition of internalization (108).

Lipid Rafts

The concept of cellular lipid rafts was introduced first by Simons (1, 109) to explain differential GSL trafficking in polarized epithe- lial cells. These domains are cholesterol and GSL enriched. The H-bond donor and acceptor capability of sphingolipids result in a close, rigid cholesterol complex—a lipid-ordered domain—as compared with the liquid crystalline, predominantly glycerolipid bilayer. In addition, membrane proteins anchored through glycoprophosphoinositol linkages preferentially accumu- late in these domains. Palmitoylated or myristylated cytosolic enzymes involved in downstream signal transduction pathways [e.g., src family kinases (110, 111)] accumulate in the cor- responding cytosolic domains of such cell surface lipid rafts. Lipid rafts serve as foci for a variety of signal transduction pathways (112) and also as access points for many pathogenic microorganisms (113). Direct GSL-mediated signaling within such rafts has been documented by using bacterial toxins that specifically recognize GSLs within these domains (114, 115). Indeed, cholera toxin binding to its receptor GSL, GM1 ganglio- side, is the gold standard marker for lipid rafts (116) in virtually all studies. However, lipid rafts as monitored by CT binding can be excluded from clathrin-coated pits (117). Moreover, recent studies have shown that the binding of cholera toxin does not correlate always with GM1 content (118) but rather fucosylated GM1 to which cholera toxin also binds (119). This finding cer- tainly will require a reevaluation of the basis of the association of cholera toxin with lipid rafts.

Phase separation in model lipid membranes is established clearly (120), but the significance of lipid rafts in cell mem- branes has been controversial (121) largely because of the harsh conditions of detergent resistance. More re- cently, methods have been developed to visualize lipid rafts in living cells (122, 123) and to identify proteins within them by less invasive methods (124).

The functional role of GSLs with in rafts is speculative but may involve linkage to cytosolic, raft-associated signal trans- duction cascades such as src family kinases (125). In this regard, we have demonstrated recently the structural similar- ity of 3′-sulfogalactose, found in GSLs, and tyrosine phosphate (126). This structural similarity is represented in Fig. 6.
that bound tyrosine phosphate and/or tyrosine sulfate (including SH2 domains from src) were found also to bind 3′sulfogalactose GSLs. Furthermore, the binding of such ligands to tyrosine sulfate lipid conjugates was found to depend on the lipid structure, a property typical of GSL recognition. We interpret this finding to indicate that the recognition of GSL carbohydrate within the context of the cell membrane and the recognition of the selective ligand binding of specific tyrosine phosphate groups in the context of a specific polypeptide background may share common principles. In modeling studies, we showed that a galactose hydroxyl group could replace a bound water molecule in tyrosine phosphate-ligand complexes, as determined by crystallography. A similar substitution binding of the carbohydrate could provide an entropic advantage such that carbohydrate-based inhibitors of specific tyrosine phosphatases/kinases might be feasible.

Terminal N-acetyl hexosamine

We described a procedure for the selective removal of terminal N-acetyl hexosamines from GSLs (132). In this procedure, the N-acetyl group first is deacetylated selectively with an aqueous base. Then, in the presence of H₂O₂, the amino function at the 2 position of the terminal amino sugar undergoes a free radical rearrangement reaction that results in the loss of the terminal sugar and some additional peeling reaction, with the likely release of NO. Internal N-acetyl hexosamine residues are unaffected. We propose a mechanism in Fig. 7. Peroxide oxidation of the amine to a nitroso group (133) results in the electronic reconfiguration to cleave the glycosidic bond and liberate NO. Although free amino sugars are rare, they might occur in lysosomes in the context of peroxide radicals, which might make this reaction a biologic source of NO.

Sphingosine double bond

Oxidative cleavage of the sphingosine double bond by ozonolysis was reported some 30 years ago (134). However, this reaction could be carried out only in large scale, and yields of the truncated GSL were very poor and required an ozone generator. This procedure was carried out with globoside and hematoside, and the equivalent glycoceramidic acid was characterized as the truncated product. We developed a new, more versatile procedure for the oxidative cleavage of the double bond of the sphingosine of glycolipids by using a more controllable potassium permanganate/potassium iodate oxidation system. This procedure allowed the oxidation of GSLs at the microgram level and under neutral conditions and generated the ceramidic acid in quantitative yield. This occurrence allowed a subsequent coupling to various inert supports (135). This coupling route has been used to conjugate glycolipids to protein carriers for generating GSL immunogens as potential anticancer therapies. However,
under basic conditions this oxidation resulted in greater truncation of the sphingoid base to give the glycosyl serine acid rather than the ceramide acid produced under neutral conditions (136). A hydroxy-acyl intermediate was identified; the oxidation of which was pH dependent. Unsaturated fatty acids also were cleaved such that the oxidation procedure could be used to define the aglycone composition of natural GSLs. The mass spectrometry analysis of the oxidative cleavage of glucosyl ceramide is shown in Table 1.

**Ganglioside coupling reactions**

Procedures for the selective deacylation of the ceramide moiety of gangliosides (137) have been used as routes to form ganglioside conjugates, primarily for immunogen development.

---

**Table 1** Mass spectroscopy of oxidized glucosyl ceramide that shows that the oxidation procedure allows the quantitation of a degree of unsaturation within the fatty acid moiety (taken from Reference 136)

Figure 7: H2O2-mediated, nonreducing terminal hexosamine cleavage. Terminal amino sugar loss is the major product (but some peeling of the n-1, n-2 sugar is seen), possibly via the rearrangement of a nitroso oxidation product to liberate NO and generate a free radical that rearranges to induce the partial loss of the next sugar, and so forth.
Gb3 was internalized by a clathrin-independent mechanism in the cells with BSA. In addition, whereas BODIPY-labeled these BODIPY- or NBD-labeled GSLs, when incorporated into the membrane (9, 148). This effect is illustrated by the fact that ficking can be affected markedly by the lipid moiety within the ficking and partition into membranes does not mimic necessarily in terms of cell uptake. C6 NDB ceramide was used as a fluorescent probe of retrograde transport from the cell surface in cultured cells, Shiga toxin internalization via endogenous Gb3 was clathrin dependent in the same cells (149).

Nevertheless, the use of fluorescent GSL analog trafficking within cells to define aberrant intracellular trafficking pathways in cells from lysosomal storage disease patients has proven valuable in establishing the link between cholesterol and GSL trafficking. Indeed, the aberrant trafficking of BODIPY-GSLs can be used as a diagnostic tool in these genetic diseases (150).

A recent alternative procedure for the fluorescent labeling of GSLs has been described; it attempts to reduce the impact of the fluor on the structure of the GSL lipid moiety (147). A strong alkali hydrolysis of gangliosides was reported to cleave the ceramide fatty acid and deacylate the sialic acid group without affecting the N-acetyl galactosamine residue. (However, in our hands we find that the strong base simultaneously deacylates N-acetyl amino sugars while decaying the ceramide moiety of neutral GSLs; see Fig. 9). The protection of the sphingosine amine with fmoc then can allow the selective reacylation of the sialic acid with acetic anhydride. The removal of the fmoc group with piperidine in DMF allows the selective coupling of the lyso-ganglioside to azido octodecanoate. The selective re-duction of the azido group without reducing the sphingosine double bond was achieved by using hydrogen sulfide. NBD fluoride then was coupled to this 2-amino function within the lipid moiety of the ganglioside (Fig. 8). In previous coupling procedures for the generation of fluorescent glycosphingolipids, the NBD has been coupled directly to the sphingosine amine. In this procedure, the advantage is that the lipid moiety of the fluorescent ganglioside is more similar to that of the native species. Because many receptor functions of GSLs are modulated by the lipid moieties, this approach provides a mechanism by which such effects will be retained, at least in part, within the derivatized GSL. This conversion is supported by the effect that the GM2 activator was shown to bind the fluorescent GM2 analog as effectively as the natural GM2 ganglioside. The disturbing effect of such chromophore conjugations within the lipid moiety has been reduced more by the use of polynucleotide substitution with fatty acids and coupling to sphingosine (151).

GSL fatty acid substitutions

Many studies have substituted the fatty acid moieties of GSLs with various fluorophores to study GSL cellular trafficking and ligand binding properties. Nitrobenzoxadiazol (NBD) has been a popular choice (143). Early studies use the direct coupling of NBD via N-hydroxysuccinimidyl ester condensation with the sphingosine amine of lyso-sphingolipids. NBD with various fatty acid chain lengths were coupled, but C6 was most useful in terms of cell uptake. C6 NBD ceramide was used as a fluorescent probe of retrograde transport from the cell surface to the Golgi apparatus and metabolized to NBD-GSLs (144). Procedures were developed later to couple the fluor within the GSL lipid moiety selectively. With neutral GSL, this coupling is achieved easily by base hydrolysis (145). For gangliosides, selective cleavage of the base labile ceramide was required first (137).

These studies were superceded largely by the use of boron dipyrromethene difluoride (BODIPY), which has the useful property of showing a differential fluorescence emission spectrum according to concentration (146). The BODIPY moiety could be coupled with a variety of hydrocarbon spacer groups, and as with NBD the 5-carbon fatty acid analog has been used frequently. BODIPY analogs of galactose, lactose sulfates, GM1 ceramide, and sphingomyelin have been synthesized. The structure of examples of NBD- and BODIPY-labeled GSLs is shown in Fig. 8. However, these fluorophore substitutions considerably alter the lipid characteristics of these analogs such that their trafficking and partition into membranes does not mimic necessarily the natural GSL, because it is an intracellular trafficking can be affected markedly by the lipid moiety within the membrane (9, 148). This effect is illustrated by the fact that these BODIPY- or NBD-labeled GSLs, when incorporated into cell membranes, can be back-extracted readily by the treatment of the cells with BSA. In addition, whereas BODIPY-labeled Gb3 was internalized by a clathrin-independent mechanism in the culture of examples of NBD- and BODIPY-labeled GSLs is shown in Fig. 8. However, these fluorophore substitutions considerably alter the lipid characteristics of these analogs such that their trafficking and partition into membranes does not mimic necessarily the natural GSL, because it is an intracellular trafficking can be affected markedly by the lipid moiety within the membrane (9, 148). This effect is illustrated by the fact that these BODIPY- or NBD-labeled GSLs, when incorporated into cell membranes, can be back-extracted readily by the treatment of the cells with BSA. In addition, whereas BODIPY-labeled Gb3 was internalized by a clathrin-independent mechanism in cultured cells, Shiga toxin internalization via endogenous Gb3 was clathrin dependent in the same cells (149).

Nevertheless, the use of fluorescent GSL analog trafficking within cells to define aberrant intracellular trafficking pathways in cells from lysosomal storage disease patients has proven valuable in establishing the link between cholesterol and GSL trafficking. Indeed, the aberrant trafficking of BODIPY-GSLs can be used as a diagnostic tool in these genetic diseases (150).

A recent alternative procedure for the fluorescent labeling of GSLs has been described; it attempts to reduce the impact of the fluor on the structure of the GSL lipid moiety (147). A strong alkali hydrolysis of gangliosides was reported to cleave the ceramide fatty acid and deacylate the sialic acid group without affecting the N-acetyl galactosamine residue. (However, in our hands we find that the strong base simultaneously deacylates N-acetyl amino sugars while decaying the ceramide moiety of neutral GSLs; see Fig. 9). The protection of the sphingosine amine with fmoc then can allow the selective reacylation of the sialic acid with acetic anhydride. The removal of the fmoc group with piperidine in DMF allows the selective coupling of the lyso-ganglioside to azido octodecanoate. The selective re-duction of the azido group without reducing the sphingosine double bond was achieved by using hydrogen sulfide. NBD fluoride then was coupled to this 2-amino function within the lipid moiety of the ganglioside (Fig. 8). In previous coupling procedures for the generation of fluorescent glycosphingolipids, the NBD has been coupled directly to the sphingosine amine. In this procedure, the advantage is that the lipid moiety of the fluorescent ganglioside is more similar to that of the native species. Because many receptor functions of GSLs are modulated by the lipid moieties, this approach provides a mechanism by which such effects will be retained, at least in part, within the derivatized GSL. This conversion is supported by the effect that the GM2 activator was shown to bind the fluorescent GM2 analog as effectively as the natural GM2 ganglioside. The disturbing effect of such chromophore conjugations within the lipid moiety has been reduced more by the use of polynucleotide substitution with fatty acids and coupling to sphingosine (151).

Radiolabeling of GSL

GSL radiolabeling is achieved commonly by the catalytic re-
duction of the sphingosine double bond using palladium and sodium borotrifluoride (152), although this, of course, generates the dihydro species that may behave differently from the native ceramide-containing glycosphingolipid. Radiolabeling with galactose oxidase is a feasible alternative that produces an aldehyde at the C6 position of terminal galactose residues, which can be reduced again with sodium borotritide (153, 154). This procedure can be adapted to label only cell surface GSLs (155). Interestingly, this reaction was found to fail when the glycolipid had a glycerol, as opposed to a sphingosine, backbone (156), which indicates the that availability of the C6 position of galac-
tose to the enzyme is restricted in the case of the glycolipid species.

Surprisingly, a good chemical method for radiolabeling all glycosphingolipids has yet to be devised. The decylation of the sphingosine under basic conditions and the recylation of...
generated amino function with radiolabeled fatty acid is a feasible method, although this method does eliminate the fatty acid heterogeneity of the native species. However, this approach is problematic when it comes to gangliosides because the sialic acid also is base labile. Similarly, in amino sugar-containing GSLs, basic hydrolysis will result in the deacetylation of the N-acetyl amino sugar, which thereby precludes the subsequent selective acylation of the sphingosine amine. We have overcome this problem in terms of amino sugar-containing GSLs by developing a procedure for the selective reacylation of either the sphingosine amine or the galactose (glucose) amino function (Fig. 9).

Chemical Glycosphingolipid Synthesis

The carbohydrate moieties of GSLs have been synthesized, but these procedures are essentially no different from the chemical synthesis of oligosaccharides found on glycoproteins (157). The major difference is the coupling of the oligosaccharide to the aglycone. Complex GSLs have been synthesized by the assembly of appropriately protected oligosaccharide donors and the coupling to a ceramide acceptor and deprotection under mild conditions, for examples, see References 158-160. These approaches are restricted by the complexity of the protection chemistry, intermediate purification, and low product yields. Combined enzymatic and chemical syntheses can address these problems. A recent innovative approach has been to reverse the hydrolytic activity of the endoglycoceramidase that normally removes the carbohydrate from GSLs, to generate a novel glycosynthase (161). In this approach, the catalytic nucleophile residue of the hydrolase is mutated to an inactive amino acid, and the reverse reaction with the appropriate fluoride sugar donor then becomes readily apparent. This process removes problems with protecting group chemistry and ensures the correct stereochemistry of the adduct.

Thioglucosyl ceramide and thiolactosyl ceramide also have been synthesized to study cellular glycolipid traffic and metabolism (162). Both \( \beta \)-thiolactosyl ceramide and lactosyl \( \beta \)-thioceramide were made. The thioglycosidic link is resistant to glycosidase degradation to ceramide, and these analogs therefore can be used as precursors to monitor cellular GSL anabolism alone. The \( \beta \)-thiolactosyl ceramide was made by coupling a protected thio-Glc-β-Gal to C-4 of a protected galactosyl sphingosine. The inversion of configuration during the \( S_N2 \) reaction generated the correct \( \beta \)-thiolactosyl ceramide. Lactosyl \( \beta \)-thioceramide and glucosyl \( \beta \)-thioceramide were made by condensation of the protected thiourea glucoside or the thioacetyl lactoside donor with a protected iodosphingosine.

The synthesis of glycolipid analogs suitable for microarrays is an important component for defining carbohydrate-binding phenotypes in “glycomics.” These conjugation procedures that allow the solid-phase presentation of the glycolipid carbohydrate moiety are most physiologic when as much of the intact ceramide moiety of the parent GSL as possible is maintained. Serine-based GSL analogs, at least in part, accomplish this. This has been achieved by the use of fluoro hydroxy methophenoxyl acid as the linker to conjugate to microtitre plates (163).
Glycosphingolipids, Chemistry of

A new procedure for GSL synthesis via olefin cross metathesis (164) is highly versatile in terms of the hydrophobic aglycone. A protected 5 carbon amino alkene diol is the central building block to which the protected carbohydrate donor, long chain fatty acid, or, by olefin cross metathesis, the long alkenyl chain of the base can be coupled, in a variety of sequences. This atypical synthetic flexibility should allow a structural approach to dissecting the role of the lipid moiety in GSL receptor function and intracellular trafficking.

Glycosphingolipid mimics

GSLs often serve a receptor function in microbial pathogenesis. Therefore, one therapeutic approach to such infections is the development of soluble inhibitors of this interaction, and such inhibitors are for the most part based on the generation of high-affinity receptor mimics. Ligands that bind GSL sugars that are distal to the glycone are less likely to be affected by the modification or removal of the lipid moiety. Cholera toxin binding to GM1 ganglioside is affected marginally by the nature of the lipid moiety (165). This occurrence has allowed the development of GM1 mimics in which the ceramide is absent. CT binds to a conformer that is similar to the global energy minimum of the free GM1 oligosaccharide (166), and the sugar has been paired away such that the sialic acid is reduced to lactic acid (167) linked to an appropriate conformationally restricted 1,2 dicarboxy-4,5-cyclohexanediol (168) that serves as a simplified mimic of the 3,4 substituted core galactose. This has been multimerized by using a tetraevalent scaffold to improve the affinity for the multivalent toxin B subunit pentamer (169).

Although the dendritic presentation of carbohydrates for glycoprotein binding lectins has been well established (170, 171), the potential multivalency of GSLs within the plasma membrane bilayer is far greater than for glycoproteins, and thus the chemical solution to the generation of synthetic oligosaccharide multimers that retain a binding affinity of the order of the natural membrane GSL has been particularly difficult. In terms of the Escherichia coli-derived verotoxin (also termed Shiga toxin), which is responsible for the development of hemolytic uremic syndrome primarily in children (172), the importance of the lipid moiety of its GSL receptor, globotriaosyl ceramide (Gb3), is clearly apparent (173). Moreover, the pentameric receptor

Figure 9 Selective ceramide deacylation of N-acetylhexosamine that contains GSLs. Gangliotriaosyl ceramide is shown as example. In organic solvent, 1 M base hydrolysis results in the cleavage of both amides, but acetylation in aqueous buffer only affects the amino sugar.

binding B subunit indicates at least five binding sites, which are suggested in the original crystal structure of the VT1 B subunit to be within the intersubunit cleft (174). Modeling studies supported this conclusion (175). However, subsequent co-crystallographic studies with the Gb3 oligosaccharide indicated as many as three binding thermodynamic minimalmonomer (35 in total) (176), which makes the design of inhibitors difficult. The interplay of these potential receptor sites still remains uncertain (177). Although the binding affinity of the lipid-free Gb3 oligosaccharide was of the order of 5 log weaker than that of the intact GSL (178), this affinity was considered an avidity problem, which could be solved by the design of an appropriate dendrimer presentation. The first, and probably the most elegant, approach was the synthesis of a pentamer of globotriaose dimers. This de-cavalent pentamer was based on coupling a globotriaose dimer to a central glucose moiety (179). The intersubunit cleft site was not the major binding site but rather a shallow trough on the surface opposite the bound membrane of each subunit monomer. This surface binding site, site 2, was targeted for occupancy by the pentameric globotriaose array. This “starfish” array proved an effective neutralizing ligand for VT1 but less so for VT2 in terms of both binding inhibition and prevention of cell cytotoxicity in vitro. Subsequent modifications of this pentameric array such that the separation between the globotriaose dimers was increased to accommodate potentially the distance between site 2 and the inter subunit cleft site (site 1) improved efficacy, and this was attributed to dual binding site occupancy (180); however, this was not seen in cocyrstals. Rather, each globotriaose within each dimer occupied equivalent sites in adjacent B subunit pentamers—a pentameric sugar sandwich—and crosslinked adjacent B subunit pentamers to inhibit cytotoxicity. Subsequent studies found that a trimer, rather than the pentamer, of dimers was a more effective ligand substitute for VT2 (181). The crystal structure of VT2 (182) has shown that the C-terminus of the A subunit that penetrates the B subunit pentamer would obstruct receptor binding in the site 3 equivalent of this toxin. The loop that contains the equivalent of site 2 is in a different conformation that also would not allow Gb3 carbohydrate binding. Thus, VT2 may show receptor binding in site 1 only. The other procedure described for the generation of multivalent globotriaose dendrimers for protection against VT1 or VT2 cytotoxicity in vivo is based on carbosilane multimers (183). These multimers are more systematic expansions of trimeric structures that are based on multiples of the tetrameric carbosilane (184). In these studies, coupling the two terminal silicon residues of a linear carboxilane trimer (“super twig”) to either 3 or 9 globotriaose oligosaccharide and the terminal to be substituted with three additional carbosilane units proved the most effective in neutralizing verotoxin in mice. Site-specific mutational studies on the B subunits of VT1 and VT2 showed that sites 1 and 2 were required for “super twig” VT1 binding but that site 3 was central for VT2 binding (184). However, this finding does not reconcile with the VT2 crystal structure that shows that site 3 is inaccessible (182). It is significant that whereas these more densely displayed globotriaose dendrimers proved more effective than the “rational designed” pentameric displays discussed above, both of these synthetic dendrimeric presentations proved less effective than the random coupling of globotriaose to a polyacrylamide support (185), which indicates that a considerable gap still exists in relating the structure of the Gb3 oligosaccharide-verotoxin B subunit complex to the Gb3 GSL binding on target cells (177). The other major GSL receptor function is that of GM1 ganglioside for cholera toxin. In contrast to the verotoxin-Gb3 system, no attempts to generate GM1 receptor mimics to prevent cholera toxin binding have been reported. Although the lipid moiety of GM1 ganglioside plays a less significant role in cholera toxin binding than that which Gb3 plays in VT1 recognition, a chemical substitution of the lipid moiety of GM1 ganglioside has been shown to modify cholera toxin cytotoxicity (186). Substitution of the ceramide moiety for cholesterol, aliphatic amines, or aminophospholipids has been shown to modify the cholera toxin response. The increased aliphatic chain length increased efficacy. The lower functional limit (C12) is similar to the fatty acid chain length dependency for the verotoxin receptor GSL function (186). The GM1-cholesterol analog proved more effective than the native GM1, which may relate to the GM1 raft requirement for cholera toxin cytopathicity (116,116), and implies differential intracellular trafficking of the toxin receptor mimic complexes. GM1 ganglioside is the gold standard marker of lipid raft assembly in plasma membranes (187). A mutation of the cholera toxin B subunit such that a nonraft ganglioside was bound preferentially resulted in the abolition of cholera toxin cytopathicity (116,116). Thus, although the lipid moiety may not be crucial for cholera toxin binding, it is crucial for plasma membrane receptor organization, which in turn defines toxin efficacy. HIV envelope adhesion gp120 binding to several GSLs has been reported (189, 190), and GSL depletion prevents HIV infection (191). HIV binding to galactosyl ceramide is implicated in the infection of CD4 negative cells (192), which has spurred the synthesis of several analogs as a means to control this infection (193–195). The glucose ring of lactose was opened and coupled to aminoundecanoic sodium carboxylate. The amino group then was C16 acylated more. This soluble analog inhibited HIV infection and syncytium formation in vitro (193). Gal Cer analogs were made in which the sphingosine base was truncated via the construction of galactosyl “seritol” (196). This was not bound by gp120, showing the importance of the hydrocarbon chains. Although conjugates that contain a C9 sphinganine did not bind gp120 (196), these could inhibit gp120/GalCer binding according to aglycone structure. Hydroxylation at the C2 position of the fatty acid (even for short chain fatty acids) promoted this inhibition (196). OH and increased hydrocarbon chain length correlated with the calculated head group conformation—at a right angle to the hydrocarbon axis, which indicates that this is the major aglycone effect. Water-soluble C-glycoside analogs of o-lyso-galactosyl ceramide were made (197) via C-glycosyl aldehyde condensation with Wittig reagent to form the trans double bond that was then reduced; the ring was opened and oxidized to form a protected C-glycosyl amino acid. This C-glycosyl amino acid then was coupled to aliphatic amines of increasing chain length. Gp120 binding of the C16 species was equivalent to o-lyso-galactosyl ceramide, and binding was hydrocarbon chain length-dependent.
The GSL carbohydrate binding specificity of gp120 in vitro is lax. The binding to N-stearyl-deoxylactosaminimidocyclon (198) prompted the synthesis of stearyl C-glycoside and azo-C-glycoside analogs of galactosyl ceramide (199). A common precursor, a C1 stearyl galactal, was constructed; it was hydroborated to give the C-glycoside, or it was transformed to a diketone from which the azo-C-glycoside was derived by reduction and amination. By Langmuir trough measurements, these stearyl glycosides showed equal or greater binding to gp120 than galactosyl ceramide. An assay of their efficacy against HIV infection will be of interest. In contrast to the O-glycosides, fatty acid–OH and head group conformation were not found important. This finding could relate to the -OH/anomeric oxygen H-bond in the O-glycosides that restricts the headgroup conformation (196). In the C-glycosides, rotation will be reduced, and this may not be necessary. In addition, a substitution of the anomeric oxygen will make the interface between the “sugar” and the hydrocarbon chain more hydrophobic, which will alter packing and thereby might reduce the effect of the hydrocarbon chain length seen for the O-glycoside. Galactosyl ceramide analogs with hydrophilic (ethylene glycol) spacer groups of increasing length might be restricted to facilitate ligand binding. We have re-considered those sugar sequences adjacent to the ceramide moiety, might be restricted to facilitate ligand binding. We have replaced the fatty acid of several GSLs with rigid carbon frames such as adamantane (202). These structures are surprisingly water-soluble and yet, unlike the lipid-free carbohydrate, retain the receptor function of the native membrane-bound GSL. Our premise is that selection of appropriate chemical substitutions within these frames can promote ligand binding and indeed modulate intracellular trafficking pathways. Adamantyl Gb3 (Pip 3D) is an effective inhibitor of verotoxin GB3 binding (203) and can protect cells against VT cytopathology in culture. However, adamantyl Gb3 is not effective in protecting against VT2 cytopathology in the mouse model (204). Adamantyl Gb3 is, nevertheless, a highly effective ligand for the HIV envelope-protein gp120 (205) and prevents HIV infection in vitro, irrespective of strain or drug-resistant status (206), via inhibition of viral-host gp120-dependent cell fusion. Using a Langmuir trough, we established that the molecular area of adamantyl Gb3 is greater than that of native Gb3. Moreover, an adamantyl Gb3 monolayer was more rigid than that of Gb3. HIV gp120 interaction with Gb3 monolayers was slow and with sigmoidal kinetics, whereas that with adamantyl Gb3 monolayers was rapid and exponential (205). Gp120 interaction with Gb3 became exponential in the presence of cholesterol, which suggests that adamantyl Gb3 may mimic a Gb3:cholesterol complex.

Members of the hsp70 family of stress proteins bind the GSL 3′sulfogalactosyl ceramide (SGC) (207). The binding site is in the N-terminal ATPase domain (208). Adamantyl SGC, similarly generated via fatty acid replacement, similarly has proven water soluble and is an effective inhibitor of hsp70-ATPase activity (209) in vitro and therefore may modulate its chaperone function in cells. Such an effect also has therapeutic potential (210). The high water solubility of these adamantyl GSL derivatives was surprising considering that the adamantane frame is at least as hydrophobic as the fatty acid it replaced. It is possible, however, that the adamantane frame together with the sphingosine acyl chain may pack sufficiently to be below the hydrophobic size that is necessary to disturb the molecular organization of water (211). This situation may provide the basis of their aqueous solubility characteristics.

Acknowledgments

Studies from our laboratory have been supported by grants from CIHR and the Ontario HIV Treatment Network.

Figure 10 Adamantyl Gb3 is a soluble mimic of Gb3 GSL.

The GSL carbohydrate binding specificity of gp120 in vitro is lax. The binding to N-stearyl-deoxylactosaminimidocyclon (198) prompted the synthesis of stearyl C-glycoside and azo-C-glycoside analogs of galactosyl ceramide (199). A common precursor, a C1 stearyl galactal, was constructed; it was hydroborated to give the C-glycoside, or it was transformed to a diketone from which the azo-C-glycoside was derived by reduction and amination. By Langmuir trough measurements, these stearyl glycosides showed equal or greater binding to gp120 than galactosyl ceramide. An assay of their efficacy against HIV infection will be of interest. In contrast to the O-glycosides, fatty acid–OH and head group conformation were not found important. This finding could relate to the -OH/anomeric oxygen H-bond in the O-glycosides that restricts the headgroup conformation (196). In the C-glycosides, rotation will be reduced, and this may not be necessary. In addition, a substitution of the anomeric oxygen will make the interface between the “sugar” and the hydrocarbon chain more hydrophobic, which will alter packing and thereby might reduce the effect of the hydrocarbon chain length seen for the O-glycoside. Galactosyl ceramide analogs with hydrophilic (ethylene glycol) spacer groups of increasing length might be restricted to facilitate ligand binding. We have re-considered those sugar sequences adjacent to the ceramide moiety, might be restricted to facilitate ligand binding. We have replaced the fatty acid of several GSLs with rigid carbon frames such as adamantane (202). These structures are surprisingly water-soluble and yet, unlike the lipid-free carbohydrate, retain the receptor function of the native membrane-bound GSL. Our premise is that selection of appropriate chemical substitutions within these frames can promote ligand binding and indeed modulate intracellular trafficking pathways. Adamantyl Gb3 (Pip 3D) is an effective inhibitor of verotoxin GB3 binding (203) and can protect cells against VT cytopathology in culture. However, adamantyl Gb3 is not effective in protecting against VT2 cytopathology in the mouse model (204). Adamantyl Gb3 is, nevertheless, a highly effective ligand for the HIV envelope-protein gp120 (205) and prevents HIV infection in vitro, irrespective of strain or drug-resistant status (206), via inhibition of viral-host gp120-dependent cell fusion. Using a Langmuir trough, we established that the molecular area of adamantyl Gb3 is greater than that of native Gb3. Moreover, an adamantyl Gb3 monolayer was more rigid than that of Gb3. HIV gp120 interaction with Gb3 monolayers was slow and with sigmoidal kinetics, whereas that with adamantyl Gb3 monolayers was rapid and exponential (205). Gp120 interaction with Gb3 became exponential in the presence of cholesterol, which suggests that adamantyl Gb3 may mimic a Gb3:cholesterol complex.

Members of the hsp70 family of stress proteins bind the GSL 3′sulfogalactosyl ceramide (SGC) (207). The binding site is in the N-terminal ATPase domain (208). Adamantyl SGC, similarly generated via fatty acid replacement, similarly has proven water soluble and is an effective inhibitor of hsp70-ATPase activity (209) in vitro and therefore may modulate its chaperone function in cells. Such an effect also has therapeutic potential (210). The high water solubility of these adamantyl GSL derivatives was surprising considering that the adamantane frame is at least as hydrophobic as the fatty acid it replaced. It is possible, however, that the adamantane frame together with the sphingosine acyl chain may pack sufficiently to be below the hydrophobic size that is necessary to disturb the molecular organization of water (211). This situation may provide the basis of their aqueous solubility characteristics.

Starch is a major storage compound in plants that is present both in leaves and in storage tissues. Biochemical and molecular biological data show that ADP-glucose is the glucosyl donor for plant starch synthesis, and its synthesis is catalyzed by ADP-glucose pyrophosphorylase. Subsequently, starch synthases catalyze the transfer of the glucosyl residue from ADP-glucose to the oligosaccharide chains of the starch components amylose and amylpectin to form new α-1,4-glucosidic residues. After elongation of these α-1,4-glucosidic chains, the branching enzyme catalyzes a cleavage of the elongated chain and transfers the cleaved portion of the oligosaccharide chain to either another region in the amylopectin molecule or to a new amylpectin and forms a new α-1,6-glucosidic linkage. Amylose synthesis is catalyzed by the granule-bound starch synthase. Regulation of starch synthesis occurs at the ADP-glucose pyrophosphorylase step. The enzyme from higher plants, green algae, and cyanobacteria is activated allosterically by 3-phosphoglycerate and inhibited by inorganic phosphate. Isolation of mutants and control analyses indicate that the allosteric activation and inhibition are of physiological and functional importance in the regulation of starch synthesis. Furthermore, evidence indicates that ADP-glucose pyrophosphorylases can also be regulated by a redox mechanism. The current knowledge of the enzyme structures and critical amino acids necessary for substrate binding, allosteric effector binding, regulation, and catalysis for the ADP-glucose pyrophosphorylase is reviewed.

The enzymatic reactions involved in starch synthesis in higher plants and algae and in glycogen synthesis in cyanobacteria are reviewed in this article. Regulation of α-1,4 and α-1,6 glucan synthesis at the enzymic level is discussed, and mutants that cause specific enzymatic deficiencies that affect starch structure are also reviewed. Recent reviews on starch synthesis have been published and are noted (1–6).

Localization of Starch in Plants

Starch is present in every type of tissue, such as leaves, fruit, pollen grains, roots, shoots, and stems. Formation of starch granules occurs in the chloroplast during exposure of leaves to bright light because of carbon uptake during photosynthesis. Loss of leaf starch occurs in low light or in long dark periods of 24-48 hours when it is degraded to products that are used for sucrose synthesis. Arabidopsis thaliana mutants that cannot synthesize starch grow as well as wild type when placed in continuous light as they can synthesize sucrose (7). However, if grown in a day-night regime, the growth rate is dramatically decreased because starch is required for sucrose synthesis at night. Thus, leaf starch synthesis and use is a dynamic process with diurnal fluctuations.

Starch synthesis occurs during development and maturation of plant storage organs. During sprouting or germination of the seed or tuber or in fruit ripening, the reserved starch is degraded, and its metabolites are sources for carbon and energy. Thus, reserved starch degradation and synthesis are time-separated events. Cereal grain starch-storage tissue is the endosperm, with starch granules located in the amyloplasts. Reserve starch content varies from 65% to 90% of the total dry weight.

The starch granule contains two polysaccharide types: amylose, which is a linear polymer, and amylpectin, which is a branched polymer. Amylose is composed of linear chains of about 800 to 22,000 α-D-glucopyranosyl units in (α-1,4) linkage.
Figure 1  Cluster model of amylopectin (10). A indicates A chains. A chains have no other oligosaccharide chains attached to them. B indicates B chains that are defined as having one or more oligosaccharide chains (either A or B) attached to them. The C chain, which is not labeled, has the only reducing end group \( \Omega \) in the polysaccharide. B3 chains are longer than B2 chains, which are longer than the B1 chains. The B2, B3, and B4 (not shown) chains extend into 2, 3 and 4 cluster regions, respectively. The average chain lengths are B1, 19; B2, 41; B3, 169; and B4, 109. For the A chains, the shortest chain length is about 13.

(molecular size \( \sim 1.36 \times 10^5 \) to \( 3.5 \times 10^6 \)). Amylose molecules may be slightly branched (branch chain, 170 to 500 glucosyl units). Amylopectin, which comprises about 70-80% of the starch granule, has 4-5% of the glucosidic linkages as branch points.

The accepted models of proposed amylopectin structures, which are known as cluster models, are those of Robin et al. (8), Manners and Matheson (9), and Hizukuri (10). Reviews that detail chemical and physical properties of starch are given by Morrison and Karkalis (11) and Hizukuri (12). Figure 1 shows the proposed cluster structure.

Starch Synthesis Reactions in Plants and Algae and Glycogen Synthesis in Cyanobacteria

ADP-glucose is used for synthesis of \( \alpha-1,4 \) glucosidic linkages in amylose and amylopectin. Its synthesis is catalyzed by ADP-glucose pyrophosphorylase (reaction 1, E.C. 2.7.7.27; ATP: \( \alpha \)-D-glucose-1-phosphate adenylyltransferase).

\[
\text{ATP + } \alpha\text{-glucose 1-P } \rightleftharpoons \text{ADP-glucose + PPI} \tag{1}
\]

Synthesis of the \( \alpha-1,4 \) glucosidic bond in starch is catalyzed by starch synthase (E.C. 2.4.1.21; ADP-glucose: 1,4-\( \alpha \)-D-glucan 4-\( \alpha \)-glucosyltransferase; reaction 2) and was first reported by Leloir (13, 14). Similar reactions are seen for glycogen synthesis in bacteria (15), and the enzyme is termed glycogen synthase (also E.C. 2.4.1.21).

\[
\text{ADP-glucose + 1, 4-\alpha-glucan } \rightarrow \text{1, 4-\alpha-glucosyl-1, 4-\alpha-glucan + ADP} \tag{2}
\]

Synthesis of the \( \alpha-1,6 \) glucosidic bonds in amylopectin is catalyzed by a branching enzyme (E.C. 2.4.1.18; 1,4-\( \alpha \)-D-glucan 6-\( \alpha \)-glucosyltransferase; reaction 3). Amylopectin contains longer chains (about 20-24 glucosyl units) and has less branching (~5% of the glucosidic linkages are \( \alpha-1,6 \)) than animal or bacterial glycogen (10-13 glucosyl units and 10% of linkages, \( \alpha-1,6 \)).

\[
\text{Elongated } \alpha-1,4\text{-malto oligosaccharide chain } \rightarrow \text{1, 4-1, 6 branched- } \alpha\text{-Glucan} \tag{3}
\]

Isozymes of plant starch synthases (2, 16–20) and branching enzymes (2, 16, 21–26) have been characterized. Presumably, they play distinct roles in amylopectin and amylose synthesis. Also, plant and Chlamydomonas reinhardtii granule-bound starch synthases (27–33) are responsible for synthesis of amylose. Mutants defective in this enzyme are known as waxy mutants and contain starch granules that have little or no amylose.

A debranching enzyme called isoamylase is involved in synthesis of the starch granule and its polysaccharide components (34–37). Mutant plants deficient in isoamylase activity accumulate a soluble \( \alpha \)-glucan designated phytoglycogen (3, 37, 38) and little starch.

Properties of the Plant 1,4-\( \alpha \)-Glucan Synthesizing Enzymes

ADP-glucose pyrophosphorylase: kinetic properties

The ADP-glucose pyrophosphorylases (ADP-Glc PPases) of higher plants, green algae, and the cyanobacteria are activated allosterically by 3-phosphoglycerate (3-PGA) and inhibited by inorganic phosphate (Pi). These effects are important in regulation of starch synthesis. Both potato tuber (2, 39-49) and spinach leaf ADP-Glc PPases (50–52) have been studied in detail with respect to kinetic properties. The kinetic and regulatory properties of the ADP-Glc PPases of several leaf extracts are similar to those of the spinach leaf enzyme (50). The results obtained with potato tuber and spinach leaf enzyme are summarized in Table 1.
heterotetrameric-subunit structure. The potato tuber ADP-Glc PPase has been shown to be heterotetramers with two homologous subunits in plants and green algae, however, the ADP-Glc PPase is homotetrameric in structure. Bacterial ADP-Glc PPase is composed exclusively of 85–95% identity (54). The small subunit of many higher plant ADP-Glc PPases is active in the presence of high concentrations of the activator 3-PGA. The PPase small subunit can be expressed as a homotetramer and is the activator 3-PGA than the heterotetramer (A0.5 = 0.63 mM) (42). The large subunit of the potato greatly increases the affinity of the small (catalytic) subunit for 3-PGA and lowers the affinity for the inhibitor Pi (41, 42).

In plants, only one conserved small (catalytic) subunit and several large (regulatory) subunits are distributed in different parts of the plant (56, 57). This finding is of physiological significance as expression of different large subunits in different plant tissues may confer distinct allosteric properties to the ADP-Glc PPase needed for the plant tissue’s distinct need for starch.

It has been shown with Arabidopsis ADP-Glc PPase that expression of its small-subunit APS1 with the different Arabidopsis large subunits, which include APL1, APL2, APL3, and APL4, resulted in heterotetramers with different regulatory and kinetic properties (56) (Table 2 and Table 3). The heterotetramer of the small-subunit APS1 with APL1, which is the predominant leaf large subunit, had the highest sensitivity to the allosteric effectors 3-PGA and Pi as well as the highest apparent affinity for the substrates ATP and Glc-1-P. The heterotetrameric pairs of APS1 with either APL3 or APL4, which are large subunits prevalent in sink or storage tissues (57), had a lower apparent affinity for the substrates ATP and Glc-1-P and a higher affinity for the inhibitor Pi (I0.5 = 0.08 mM in the presence of 3-mM 3-PGA) as compared with the heterotetramer (I0.5 = 0.63 mM) (42).

Table 1: Kinetic constants of ADP-Glc PPases from Spinach leaf and potato tuber. S0.5 is the concentration of substrate ATP or Glc-1-P required to attain 50% of Vmax. A0.5 is the concentration of activator 3-PGA required for 50% maximal activation. I0.5 is the concentration of inhibitor need for 50% inhibition. Table 2: Kinetic parameters for the 3-PGA of A. thaliana recombinant ADP-Glc PPase in the synthesis direction (56)
The similarity between the small and large subunits (large subunits
relationships conferred by the Arabidopsis large subunits were found in vitro. Differences noted for source and sink large-subunit pro-
teins strongly suggest that starch synthesis is modulated in a tissue-specific manner in response to 3-PGA and Pi, as well as to the substrate levels. APS1 and APL1 would be regulated finely in source tissues by both effectors and substrates, whereas in sink tissues, the heterotetramers of APS1 with APL2, APL3, or APL4 with lower sensitivity to effectors, and substrates would be controlled more by the supply of substrates. Based on mRNA expression, APS1 is the main small subunit or catalytic isoform responsible for ADP-Glc PPase activity in all tissues of the plant. APL1 is the main large subunit in source tissues, whereas APL3 and APL4 are the main isoforms present in sink tissues. It was also found that sugar regulation of ADP-Glc PPase genes was restricted to APS1 and APL4 in leaves (57). Sucrose induction of APL3 and APL4 transcription in leaves allowed formation of heterotetramers less sensitive to the allosteric effectors, which resembles the situation in sink tissues.

Relationship between the small and large subunits

The similarity between the small and large subunits (~50 to 60% identity) suggests a common origin (54). In both sink and source tissues, the small subunit has catalytic activity, whereas catalytic activity is only observed for the large subunits that may reside in the leaf and not in the sink large subunits (55). Gene duplication and divergence probably has led to different and functional catalytic and regulatory roles for the subunits. The ancestor of small and large subunits possibly is a bacterial subunit that has both catalytic as well as regulatory function in the same subunit. This suggestion is supported by the similarity between the two plant subunits with many active bacterial ADP-Glc PPases (5, 53).

The large subunit from the potato (Solanum tuberosum L.) tuber ADP-Glc PPase was shown to bind substrates (44). Therefore, the plant heterotetramer, and bacterial homotetramers bind four ADP- [14 C] glucose molecules (44, 58). It can be postulated that the large subunit maintained its structure needed for binding of substrate, but catalytic ability was eliminated by mutations of essential residues. To test this hypothesis, it was attempted to create a large subunit with significant catalytic activity by mutating as few residues as possible (49). Thus, sequence alignments of ADP-Glc PPase large and small subunits with reported activity were compared to identify critical missing residues for catalytic activity in the large subunit (49). The subset of the residues absent in the large subunit was of particular interest. In the large subunit of potato tuber, Lys44 and Thr54 were selected as the best candidates to study because the homologous residues Arg33 and Lys43 in the small (catalytic) subunit were conserved completely in the active bacterial and plant catalytic subunits. Moreover, Lys44 and Thr54 are in a highly conserved region of ADP-Glc PPases (Table 4).

The modulatory large subunits Lys44 and Thr54 were mutated to Arg44 and Lys44, respectively. The mutant, LargeK44R/T54K, was expressed in the absence of the small subunit, and it had no activity. Possibly the large subunit cannot form a stable tetramer in absence of the small subunit as observed earlier with the Arabidopsis enzyme (56). Because a wild-type small subunit has intrinsic activity, the activity of the large-subunit mutants cannot be tested when coexpressed. Thus, the large-subunit mutants were coexpressed with inactive small-subunit D145N, in which the catalytic residue Asp145 was mutated (59), and small subunit activity was reduced by more than three orders of magnitude (Table 5). Coexpression of the large-subunit double mutant K44R/T54K with smallD145N generated an enzyme that had 10% and 18% of the wild-type enzyme in the ADP-glucose synthetic and pyrophosphorylating directions, respectively (Table 5). Single mutations of K44R or T54K generated enzymes with no significant activity. The combination of both mutations in the large subunit (smallD145N/largeK44R/T54K) gave the most dramatic effect (Table 5). Therefore, it was concluded that the two residues Arg44 and Lys54 are needed for restoring catalytic activity to the large subunit. Replacement of the homologous two residues with Lys and Thr in the small subunit (mutations R33K and K43T) decreased the activity by one and two orders of magnitude, respectively (Table 5).

The similarity between the small and large subunits (~50 to 60% identity) suggests a common origin (54). In both sink and source tissues, the small subunit has catalytic activity, whereas catalytic activity is only observed for the large subunits that may reside in the leaf and not in the sink large subunits (55). Gene duplication and divergence probably has led to different and functional catalytic and regulatory roles for the subunits. The ancestor of small and large subunits possibly is a bacterial subunit that has both catalytic as well as regulatory function in the same subunit. This suggestion is supported by the similarity between the two plant subunits with many active bacterial ADP-Glc PPases (5, 53).

20 mM of 3-PGA was used for the APS1 enzyme in determining the ATP and the Glc-1-P kinetic constants. For the APS1/apl1 kinetic study, 0.1 mM of 3-PGA was used. 4 mM of 3-PGA was used for the APS1/apl2. 2 mM of 3-PGA was used for the APS1/apl3, and 1 mM of 3-PGA was used for the APS1/apl4 kinetic studies. These concentrations were five times the 3-PGA A0.5 of each enzyme, respectively.

Intermediate sensitivity to the allosteric effectors and intermediate affinity for the substrates ATP and Glc-1-P (57). APL2 also present mainly in sink tissues had low affinity for either 3-PGA or Pi (56). Thus, differences on the regulatory properties conferred by the Arabidopsis large subunits were found in vitro. Differences noted for source and sink large-subunit proteins strongly suggest that starch synthesis is modulated in a tissue-specific manner in response to 3-PGA and Pi, as well as to the substrate levels. APS1 and APL1 would be regulated finely in source tissues by both effectors and substrates, whereas in sink tissues, the heterotetramers of APS1 with APL2, APL3, or APL4 with lower sensitivity to effectors, and substrates would be controlled more by the supply of substrates. Based on mRNA expression, APS1 is the main small subunit or catalytic isoform responsible for ADP-Glc PPase activity in all tissues of the plant. APL1 is the main large subunit in source tissues, whereas APL3 and APL4 are the main isoforms present in sink tissues. It was also found that sugar regulation of ADP-Glc PPase genes was restricted to APS1 and APL4 in leaves (57). Sucrose induction of APL3 and APL4 transcription in leaves allowed formation of heterotetramers less sensitive to the allosteric effectors, which resembles the situation in sink tissues.
and not smallD145N was the catalytic subunit. In the wild-type small subunit did not indicate the large subunit double mutant, K213R mutation of a large subunit severely decreased the apparent affinities of Lys198 in the small subunit of the wild-type enzyme, decreased the Glc-1-P affinity was observed; disruption of the substrate site domain has been conserved. The apparent affinities for the substrates and the allosteric properties of small subunit were very similar kinetic properties, which indicated that the substrate site domain has been conserved. The apparent affinities for the substrates and the allosteric properties of small subunit were very similar kinetic properties, which indicated that the subunit is essential for catalysis, but homologous Asp160 in the large subunit is not essential for catalysis (59). In addition, mutation of D160 to N or E in the active large subunit, LK44R/T54K abolished activity. This result confirms that catalysis of smallD145Nlarge K44R/T54K does occur in the large subunit.

A comparative model of LK44R/T54K shows the predicted role of Arg44 and Lys54 (Fig. 2). In the model, Asp160, which is homologous to the catalytic Asp145 in the small subunit and catalytic Asp142 in the E. coli ADP-Glc PPase (59, 60), interacts with Lys54. This type of interaction (Lys54-Asp145) has also been observed in crystal structures of enzymes that catalyze similar reactions, such as dTDP-glucose pyrophosphorylase (dTDP-Glc PPase) and UDPN-N-acetyl-glucosamine pyrophosphorylase (UDPGalNAc PPase). It is postulated to be important for catalysis by orienting the aspartate residue correctly (61–63). Lys54 interacts with the oxygen that bridges the γ-phosphates of ATP, which correlates with the transition state and makes PPi a better leaving group. Arg44 interacts in the model with the ζ-phosphates as it has been observed in the crystal structure of E. coli dTDP-Glc PPase (63). The interaction neutralizes a negative charge density to stabilize the transition state and make PPi a better leaving group. A n44 interacts in the model with the ζ- and γ-phosphates of ATP, which correspond to the PPI byproduct (Fig. 2). Likewise, Arg15 in the E. coli dTDP-Glc PPase (63).

The enzymes activities of purified coexpressed small and large subunits were measured for ADP-glucose synthetic activity or ADP-glucose pyrophosphorylase (ATP synthesis) activity. For ADP-glucose synthesis, 4 mM of 3-PGA (activator), 2 mM of ATP, and 0.5 mM of Glc-1-P were used. For pyrophosphorylase, 4 mM of 3-PGA, mM of ADP-Glc, and 1.4 mM of PPI were used.
The crystal structure of potato tuber homotetrameric small subunits ADP-Glc PPase was also inhibited by inorganic sulfate with the $K_i$ value of 2.8 mM in the presence of 6 mM 3-PGA (48). Sulfate is considered as an analog of phosphate, which is the allosteric inhibitor of plant ADP-Glc PPases. Thus, the atomic resolution structure of the ADP-Glc PPase probably presents a conformation of the allosteric enzyme in its inhibited state. The crystal structure of the potato tuber ADP-Glc PPase (48) allows one to determine the location of the activator and substrate sites in the three-dimensional structure and their relation to the catalytic residue Asp145. The structure also provides insights into the mechanism of allosteric regulation.

Supporting data for the physiological importance of regulation of ADP-glucose pyrophosphorylase

The reaction catalyzed by plant ADP-Glc PPases is activated by 3-P-glycerate and inhibited by orthophosphatase; it is an important step for regulation of starch synthesis in higher plants as well as in the cyanobacteria (see reviews in Reference 5 and 33). In addition, it has been shown that in higher plants the enzyme activity can also be regulated by its redox state (46, 47).

Considerable experimental evidence is available to support the concept that ADP-Glc PPase is an important regulatory enzyme for the synthesis of plant starch. A class of C. reinhardtii starch-deficient mutants have been isolated and shown to contain an ADP-Glc PPase not activated by 3-P-Glca (64, 65). Evidence for the allosteric regulation by ADP-Glc PPase being pertinent in vivo has also been obtained with A. thaliana (66, 67). Mutant TL25 lacked both subunits and accumulated less than 2% of the limits of detection of starch observed in the normal plant (66), which would indicate that starch synthesis is almost completely dependent on the synthesis of ADP-glucose. The mutant TL 46 is also starch deficient, and it lacked the regulatory 54-kDa subunit (67). The mutant had only 7% of the wild-type ADP-Glc PPase activity in potato tuber and wheat endosperm (71) leads to increase of starch. This finding also has been shown for rice (72) as well as for cassava root (73). These results confirm that ADP-Glc synthesis is rate limiting for starch synthesis. Thus, data observed with the allosteric mutant ADP-Glc PPases of C. reinhardtii (64), maize endosperm (68), and Arabidopsis (66, 67) present strong evidence that in vitro allosteric effects are functional in vivo.

**Phylogenetic analysis of the large and small subunits**

A phylogenetic tree of the ADP-Glc PPases present in photosynthetic eukaryotes also sheds information about the origin of the subunits (Fig. 3). The tree shows that plant small and large subunits can be divided into two and four distinct groups, respectively (49). The two main groups of small subunits are from dicot and monocot plants, whereas large-subunit groups correlate better with their documented tissue expression. The first large-subunit group, which is termed group 1, is generally expressed in photosynthetic tissues (49) and comprises large subunits from dicots and monocots. These subunits have been shown recently to have catalytic activity and have in their sequences Arg and Lys in the equivalent residues of 102 and 112 of A. thaliana large subunit, APL1. Group 2 displays a broader expression pattern, whereas groups 3 and 4 are expressed in storage organs (roots, stems, tubers, seeds). Subunits from group 3 are only from dicot plants, whereas group 4 includes seed-specific subunits from monocots. These last two groups stem from the same branch of the phylogenetic tree and split before monocot and dicot separation (49). These subunits are probably inactive in catalytic activity as they are lacking Arg and Lys in the homologous residues observed in A. thaliana APL1 and APL2.

**Crystal structure of potato tuber ADP-Glc PPase**

The crystal structure of potato tuber homotetrameric small subunits ADP-Glc PPase has been determined to 2.1Å resolution (48). The structures of the enzyme in complex with ATP and ADP-Glc were determined to 2.6 and 2.2 Å resolution, respectively. Ammonium sulfate was used in the crystallization process and was found tightly bound to the crystalline enzyme. It was also shown that the small-subunit homotetrameric potato tuber ADP-Glc PPase was also inhibited by inorganic sulfate with the $K_i$ value of 2.8 mM in the presence of 6 mM 3-PGA (48). Sulfate is considered as an analog of phosphate, which is the allosteric inhibitor of plant ADP-Glc PPases. Thus, the atomic resolution structure of the ADP-Glc PPase probably presents a conformation of the allosteric enzyme in its inhibited state. The crystal structure of the potato tuber ADP-Glc PPase (48) allows one to determine the location of the activator and substrate sites in the three-dimensional structure and their relation to the catalytic residue Asp145. The structure also provides insights into the mechanism of allosteric regulation.

**Figure 2** Involvement of large (regulatory) subunit mutant K44R/T54L in ADP-Glc PPase catalysis. The WT and double-mutant large subunits were modeled based on the dTDP-Glc PPase and UDP-UDPGlcNAc PPase crystal structures as indicated in the text. Portions of ADP-Glc PPase residues 31–73 and 111–134 are shown. The dessolvation triphosphate portion common to dTTP and ATP is modeled with Mg$^{2+}$ as a black sphere. The dotted lines depict hydrogen bonds.
Plant ADP-Glc PPases can be activated by thioredoxin

ADP-Glc PPase from potato tuber has an intermolecular disulfide bridge that links the two small subunits by the Cys12 residue; it can be activated by reduction of the Cys12 disulfide linkage (46). At low concentrations (10\(\mu\)M) of 3-PGA, both spinach leaf reduced thioredoxin f and m reduce and activate the enzyme. Fifty percent activation was observed for 4.5- and 8.7- \(\mu\)M reduced thioredoxin f and m (47). The activation was reversed by oxidized thioredoxin. Cys12 is conserved in the ADP-Glc PPases from plant leaves and other tissues except for the monocot endosperm enzymes. In photosynthetic tissues, this reduction may also be physiologically pertinent in the fine regulation of the ADP-Glc PPase.

Both potato tuber and potato leaf ADP-Glc PPases are plastidic; the leaf enzyme is in the chloroplast, and the tuber enzyme is in the amyloplast (74). The ferredoxin/thioredoxin system is located in the chloroplast and thus, with photosynthesis, reduced thioredoxin is formed and activated within the leaf ADP-Glc PPase. At night, oxidized thioredoxin is formed; it oxidizes and inactivates the ADP-Glc PPase. This activation/inactivation process during the light/dark cycle allows a fine tuning and dynamic regulation of starch synthesis in the chloroplasts. Thioredoxin isoforms are present in many different subcellular locations of plant tissues: cytosol, mitochondria, chloroplasts, and even nuclei (75) and are also present in amyloplasts (76).

It has been shown starch synthesis that occurs in potato tubers from growing plants is inhibited within 24 hours after detachment (77) despite having high in vitro ADP-Glc PPase activity and high levels of substrates, as well as ATP and Glc-1-P and an increased 3-PGA/Pi ratio. In the detached tubers, the small subunit in nonreducing SDS-PAGE is solely in dimeric form and relatively inactive in contrast to the enzyme form of growing tubers where it was composed as a mixture of monomers and dimers. The detached tuber enzyme had a great decrease in affinity for the substrates as well as for the activator. Treatment of tuber slices with either DTT or sucrose reduced dimerization of the ADP-Glc PPase small subunit and stimulated starch synthesis in vivo. These results indicate that inactivative activation, which was observed in vitro of the tuber ADP-Glc PPase (46, 47), is important for regulating starch synthesis (77). A strong correlation between sucrose content in the tuber and the reduced/activated ADP-Glc PPase was noted.

Characterization of ADP-Glc PPases from some different sources

As previously indicated, Table 1 summarizes the kinetic and regulatory properties of purified potato tuber and spinach leaf ADP-Glc PPases. As reviewed in References 5 and 53, the properties of many other plant, algae, and cyanobacterial ADP-Glc PPases are similar. However, some ADP-Glc PPases within plant reserve tissue show some differences with respect to allosteric properties and their nonplastidic location. These examples are summarized below.
Barley

The barley leaf ADP-Glc PPase has been purified to homogeneity (93 U/mg), and it shows high sensitivity toward activation by 3-PGA and inhibition by phosphate (78). Substrate kinetics and product inhibition studies in the synthesis direction suggested a sequential (ordered) Bi Bi kinetic mechanism (78). ATP or ADP-Glc bind first to the enzyme in the synthesis or pyrophosphorylation direction, respectively, which is similar to the E. coli enzyme (58).

Partially purified barley endosperm ADP-Glc PPase was shown to have low sensitivity to the regulators 3-PGA and Pi (78). However, 3-PGA decreased up to threefold the $S_{0.5}$ for ATP and the Hill coefficient. At 0.1-mM ATP, the activation by 3-PGA was around fourfold (79), and phosphate 2.5 mM reversed the effect. A recombinant enzyme with a (His)$_6$-tag from barley endosperm was expressed using the baculovirus insect cell system (80). It shows no sensitivity to regulation by 3-PGA and Pi. However, the enzyme was assayed at saturating concentration of substrates and only in the pyrophosphorylation direction. For ADP-Glc PPases, the synthetic direction is more sensitive to activation. When the recombinant enzyme without the (His)$_6$-tag is expressed in insect cells, the heterotetrameric form still was not activated by 3-PGA nor inhibited by Pi at saturating levels of substrates (82). Whether 3-PGA had any effect on the affinity for the substrates as shown in the enzyme purified from the endosperm was not reported. Of interest is that the small (catalytic) subunit, when expressed alone it is very sensitive to activation by 3-PGA, and inhibition by Pi is opposite of what is observed for large subunits of potato tuber (42, 45) and Arabidopsis (56).

Identification of Important Amino Acid Residues Within the ADP-Glc PPases

Amino acid residues that play important roles in the binding of substrates and allosteric regulators have been identified in the ADP-Glc PPases mainly by chemical modification and site-directed mutagenesis studies. Thus, photoaffinity analogs of ATP and ADP-Glc, 8-azido-ATP, and 8-azido-ADP-Glc were used to identify Tyr114 as an important residue in the enzyme from E. coli (95, 96). Site-directed mutagenesis of this residue rendered a mutant enzyme that exhibits a marked increase in $S_{0.5}$ for ATP as well as a lower apparent affinity for Glc-1-P and the activator Fru1,6-bisP (95). The Tyr residue must be close to the adenine ring of ATP or ADP-Glc but probably also near the Glc-1-P and the activator regulatory sites. The homologous Tyr114 in the enzyme from plants is a Phe residue (54), which suggests that the functionality is not given by the specific residue but by its hydrophobicity.

Chemical modification studies on the E. coli ADP-Glc PPase that showed involvement of Lys198 in the binding of Glc-1-P (97, 98) were confirmed by site-directed mutagenesis (99). Site-directed mutagenesis was also used to determine the role of this conserved residue in the small subunit Lys198 and large-subunit Lys213 of the potato tuber ADP-Glc PPase (44). Mutation of Lys198 of the small subunit with Arg, Ala, or Glu decreased the apparent affinity for Glc-1-P 135-fold to 550-fold. Little effect is observed on kinetic parameters for ATP, Mg$^+$, 3-PGA, and Pi. The results show that the Lys198 in the small subunit is involved directly in the binding of Glc-1-P. However, the homologous site residue Lys213 in the large subunit does not seem to be involved because similar mutations on Lys213 had little effect on the affinity for Glc-1-P (44). This finding is consistent with the view that the potato tuber large subunit is a modulatory subunit and does not have a catalytic role (42).

Maize endosperm

Partially purified maize endosperm ADP-Glc PPase (34 U/mg) was found to be activated by 3-PGA and Fru 6-P (23- and 17-fold, respectively) and inhibited by Pi (94). The heterotrimeric endosperm enzyme has been cloned and expressed in E. coli, and its regulatory properties were compared with an isolated allosteric mutant less sensitive to Pi inhibition (69). As indicated above, the increase of starch noted in the mutant maize endosperm ADP-Glc PPase insensitive to Pi inhibition supports the importance of the allosteric effects of 3-PGA and Pi in vivo. Also as indicated above, it is believed that the major endosperm ADP-Glc PPase isoform is located in the cytosol (83).
potato tuber ADP-Glc PPase. The homologous residues of the small subunit Asp145 and large subunit Asp160 were replaced separately by either Asn or Glu residues (59). Mutation of the Asp145 of the small subunit rendered the enzymes almost completely inactive. D145N mutant activity decreased by four orders of magnitude, whereas D145E, which is a more conservative mutation, decreased in specific activity by just two orders of magnitude. The homologous mutations in the large subunit alone (D160) did not alter the specific activity, but they did affect the apparent affinity for 3-PGA (59). Thus, these results agree with the view that each subunit in potato tuber ADP-Glc PPase plays a particular role: the small subunit controls catalysis and the large subunit plays a regulatory role.

Pyridoxal-5-phosphate (PLP) could be considered to have some structural analogy to 3-PGA, and it was found to activate both the enzymes from spinach leaf and *Anabaena*. In spinach ADP-Glc PPase, PLP bound at Lys440, which is very close to the C-terminal of the small subunit, and bound to three Lys residues in the large subunit. Binding to these sites was prevented by the allosteric effector 3-PGA, which indicated that they are close to or are involved directly in the binding of this activator (100, 101).

With *Anabaena* ADP-Glc PPase, PLP modified Lys439 and Lys382. That these residues were regulatory binding sites was confirmed by site-directed mutagenesis of the *Anabaena* ADP-Glc PPase (102, 103). Mutation of the homologous Lys residues in the potato tuber enzyme small-subunit Lys441 and Lys404 indicated that they were also part of the 3-PGA site in heterotetrameric ADP-Glc PPases and that they contribute additively to the binding of the activator (45). Moreover, mutation on the small subunit yielded enzymes with lesser affinity to 3-PGA, measured by 3090-fold and 54-fold, respectively, than the homologous mutants on the large subunit. Results indicate that Lys404 and Lys441 on the potato tuber small subunit are more important than their homologous counterparts on the large-subunit Lys417 and 455. It seems that the large subunit seems to contribute to the enzyme activation by making the activator sites already present in the small subunit more efficient rather than by providing more effective allosteric sites (45).

Arginine residues were found in ADP-Glc PPases from cyanobacteria to be functionally important as shown by chemical modification with phenylglyoxal (104, 105). A loss, the role played by Arg294 in the inhibition by Pi of the enzyme from *Anabaena* PCC 7120 was shown by Ala-scanning mutagenesis studies (105). More recently, it was found that replacement of this residue with Ala or Gin produces mutant enzymes with a changed pattern of inhibitor specificity; it was found that they have NADPH rather than Pi as the main inhibitor (126). All these results suggest that the positive charge of Arg294 may play a key role in determining inhibitor selectivity rather than being specifically involved in Pi binding. However, studies on the role of Arg residues located in the N-terminal of the enzyme from *A. tumefaciens* tumefaciens demonstrated the presence of separate subsites for the activators Fructose-6-P and pyruvate as well as a deamidization of R33A and R45A mutants to Pi inhibition (107).

Random mutagenesis experiments performed on the potato tuber ADP-Glc PPase have been useful to identify residues that are important for the enzyme. Mutation of Asp253 on the small subunit showed a specific effect on the Km for Glc-1-P, which increased 10-fold with respect to the wild-type enzyme (108). The small magnitude in the increase (only one, rather than three to four orders of magnitude) suggests that the Asp253 residue is not involved in directly Glc-1-P binding. This residue, however, is conserved in the NDP-sugar PPases that have been crystallized and the structure solved (61-63). Alignment of Asp253 in the structure according to the secondary structure prediction (109) places the residue close to the substrate site without direct interaction with Glc-1-P. This suggests that substitution of the Asp 253 causes an indirect effect on the Glc-1-P by alteration of the Glc-1-P-binding domain. Another random mutagenesis study (110) concerns A. sp416 (described in the article as Asp413) of the potato tuber ADP-Glc PPase small subunit and its effect on 3-PGA activation. This residue is adjacent to Lys417, which has been shown to be a site for PLP binding and 3-PGA activation (100). Also, several modifications on the C-terminus caused modifications on the regulation of different plant ADP-Glc PPases (69, 111).

The finding that Lys and Arg residues are important in allosteric effector binding and are situated at the C-terminus in ADP-Glc PPases of plants and cyanobacteria is different with what is observed for the bacterial ADP-Glc PPases. Lys338 (E. coli) and Arg residues in the N-terminal of the *A. tumefaciens* enzyme were shown to be important for the interaction of the activators and inhibitors (97, 98, 107, 112). These results suggest that the regulatory domains may be at different sites in the bacterial and plant enzymes. Other studies, however, with chimeric ADP-Glc PPases constructed from *E. coli* and *A. tumefaciens* have shown that the C-terminus in the bacterial and plant enzymes is functional in determining effector specificity and affinity (113). Regulation of ADP-Glc PPases most likely is determined by interactions that occur between the N- and C-termini in the enzyme.

**Characterization of the regulatory domain**

Truncation of 10 amino acids in the small subunit of potato tuber ADP-Glc PPase affected its regulatory properties by increasing the apparent affinity for the activator 3-PGA and decreasing the inhibitor Pi affinity (42). When the large (regulatory) subunit was truncated by 17 amino acids at the N-terminal, similar results were observed (114). The regulatory properties of the E. coli enzyme were also affected when the N-terminal is shortened by 11 amino acids (115, 116). The N-terminal region of the ADP-Glc PPase is predicted to be a loop, and the data suggests it regulates enzyme activity by acting as the “allosteric switch”; it is involved in the transition between the activated and nonactivated conformations of the enzyme. A shorter N-terminus allows the enzyme to be in an “activated” conformation.

Phosphorylase stimulation and branching linkage assays units are µmol/min (126). The iodine stain assay unit is (127), a decrease of one Absorbance unit per min.

Starch Synthases and Branching Enzymes

Starch synthase catalyzes transfer of the glucosyl moiety of ADP-glucose either to a maltosaccharide or to the starch polymers, amylase, and amylpectin, which form a new α-1,4-glucosidic linkage in ADP-glucose is, and thus the newly formed glucosidic linkage is retained. The starch synthase is therefore characterized as retaining GT-B glycosyltransferase (117). More than one form of starch synthase is present in many plant tissues. This finding has been summarized in several publications (1–4, 118), and the starch synthases are encoded by more than just one gene. Some starch synthases are bound to the starch granule and are designated as starch granule-bound starch synthases. They may be solubilized by α-amylase digestion of the granule, whereas others designated as soluble starch synthases can be found in the soluble portion of the plastid fraction.

Starch synthase or glycogen synthase activity can be measured by transfer of [14C]glucose from ADP-glucose into an appropriate primer such as amylopectin or rabbit glycogen and then precipitation of the labeled polymer with ethanol (119).

Characterization of the starch synthases

A phylogenetic tree based on the various deduced amino acid sequences of the plant starch synthases and green algae, Chlamydomonas, have identified five subfamilies of starch synthases (2). These subfamilies are known as granule-bound starch synthase (GBSS), starch synthase 1 (SS1), starch synthase 2 (SS2), starch synthase 3 (SS3), and starch synthase 4 (SS4). Additional data indicates that the SS2 class may have diverged even more to classes SS2a and SS2b (120). Also, the GBSS family may have also diverged into another class, GBSS1, GBSS1b or GBSS2 (121–123). The starch synthases are reviewed in detail in Reference 124.

Branching enzyme

As with starch synthases, many isozymes have been found for the Branching Enzyme, and they have been characterized in a number of plants.

Maize endosperm has three branching enzyme (BE) isoforms (24, 25) BE I, IIa, and IIb from maize kernels (3, 125, 126). Molecular weights were 82 KDa for BEI and 80 KDa for BE's IIa and IIb. Table 6 summarizes the in vitro properties of the various maize endosperm BE isoforms from the studies of Takeda et al. (127) and Guan et al. (24, 25). BEI had the highest activity in branching amylose, and its ratio of branching amylpectin was about 3% observed with amylose. The BEIIa and BEIIb isozymes branched amylopectin at twice the rate they branched amylose, and they catalyzed branching of amylopectin at 2.5 to six times the rate observed with BEI. BEI catalyzes the transfer of longer branched chains, and BEIIa and IIb catalyze the transfer of shorter chains (127). This finding may suggest that BEI produces a slightly branched polysaccharide that serves as a substrate for enzyme complexes of starch synthases and BEII isoforms to synthesize amylopectin. BE II isoforms may also play a predominant role in forming the short chains present in amylopectin. Moreover, BEI may be more involved in producing the more interior B-chains of the amylopectin, whereas BEIIa and BEIIb would be involved in forming the exterior (A) chains.

Potato branching enzyme thus shows a high degree of similarity to maize BEI and to maize BEII isoforms, however to a lesser extent (128, 129). As observed with the maize-branching enzymes, potato BEI was more active on amylose than BEII, and BEII was more active on amylopectin than BEI (130–132). Branching isozymes from rice (21, 133), wheat (134, 135), and barley (136, 137) have also been characterized. The effects on starch structure in plants that have mutations in the starch-branching enzymes have been reviewed (2–4, 118, 124).

Chemistry of Lipid Domains

Richard M. Epand, McMaster University Health Sciences Centre, Hamilton, Ontario, Canada
doi: 10.1002/9780470048672.wecb283

Biological Background

To begin with, biological membranes are not uniform with respect to membrane sidedness. Both the protein and the lipid composition of these membranes exhibit transbilayer asymmetry. In addition, in polarized mammalian cells, a segregation of both protein and lipid molecules exists between the apical and basolateral surfaces (1–4). Both transbilayer asymmetry and segregation in polarized cells occur over a long time period with slow exchange between domains. In addition, smaller, more transient domains are present along the plane of the membrane. The roles of these transient lateral domains are likely to be the clustering of molecules in the small volume of a membrane domain to allow for their efficient interaction, which may be particularly important for signal transduction processes in which a series of chemical reactions can lead to amplification of a signal. In addition, the nonuniform distribution of lipid components will result in the physical properties of the membrane varying between a domain and the bulk of the membrane, which, in turn, will modulate the activity of membrane proteins.

Chemistry

We will discuss the chemical composition, size, and lifetime of domains in biological and model membranes. This area is currently under very active investigation, and we are likely to see further developments in the future. We will focus particularly on two types of membrane domains for which there is more evidence for their existence in biological membranes and more characterization of their properties. We can classify...
these domains as either cholesterol-rich domains or anionic lipid clusters.

**Cholesterol-Rich Domains**

Cholesterol is a major lipid component of mammalian cell plasma membranes, accounting for approximately 35% of the total lipid of the membrane. Cholesterol has a chemical structure that is very different from the major polar lipid constituents, which is a consequence of the fused ring system of cholesterol that gives this lipid less conformational flexibility than the straight chains of the polar lipids. It is thus not surprising that cholesterol does not mix well in membranes and that cholesterol segregates as crystals at around 50–60 mol% in bilayers of several lipids and at a much lower molar fraction of cholesterol in bilayers comprising lipids with unsaturated acyl chains (5).

The lateral distribution of molecules in a membrane will be the result of differences in the interaction energies between different groups of molecules. As the chemical structure of cholesterol is very different from that of polar lipids, differences will likely exist in the stability of complexes of peptides or proteins with cholesterol versus those with phospholipids. This property will result in cholesterol being distributed nonuniformly in the membrane at thermodynamic equilibrium. In addition, cholesterol will have different extents of interaction with saturated versus unsaturated polar lipids, a well-studied example of which is in model liposomes is the fluid–fluid immiscibility resulting in the formation of domains in mixtures of dioleoylphosphatidylcholine (DOPC), sphingomyelin, and cholesterol. In these mixtures, a saturated acyl chain of sphingomyelin has more favorable interactions with cholesterol than do the unsaturated acyl chains. If a phosphatidylcholine with saturated acyl chains, dioleoylphosphatidylcholine (DOPC), replaces palmitoyl sphingomyelin (PSM) in mixtures with DOPC and cholesterol, the two phase diagrams are essentially identical (6). The size of the domains formed in such a lipid mixture is of the order of micrometers in diameter (7, 8). One domain is highly enriched in sphingomyelin, whereas the other contains phosphatidylcholine as the major phospholipid. As indicated above, the cholesterol partitioning is preferentially into the more ordered sphingomyelin domain, although the segregation of cholesterol between the domains is only partial (9). Interestingly, substituting DOPC with 1-palmitoyl-2-oleoyl phosphatidylcholine (POPC) into these ternary lipid mixtures with cholesterol results in a large difference between the phase diagrams of POPC/cholesterol/PSM and POPC/cholesterol/DPPC with no miscibility transition observed with the latter mixture (6). In addition to differing in chemical composition, the two immiscible domains have different physical properties. The more ordered domain is the one enriched in sphingomyelin. This phase is still a fluid phase, but it has increased order and has been termed a liquid-ordered phase. Specific properties of the liquid-ordered phase place it between a liquid-disordered phase and an ordered phase. The rate of lateral diffusion of the lipid in the liquid-ordered phase is similar to that in a liquid-disordered phase, making it a liquid phase. In contrast, the acyl chain order parameters are closer to that of an ordered or solid phase, which is a consequence of the neighboring cholesterol inhibiting trans to gauche isomerization of the carbon–carbon single bonds. The coexistence of a liquid-ordered and liquid-disordered domain in a mixture of phospholipids and cholesterol will depend on the chemical nature of the phospholipids, the relative proportion of each of the lipid components, and the temperature. The phase diagram of several three-component systems (two phospholipids and cholesterol) in excess water as a function of temperature has been determined.

Although the characterization of membrane domains that depend on the presence of cholesterol have been well studied and largely understood in model systems, the relevance of this behavior to domains in biological membranes is controversial. However, one type of cholesterol-rich domain exists in the plasma membrane of certain mammalian cells for which there is considerable evidence (10): the caveolae. Caveolae have a lipid composition with an enrichment of cholesterol and sphingomyelin (11) and would therefore be expected to form a liquid-ordered domain that is segregated from the surrounding membrane in a liquid-disordered phase. Caveolae have a distinctive morphological structure of a flask-shaped invagination of approximately 65 nm in diameter that can readily be identified with electron microscopy. This characteristic shape is a consequence of this domain containing a high content of the membrane protein caveolin. Caveolae can be isolated after breaking up the cell membrane, without the use of any detergents (12). Caveolae domains are large, stable, and enriched in cholesterol and sphingomyelin. Their lipid composition and physical state are similar to what is expected for membrane rafts, but the size and lifetime of rafts in biological membranes are much less (13).

The term “raft” has been extensively used in the literature to specify a particular kind of domain in a biological membrane, but its use has often evaded a precise definition. We suggest that a raft be defined as a non-caveolae, cholesterol-rich domain in a biological membrane. As this domain is one with a phase boundary separating it from its surroundings, it would be in a liquid-ordered state. A raft domain would be similar to caveolae except for the distinguishing morphology and presence of the protein caveolin in the latter case. Such a raft domain could be visualized by several imaging methods described below, or its presence could be ascertained with spectroscopic methods. This definition of the physical presence of a cholesterol-rich cluster of molecules in a biological membrane is different from rafts that are defined on the basis of detergent insolubility. The membrane fraction that is insoluble in cold detergent and is in a low density fraction upon ultracentrifugation has been suggested to be similar to raft domains in biological membranes; but it is an extrapolation that is increasingly questioned. This fraction should be referred to as the low density, detergent-resistant fraction and not necessarily representing a raft. Detergent resistance is a phenomenological definition, whereas the term raft should be restricted to a physical structure, a domain, in a membrane.

Several additional features of domains exist in biological membranes that are not present in model systems. Two fundamental features of biological membranes that are not present in model membranes are the presence of proteins and the transbilayer asymmetry. In particular, proteins are a major component of plasma membranes, comprising approximately 50% of
weight of the material. They are also important for domain formation, which is most clear in the case of caveolae, whose presence in cells is closely tied to the expression of caveolin (14). These structures can even be induced to form in cells normally lacking caveolae by inducing the expression of caveolin (15), and caveolae are lost in mice lacking caveolin 1 and 3 (16, 17). However, this example is only one that is specific and well-documented of a protein that affects domain formation. In general, any protein that interacts more favorably with some lipids than with others will result in domain formation. It would be anticipated that, as a consequence of cholesterol increasing the packing density of the membrane, many proteins would be excluded from cholesterol-rich regions (18). The preferential interaction of proteins with cholesterol-depleted domains will result in cholesterol concentrating in a different region of the membrane, resulting in the formation of cholesterol-rich domains. An example of such behavior has been shown with an amphipathic helical peptide (19).

Electrostatically Driven Domain Formation

Another mechanism for domain formation is through the clustering of anionic lipids by cations or by polycationic protein segments. There has been particular interest in the role of proteins with cationic clusters in causing the formation of domains enriched in the polyanionic phospholipid phosphatidylinositol 4,5-bisphosphate (PIP2) (20). In particular, three proteins have been identified that contain cationic clusters, sequester PIP2, and are largely devoid of structure. These proteins are the myristoylated alanine-rich C-kinase substrate (MARCKS), growth-associated protein 43 (GAP43), and neuronal acetyl membrane protein (NAP-22 or CAP23 for the form found in chicken) (21). These proteins have been termed “pipmodulins” because of their ability to modulate the availability of free PIP2. In the case of the MARCKS protein, the electrostatically driven sequestering of PIP2 by the cationic cluster of residues in this protein can be reversed by phosphorylation of Ser residues in this cluster by protein kinase C (22). Another modulation of the sequestering of PIP2 by MARCKS results from the competition between Calcium-calmodulin and the anionic lipid surface for the cluster of basic residues in MARCKS (23, 24).

There has been a suggestion that electrostatically driven formation of PIP2 domains have a relationship to membrane rafts. It is known that several proteins that sequester PIP2 locate in raft domains (25, 26). In addition, the domain localization of PIP2 is dependent on the presence of cholesterol (27-29). However, the conclusion that PIP2 is localized in raft domains (25, 26). In addition, the domain localization of PIP2 is dependent on the presence of cholesterol (27-29). However, the conclusion that PIP2 is localized in raft domains is close to being overturned by the data from the cationic MARCKS cluster (21). These proteins have been termed “pipmodulins” because of their ability to modulate the availability of free PIP2. In the case of the MARCKS protein, the electrostatically driven sequestering of PIP2 by the cationic cluster of residues in this protein can be reversed by phosphorylation of Ser residues in this cluster by protein kinase C (22). Another modulation of the sequestering of PIP2 by MARCKS results from the competition between Calcium-calmodulin and the anionic lipid surface for the cluster of basic residues in MARCKS (23, 24).

Fractionation

Cholesterol-rich domains of biological membranes have been isolated on the basis of their insolubility in 1% Triton at 4°C (36). This method has come into question because of the possibility that the Triton itself causes rearrangement of membrane components (37, 38). As indicated above, this fraction should not be referred to as a raft. However, the cholesterol-rich domain in the form of caveolae can be isolated without use of detergent (39, 40), providing stronger evidence that this cholesterol-rich domain exists in a biological membrane before extraction.

Fluorescence Methods

Fluorescence microscopy has been used extensively to study the formation of membrane domains. It has been particularly successful in determining the phase behavior of model membranes in the form of giant unilamellar vesicles (41). One of the limitations of imaging with light microscopy is that only relatively larger domains can be visualized because the method is limited by the wavelength of light. However, higher resolution can be attained with a near-field scanning optical microscope (NSOM) (42). In addition, recently, the method of stimulated emission depletion has been applied to biological systems that will allow imaging of smaller domains (43). Fluorescent-based methods have also been used to measure the interaction between molecules in small domains of nanometer, rather than micron, size. Fluorescence quenching and fluorescence resonance energy transfer methods have been used to demonstrate the presence of small domains in both model as well as biological membranes (44-46). However, application of these methods to biological membranes has not led to definitive results (45). Recent modeling studies have indicated that the lateral mobility of proteins in membranes is sensitive to the protein dimensions, including protein-lipid interactions (47). Measurements of the lateral diffusion of proteins in the apical plasma membrane of epithelial cells have indicated that certain proteins can be highly mobile (48), whereas others are less mobile (49). These differences in mobility have been correlated with the lateral distribution of proteins within the membrane, providing further evidence for the existence of lipid rafts (50).
cells using fluorescence recovery after photobleaching gives evidence for the presence of at least two coexisting liquid phases (2). A further method for the measurement of lateral diffusion in membranes that holds promise for the future is fluorescence correlation spectroscopy (48).

Atomic Force Microscopy (AFM)

AFM can readily be applied to bilayers deposited on a solid support. The method has the advantage that it can give nanometer resolution and that it is sensitive to measurements of height. It has been used for studying phase separation in lipid membranes (49). One also has to consider possible interactions between the solid support and the bilayer, particularly with regard to measuring rates of lateral diffusion. One can also use AFM in combination with fluorescence microscopy or with total internal reflection fluorescence (TIRF) microscopy to locate labeled molecules in the membrane. However, one must be cautious about the fluorescent probe affecting the domain localization (32). It is also possible to use force measurements in AFM to determine the extent of the electrical double layer (30) and thereby examine the clustering of charged lipids in a bilayer.

Future Directions

Important questions still need to be resolved regarding the nature of the interactions among membrane components that can lead to fluid–fluid immiscibility. However, to extend these model system studies to biological membranes, a deeper understanding of the role of proteins in determining domain formation is required. This task is complicated because there are a large variety of proteins in biological membranes and many motifs by which they can interact with surrounding molecules. Domains can be formed if the proteins interact preferentially with certain membrane components, provided these interactions are sufficiently strong to overcome the entropy of mixing. In addition, a more accurate and complete characterization of domains in biological membranes is required and is an active area of research. These domains are heterogeneous and, therefore, no single description of their size, shape, lifetime, or transbilayer properties exists. Each type of membrane domain will have to be studied in its own right. This complex task will require the coordinated effort of membrane biophysicists, cell biologists, and others. It will likely lead to a better understanding of the coordinated behavior of membrane proteins and the functioning of certain domain-related biological processes such as signal transduction and certain cases of endocytosis and viral fusion.

Essential fatty acids (EFAs)—linoleic acid (LA) and α-linolenic acid (ALA)—are essential for the brain growth and development of humans. EFAs are readily available in the diet, and hence their deficiency is not common. But, to provide their full benefit, EFAs have to be metabolized to their long-chain metabolites. EFAs form precursors to various prostaglandins (PGs), thromboxanes (TXs), leukotrienes (LTs), lipoxins (LXs), resolvins, neuroprotectins, isoprostanes, and hydroxy- and hydroperoxyeicosa-tetraenoates. Certain PGs, TXs, and LTs have pro-inflammatory actions, whereas LXs, resolvins, and neuroprotectins are anti-inflammatory in nature and are critical for wound healing, the resolution of inflammation, and the repair of tissues. EFAs and some of their long-chain metabolites inhibit the activities of angiotensin-converting and HMG-CoA reductase enzymes and cholesteryl ester transfer protein (CETP), enhance acetylcholine levels in the brain, increase the synthesis of endothelial nitric oxide, augment diuresis, enhance insulin action, and could regulate telomerase activity. Thus, EFAs and their metabolites may function as an endogenous “polypill.” In addition, EFAs and their long-chain metabolites react with nitric oxide (NO) to yield respective nitroalkene derivatives that exert cell-signaling actions via ligation and activation of peroxisome proliferator-activated receptors (PPARs). Thus, EFAs and their derivatives have varied biologic actions that may have relevance to their involvement in several physiologic processes and clinical conditions.

Metabolism of Essential Fatty Acids

EFAs also are polyunsaturated fatty acids (PUFAs) because they contain two or more double bonds. PUFAs are fatty acids, some of which have at least two carbon-to-carbon double bonds in a hydrophobic hydrocarbon chain. At least four independent families of PUFA exist, depending on the parent fatty acid from which they are synthesized. They include:

The “ω-3” series, which is derived from α-linolenic acid (ALA, 18:3, ω-3).

The “ω-6” series, which is derived from cis-linoleic acid (LA, 18:2, ω-6).

The “ω-9” series, which is derived from oleic acid (OA, 18:1, ω-9).

The “ω-7” series, which is derived from palmitoleic acid (PA, 16:1, ω-7).

Essential fatty acids (EFAs) are essential for the survival of humans and other mammals; they cannot be synthesized in the body and, hence, have to be obtained in our diet and, thus, are essential (1–4). EFAs are an important constituent of cell membranes and confer on membranes properties of fluidity; thus, they determine and influence the behavior of membrane-bound enzymes and receptors. Two types of naturally occurring EFAs exist in the body: the ω-6 series derived from linoleic acid (L.A, 18:2) and the ω-3 series derived from α-linolenic acid (ALA, 18:3, ω-3). Both the ω-6 and the ω-3 series are metabolized by the same set of enzymes to their respective long-chain metabolites. Although some functions of EFAs require their conversion to eicosanoids and other products, in most instances the fatty acids themselves are active. The longer-chain metabolites of LA and ALA regulate membrane function and are of major importance in the brain, retina, liver, kidney, adrenal glands, and gonads.

Metabolism of Essential Fatty Acids

EFAs also are polyunsaturated fatty acids (PUFAs) because they contain two or more double bonds. PUFAs are fatty acids, some of which have at least two carbon-to-carbon double bonds in a hydrophobic hydrocarbon chain. At least four independent families of PUFAs exist, depending on the parent fatty acid from which they are synthesized. They include:

The “ω-3” series, which is derived from α-linolenic acid (ALA, 18:3, ω-3).

The “ω-6” series, which is derived from cis-linoleic acid (LA, 18:2, ω-6).

The “ω-9” series, which is derived from oleic acid (OA, 18:1, ω-9).

The “ω-7” series, which is derived from palmitoleic acid (PA, 16:1, ω-7).
LA is converted to γ-linolenic acid (GLA, 18:3, n-6) by the action of the enzyme Δ6 desaturase (d-6-d), and GLA is elongated to form dihomo-GLA (DGLA, 20:3, n-6), the precursor of the 3 series of prostaglandins (PGs). DGLA also can be converted to arachidonic acid (AA, 20:4, n-6) by the action of the enzyme Δ5 desaturase (d-5-d). AA forms the precursor of the 2 series of prostaglandins, thromboxanes, and the 4 series of leukotrienes. ALA is converted to eicosapentaenoic acid (EPA, 20:5, n-3) by d-6-d and d-5-d. EPA forms the precursor of the 3 series of prostaglandins and the 5 series of leukotrienes. LA, GLA, DGLA, AA, ALA, EPA and docosahexaenoic acid (DHA, 22:6, n-3) are all PUFAs, but only LA and ALA are EFAs (see Fig. 1 for the metabolism of EFAs). AA and EPA give rise to their respective hydroxy acids, which, in turn, are converted to their respective leukotrienes (LTs). In addition, AA, EPA, and DHA form the precursor to anti-inflammatory compounds such as lipoxins and resolvins. PGs, LTs, lipoxins (LXs), and resolvins are highly active, modulate inflammation, and are involved in several pathophysiological processes, such as atherosclerosis, bronchial asthma, inflammatory bowel disease, and other inflammatory conditions (5–8). In general, for the sake of brevity, the term "EFAs" is used to refer to all unsaturated fatty acids: LA, GLA, DGLA, AA, ALA, EPA, and DHA; and the term polyunsaturated fatty acids (PUFAs) refers to GLA, DGLA, AA, EPA, and DHA. Although the terms EFAs and PUFAs are used interchangeably for the sake of convenience, it should be understood that all EFAs are PUFAs but all PUFAs are not EFAs. Many functions of EFAs are also brought about by PUFAs, and EFA-deficiency states can be corrected largely by PUFAs; that led to the suggestion that PUFAs are "functional EFAs." Hence, in general, many authors use the terms EFAs and PUFAs interchangeably. This convention is followed in the current discussion also.

EFAs/PUFAs play a significant role in the pathology of clinical conditions such as collagen vascular diseases, hypertension, diabetes mellitus, metabolic syndrome X, pсорiasis, eczema, atopic dermatitis, coronary heart disease, atherosclerosis, and cancer (1–8). This role is in addition to the role of PGs and LTs in these conditions. For instance, in ulcerative colitis, the inflammatory events are initiated and perpetuated by PGs and LTs produced from AA, whereas when significant amounts of EPA and DHA are given, the inflammatory process is abrogated to a large extent. This beneficial action of EPA/DHA when supplemented from external sources has been attributed to the displacement AA from the cell membrane phospholipid pool and formation of less pro-inflammatory PGs and LTs from them, and anti-inflammatory molecules LXs and resolvins and hence the favorable response. If the molecular mechanism(s) by which various stimuli can induce preferentially the release of AA, EPA, and/or DHA and convert them to their respective pro- and anti-inflammatory products, then it is possible to develop methods to treat various inflammatory conditions based on this knowledge. Such an understanding and knowledge is expected to lead to strategies that will help to enhance preferentially the formation of less pro-inflammatory molecules from EPA/DHA and to stimulate the synthesis and release of anti-inflammatory molecules such as LXs and resolvins that could lead to suppression of inflammation and wound healing. LXs and resolvins resolve inflammation by suppressing leukocyte infiltration and clearing cellular debris from the site of inflammation. In view of this action, it is important to know the molecular regulation of their formation and release in various cells and tissues and various diseases that is expected ultimately to develop better methods of managing various inflammatory conditions. Thus, PUFAs form precursors to both pro- and anti-inflammatory molecules, and the balance between these mutually antagonistic compounds could determine the final outcome of the disease process.

**Dietary Sources of EFAs**

The EFAs LA and ALA are present in human diet in abundant amounts, and, hence, EFA deficiency is uncommon. In certain specific conditions, such as total parenteral nutrition (TPN) and severe malabsorption, occasionally EFA deficiency could be seen. The current TPN solutions contain adequate amounts of EFAs. The manifestations of an EFA deficiency include inappropriate water loss through the skin, dehydration, scalp dermatitis, alopecia, and depigmentation of hair (9, 10). EFAs are distributed widely in normal human diet. The main dietary sources of EFAs are as follows.

**Dietary Sources of EFAs**

- **Human breast milk** is rich in all types of PUFAs (11); this explains why breast-fed children are healthier compared with bottle-fed children. LA and ALA are present in significant amounts in dairy products, in organ meats such as liver, and in many vegetable oils such as sunflower, safflower, corn, and...
soy. GLA is present in evening primrose oil at concentrations of 7-14% of total fatty acids, in borage seed oil at 20-27%, and in black currant seed oil at 15-20%. GLA also is found in some fungal sources (1-4, 12). DGLA is found in liver, testes, adrenals, and kidneys. AA is present in meat, egg yolks, some seaweeds, and some shrimps. The average daily intake of AA is estimated to be in the region of 100-200 mg/day, more than enough to account for the total daily production of various PGs. EPA and DHA are present mainly in marine fish. Cow milk contains very small amounts of GLA, DGLA, and AA.

EFA deficiencies are unattractive because of the presence of two or more double bonds in their structure: therefore, essential fatty acid deficiency often occurs during food processing and the hydrogenation of oils. When exposed to high temperatures and during hydrogenation, EPA and DHA are denatured and converted into trans fats that are harmful to the body (13-15). Human diet was rich in ω-3 fatty acids in the early humans. But, with the progress in industrialization and the development of fast foods, the content of ω-3 fatty acids in the human diet dwindled, whereas that of ω-6 fatty acids increased. Thus, the ratio of ω-3 to ω-6 fatty acids in the diet should be about 1 or > 1, whereas this ratio now is believed to be about 3 and around 10:1 to 20:25:1 (16). It is recommended that the ratio between ω-3 to ω-6 fatty acids in the diet of early humans was ω-3, whereas this ratio now is believed to be about 2-3 and preferably 2-3:1. It is believed that the fall in the intake of ω-3 fatty acids EPA and DHA in the last 50 years is responsible for the increasing incidence of modern diseases such as atherosclerosis, CHD, hypertension, metabolic syndrome X, obesity, collagen vascular diseases, and, possibly, cancer. This reason explains why trans fats, saturated fats, and cholesterol have pro-inflammatory actions, whereas EFAs and PUFA s possess anti-inflammatory properties. This reason explains why trans fats, saturated fats, and cholesterol are more likely to inhibit the formation of LXs, resolvins, PGI2 (prostacyclin), and other beneficial eicosanoids that prevent platelet aggregation, leukocyte chemotaxis, and activation of pro-inflammatory cytokines. In contrast, trans fats, saturated fats, and cholesterol may activate leukocytes directly, induce the generation of free radicals, and enhance the production and release of pro-inflammatory cytokines that facilitate atherosclerosis (14, 15, 25-29). The direct action of trans fats, saturated fats, and cholesterol interferes with EFA metabolism and promotes inflammation, atherosclerosis, and coronary heart disease (14, 15, 23, 24). Thus, trans fats, saturated fats, and cholesterol have been described as being anti-inflammatory, whereas EFAs and PUFA s possess anti-inflammatory properties.

Based on these studies, it is proposed that EFAs, especially EPA and DHA, from dietary LA and ALA, and AA. This interference, in turn, could lead to the decreased formation of LXs, resolvins, PGI2, and PGI3. It is likely that trans fats, saturated fats, and cholesterol may affect the formation of LXs, resolvins, PGI2, and PGI3. It is likely that trans fats, saturated fats, and cholesterol have pro-inflammatory actions. In contrast, trans fats, saturated fats, and cholesterol may interfere with EFA metabolism and promote inflammation, atherosclerosis, and coronary heart disease (14, 15, 23, 24). Thus, trans fats, saturated fats, and cholesterol have been described as being anti-inflammatory, whereas EFAs and PUFA s possess anti-inflammatory properties.
free radical-induced damage. This finding implies that for endothelial cells to be healthy, they need adequate amounts of EFAs, especially AA, EPA, and DHA so that they can generate physiologic amounts of eNO not only to prevent pathologic platelet aggregation and atherosclerosis but also to protect themselves from the cytotoxic actions of free radicals. Furthermore, NO reacts with PUFA s to yield their respective nitroalkene derivatives that can be detected in plasma. These nitroalkene derivatives, termed nitrolipids, produce vascular relaxation, inhibit neutrophil degranulation and superoxide formation, inhibit platelet activation, and show anti-atherosclerotic properties (3, 4, 31–34). Thus, a close interaction seems to exist between EFAs and their products and trans fats, saturated fats, and cholesterol with regard to the ability of endothelial cells to produce PG1, PG2, NO, and other anti-atherosclerotic and beneficial molecules.

**Actions of EFAs/PUFAs Relevant to Various Clinical Conditions**

**Cell membrane fluidity and modification of receptor properties**

Cell membrane fluidity is determined by its lipid composition. The cell membrane is rendered more rigid if increased amounts of saturated fatty acids and cholesterol are incorporated into the membrane phospholipids. In contrast, increased incorporation of unsaturated fatty acids into the membrane will make it more fluid. This increase in membrane fluidity has been shown to increase the number of receptors and their affinity to their respective hormones or growth factors. For instance, an increase in the rigidity of the cell membrane reduces the number of insulin receptors and their affinity to insulin that, in turn, could cause insulin resistance. Alternatively, an increase in cell membrane fluidity because of an increase in the unsaturated fatty acid content in the membrane phospholipids increases the number of insulin receptors and their affinity to insulin and, thus, decreases insulin resistance (35–42).

This action of EFAs/PUFAs has relevance to the growth and development of the brain during the perinatal and postnatal periods, periods of brain growth, is important for proper development of neurons, synapse formation, and cognitive function. The growth and development of the brain during the perinatal period and adolescence is dependent on the availability of ω-3 and ω-6 fatty acids (43–45). Hence, decreased availability of ω-3 and ω-6 fatty acids during this critical period of growth may impair brain growth and the development of appropriate synaptic connections that, in turn, may lead to the development of neuropsychologic conditions such as dementia, depression, schizophrenia, Alzheimer's disease, and neurodegenerative diseases (Huntington's disease, Parkinson's disease, and spinocerebellar degeneration). The alterations in the neuronal cell membrane fluidity also might influence the cognitive function. This suggestion is supported by the recent observation that EPA/PUFAs activate syntaxin, a plasma membrane protein that has an important role in the growth of neurites. For proper neuronal development and increase in cell membrane surface area, the growth of neurite processes from the cell body is critical (46). Nerve growth cones are highly enriched with AA-releasing phospholipases, which have been implicated in neurite outgrowth (47, 48). Cell membrane expansion occurs through the fusion of transport organelles with plasma membrane, and syntaxin 3, a plasma membrane protein that plays a significant role in the growth of neurites, has been shown to be a direct target for AA, DHA, and other PUFAs (49). AA, DHA, and other PUFAs but not saturated and monounsaturated fatty acids activate syntaxin 3. Of all the fatty acids tested, AA and DHA were found to be the most potent compared with LA and ALA. Even syntaxin 3 that is involved specifically in fast calcium-triggered exocytosis of neurotransmitters and in neurite outgrowth. It is interesting that SNAP25 (synaptosomal-associated protein of 25 kDa), a syntaxin partner implicated in neurite outgrowth, interacted with syntaxin 3 only in the presence of AA that allowed the formation of the binary syntaxin 3-SNAP 25 complex. AA stimulated syntaxin 3 to form the ternary SNARE (soluble N-ethylmaleimide-sensitive factor attachment protein receptor) complex, which is needed for the fusion of plasmalemmal precursor vesicles into the cell surface membrane that leads to membrane fusion. These results clearly demonstrated that AA and DHA change the ω-helical syntaxin structure to expose the SNARE motif for immediate SNAP 25 engagement and, thus, facilitate neurite outgrowth. Hence, the availability of optimal amounts of EFAs/PUFAs during the perinatal and postnatal periods, periods of brain growth, is important for proper development of neurons, synapse formation, and cognitive function.

**Second Messenger Actions of EFAs and their Metabolites**

Several hormones and growth factors activate phospholipase A2 (PLA2) that, in turn, induces the release of DGLA, AA, EPA, and DHA from the cell membrane lipid pool. These fatty acids are used for the formation of various eicosanoids and bring about their actions. The inhibition of PLA2 interferes with the action of several growth factors and cytokines. For example, the tumoroidal action of TNF-α is dependent on its ability to induce PLA2, and inhibitors of PLA2 completely blocked its TNF-α antitumor action (51–54). Activation of PLA2 leads to the release of various PUFAs including AA. PUFAs enhance the activity of protein kinase C (PKC), a well-known second messenger, activate macrophages and polymorphonuclear leukocytes (PMNs), and increase free radical generation (1–4, 53, 56). The effects of various types of PUFAs on the activation of macrophages and PMNs and their ability to generate free radicals depends on the type of EFA s/PUFAs used, on the degree of unsaturation, concentration(s) of the fatty acid, and on the conditions under which the experiments are performed. Thus, the effects of various PUFAs on macrophages and PMNs are complex and have to be interpreted with caution taking into consideration all of the variables involved.
Anti-Inf ective Properties of EFAs

Previously, I proposed that EFA s/PUFAs such as GLA, DGLA, AA, EPA, and DHA might behave as endogenous antibacterials, antifungal, antiviral, and immunomodulating agents (57, 58). LA and ALA have bacteriostatic effect on both gram-positive and gram-negative bacteria (58, 59). Staphylococcus aureus are killed rapidly by ALA, and a variety of bacteria were found to be sensitive to the growth inhibitory actions of LA and ALA in vitro (60, 61). Hydrolyzed linseed oil, which contains 52% ALA, and pure ALA were found to be capable of killing methicillin-resistant S. aureus (62). A nimal herpes, influenza, Sendai, and Sindbis viruses could be inactivated by LA and AA within minutes of contact (63). Furthermore, both prostaglandin E1 (PGE1) and PGA, derived from DGLA, AA, and EPA, have the ability to inhibit viral replication and behave as antiviral compounds (64, 65). It was reported that the remission of myosis fungoides, a rare skin disease of viral etiology, is possible with the oral administration of LA as safflower oil (which contains 76% LA) in dogs that correlated with an increase in the plasma levels of LA and AA (66).

Patients with Plasmodium falciparum showed suppressed lympho-proliferative responses to malaria antigens. This suppressed lymphocyte response has been attributed to the increased production of various prostaglandins (PGs) by monocytes/macrophages. This finding is supported by the observation that enhanced lymphocyte responses to several malaria antigens were enhanced particularly by indomethacin, a cyclo-oxygenase inhibitor, which suggests that malaria-specific T-cells are especially sensitive to the effects of PGs (67). In a related study, it was noted that during intra-erythrocytic development of the parasite, the phospholipid composition of the IEPM (infected erythrocyte plasma membrane) contained more phosphatidylcholine (38.7% versus 31.7%) and phosphatidylinositol (21.2% versus 0.8%) and less sphingomyelin (14.6% versus 28.0%) than normal uninfected erythrocytes. The percentage of PUFAs in normal erythrocyte phospholipids (39.4%) was much higher than in phospholipids from purified parasites (23.3%) or IEPM (24.1%). Large increases in palmitic acid (from 21.88% to 31.21%) and in oleic acid (from 14.64% to 24.60%) and significant decreases in AA (from 17.36% to 7.85%) and in DHA (from 4.34% to 1.89%) occurred because of the infection. The fatty acid profiles of individual phospholipid classes from IEPM resembled the fatty acid profiles of parasite phospholipids rather than those of uninfected erythrocytes, which suggests that these alterations are because of the parasite-directed metabolism of erythrocyte lipids (68). These results are interesting because it has been shown that iloprost, a synthetic prostacyclin (PGI2) analog, not only prevented the development of cerebral malaria in mice but also suppressed malaria antigen-induced tumor necrosis factor (TNF) production (69). PGI2 and PGF2α are derived from AA and EPA, respectively. Furthermore, AA, LA, EPA, and DHA inhibited the growth of P. falciparum in vitro, whereas oleic or docosanoic acids were ineffective. Parasite killing was increased significantly when oxidized forms of LA, AA, EPA, and DHA were used. Antioxidants greatly reduced the fatty acid-induced killing. Mice infected with P. berghei and treated for 4 days with DHA showed marked reduction in parasitemia (70). In this context, it is interesting to note that the cytotoxic effect of the fatty acids was very rapid: The full inhibition of nucleic acids and protein syntheses was observed in less than 30 minutes without showing any effects on RBCs such as the hemolysis of infected cells up to 500 µg/ml; also no effect on the lipid peroxidation, ATP levels, transport through the parasite-induced permeability pathways, or on the phagocytosis of the infected cells was noted (71). Furthermore, mice fed vitamin E-deficient diets that contain ω-3 fatty acids survive infection with lethal P. yoelii. Experiments performed in nu/nu mice (which lack alpha-beta T-cell-receptor-positive T cells and do not produce antimalarial antibody) and nu/nu mice revealed that animals fed casein-based diets that contain 4% menhaden oil with vitamin E supplementation for 4 weeks before infection with lethal P. yoelii developed fulminating parasitemias and quickly died, whereas both nu/nu and nu/nu mice fed diets deficient in vitamin E controlled their parasitemias for the first 18 days of infection. Therefore, the nu/nu mice become anemic and died, whereas the nu/nu mice produced antimalarial antibodies and survived. In an extension of this study, when scid/scid/bg/bg mice (which lack B cells and alpha-beta and gamma-delta T cells and have reduced NK-cell activity) were fed the experimental diet for 6 weeks and then infected with the less-virulent J774.A1 strain of P. yoelii, the animals fed vitamin E-containing diets quickly died, whereas those fed the vitamin E-deficient diet survived without developing detectable parasitemias. These results suggest that under pro-oxidant dietary conditions, mice could control and even survive malaria in the absence of malaria-primed T cells and the antimalarial antibody (72), which implies that fatty acids need to be oxidized to produce their antimalarial action and eliminate malaria parasite. Our studies showed that in patients with P. falciparum malaria, the levels of lipid peroxides (a marker of free radical generation), nitric oxide (a potent free radical with immunomodulatory actions), and concentrations of LA and ALA are low, whereas those of EPA are high. Because the ability of the fatty acids to kill P. falciparum is dependent on their capacity to stimulate free radical generation in neutrophils and macrophages and EPA is more potent than LA in killing the parasite, these results imply that decreased levels of lipid peroxides and nitric oxide may contribute to the susceptibility of P. falciparum infection (73). In addition, it was reported that mice infected with P. berghei ANKA (which developed cerebral malaria) showed increased phosphatidylase A2 mRNA expression in the spleen and cyclooxygenase 1 (COX1) and COX2 expression in the brain and had higher serum LTβ intact levels than the control mice; also it was reported that aspirin-treated infected mice had higher serum LTβ and lower serum unmetabolized infected mice, which suggests that PGs are protective whereas LTs are detrimental in cerebral malaria (74). These results, coupled with the observations that elevated PGE2 in healthy malaria-exposed children may protect against malaria (75), that some PGs actually may reverse chloroquine-resistance of the malarial parasite (76), and that increased production of TXs may be involved in the pathogenesis of some complications associated with malaria suggest that EFA s/PUFAs and their eicosanoid metabolites play a significant role in the protection and the pathogenesis of malaria.
These observations suggest that EFAs/PUFAs and their products have antibacterial, antifungal, antiviral, and antiparasitic actions. Both lymphocytes and macrophages contain significant amounts of PUFAs and are capable of releasing them on appropriate stimulation. In addition, PUFAs stimulate NADPH-dependent superoxide production by macrophages, neutrophils, and lymphocytes that are capable of killing the invading microorganisms. In view of these evidences, it is reasonable to believe that an increased intake of LA, ALA, EPA, and DHA protects against and/or reduces the risk of various infections. Recent studies showed that AA, EPA, and DHA could give rise to anti-inflammatory compounds such as lipoxins (LXs) and resolvins that are essential to limit and resolve inflammation (3, 4). These studies imply that a deficiency of LXs and resolvins could lead to the perpetuation of inflammation and tissue damage. In the light of these facts, it will be interesting to study whether a subclinical deficiency of PUFAs, decreased formation of LXs and resolvins, occurs in subjects who develop the various types of infections and their complications. Because, PUFAs can inactivate enveloped viruses including influenza, it is probably worthwhile to study the effect of various fatty acids on the bird flu virus, specifically, whether increased intake of these fatty acids could reduce the risk of flu.

It is interesting to note that an analog of myristic acid (14:0) showed selective toxicity to African Trypanosomes (77), PUFAs also can kill Helicobacter pylori (78), and the actions of some antibiotics could be potentiated by PUFAs (79), which lends support to the concept that PUFAs may function as endogenous anti-infective-like molecules (80, 81).

**Actions that Could Qualify Pufas to be an Endogenous “Polypill”**

Coronary heart disease (CHD), stroke, peripheral vascular disease, and underlying atherosclerosis are the common cardiovascular diseases (CVD) that are responsible for considerable morbidity and mortality both in the developed and developing countries. Several studies revealed that smoking cessation, β-blockers, antipalpebral agents in the form of low-dose aspirin and other drugs, inhibitors of angiotensin-converting enzyme (ACE), and lipid-lowering agents such as statins that inhibit the activity of HMG-CoA reductase, each reduce the risk of vascular events to a moderate but important degree (82–90). In addition, observational studies suggested lower rates of fractures with statins, higher rates of obstructive airways disease at lower cholesterol concentrations, lower rates of cataracts, and lower rates of dementia with MRC/BHF-HPS study (90). The results of the MRC/BHF-HPS study led to the suggestion that about one-third to three-quarters of future vascular events could be prevented (see Table 1). This suggestion indicates that a combination of aspirin, β-blockers, lipid-lowering (by 1–5 mmol) and the use of statins, and ACE inhibitors could reduce cardiovascular diseases by over 70–80% (91). This concept led to the suggestion that a combination pill (popularly called a “polypill”) consisting of atorvastatin 10 mg or simvastatin 40 mg; and aspirin 75 mg could reduce CHD events by 88% (95% confidence interval 84% to 91%) and stroke by 80% (71% to 87%) (see Table 1 for a possible formulation of one such polypill). It was suggested that one third of the people taking such a combination pill from age 55 years of age would benefit, gaining on an average about 13 years of life free from an CHD event or stroke (92).

**Pufas Inhibit ACE and HMG-CoA Reductase Activities and Augment Endothelial Nitric Oxide Generation**

PUFAs inhibited leukocyte ACE activity (93) and enhanced endothelial nitric oxide (eNOS) generation (94). This finding implies that when tissue concentrations of PUFAs are low, the activity of ACE will be high, which results in increased formation of angiotensin-II and a simultaneous decrease in eNO. It was reported that transgenic rats overexpressing human renin and angiotensinogen genes (dTGR) that develop hypertension, inflammation, and renal failure showed specific renal P450-dependent AA metabolism changes that led to decreased formation of epoxy-eicosatrienoic acids (5,6-, 8,9-, 11,12- and 14,15-EETs) and hydroxyeicosatetraenoic acids (19- and 20-HETEs). Both EETs and HETEs inhibit IL-6 and TNF-α-induced activation of endothelial nitric oxide synthase (eNOS). These observations suggest that EFAs/PUFAs and their products have antibacterial, antifungal, antiviral, and antiparasitic actions. Both lymphocytes and macrophages contain significant amounts of PUFAs and are capable of releasing them on appropriate stimulation. In addition, PUFAs stimulate NADPH-dependent superoxide production by macrophages, neutrophils, and lymphocytes that are capable of killing the invading microorganisms. In view of these evidences, it is reasonable to believe that an increased intake of LA, ALA, EPA, and DHA protects against and/or reduces the risk of various infections. Recent studies showed that AA, EPA, and DHA could give rise to anti-inflammatory compounds such as lipoxins (LXs) and resolvins that are essential to limit and resolve inflammation (3, 4). These studies imply that a deficiency of LXs and resolvins could lead to the perpetuation of inflammation and tissue damage. In the light of these facts, it will be interesting to study whether a subclinical deficiency of PUFAs, decreased formation of LXs and resolvins, occurs in subjects who develop the various types of infections and their complications. Because, PUFAs can inactivate enveloped viruses including influenza, it is probably worthwhile to study the effect of various fatty acids on the bird flu virus, specifically, whether increased intake of these fatty acids could reduce the risk of flu.

It is interesting to note that an analog of myristic acid (14:0) showed selective toxicity to African Trypanosomes (77), PUFAs also can kill Helicobacter pylori (78), and the actions of some antibiotics could be potentiated by PUFAs (79), which lends support to the concept that PUFAs may function as endogenous anti-infective-like molecules (80, 81).

**Actions that Could Qualify Pufas to be an Endogenous “Polypill”**

Coronary heart disease (CHD), stroke, peripheral vascular disease, and underlying atherosclerosis are the common cardiovascular diseases (CVD) that are responsible for considerable morbidity and mortality both in the developed and developing countries. Several studies revealed that smoking cessation, β-blockers, antipalpebral agents in the form of low-dose aspirin and other drugs, inhibitors of angiotensin-converting enzyme (ACE), and lipid-lowering agents such as statins that inhibit the activity of HMG-CoA reductase, each reduce the risk of vascular events to a moderate but important degree (82–90). In addition, observational studies suggested lower rates of fractures with statins, higher rates of obstructive airways disease at lower cholesterol concentrations, lower rates of cataracts, and lower rates of dementia with MRC/BHF-HPS study (90). The results of the MRC/BHF-HPS study led to the suggestion that about one-third to three-quarters of future vascular events could be prevented (see Table 1). This suggestion indicates that a combination of aspirin, β-blockers, lipid-lowering (by 1–5 mmol) and the use of statins, and ACE inhibitors could reduce cardiovascular diseases by over 70–80% (91). This concept led to the suggestion that a combination pill (popularly called a “polypill”) consisting of atorvastatin 10 mg or simvastatin 40 mg; and aspirin 75 mg could reduce CHD events by 88% (95% confidence interval 84% to 91%) and stroke by 80% (71% to 87%) (see Table 1 for a possible formulation of one such polypill). It was suggested that one third of the people taking such a combination pill from age 55 years of age would benefit, gaining on an average about 13 years of life free from an CHD event or stroke (92).

**Pufas Inhibit ACE and HMG-CoA Reductase Activities and Augment Endothelial Nitric Oxide Generation**

PUFAs inhibited leukocyte ACE activity (93) and enhanced endothelial nitric oxide (eNOS) generation (94). This finding implies that when tissue concentrations of PUFAs are low, the activity of ACE will be high, which results in increased formation of angiotensin-II and a simultaneous decrease in eNO. It was reported that transgenic rats overexpressing human renin and angiotensinogen genes (dTGR) that develop hypertension, inflammation, and renal failure showed specific renal P450-dependent AA metabolism changes that led to decreased formation of epoxy-eicosatrienoic acids (5,6-, 8,9-, 11,12- and 14,15-EETs) and hydroxyeicosatetraenoic acids (19- and 20-HETEs). Both EETs and HETEs inhibit IL-6 and TNF-α-induced activation of endothelial nitric oxide synthase (eNOS). These observations suggest that EFAs/PUFAs and their products have antibacterial, antifungal, antiviral, and antiparasitic actions. Both lymphocytes and macrophages contain significant amounts of PUFAs and are capable of releasing them on appropriate stimulation. In addition, PUFAs stimulate NADPH-dependent superoxide production by macrophages, neutrophils, and lymphocytes that are capable of killing the invading microorganisms. In view of these evidences, it is reasonable to believe that an increased intake of LA, ALA, EPA, and DHA protects against and/or reduces the risk of various infections.

Recent studies showed that AA, EPA, and DHA could give rise to anti-inflammatory compounds such as lipoxins (LXs) and resolvins that are essential to limit and resolve inflammation (3, 4). These studies imply that a deficiency of LXs and resolvins could lead to the perpetuation of inflammation and tissue damage. In the light of these facts, it will be interesting to study whether a subclinical deficiency of PUFAs, decreased formation of LXs and resolvins, occurs in subjects who develop the various types of infections and their complications. Because, PUFAs can inactivate enveloped viruses including influenza, it is probably worthwhile to study the effect of various fatty acids on the bird flu virus, specifically, whether increased intake of these fatty acids could reduce the risk of flu.

It is interesting to note that an analog of myristic acid (14:0) showed selective toxicity to African Trypanosomes (77), PUFAs also can kill Helicobacter pylori (78), and the actions of some antibiotics could be potentiated by PUFAs (79), which lends support to the concept that PUFAs may function as endogenous anti-infective-like molecules (80, 81).

**Actions that Could Qualify Pufas to be an Endogenous “Polypill”**

Coronary heart disease (CHD), stroke, peripheral vascular disease, and underlying atherosclerosis are the common cardiovascular diseases (CVD) that are responsible for considerable morbidity and mortality both in the developed and developing countries. Several studies revealed that smoking cessation, β-blockers, antipalpebral agents in the form of low-dose aspirin and other drugs, inhibitors of angiotensin-converting enzyme (ACE), and lipid-lowering agents such as statins that inhibit the activity of HMG-CoA reductase, each reduce the risk of vascular events to a moderate but important degree (82–90). In addition, observational studies suggested lower rates of fractures with statins, higher rates of obstructive airways disease at lower cholesterol concentrations, lower rates of cataracts, and lower rates of dementia with MRC/BHF-HPS study (90). The results of the MRC/BHF-HPS study led to the suggestion that about two-thirds to three-quarters of future vascular events could be prevented (see Table 1). This suggestion indicates that a combination of aspirin, β-blockers, lipid-lowering (by 1–5 mmol) and the use of statins, and ACE inhibitors could reduce cardiovascular diseases by over 70–80% (91). This concept led to the suggestion that a combination pill (popularly called a “polypill”) consisting of atorvastatin 10 mg or simvastatin 40 mg; three blood pressure lowering drugs such as a thiazide, a
NF-κB and prevent vascular inflammation (95), which suggests that AA and other PUFAs not only regulate ACE activity and Ang-II levels in the tissues but also possess anti-inflammatory properties by generating anti-inflammatory metabolites.

In the presence of aspirin, AA, EPA, and DHA are converted to form epi-lipoxins, lipoxins, and resolvins that, in turn, enhance the formation of eNO (3, 4, 96). Lipoxins possess potent anti-inflammatory actions (reviewed in References 3 and 4). In addition, NO not only blocks the interaction between leukocytes and the vascular endothelium during inflammation but also stimulates the formation of PGi2, a potent vasodilator and platelet anti-aggregator, from AA (97, 98).

PUFAs are potent inhibitors of the HMG-CoA reductase enzyme and similar to statins are useful in the treatment of hyperlipidemias (99–102). Statins enhance plasma AA levels and decrease the ratio of EPA to AA significantly (100). This finding suggests that PUFAs mediate many actions of statins (103) and that this could be one mechanism by which they lower cholesterol levels. Statins and PUFAs have many overlap actions such as the inhibition of IL-6 and TNF-α production and NF-κB activation plus the ability to enhance eNO production; thus, both possess anti-inflammatory actions and both are useful in atherosclerosis, coronary heart disease, osteoporosis, stroke, Alzheimer’s disease, and inflammatory conditions such as lupus and cancer (3, 4, 94, 104–121). These similar and overlap actions strongly indicate that the molecular mechanisms of actions of statins and PUFAs are similar, if not identical. Furthermore, when a combination of statins and PUFAs are given together, a synergistic beneficial effect was seen in patients with combined hyperlipemia (122).

Both PUFAs and statins by inhibiting the HMG-CoA reductase enzyme reduce the formation of isoprenoid that contains compounds that are formed from mevalonate (because the HMG-CoA reductase enzyme reduces the formation of mevalonate). These isoprenoid precursors are necessary for the posttranslational lipid modification (prenylation) and, hence, the function of Ras and other small GTPases. Small GTPases, the prenylated products of the mevalonate pathway, have negative regulatory control on the expression of BMPs (bone morphogenetic proteins). BMPs are essential for neuronal growth, proliferation, and differentiation (123) and also for bone growth (105, 114). Thus, PUFAs modulate brain growth and development and neuronal differentiation. This finding explains why PUFAs are useful in the prevention and treatment of dementia and Alzheimer’s disease (115–120). Similar to PUFAs, statins also enhance the concentrations of BMPs in brain and bone and thus could be of benefit in the treatment of Alzheimer’s disease and osteoporosis (105, 109, 113). Yet another action of PUFAs and statins that contributes to their beneficial actions is their ability to enhance eNO (30, 124), a pleiotropic molecule that has many biologic actions including its ability to function as a neurotransmitter (125) and prevent osteoporosis (126, 127). But unlike statins that cannot be given during pregnancy, PUFAs can be consumed confidently during pregnancy, lactation, and infancy. In fact, PUFAs are recommended during pregnancy, lactation, and infancy to improve brain growth and development (1–4, 43, 44).

**Pufas and Cholesteryl Ester Transfer Protein (CETP) Activity**

Several studies suggested that HDL-cholesterol (high-density lipoprotein-cholesterol, HDL-C) is an independent risk factor for CHD. Higher plasma LDL-C is associated with a decreased incidence of CHD (128). This finding led to the suggestion that therapeutic strategies that raise HDL-C could be of benefit in preventing CHD with the hope that raising HDL-C will increase the movement of cholesterol from the periphery back to the liver (the so-called reverse cholesterol transport or RCT pathway) and protection from CHD will follow.

CETP is a hydrophobic plasma glycoprotein, mainly synthesized in the liver, that possesses the unique ability to facilitate the transfer of cholesteryl ester (CE). CETP circulates in the blood, bound predominantly to HDL. CETP mediates the transfer of cholesteryl esters from HDL to VLDL and LDL in exchange for triglycerides. CETP also promotes the transformation of HDL2 to HDL3, an action that could promote reverse cholesterol transport. CETP inhibition produces an increase in HDL by markedly delaying the catabolism of apoA-I and A-II (129), an action that increases reverse cholesterol transport. These actions of CETP suggest that CETP inhibition could prevent atherosclerosis (130–132).

In a study performed in healthy, normolipidemic men, it was observed that a lipid-lowering diet rich in monounsaturated fatty acid (oleic acid) decreased CETP concentrations to a significant degree (133). In HepG2 cells, it was noted that 0.5 mM of AA, EPA, and DHA reduced the levels of CETP mRNA by more than 50% of the control levels with a corresponding significant decrease in the CETP mass (134). This finding is supported by the observation that in type 2 diabetic subjects, CETP activity was correlated significantly with the HDL-C to apoA-I ratio and to the LDL-C to HDL-C ratio. In addition, a significant negative correlation was found between plasma CETP activity and monounsaturated fatty acid content of plasma phospholipids or free PUFAs, especially with ω-3 fatty acids, which suggests that PUFAs suppress CETP activity (135).

Torcetrapib, a small molecule inhibitor of CETP, is very effective at raising HDL-C and apolipoprotein A-I and decreasing levels of LDL-C and triglycerides. In fact, it was observed that the administration of torcetrapib with atorvastatin led to the initiation of clinical trials. In patients with familial hypercholesterolemia, torcetrapib with atorvastatin as compared with atorvastatin alone did not result in the reduction of the progression of atherosclerosis as measured by carotid arterial-wall thickness, despite a significant increase in HDL-C levels and a decrease in levels of LDL-C and triglycerides. In another study that involved the use of torcetrapib alone or in combination with other statins, torcetrapib did not reduce CHD. Higher plasma HDL-C is associated with a decreased incidence of CHD (128). This finding led to the suggestion that therapeutic strategies that raise HDL-C could be of benefit in preventing CHD with the hope that raising HDL-C will increase the movement of cholesterol from the periphery back to the liver (the so-called reverse cholesterol transport or RCT pathway) and protection from CHD will follow.

CETP is a hydrophobic plasma glycoprotein, mainly synthesized in the liver, that possesses the unique ability to facilitate the transfer of cholesteryl ester (CE). CETP circulates in the blood, bound predominantly to HDL. CETP mediates the transfer of cholesteryl esters from HDL to VLDL and LDL in exchange for triglycerides. CETP also promotes the transformation of HDL2 to HDL3, an action that could promote reverse cholesterol transport. CETP inhibition produces an increase in HDL by markedly delaying the catabolism of apoA-I and A-II (129), an action that increases reverse cholesterol transport. These actions of CETP suggest that CETP inhibition could prevent atherosclerosis (130–132).

Higher plasma HDL-C is associated with a decreased incidence of CHD (128). This finding led to the suggestion that therapeutic strategies that raise HDL-C could be of benefit in preventing CHD with the hope that raising HDL-C will increase the movement of cholesterol from the periphery back to the liver (the so-called reverse cholesterol transport or RCT pathway) and protection from CHD will follow.
with atorvastatin, an increase in blood pressure with no significant decrease in the progression of coronary atherosclerosis was noted (138).

These results with torcetrapib and atorvastatin suggest that the simultaneous inhibition of CETP and the HMG-CoA reductase enzyme leads to an elevation of plasma HDL-C and a decrease in LDL-C, triglycerides, and cholesterol but that it does not arrest the progression of atherosclerosis. In contrast, PUFAs, especially ω-3 EPA and DHA, not only inhibit CETP and the HMG-CoA reductase enzyme and lower plasma triglycerides, cholesterol, and LDL-C with little or no change in HDL-C but also are effective in arresting atherosclerosis and preventing CHD (139-151). In contrast to the results with torcetrapib and atorvastatin, Yokoyama et al. (152) reported that a combination of ethyl EPA and 10 mg of pravastatin or 5 mg of simvastatin prevented major coronary events and especially nonfatal coronary events in Japanese hypercholesterolemic patients with a mean period of follow up of 4.6 years. It is interesting to note that the benefits were in addition to statin treatment and that fish oil was found to be safe and well tolerated. These results once again confirm that EPA and DHA are of benefit in the prevention and treatment of cardiovascular diseases. Thus, PUFAs seem to be superior to CETP and statins in the prevention of CVD despite the fact that they do not necessarily increase plasma HDL-C levels.

Effects on Platelets and Other Hemostatic Indices

Both EPA and DHA, when given orally, are incorporated rapidly into platelets and compete with AA for the 2-acyl position of membrane phospholipid and as a substrate for the cyclooxygenase (CO) and lipoxygenase (LO) enzymes. As a result, when stimulated, such platelets produce less amounts of TXA2 and more of PGI2 that is less potent in inducing platelet aggregation and thrombosis (153). Increased intake of fish oil rich in EPA and DHA produces a lower platelet count, less platelet aggregation, a longer bleeding time, higher urinary fish oil rich in EPA and DHA produces a lower platelet count, from CAD/CVD. (PAI-1), they are effective still in preventing overall mortality and on the activity of plasminogen activity inhibitor-type-1 have a very significant effect on blood lipids, on fibrinolysis, ω-3 EPA and DHA as an “endogenous polypill,” then it is imperative that they (PUFAs) should show beneficial actions similar to those observed with conventional, synthetic diuretics. These beneficial actions of PUFAs can be attributed to the formation of beneficial PGA, PGE2, PGJ2, PGI2, and recently identified resolvins and protectins and a decrease in the production of TXA2 and LTs (165). In this context, it is interesting to note that diuretic furosemide enhances endothelial synthesis and the release of bradykinin and related kinins that, in turn, stimulates endothelial PGI2 formation via B2 kinin receptor activation (166); also, COX-2 derived PGs interact with the renin-angiotensin system to regulate renal function (167).
**Pufas and the Parasympathetic Nervous System**

An autonomic function can be assessed by the measurement of heart rate variability (HRV) and the evaluation of baroreflex sensitivity (BRS). HRV reflects the physiologic levels of tonic autonomic regulation, whereas BRS indicates the capacity of reflex autonomic regulation. Both low HRV and low BRS are associated with increased cardiovascular risk. Vagal stimulation by a release of acetylcholine (ACh) and adrenergic stimulation mediated by norepinephrine and epinephrine regulate the autonomic function and thus the variations in HRV and BRS. Several studies revealed that ω-3 fatty acids reduce the risk of sudden death by preventing life-threatening cardiac arrhythmias and by significantly increasing HRV (168). Furthermore, a direct positive correlation was noted between the content of DHA in cell membranes and the HRV index, which suggests an anti-arrhythmic effect of the ω-3 fatty acids (169). Because increased parasympathetic tone is responsible for an increase in the ventricular fibrillation threshold and protects against ventricular arrhythmias, it is likely that EPA/DHA supplementation enhances the parasympathetic tone. This suggestion is supported by the observation that EPA/DHA supplementation increases hippocampal ACh levels, the principal neurotransmitter of parasympathetic nerves (170). Hence, it is likely that EPA/DHA supplementation increases the brain ACh levels that lead to an increase in the parasympathetic tone and so to an increase in HRV and protection from ventricular arrhythmias.

Vagus nerve stimulation also inhibits TNF synthesis in the liver, and ACh, the principal vagal neurotransmitter, significantly attenuated the release of the proinflammatory cytokines TNF-α, IL-16, IL-18, and IL-22 but not the anti-inflammatory cytokine IL-10 by stimulated macrophages in vitro and in vivo (171–174). Because EPA/DHA enhances brain ACh levels (170) and evidence suggests that even AA augments ACh release (175), it is possible that Pufas enhance parasympathetic tone and, thus, increase HRV and prevent ventricular arrhythmias. These results imply that an inverse correlation could exist between the TNF levels and the parasympathetic tone. The higher the TNF levels are, the lower parasympathetic tone is and vice versa. Also, the higher the parasympathetic tone, the higher the brain ACh levels, and so the higher the plasma, cardiac, and brain EPA/DHA/AAs levels are. Because normally a balance is maintained between the parasympathetic and sympathetic tones, it is reasonable to suggest that whenever the parasympathetic tone (vagal tone) is enhanced sympathetic tone is reduced (akin to the blocking of β-receptors as it occurs in instances of the use of β-blockers). Thus, indirectly Pufas may function like β-blockers.

Thus, Pufas, especially an optimal combination of EPA, DHA and possibly, GLA, DGLA, and AA, show all the qualities of the suggested “polydrug,” viz they show aspirin-like action, inhibit the activities of HMG-CoA and ACE enzymes, possess diuretic and antihypertensive actions, and indirectly show β-blocker-like action.

**Pufas Possess Anti-Inflammatory Actions**

AA, EPA, DHA, GLA, DGLA, LXs and resolvins suppress IL-1, IL-2, IL-6, and TNF-α production by T cells (110–112, 149, 176–180). This claim suggests that EFA/Pufas and their metabolites function as endogenous anti-inflammatory molecules and regulate immune response and thus are likely to be of benefit in obesity, insulin resistance, atherosclerosis, metabolic syndrome X, type 2 diabetes mellitus, CHD, depression, and Alzheimer’s disease that are considered as diseases of low-grade systemic inflammation (1–8, 24, 120). Some beneficial actions of Pufas in various inflammatory conditions are because of the formation of anti-inflammatory compounds such as lipoxins, resolvins, and neuroprotection D1.

**Role of Efas/Pufas in Some Clinical Conditions**

It is evident from the preceding discussion that Pufas/Pufas and their metabolites are useful in many clinical conditions as outlined below.

**Inflammatory conditions**

Pufas and their products have the ability to modulate inflammation. The amount and type of Pufa(s) released and their products formed in response to inflammatory stimuli depend on the cell membrane phospholipid fatty acid content and the activity of the CO and LO enzymes. Because Pufas are obtained from diet, it suggests that dietary content of Pufas is one factor that modulates the degree of inflammation. Increased dietary intake of GLA, DGLA, and EPA/DHA substantially decreases inflammatory response. This beneficial action can be ascribed to the decreased formation of pro-inflammatory eicosanoids and cytokines and to an increase in the production of beneficial molecules such as PGE1, PG I2, PG I3, aNO, LXs, resolvins, and NPD1. When the cell membrane lipid pool is rich in GLA/DGLA/EPA/DHA and contains appropriate amounts of AA, there could occur specific activation of sPLA2 and cPLA2 (soluble and cytosolic phospholipase A2, respectively) in response to an injury/inflammatory stimuli that leads to the formation of increased amounts of LXs, PGD2, and 15deoxy-Δ12,14PGJ2, which results in the prevention and the resolution of inflammation. Several studies showed that oral or parenteral supplementation of GLA/EPA/DHA is of benefit to patients with insulin resistance, metabolic syndrome X, CHD, rheumatoid arthritis, lupus, psoriasis, sepsis, inflammatory bowel disease, nephritis, bronchial asthma, dermatitis, and other inflammatory conditions (reviewed in References 1–8, 24, 92, 116, 151, 152, 157).
Atherosclerosis

Healthy endothelial cells release adequate amounts of NO, PG12, and PGE1, to prevent the aggregation of platelets so that atherosclerosis is prevented. An increased production of pro-inflammatory cytokines and free radicals occurs because of sheer stress, hyperglycemia, clinical or subclinical infections, low-grade systemic inflammation as seen in type 2 diabetes mellitus, hypertension, hyperlipidemia, and metabolic syndrome X. EPA/DHA/ALA/DGLA inhibit free radical generation, suppress IL-6 and TNF-α synthesis and secretion, enhance eN0 synthesis, and, thus, prevent oxidant stress (reviewed in References 149, 150 and 183). Endothelial cells that line atherosclerosis-free blood vessel walls have abundant concentrations of the essential fatty acid linoleate, whereas fatty streaks (an early stage of atherosclerosis) are deficient in EFAs (183-186). An EFA deficiency promotes respiratory uncoupling (187, 188) and atherosclerosis (3, 183, 189). Bernal-Mizrachi et al. (184) showed that oxidative stress increases ROS generation and decreases NO formation. These evidences suggest that endothelial cell deficiency of PUFAs increases the production of pro-inflammatory cytokines and free radicals that results in the development of insulin resistance, a decrease in plasma and cellular HDL concentrations, and a decrease in the formation of eNO, PGE1, PG12, PGA2, LXs, resolvins, and ND1 that ultimately may promote atherosclerosis. Providing adequate amounts of various PUFAs can restore normalcy.

Metabolic Syndrome X

Metabolic syndrome X is a low-grade systemic inflammatory condition in which plasma levels of C-reactive protein (CRP), TNF-α, and IL-6 are elevated. A negative correlation exists between plasma TNF-α and HDL cholesterol, glycosylated hemoglobin, and serum insulin concentrations. EPA, DHA, and AA, inhibit TNF-α and IL-6 production (111, 112), enhance eN0 generation (30), inhibit HM-G-CoA reduce (103) and ACE enzyme activities (83), function as endogenous ligands for PPARs (reviewed in References 3 and 4), modulate leptin gene expression (190, 191), enhance the production of adiponectin (192), and decrease insulin resistance (193). This finding may explain why PUFAs are useful to protect against CHD, prevent the progression of atherosclerosis, and decrease blood pressure.

Brain Growth and Development and Cognitive Functions

Several studies showed that AA, EPA, and DHA are essential not only for brain growth and development but also to modulate the synthesis, release, and action of various neuropeptides. Because the brain is rich in AA, EPA, and DHA, one important function of these fatty acids in the brain could be to ensure the presence of an adequate number of insulin receptors; the insulin receptor number depends on the amounts of PUFAs incorporated in the cell membrane phospholipids (35-42). Thus a defect in the metabolism of PUFAs or not having adequate amounts of PUFAs incorporated into the neuronal cell membranes during fetal development and infancy may cause a defect in the expression or function of insulin receptors in the brain. This defect may lead to the development of type 2 diabetes as seen in NIRKO mice (194). Furthermore, systemic injections of either glucose or insulin in ad libitum fed rats resulted in an increase in extracellular acetylcholine in the amygdala (195). Aetylcholine modulates dopamine release that, in turn, regulates appetite (196). As already discussed above, ACh inhibits the production of pro-inflammatory cytokines in the brain and thus, ACh3, exists the neurons from the cytotoxic actions of TNF-α.

For proper neuronal development and increase in cell membrane surface area, growth of neurite processes from the cell body is critical (197). Nerve growth cones are highly enriched with AA-releasing phospholipases, which have been implicated in neurite outgrowth (198, 199). Cell membrane expansion occurs through the fusion of transport organelles with plasma membrane (200), and syntaxin 3, a plasma membrane protein that has an important role in the growth of neurites, is a direct target for AA, DHA, and other PUFAs (201). It was reported that AA, DHA, and other PUFAs activate syntaxin 3. Even syntaxin 1 that is specifically involved in fast calcium-triggered exocytosis of neurotransmitters is sensitive to AA (201). These results imply that AA, EPA, and DHA are involved both in the exocytosis of neurotransmitters and in neurite outgrowth. SNA P25 (synaptosomal-associated protein of 25 kDa), a syntaxin partner implicated in neurite outgrowth, interacted with syntaxin 3 only in the presence of AA that allowed the formation of the binary syntaxin 3-SNAP 25 complex (soluble N-ethylmaleimide-sensitive factor attachment protein receptor), which is needed for the fusion of plasmalemmal precursor vesicles into the cell surface membrane that leads to membrane fusion (202). These results clearly demonstrated that AA and DHA change the ω3-helical syntaxin structure to expose a SNARE motif for immediate SNAP 25 engagement and, thus, facilitate neurite outgrowth.

Puskas and his colleagues (203-205) noted that during brain growth and development, feeding with ω-3 DHA/ALA diets altered the expression of genes involved in synaptic plasticity, cytoskeleton, signal transduction, ion channel formation, energy metabolism, and regulatory proteins. These results imply that perinatal supplementation of PUFAs may play a critical role in the pathobiology of several adult diseases including metabolic syndrome X and Alzheimer’s disease (3, 4, 43, 44, 206-208).

Alzheimer’s Disease

Fish and fish oil components, EPA, and DHA are of benefit in Alzheimer’s disease (209-211). A reduction in dietary DHA in an Alzheimer’s mouse model showed a loss of postsynaptic protein teins associated with increased oxidation and showed increased caspase-cleaved actin, which was localized in dendrites; however, DHA-restricted mice when given DHA were protected against dendritic pathology and behavioral deficits and showed increased antiapoptotic B A D phosphorylation, which implies that DHA could be useful in preventing Alzheimer’s disease
in which synaptic loss is critical (212, 233). DHA attenuated amyloid-β secretion accompanied by the formation of neuroprotectin D1 (NPD1), a DHA-derived 10,17-docosatriene (214). In Alzheimer’s hippocampal cornu ammonis region, DHA and NPD1 were reduced, including the expression of enzymes involved in NPD1 synthesis, cytosolic phospholipase A2, and 15-lipoxygenase. NPD1 repressed amyloid-β-induced activation of pro-inflammatory genes and upregulated the antiapoptotic genes encoding Bcl-2, Bcl-xl, and Bcl-2-Related-Omics (Bcl-2) (211), which indicates its (NPDI) anti-inflammatory nature. Soluble amyloid precursor protein NPD1 synthesis from DHA (214).

Presenilin, a major component of γ-secretase, generates amyloid-β. Overexpression of phospholipase D1 decreases the catalytic activity of γ-secretase. PUFAs (especially AA and DHA) enhance acetylcholine release in the brain and, thus, bring about some of their beneficial effects in Alzheimer’s. Furthermore, EPA and DHA have the ability to enhance NO generation (30), suppress production of pro-inflammatory cytokines (110–113), and enhance brain acetylcholine levels (170), a neurotransmitter whose levels are decreased in Alzheimer’s disease (217). Thus, PUFAs modulate neural function, including neurotransmission, membrane fluidity, ion channel, enzyme regulation, and gene expression, as well as prevent inflammation; thus, they bring about their beneficial actions in Alzheimer’s disease.

Fetal-Alcohol Syndrome

Ethanol exposure during brain development induces neurodevelopmental defects referred to as fetal-alcohol syndrome (FAS) that is characterized by hyperactivity, learning and memory deficits, mental retardation, psychosis, depression, and schizophrenia. Ethanol-induced neurotoxicity, oxidative stress, induction of apoptosis, excitoactivity, interference with the action of growth factors, and EPA metabolism all could be responsible for the development of FAS. Neurons are susceptible to ethanol-induced apoptotic cell death during synapticogenesis during a brain growth spurt, which occurs during the third trimester of pregnancy and in the perinatal period. Recent studies showed that nicotine/nicotine enhanced the neuronal survival following free radical exposure and oxidative stress (218, 219). Nicotinamide is a cofactor in the metabolism of EFAs, which could explain the beneficial action of nicotinamide in FAS (220).

Depression

Depression is more likely to occur in individuals whose intake of PUFAs, especially of n-3 fatty acids, is lower (221). Pro-inflammatory cytokines might cause depressive illness (222). A significant decrease of w-3 fatty acids in plasma and/or in the membranes of red blood cells in subjects with depression has been reported (223–225). Because w-3 fatty acids suppress the production of IL-1β, IL-2, IL-6, and TNF-α, this finding suggests that these fatty acids could play a role in depression (222). In addition, antidepressants act like inhibitors of cyclo-oxygenase (222). Double-blind placebo-controlled and other studies (226–228) revealed that an addition of the w-3 fatty acids EPA and DHA was associated with a longer period of remission among depressed patients. Thus, epidemiological, experimental, and clinical data favor the idea that PUFAs play a role in the pathogenesis and/or the treatment of depression.

Schizophrenia and Huntington’s Disease

Patients with schizophrenia have increased concentrations of pro-inflammatory cytokines both in the systemic circulation and cerebrospinal fluid and showed decreased EPA and DHA in the plasma phospholipid. Clinical trials showed that supplementation of efflux DHA is of significant benefit to these patients (228). Huntington’s disease is an inherited neurodegenerative disorder because of a mutation in exon 1 of the Huntingtin gene that encodes a stretch of polyglutamine (poly Q) residues close to the N-terminus of the Huntington protein. Aggregated poly Q residues are toxic to the neuronal cells. Transgenic R6/1 mice that develop motor abnormalities of Huntington’s disease showed increased survival rates and decreased neurologic deficits when supplemented with ethyl EPA (229), which suggests that unsaturated fatty acids may prevent or arrest poly Q aggregation. These results suggest that PUFAs are useful in various neurological diseases. Understanding the molecular mechanisms of action of EPA/DHA as to why DHA is useful in Alzheimer’s disease whereas ethyl EPA is of benefit in Huntington’s disease and schizophrenia may throw more light on the pathobiology of these diseases.

Conclusions

It is evident from the preceding discussion that EFAs and their metabolites such as GLA, AA, EPA, DHA, eicosanoids, LXs, resolvins, NPD1, and nitrolypins have many actions and participate in several disease processes (Figure 2). In this context, it is important to note that certain PUFAs, such as GLA, have both antimutagenic and anticancer actions that have been discussed in detail elsewhere (230). Mutagens and carcinogens block ∆5 and ∆6 desaturases in normal cells much before their conversion into malignant cells. Pretreatment or simultaneous treatment with GLA completely prevented DNA damage induced by mutagens and carcinogens, which implies that GLA and other PUFAs could function as endogenous antimutagenic and anticancer molecules. GLA has selective tumorcidal action and is effective against human malignant glioma and other cancers (5, 231).

NO reacts with PUFAs to yield their respective nitroalkene derivatives that can be detected in plasma. These nitroalkene derivatives of various EFAs induce vascular relaxation, inhibit neutrophil degranulation and superoxide formation, inhibit platelet activation, and have endogenous PPAR-γ ligand activity.
and decay in the blood to release NO. This finding suggests that EFA sPUFAs not only form precursors to various eicosanoids, resolvins, LXs, and NPD1 but also react with various other molecules to form novel compounds that have significant biologic activity.

The major question is how these simple fatty acids can have so many biologic—and at times diametrically opposite—actions. One reason could be their ability to give rise to many metabolites that have specific biologic actions. Furthermore, these fatty acids when incorporated into the cell membrane alter its properties including fluidity that, in turn, modulates the number and affinity of various receptors to their respective growth factors, hormones, peptides, and proteins. Yet another action is their ability to form complexes with other biologically active molecules as is seen with NO to form various nitroalkene derivatives. Formation of such complexes between EFAs and other biologically active molecules could impart specific and distinct properties to these newly formed entities that in turn may show varied biologic actions. Deciphering the formation of such complexes is not only interesting but also challenging because such complexes may form the basis of understanding certain less well understood physiologic and pathologic processes.

A through structurally EFAs are simple, they form precursors to a variety of compounds with many biologic actions. We are yet to understand the molecular triggers that facilitate the formation of specific biologically active molecules in various cells and tissues. Such an understanding may lead to the development of methods to enhance selectively the formation of the desired lipid(s) to obtain a specific function or action. In view of their varied actions, EFA sPUFAs and their products could form the basis for the development of many drugs.

Lipid bilayers, Properties of

Lipid bilayers are the structural basis of biological membranes; they provide excellent structures for microencapsulation and are interesting objects of study as thermotropic and lyotropic smectic liquid crystals. This article introduces the fundamental principles that lead to the formation of lipid bilayers and briefly lists some amphiphiles that form lipid bilayers in biological systems. The temperature-dependent phase behavior of bilayers formed from a single lipid species is discussed briefly followed by a discussion of bilayer dimensions and hydration. The article then introduces the reader to phase behavior of bilayers formed from mixtures of lipids and the consequences of phase coexistence for component compartmentalization and percolation in lipid bilayers. Special emphasis is placed on the phase behavior of bilayers that contain sterols. The article introduces the reader to some physical properties of lipid bilayers, which include the hydration force, elasto-mechanical properties, and the resistance of bilayers to lateral stretching and/or compression and bending. Brief discussions of molecular dynamics in lipid bilayers from trans/gauche isomerism and rotation of lipid chains in bilayers to rotational, wobbling, and translational diffusion of lipids in bilayers is followed by an introduction to the dynamics of insertion, desorption, and transverse translocation of lipids in bilayers. Lipid bilayers are then discussed in terms of their permeability to aqueous solutes and some models for bilayer permeation are mentioned briefly. Finally, the reader is introduced to the electrical properties of lipid bilayers with brief discussions of the dipolar potential, the surface electrostatic potential, and the transmembrane potential. The article ends with a brief discussion of lipid compositional asymmetry across the lipid bilayer in biological membranes and its possible causes. Key references are cited wherever relevant.

Lipid bilayers are formed by many amphiphilic molecules in the presence of water. Their interest derives not only from the fact that they are a major, if not the only, organizing principle of biological membranes (1), but also because they tend to form closed (usually) spherical structures (liposomes or lipid bilayer vesicles) in which inner and outer aqueous spaces are separated by the lipid bilayers (2) which thereby provides a means of encapsulation (3, 4).

Amphiphilic molecules (or amphiphiles), in general, tend to aggregate in aqueous solution above some critical concentration (the critical micellar concentration or CM C) because of the hydrophobic effect (5). The aggregate structure secludes the apolar portions of these molecules from the aqueous medium and exposes the polar portions to water at the surface. The form of the aggregate is dictated by packing constraints (6) given by the optimal area per amphiphile,\(^1\) A\(_0\); at the interface of the aggregate and the aqueous phase, the mean volume of the amphiphiles, V; and their critical length,\(^2\) l\(_c\). Lipid bilayers are formed when the packing parameter p = V /A\(_0\) l\(_c\) = 1. Thus, a lipid bilayer is a self-aggregated sheet of amphiphiles (usually two molecules thick) in which the polar portions of the constituent molecules are exposed to water at the two surfaces of the sheet and the apolar portions are secluded from water in the volume between these two surfaces. Partial or total interdigitation of the apolar portions of the amphiphiles from the two monolayers of the bilayer is possible under certain conditions. The surfaces of the bilayer in contact with the aqueous

\[1\]The “optimal area per amphiphile” is defined as the mean area per amphiphile at the surface of the aggregate when the free energy per amphiphile in the aggregate is a minimum.

\[2\]The critical length is the mean length of the amphiphiles in an aggregate along the normal to the aggregate/aqueous interface.
Lipid Bilayers, Properties of

phase may be charged depending on the chemical identity of the polar portion of the amphiphiles and the conditions (pH, ionic strength) of the aqueous phase; the bilayer interior always is an apolar environment. The chemical nature of the apolar portions (usually long aliphatic chains) and the fact that these chains are anchored to the polar head groups of the amphiphiles located at the bilayer-water interface, make the lipid bilayer a highly anisotropic structure. Figure 1 (7, 8) shows some typical lipid bilayers.

This article discusses lipid bilayers formed by lipids of interest to biological membranes. The physics of these lipid bilayers have been the subject of excellent monographs (9, 10) and bilayers have been discussed in the context of their colloidal properties (11). Compilations of data on the physical properties of lipid bilayers may be found in References 12 and 13. Most generic physico-chemical properties are common to all bilayers. Much of our knowledge on the properties of lipid bilayers is the result of studies on bilayers formed in the laboratory by hydration of chemically defined diacyl lipids, phosphoglycerolipids, or sphingolipids. The aggregates formed by these lipids in water are lyotropic and thermotropic in character (i.e., the structure depends on the molar fraction of water and the temperature (14–16)). These so-called “model” lipid bilayers form spontaneously on hydration of the amphiphiles. Usually, they are studied as oriented single bilayers or on stacked multibilayers on solid supports, multilamellar liposomes or vesicles (MLV), or unilamellar vesicles of different diameters: small unilamellar vesicles with a diameter of about 20 nm (17); large unilamellar vesicles with a diameter of about 100 nm (18); and giant unilamellar vesicles with a diameter in the µm range, usually 10-50 µm (19, 20). MLVs are composed of several concentric lipid bilayer vesicles each separated from the one inside and the one outside by a thin layer of water. This form of lipid bilayer is, therefore, a smectic liquid crystalline phase.

Chemical Composition

The main lipid constituents of bilayers in biological membranes are derivatives of sn-1,2- (or sn-2,3-) diacylglycerol (phosphatic acids, phosphatidylethanolamines, phosphatidylcholines, phosphatidylserines, phosphatidylglycerols, phosphatidylinositol, and glycosylated diacylglycerols), derivatives of sphingosine (sphingomyelin, ceramide, and glycosylated derivatives of ceramides), and steroids (cholesterol in mammalian membranes, β-sitosterol, campesterol, and stigmasterol in plants, and ergosterol in eukaryotic microorganisms such as fungi). Cardiolipins (1,3-diphosphatidylglycerol) are important constituents of bacterial membranes and the membranes of mitochondria and chloroplasts. The aliphatic chains of glycolipids may sometimes be linked to the glycerol by ether linkages as in the case of plasmalogens (important constituents of some mammalian membranes) and some bacterial glycolipids. The membranes of extremophiles contain variable amounts of lipids in which long-chain (usually branched) α,ω-aliphatic diols are attached by ether linkage to two polyols (usually glycerol) to form bipolar lipid molecules that span the entire lipid bilayer. The aliphatic chains of naturally occurring lipids are usually from 14 to 24 carbon atoms long, and may be fully saturated or unsaturated with from 1 to 4 (usually 3) double bonds. The aliphatic chains of bacterial lipids are often branched and may include cyclic (3- to 6-membered ring) structures. Figure 2 shows the chemical structures of some lipids of biological importance.

Physical Properties

Phase behavior and phase transitions

At low temperatures, in lipid bilayers prepared from a single lipid species, the acyl/alkyl chains of the lipids in the bilayer are characterized by a high trans/gauche configurational ratio.

The chains, viewed along their long axes, are packed parallel to each other in a more or less hexagonal lattice with a lattice spacing of about 0.4 nm, and the bilayers are characterized by a high degree of conformational, rotational, and translational order. These bilayers are said to be in the "gel" phase. In gel phase, the acyl/alkyl chain axes may be oriented perpendicular to the bilayer plane (the \( L_\beta \) phase) or be slightly tilted relative to this plane (the \( L_\beta' \) phase). The tilt is understood to be the result of the in-plane area of the head groups being slightly larger than the in-plane area of two acyl chains. Depending on the chemical identities of the lipids and the temperature, more than one ordered phase has been characterized in lipid bilayers. In the so-called "sub-gel" or \( L_c \) phase (or \( L_c' \) when the chains are tilted relative to the bilayer normal) phase, which is observed at very low temperatures, the acyl chain order is at least equal to but may be greater than in the \( L_\beta \) (or \( L_\beta' \)) phase and may include a crystalline ordering of the lipid molecules. The "rippled" or \( P_{\beta'} \) phase, which is observed in some ordered bilayers at higher temperatures, shows a periodic saw-tooth ripple in the bilayer plane. This rippled pattern has two types of domains, the two faces of the saw-tooth pattern, with distinctly different packing of the lipids, the transition from one domain to the next possibly including some disordered phase lipid (7, 8). The acyl chain order in the \( P_{\beta'} \) phase is lower than that in the \( L_\beta \) (or \( L_\beta' \)) and \( L_c \) (or \( L_c' \)) phases. Transitions between the various phases in ordered lipid bilayers occur at characteristic temperatures that depend on the chemical identity of the lipids and their acyl chain lengths. When raising the temperature above a characteristic temperature, \( T_m \), which depends on the type of lipid that constitutes the bilayer, the ordered or gel phase is converted into a so-called "liquid-crystalline," "fluid," or \( L_\alpha \) phase in which the acyl chain configuration is characterized by a low trans/gauche configurational ratio and the chains are still packed in a more or less hexagonal lattice but with a low coherence length and

Bipolar lipid

Figure 2 (Continued)

Lipid bilayers in the fluid phase have low conformational, rotational, and translational order. The chain-melting transition at \( T_m \) is observed in all lipid bilayers regardless of the chemical identity of the lipid that constitutes the bilayer. The different transitions in the gel phase do not occur in all lipid bilayers, in which transitions depend on the lipid species of which the bilayer is constituted. When heating some lipid bilayers in the \( L_\alpha \) phase even more (e.g., those formed from some phosphatidylethanolamines), the hydrated lipid aggregate may be converted into one of several other phases that include inverted hexagonal and cubic phases. In bilayers formed from a given class of lipids, the characteristic temperatures at which the various phase transitions occur are dependent on the acyl chain lengths of the lipids and their degree of saturation.

The dependence of the “chain-melting” or main phase transition temperature in a lipid bilayer, \( T_m \), on the nature of the lipid head group as well as the length of the acyl chains and the degree and type (cis– or trans–) of unsaturation of the acyl chains has been studied exhaustively for some diacyl phospholipid classes (21). Bulkier head groups result in lower values of \( T_m \) for equivalent acyl chains. For head group homologs with two identical acyl chains, \( T_m \) increases monotonically, albeit in a nonlinear manner, with increasing acyl chain length. Usually, naturally occurring lipids have one saturated and one unsaturated acyl chain with one or more carbon-carbon double bonds, the latter usually in the cis– configuration. When more than one double bond occurs in the same acyl chain, these are usually separated from each other by a methylene group. The unsaturated chain is usually attached to the \( sn-2 \) position of glycerol. Lipids with unsaturated acyl chains in the \( sn-2 \) position have \( T_m \) values that are considerably lower than their fully saturated homologs, the reduction depends on the position and the number of unsaturated bonds. Introduction of a single double bond results in a very large drop in \( T_m \), the second unsaturated bond causes a smaller reduction in \( T_m \), and little or no reduction occurs in \( T_m \) on further addition of double bonds in an acyl chain. In the case of lipids with a single double bond in the \( sn-2 \) acyl chain, the largest effect on \( T_m \) is observed when the position of the double bond is roughly in the middle of the acyl chain.
As might be expected, the lipid bilayer phase transitions from a more ordered to a less ordered state are endothermic in nature and can be followed by differential scanning calorimetry (15). Bilayers prepared from dipalmitoylphosphatidylcholine (DPPC), for example, show at least three endothermic transitions: 1) the so-called subtransition (from the L_{α}′ to the L_{β}′ phase), which occurs at about 35°C with a transition enthalpy of 6.5 kJ mol\(^{-1}\); 2) the so-called pre-transition (from the L_{α}′ to the P3 phase), which occurs at 35°C with a transition enthalpy of 6.5 kJ mol\(^{-1}\); and 3) the so-called main (or chain-melting) transition, which occurs at 41.5°C with a transition enthalpy of 36.5 kJ mol\(^{-1}\). The enthalpies of the sub-transitions (when these occur) have been found to be more or less the same for bilayers prepared from different lipids irrespective of acyl chain lengths or head group structure. The same seems to be true for the enthalpies of the pre-transition. The enthalpy of the main or chain-melting transition, however, is very dependent on the acyl chain lengths and the degree as well as the type (cis- or trans-) of unsaturation of the lipid that forms the bilayer. It is similar for similar chain lengths in bilayers formed from lipids with different head groups. The phase transitions are also accompanied by nonmonotonic changes in lipid bilayer volume.

**Molecular and supramolecular dimensions in lipid bilayers**

The exact dimensions of a phospholipid bilayer membrane in terms of the in-plane area and the height of the lipid molecules as well as the thickness of the water layer that is associated with them is dependent on the chemical identity of the phospholipid head group, the length and the degree of saturation of the acyl chains, and the degree of hydration. This information may be obtained from a combination of small-angle X-ray diffraction by MLV or oriented multi-bilayer samples of phospholipids in excess water, electron and/or neutron density profiles across lipid bilayers, and atomic level molecular dynamics simulations of hydrated lipid bilayers. NMR studies on selectively deuterated phospholipids have also been important in elucidating acyl chain and lipid head group conformations. Our current understanding of the structure of phospholipid bilayers in terms of atomic/molecular detail has been summarized critically in an excellent review (23). The structural details of lipid bilayers in ordered (or gel) phases have been easier to define than in fluid (or liquid crystalline) phases that are more relevant for biological membranes. The reasons for this difficulty have to do with the poor diffraction patterns that result from long wavelength fluctuations or undulations in liquid crystalline phase bilayers, which destroy crystalline long-range order in the multilayer and local molecular fluctuations within each bilayer of the liquid crystalline lipid bilayer stacks. In L_{α} phase phosphatidylcholine bilayers, the choline head group has a probability distribution function that places it very close to the probability distribution function for the phosphate group (i.e., the choline head group lies roughly parallel to the bilayer plane and only slightly above the level of the phosphate group). The glycerol backbone of the lipid is oriented almost perpendicular to the membrane plane and the sn-1 acyl chain proceeds vertically into the bilayer, whereas the sn-2 acyl chain is kinked at the second carbon.

This structure makes the effective length of the sn-2 chain slightly (about 1.5 methylene groups) shorter than the sn-1 acyl chain. Table 1 lists some structural parameters for several phosphatidylcholine bilayers and one phosphatidyl-ethanolamine bilayer in the L_{α} phase. For comparison, the same structural parameters are listed for two of these bilayers [DPPC and dilauroylphosphatidyl-ethanolamine (DLPE)] in the gel phase as well. The most obvious structural differences among the L_{α} phase bilayer membranes listed in Table 1 can be attributed to the identity of the head group—the number of water molecules associated with the lipid bilayer is significantly different for the phosphatidylcholine (or phosphatidyl-ethanolamine) bilayers [DLPE] than when they are saturated (DPPC and DMPC). As might be expected, when gel phase bilayers are compared with L_{α} phase bilayers formed from the same lipid chemical species, the hydrophobic core thickness is significantly larger and the area per lipid is significantly lower in the gel phase (fully extended lipid chains). The number of water molecules associated with the lipid bilayers is also significantly reduced in the gel phase compared with the L_{α} phase (13 compared with 30 in DPPC and 6 compared with 9 in DLPE).

**Phase coexistence in lipid bilayers**

The properties of lipid bilayers formed from mixtures of lipids are very relevant to the understanding of the lipid bilayers that form the basis of biological membranes. Detailed studies have been performed on bilayers formed from binary lipid mixtures, and some reports in the recent literature describe phase diagrams of lipid bilayers prepared from ternary mixtures that include cholesterol. Figure 4 (24–31) shows some phase diagrams of lipid bilayers formed from binary and ternary mixtures of lipids. The general observation is that lipids in a bilayer are not very
miscible with each other in the gel phase. In binary mixtures of phosphatidylcholines, for example, differences in chemical identity of the head group and differences in chain length of four carbon atoms or more lead to gel phase immiscibility. Also, lipids with the capacity to form interdigitated gel phases do not mix well with lipids that do not have this capacity, even though their polar head groups and molecular masses are identical. Lipids generally seem to be mutually miscible in the fluid phase, although at least one report discusses immiscibility in the fluid phase of a bilayer prepared from a binary lipid mixture in which the polar head groups of the two chemical constituents of the bilayer were different.

Lipid bilayers that contain sterols are particularly interesting from the biological perspective because the plasma membranes of the cells of most eukaryotic organisms contain very large molar fractions of sterols (typically 30-50 mol%). In recent years, this aspect has received much attention because of the “raft” hypothesis (for a review on “rafts” see Reference 29). The condensing effect of cholesterol on fatty acids and phosphatidylcholine in monolayers has been known for a long time (32) and has been studied in detail. It was generally accepted that the condensing effect of cholesterol was a result of cholesterol–acyl chain interactions that forced the acyl chains in the lipid-expanded monolayer film to assume a conformation with higher trans/gauche configurational ratio. Studies on bilayers that contain high cholesterol concentrations confirmed these conclusions for bilayers as well; they showed that cholesterol significantly increased the trans/gauche ratio (conformational order) in the acyl chains of the lipids to values expected for rotating all-trans chains and were significantly higher than those typical for the cholesterol-free L1 phase. Translational diffusion in the cholesterol-rich bilayers was also shown to be slower compared with cholesterol-free bilayers. The reduction of the long-range translational diffusion coefficient has been reported to be from about 2-3 fold (28, 33) up to about 10-fold (34). In 1987, (pen et al. (35) integrated this information into a thermodynamic and a microscopic model for the interaction of cholesterol with the phospholipid molecules. They proposed that cholesterol forms an Ld phase with lipids in which the lipid chains are ordered conformationally. This phase, which was denominated the liquid ordered (Lo or L1 phase), is distinct from the Ld phase with conformationally disordered chains (which was denominated the Ld or Ld phase) observed in cholesterol-free lipid bilayers at temperatures above Tm. The formation of the Ld liquid-ordered phase is the consequence of the flat and rigid cholesterol structure that maximizes its interaction with the lipid acyl chains in an L1 phase bilayer by forcing these into a predominantly all-trans conformation but, at the same time, cholesterol cannot be incorporated into the in-plane crystalline lattice of a gel phase bilayer because of its size and shape. A compromise solution is to retain the all-trans configuration of the chains and simultaneously maintain the translational order of the fluid phase. Thus, in lipid bilayers that contain cholesterol, two fluid phases could possibly coexist in the lipid bilayer (see phase diagrams for ternary lipid mixtures in Fig. 4) depending on the molar fraction of cholesterol.

Phase coexistence in lipid bilayers may be an important physical property for membranes of cells. When two phases coexist in a bilayer, depending upon the relative mass fractions of the phases and the shapes of their domains, one of the phases is the percolative (physically continuous) and the other is nonpercolative (physically discontinuous or dispersed as isolated domains). Changes in the physico-chemical properties of the membrane (lateral pressure, temperature, and chemical composition are the most relevant for biological membranes) result in interconversion between the two phases— one phase grows at the expense of the other. In phase-separated systems of this type, a critical mass ratio of phases called the percolation threshold, at which the previously continuous phase becomes discontinuous and the previously discontinuous phase becomes continuous, becomes

(30)]; lipid bilayers prepared from ternary mixtures of DSPC, DOPC, and cholesterol (31).

Phase separation in a membrane may lead to segregation of membrane components, which includes proteins (in-plane compartmentalization) based on their preferred solubility in one or the other of the coexisting phases; this segregation may have important consequences for in-plane bimolecular reactions that occur in these membranes (37). Crossing a percolation threshold (changes in the phase mass ratio may be induced by osmotic stress, temperature changes, or changes in chemical composition) can connect previously disconnected domains and their constituents. The previously continuous domain, and its constituents, becomes simultaneously discontinuous.

In systems with phase coexistence, the free energy of the system is discontinuous at the interface between the phases. This discontinuity results in an interfacial tension that drives the system toward a minimization of the interface. In three-dimensional systems, the interfacial tension acts on the area (surface tension); in two-dimensional systems, it acts along the line (line tension) that separates the phases. In both cases, if the interfacial tension is large enough, then it may be expected that...
the coexisting phases separate into macroscopic domains with the smallest possible separating surface or line between them (a so-called bulk phase separation) at equilibrium. Interfacial tension may be reduced by surface-active agents, which are amphiphilic molecules that locate in the interfacial region and interact more favorably on one side with one of the phases and on the other side with the other phase. Such a reduction in interfacial tension is observed in thermodynamically stable emulsions and in metastable dispersions of immiscible phases. In the lipid bilayers of biological membranes, it is conceivable that some lipids and proteins may act as the amphiphiles that reduce interfacial line tension between domains of coexisting phases in the lipid bilayer.

Although the question of whether phase separations do occur in the lipid bilayers of biological membranes is hotly debated, it is generally accepted that these membranes do show spatial and temporal heterogeneities (domains) in lipid bilayer order. These heterogeneities may have several origins. First, membrane physiology involves processes of vesicle fusion with and budding from a given membrane. These processes will result in localized heterogeneities in chemical composition and physical properties in the lipid bilayer, which dissipate in a diffusion-limited manner within a short time. Second, protein aggregation by some force external to the lipid bilayer (reorganization of the cytoskeleton with its attached proteins; extra-membranal cross-linking of proteins, etc.) may cause a coalescence of the boundary lipid shells around the proteins, which results in a localized change in lipid order that is associated with the protein aggregate. Because the boundary layer has a coherence length of about two lipid shells around the protein surface, this heterogeneity may be expected to dissipate with the disintegration of the protein aggregate. Third, assuming that the system is in a steady state, the lipid bilayer of biological membranes may be a multiphase system because of its compositional complexity and the mutual immiscibility of its chemical constituents. Domains of these phases would be thermodynamically stable. As discussed above, if the line tension around the phase domains is small enough to be insufficient to drive domain growth, then phase coexistence in the bilayer does not necessarily imply a bulk phase separation or that the small dispersed domains of a given phase grow in time. They may, however, be dragged together by forces external to the membrane to form larger domains or platforms.

As discussed at the beginning of this article, the formation of lamellar aggregates such as bilayers by hydrated lipids is dependent on the shape of the lipid molecules, which are characterized by a critical packing parameter, \( p \), whose value must be above equal to 1. When \( p \approx 1 \), spherical micellar aggregates are formed, and for \( p > 1 \) the aggregate formed is an inverted micelle or an inverted hexagonal phase. Both aggregates are characterized by very large curvatures (curvature \( \approx 1/R \), where \( R \) is the radius of curvature; see Fig. 5b for definitions) (38), the normal micellar aggregate has a positive and the inverted aggregate a negative curvature. Some physiological events such as membrane fusion, membrane fission, and the drawing out of very narrow tubular membrane structures require the localized formation of membrane structures with high curvatures. Thus, to be responsive to these physiological events, the lipid bilayers in biological membranes must contain a certain amount of lipids that are readily available for and that can form these highly curved structures. At the same time, the presence of these lipids should not cause a significant perturbation of the bilayer membrane and its physical properties. This balance is maintained by biochemical mechanisms that change membrane lipid composition according to need (39).

**The hydration force**

The characteristics of the water associated with the polar lipid bilayer surfaces are of particular interest because they become very important in processes of physiological significance such as membrane fusion, and they may play a role in the mechanisms of association of proteins and small molecules with lipid bilayers and biological membranes. A very small fraction of the lipid bilayer-associated water molecules are actually immobilized, and a larger fraction (about 30% of the total bilayer-associated water in multilamellar PC bilayers in the L\(_c\) phase) has a probability distribution function that is more or less coincident with the probability distribution function for the polar head group of the lipids. Nevertheless, the pressure, \( P \), which must be exerted to remove the bilayer-associated water, is large and varies (from \(-0.5\) to \(-500 \text{ N cm}^{-2}\)) with the thickness of the inter-bilayer water space as:

\[
P = P_0 \exp\left(-\frac{\alpha}{\lambda}\right)
\]

where \( d_w \) and \( \lambda \) are the inter-bilayer water thickness in a multibilayer stack, and \( \lambda \) is a characteristic length (\( \approx 0.2 \text{ nm} \) in L\(_c\) phase PC bilayers). The resistance to removal of the inter-bilayer water has been called the “hydration force”; it is the consequence of contradictory interaction forces: A van der Waals interaction that brings bilayers together is counterpoised by repulsive interactions that result from long-range undulation fluctuations of the fluid lipid layers, static repulsion of the head groups, and water dipoles with a preferred orientation at the bilayer-water interface (surface hydration). This phenomenon has been discussed by Parsegian and coworkers in excellent reviews (40, 41).

**Elasto-mechanical properties of lipid bilayers**

Lipid bilayers fall into the category of materials that have come to be known as “soft matter.” These materials are condensed phases that possess many characteristics of liquids but are simultaneously structured. The intermolecular interactions that cause lipid molecules to self-aggregate to fluid bilayers in the presence of water also impart a degree of “toughness” to these bilayers compared with conventional liquids. For detailed discussions of these properties of lipid bilayers, the reader is referred to References 10, 38, and 42. Toughness implies resistance to forces that shear, break, or bend the bilayer (Fig. 5). Bending without breaking and resistance to shear stresses, for instance, are essential properties of the membranes of cells (particularly erythrocytes and platelets) that are forced in the blood stream to squeeze through very narrow capillaries. This property is also essential to cell membranes (in particular the apical surface membranes of epithelial and endothelial cells).

that line the lumen of tubes in the body through which relatively viscous fluids flow (for example, the endothelial cells of blood vessels, the epithelial cells of the gastrointestinal tract, the kidney and the urinary tract, the respiratory tract, etc.).

The lipid bilayer membrane in living cells is a fluid membrane and, therefore, has no shear rigidity. However, within the cell and subjacent to the membrane lies an intricate network of the cytoskeleton that is attached with some regularity to the lipid bilayer that constitutes the cell membrane via proteins that are anchored in the bilayer. The shear rigidity of cell membranes is thus provided in a large measure by the cell cytoskeleton.

Resistance of an infinitely thin sheet to stretching (or in-plane compression) and bending stresses are expressed in terms of the respective elasto-mechanical moduli. The area compressibility modulus, $K_A$, is defined via the energy required per unit area $E_{KA}$ to produce an area increment $\Delta A$ in a sheet of reference area $A_0$: $E_{KA} = \frac{1}{2} K_A (\frac{\Delta A}{A_0})^2$.

The resistance to bending is expressed in terms of two moduli: the mean curvature modulus, $\kappa_C$, and the Gaussian curvature modulus, $\kappa_G$, which are both defined via the energy, $E_C$, required for bending the sheet (43): $E_C = \left[ \frac{\kappa_C}{2 R_1^2} + \frac{\kappa_G}{2 R_2^2} + \frac{K_C}{R_1 R_2} \right] A$, where $A$ is the area of membrane, $R_1$ and $R_2$ are the principal radii of curvature, and $R_0$ is the radius of spontaneous curvature of the sheet (see Fig. 5 for definitions). In the case of lipid bilayers, the spontaneous curvature is the result of the packing parameter, $p$, for the lipids that constitute the two monolayers of the lipid bilayer (see above for definition) not being exactly equal to 1. For bilaterally symmetrical bilayers, the spontaneous curvature ($C_0 = R_0 - 1$) is zero because the two monolayers curve in opposite directions and the force resulting from the hydrophobic effect symmetrically forces them together. For asymmetric bilayers, however, this may not be the case. The mean curvature modulus of a bilayer, $\kappa_C$, and the area compressibility modulus, $K_A$, are related to each other ($K_C = K_A d^2$, for the simplest case of an infinitely thin sheet), the exact relationship is dependent on the coupling between the monolayers and whether the lateral pressure distribution is uniform across the bilayer (38). $\kappa_C$ has a quadratic dependence on the thickness of the bilayer.

Marsh (38) has listed several measured values of the elastic moduli of lipid bilayers. Typically, the area compressibility moduli are in the range of 200-250 mN m$^{-1}$ for fully hydrated symmetric bilayers in the $L_\alpha$ phase prepared from phosphatidylcholines, and they are not very dependent on the degree of saturation of the acyl chains. Cholesterol has a significant effect on the area compressibility modulus of a bilayer. Thus, $K_A$ for bilayers of 1-stearoyl-2-oleoylphosphatidylcholine (SOPC) increases from 235 mN m$^{-1}$ in the absence of cholesterol ($L_\alpha$ liquid-disordered phase) to 640 mN m$^{-1}$ in bilayers with 40 mol% cholesterol ($L_{eta'}$-rich ordered phase).
made from an equimolar mixture of SOPC and cholesterol (Lα, liquid-ordered phase). The mean curvature elastic moduli have been reported to be in the range of $10^{-12}$ for Lα phase phosphatidylcholine bilayers, but the exact value is dependent on the method used for their determination.

Molecular dynamics, diffusion, trans-bilayer translocation, and lipid exchange in bilayers

The dynamics of molecules in a lipid bilayer is of fundamental importance in the role that the lipid bilayer plays in a biological membrane. Dynamics in a lipid bilayer spans a frequency scale from $10^{12}$ s$^{-1}$ (for the vibrational dynamics of single bonds in the lipid molecules) through $10^{-10}$ s$^{-1}$ for trans-membrane translocation ("flip-flop") of a lipid molecule. From a functional perspective, the most important dynamic modes that have to be considered are the trans-gauche configurational isomerism in lipid molecules and the rotational and translational directional dynamics of these in the bilayer. These dynamic modes determine how fast the lipid bilayer responds to changes in volume and pressure (including localized changes resulting from conformational transitions of proteins associated with the bilayer of biological membranes) and the rate at which lipids exchange between different environments in a bilayer. A rather important dynamic mode is the rate at which lipid molecules spontaneously desorb from and insert into lipid bilayers, because these rates determine the lower limit (noncatalyzed rates) at which lipids can exchange between the different (presumed noncontiguous) membrane environments in cells.

Changes in the configuration (trans-gauche isomerism) of single bonds in lipid molecules result in rotational motions in the lipid acyl chains and head groups; an increased configurational entropy is the cause of phase transitions in lipid bilayers. The global lipid conformation is a result of the combination of configurations about single bonds in the acyl chains and the head group. The headgroup and acyl chains may be viewed as anchored positionally at the glycerophosphate group at the aqueous interface, and they have the freedom to execute angular excursions relative to the bilayer normal. The headgroup is, therefore, capable of motion in a cone whose vertex lies at the carbon atom linked to the phosphate group and has some preferred orientation, which is known to be more or less parallel to the bilayer surface in bilayers prepared from phosphatidylcholines and from phosphatidylethanolamines. Each acyl chain is also capable of a conical excursion with the vertex close to the carbonyl group. The angular excursion executed by each carbon atom in the chain varies with the position of the carbon atom in the chain. In general, carbon atoms closer to the glycerophosphate anchor (approximately up to carbon atom 10) execute a smaller angular excursion than those farther away from it. The excursion angle is usually expressed in terms of the C-H bond order parameters measured by H{H-NMR on lipid bilayers prepared from deuterated lipid molecules (44, 45). Frequencies for trans-gauche isomerization depend, as might be expected, on the physical state of the lipid bilayer, and are found to be $10^{-11}$ s$^{-1}$ for the head group and $10^{-9}$ s$^{-1}$ in the chains in the crystalline (Lc) phase and increase to $10^{8}$ s$^{-1}$ in the fluid (Lα) phase (7).

In the fluid (Lα) phase, the constituents of a lipid bilayer have diffusional freedom that may be described in terms of the diffusion coefficients for wobbling motions of the lipid long axis (D⊥), rotation of the lipids around their long axis (D∥), and the translational diffusion in the plane of the lipid bilayer (D,) and the transmembrane direction (D.). Deuterium NMR studies (46) and Molecular Dynamics simulations (47) of pure dimyristoylphosphatidylcholine (DMPC) bilayers at 40-45°C give values of D⊥ in the range of $10^{6}$ to $10^{7}$ s$^{-1}$ and values of D∥ of $10^{-3}$ s$^{-1}$. In Lα, liquid-ordered phase bilayers prepared from equimolar binary mixtures of DMPC and cholesterol, D⊥ increases about threefold, whereas D∥ decreases over 10-fold (48), which is consistent with a higher order and reduced chain entanglement in the liquid-ordered compared with the liquid-disordered phase. The translational diffusion coefficient (D,) has been measured using a wide variety of techniques. In Lα, liquid-disordered phase lipid bilayers prepared from pure phosphatidylcholines, D⊥ from $10^{-10}$ to $10^{-11}$ m$^{2}$ s$^{-1}$ depending on the lipid and the temperature (49), which corresponds to a hopping frequency ($ν_h$) of $10^{7}$ to $10^{8}$ s$^{-1}$ assuming the area per lipid molecule in the bilayers to be $0.5$ nm$^{2}$. In gel phase (Lβx-1), phase phosphatidylcholine bilayer D⊥ has been reported to be from 3 to 9 orders of magnitude slower ($10^{-15}$ s$^{-1}$) than in the fluid phase (for a review see Reference 50).

In Lα, liquid-disordered phase membranes prepared from binary mixtures of a phosphatidylcholine and cholesterol, the value of D⊥ has been reported to be from $2-3$ times lower to about $10$ times lower than it is in Lα liquid-disordered phase membranes prepared from the phosphatidylcholine alone (28, 33, 34).

The theoretical description of translational diffusion in a lipid bilayer depends on the size of the diffusing particle. Theoretical descriptions based on fluid hydrodynamic theory (51, 52) have been shown to be applicable to particles whose radius in the plane of the bilayer is significantly larger than the radius of the lipid molecules that constitute the bilayer, in which case the diffusion coefficient may be given by:

$$D_i = \frac{kT}{4\pi \eta b} \left( \frac{v_w}{\eta_w} \right)^{-1} \left[ \frac{R}{h} \right]^{-1}$$

where $k$ is the Boltzmann constant, $T$ is the temperature, $h$ is the thickness of the bilayer sheet and height of the embedded diffusing particle considered to be a cylinder of radius $R$, $\eta$ are the viscosities of the bilayer fluid and the bounding water, respectively, with $\eta_w < \eta$, and $\gamma = 0.5772$ is Euler's constant. The diffusion of lipids or particles with a radius that is equal to or smaller than that of the lipid molecules in a lipid bilayer is not described adequately by the continuum fluid hydrodynamic model; a theoretical model based on free volume theory has been proposed for this purpose according to which D⊥ may be given by (48, 50):

$$D_i = \frac{kT}{4\pi \eta b} \left[ e^{-\gamma} / (\gamma \eta b + 1) \right]^{1/2}$$

where γ is a factor that accounts for overlapping free volumes ($0.5 \leq \gamma \leq 1$). $v_w$ is the van der Waals molecular volume of a
lipid in the bilayer, \( v^* \) is a critical free volume below which the diffusing particle does not move into an adjacent free volume, \( v_{fp} \) is the free volume at the phase transition temperature, \( T_m \), and \( v \) is the coefficient of volume expansion of the fluid lipid bilayer. In this model, particles that span the entire thickness of the bilayer feel the translational frictional drag, \( 1 \), at both the bilayer-water interfaces. Particles that span only a single monolayer feel the frictional drag at one of the bilayer-water interfaces and at the bilayer midplane. There are no dissipative interactions within the bilayer itself. The free volume, \( v_m \), of the fluid lipid bilayer is the difference between the volume per lipid at temperature \( T \) and the van der Waals volume of the lipid:

\[
v_m = v - v = v_0 + 6[1 - (T_m - T)]
\]

The viscous drag felt at the bilayer-water interface can be large when the bounding fluid viscosity approaches the viscosity of the membrane (53) or when the fluid lipid bilayer is associated with a rigid substrate (54).

The lipids in a lipid bilayer may translocate across the bilayer from one monolayer to the apposed monolayer. This transmembrane translocation process, which is also known as "flip-flop," is slow for lipids with large polar head groups such as glycero-lipids and sphingoglycosphospholipids but can be fast in the case of lipids with very small polar moieties such as cholesterol. Typical first-order rate constants for transmembrane translocation of a phospholipid-like molecule in \( L_\alpha \) liquid-disordered phase bilayers prepared from 1-palmitoyl-2-oleoylphosphatidylcholine (POPC) are \(-10^{-8} \text{ s}^{-1}\) and may be about 10-fold slower in \( L_\alpha \) liquid-ordered phase bilayers prepared from binary mixtures of the same phosphatidylcholine and cholesterol but is much slower (\(-10^{-3} \text{ s}^{-1}\)) in \( L_\alpha \) liquid-ordered phase membranes prepared from sphingomyelin and cholesterol (55). The activation free energy for the process, which corresponds to the energy necessary to put the translocating lipid molecule at the bilayer mid-plane, is \(-100 \text{ kJ mol}^{-1}\). In contrast, the rate constant for transmembrane translocation of cholesterol may be \(-1 \text{ s}^{-1}\) (56).

In any system that contains noncontiguous lipid bilayers, such as a living cell, the lipid components of these bilayers can exchange through a process that involves noncatalyzed desorption of single lipid molecules from one membrane and insertion into another. This lipid exchange involves three processes: 1) a first-order desorption of lipid molecules from the donor bilayer, 2) a diffusion-limited second-order encounter of the lipids in the aqueous phase with the surface of the acceptor bilayer to form an encounter complex, and 3) a first-order insertion of the surface located lipid molecules into the acceptor bilayer. The rate constants for the first and last processes have been measured for lipid-derived probes (57). Desorption rate constants are on the order of \(10^{-9} \text{ s}^{-1}\) from \( L_\alpha \) liquid-disordered phase bilayers prepared from POPC and are about 10-fold slower when the bilayer is an \( L_\alpha \) liquid-ordered phase prepared from sphingomyelin and cholesterol. Insertion rate constants are on the order of \(10^{-6} \text{ s}^{-1}\) in \( L_\alpha \) phase bilayer membranes prepared from POPC, with or without cholesterol, and about 10-fold slower when the acceptor membrane is an \( L_\alpha \) liquid-ordered phase prepared from a binary mixture of sphingomyelin and cholesterol. Thus, the noncatalyzed exchange of lipids between noncontiguous lipid bilayers in a cell is a slow process that is limited by the rate of desorption from the donor lipid bilayers.

**Lipid bilayers as permeability barriers**

Because of its apolar interior, the lipid bilayer is a barrier to diffusional equilibration of solutes between the two aqueous compartments that it separates. The ability of most small solute molecules (50 < molecular weight < 300) to cross the bilayer is directly proportional to their ability to partition into hexadecane or olive oil from an aqueous solution (58), which is an observation first made by Overton (59) and is often referred to as "Overton's Law." Permeation of lipid bilayers by small polar molecules and ions seems to occur via one or a combination of both of two mechanisms depending on the nature of the permeants and the nature of the bilayers. First, a "solubility-diffusion" mechanism treats the bilayer as a slab of liquid hydrocarbon sandwiched between two bulk aqueous compartments. The permeant must partition into the bilayer slab from one of the aqueous compartments, diffuse across it, and leave by dissolving into the second aqueous compartment. In this case, the permeability coefficient, \( P \), is given by:

\[
P = \frac{K v D_m}{d}
\]

where \( K \) is the partition coefficient of the permeant between the bilayer and aqueous phases, \( D_m \) is its translational diffusion coefficient in the bilayer phase and \( d \) is the bilayer thickness. Second, a pore mechanism assumes the formation of transient water-filled pores (often referred to as "water wires") across the bilayer because of density fluctuations in it. The permeant (in a partially or fully hydrated state) is then assumed to diffuse through the bilayer via these transient pores. In this case, the permeation coefficient is proportional to the probability of formation of pores that span the entire bilayer, the mean pore radius, and the translational diffusion coefficient of the permeant in water. The expected dependence of the permeation coefficient on bilayer thickness is steeper in the case of the pore mechanism than it is in the solubility-diffusion mechanism, which thereby provides the basis for a critical test of which mechanism is applicable to the permeation of a given permeant particle (60).

Uncharged, small polar molecules such as water, glycerol, and urea permeate bilayers, regardless of their thickness, via the solubility-diffusion mechanism. Protons seem to permeate bilayers predominantly via the pore mechanism for bilayers with an apolar layer thickness of up to \(-3 \text{ nm}\) (phosphatidylcholine bilayers with acyl chains up to about 16 to 18 carbon atoms); the solubility-diffusion mechanism becomes predominant for thicker bilayers. Potassium and halide ions permeate bilayers almost completely via a solubility-diffusion mechanism when the bilayers are thicker than \(-2 \text{ nm}\) (60, 61). Typical permeability coefficients, for permeation of bilayers prepared from phosphatidylcholines in the \( L_\alpha \) liquid-disordered phase with a 3 nm hydrophobic thickness, are \(-10^{-3} \text{ m s}^{-1}\) for water permeation, \(-10^{-9} \text{ m s}^{-1}\) for the permeation of protons, \(-3 \times 10^{-11} \text{ m s}^{-1}\) for potassium ions, and \(-6 \times 10^{-12} \text{ m s}^{-1}\) for chloride ions.
Electrical properties of lipid bilayers

Lipid bilayers have electrical properties that are not just a result of the charges on the lipid molecules. The association of any charged particle with a lipid bilayer and/or the permeation of lipid bilayers by any charged particle are strongly conditioned by the electrical properties of the bilayer. There are three types of electrical potentials associated with lipid bilayers suspended in aqueous electrolyte solutions: 1) a dipole potential, 2) a surface potential, and 3) a transmembrane potential.

The dipole potential (discussed in Reference 62) results from the anisotropic orientation of the lipids in a bilayer and from orientation of water dipoles at the lipid bilayer-water interface. The dipole potential of an L_2 liquid-disordered phase phosphatidylcholine bilayer is ~250 mV, which is positive inside the bilayer. The anisotropic orientation of the lipid molecules in a bilayer results in a “surface dipole moment” whose main contributions come from the dipole moments of the terminal methyl groups and the carbonyl groups of the lipid acyl chains, particularly the carbonyl group of the acyl chain attached to the sn-2 position of glycerol. The dipole moments of the lipid head groups and the chain methylene groups are assumed to contribute nothing because of their orientation parallel to the surface. A very significant, if not the major, contribution to the dipole potential may have its origin in the orientation of bound water dipoles at the membrane-water interface (63). As observed earlier, the orientation of water molecules at the bilayer surface is an important cause of the hydration force. The dipole potential of a lipid bilayer, which is dependent on lipid orientation, is different for different lipid phases. More ordered lipid bilayers might be generally expected to have a larger dipole potential. Differences in the dipole potential of different coexisting phases in a bilayer are responsible for determining the size, shape, and arrangement of domains in lipid monolayers (and possibly bilayers as well) and may make the coalescence of dispersed domains of the same phase to a macroscopically separated phase in the bilayer a very slow process (64). It may even determine the transverse superposition of domains of the same (or similar) phase across the lipid bilayer with phase coexistence (65).

The surface potential of a bilayer is a result of having charged lipids in this bilayer (for reviews see References 63 and 66). In fluid phase bilayers, rapid translational diffusion of the lipids allows the surface charge associated with the lipids to be considered a smeared charge and the electrostatic potential at the surface of the bilayer, \( \psi_s \), is well described by the Gouy-Chapman equation:

\[
\sinh(2e\zeta_0 T/2kT) = A_0/(c\zeta_0)^{1/2}
\]

where \( \zeta \) is the valence of the counter ion in the electrolyte solution, \( e \) is the electronic charge, \( k \) is the Boltzmann constant, \( T \) is the temperature, \( \sigma \) is the surface charge density, \( c \) is the number of ions of a z+2 electrolyte in the aqueous solution, \( A_0 = (\kappa_0 z e_{\text{water}} T)^{-1} \) is a constant, \( e_0 \) is the permittivity of free space, and \( \kappa_0 \) is the dielectric constant of water (~80). The electrostatic potential varies with distance, \( x \), from the charged surface as:

\[
\psi_s = \frac{kT}{e} \ln \left[ \frac{1 - \exp(-\alpha x)}{1 + \exp(-\alpha x)} \right]
\]

where \( \alpha = (\exp(e\zeta_0 T/2kT) - 1)/(e\exp(e\zeta_0 T/2kT) + 1) \) and \( \alpha^2 = ([\kappa_0 z e_{\text{water}} T]/2z^2 e^2 e_0)^{1/2} \) is the Debye length. For small surface potentials, the Gouy-Chapman equation for the surface potential reduces to:

\[
\psi_s = \varphi_0/z \exp(-\alpha x)
\]

and the expression for the distance-dependent potential reduces to:

\[
\psi_s = \varphi_0 \exp(-\alpha x)
\]

The surface potential results in a concentration of the counter-ions and a depletion of the co-ions in the aqueous phase close to the charged surface, which results in the so-called electrical double layer. The ion concentrations in the aqueous phase at a given distance \( x \) from the charged surface are given by:

\[
c_+ = c \exp(-2\zeta_0 \psi_s/kT)
\]

It is important to note that each monolayer that constitutes a lipid bilayer has its own surface potential, and whether the surface potential is equal on both sides of the lipid bilayer will depend on the transverse compositional symmetry of the bilayer. Lipid bilayers in biological membranes are usually compositionally asymmetric, which is a fact that could originate a potential difference (generally given as \( \Delta \Phi \) in the literature) between the two membrane surfaces that may be expected to play a role in ion permeation of the lipid bilayer and, therefore, be important in cell membrane physiology. One consequence of the surface potential is that protons are concentrated (or depleted in the case of a positively charged surface) in the electrical double layer with the resulting consequence that the apparent \( pK_a \) of ionizable groups that suffer acid-base equilibria close to the surface of the bilayer is different from what it would be in bulk aqueous solution. The value of this apparent \( pK_a \) is dependent on the ionic strength of the bulk aqueous electrolyte solution and approaches the value of the \( pK_a \) in bulk solution as the ionic strength is raised.

The transmembrane potential is the difference in the electrical potentials of the two bulk aqueous phases separated by the bilayer (for a detailed treatment see Reference 67). The lipid bilayer may be viewed as an electrical capacitor in which the electrical potential works on the flux of the ions in a direction that is contrary to that of the diffusion potential. At equilibrium, the electrical potential and the diffusion potential are exactly balanced so that no net flux of ions occurs. The resulting transmembrane potential with respect to a given ion, \( \psi_{\text{membrane}} \), is given by the Nernst equation:

\[
\Delta \psi_{\text{membrane}} = \psi_0 - \psi_1 = \frac{RT}{F} \ln \left[ \frac{[\text{co-ion}]}{[\text{counter-ion}]} \right]
\]
where $R$ is the gas constant, $F$ is the Faraday constant, $C_i$ are the concentrations of the ion $N_i$, and the subscripts (1) and (2) represent the electrolyte solutions on the two sides of the bilayer. A biological membrane is bathed in electrolyte solutions that have different ions that permeate the bilayer, each at its own rate. Thus, if the bilayer is bathed in aqueous solutions of NaCl, then the concentrations of both Na$^+$ and Cl$^-$ on both sides of the bilayer and the respective permeation coefficients, $P_{Na^+}$ and $P_{Cl^-}$, must be taken into account to account for the global transmembrane potential, which is done in the Goldman-Hodgkin-Katz equation:

$$
\Delta \Psi = \frac{RT}{F} \left( \frac{P_{Na^+}c_{Na^+}}{c_{Na^+}} + \frac{P_{Cl^-}c_{Cl^-}}{c_{Cl^-}} \right)
$$

where the subscripts (1) and (2) refer, as before, to the electrolyte solutions on the two sides of the bilayer.

In living cells, ion channels and energy-dependent pumping mechanisms (with more or less specificity) facilitate or catalyze the permeation of certain ions in one direction or the other across the lipid bilayers that constitute the cell membranes. This mechanism makes the permeation of certain ions several orders of magnitude faster than the permeation of others; which thereby accentuates the transmembrane potentials discussed above. These processes are particularly important in the creation and the transmission of the action potential in nerves.

Lipid bilayer asymmetry in biological membranes and its possible causes

Most lipid bilayers prepared by hydration of lipids in the laboratory (the so-called model systems) are bilaterally symmetric at equilibrium (i.e., the chemical composition with regard to the lipids of each monolayer that constitutes these bilayers is identical). That is not the case in the lipid bilayers of biological membranes that are known to be compositionally asymmetric in all examined cases. A important contribution to the transverse asymmetry observed in biological membranes comes from the vectorial nature of lipid biosynthesis in cell organelles such as the endoplasmic reticulum and the Golgi compartments. Other contributions certainly come from the relatively slow transmembrane translocation (see above) of lipids in lipid bilayers, the asymmetric chemical composition of the aqueous compartments on the two sides of the membrane, and from the lipid shape-dependent (see discussion on the packing parameter above) spontaneous curvature of lipid monolayers. When all contributions are insufficient, the living cell seems to maintain lipid asymmetry in its membranes enzymatically using the so-called “flipases” that may or may not be dependent on metabolic energy (68, 69). Transverse translocation of most polar lipids across a lipid bilayer involves an intermediate “transesterification state,” in which the polar portion of the lipid molecule lies in the highly apolar bilayer midplane, with an activation free energy ($\Delta G^{\circ}$) on the order of 100 kJ mol$^{-1}$. It would seem, therefore, that transverse asymmetry is of paramount importance in cell membrane structure and physiology. It will be an important challenge from the perspective of Cell Biology and Biochemistry to understand why. From the perspective of lipid bilayer Physics and Chemistry it will be a nontrivial challenge to make relatively stable compositionally asymmetric lipid bilayers.

Lipids represent some of the most complex biologic molecules, and their diversity is crucial for their cellular functions. The wide range of chemical and physical properties of different lipids determines a variety of roles for these compounds in biologic processes. According to their structures, lipids can be divided into two main groups: the nonpolar lipids (acylglycerols, sterols, free fatty acids, hydrocarbons, alcohols, wax, and steryl esters) and the polar lipids (phosphoglycerides, glycosylglycerides, and sphingolipids). Triacylglycerols act as energy stores and metabolic fuels. Polar lipids and sterols are important structural components of cell membranes where they may have many diverse functions. Arranged as bilayers, they establish permeability barriers for cells and organelles and provide a microenvironment for membrane-associated proteins as well as participate directly in metabolism and a multitude of membrane fusion events (1). Waxes as surface coverings are integral to water balance and protect organisms from noxious environmental conditions. In addition to a structural role, lipids serve as important intermediates in cell signaling pathways (e.g., sphingolipids, inositol lipids, phosphatidic acid, lysophospholipids, oxidative products) and play a role in mediating cellular responses to the environment (2). In this article, we will summarize our knowledge on the structural diversity of lipids that provide information on the various lipid classes and the fatty acids that occur naturally.

Glycerolipids

Acylglycerols (glycerides)

The basic structure of glycerolipids is a glycerol (propane-1,2,3-triol) backbone to which the hydrophobic acyl groups (fatty acids) are esterified. Monoacylglycerols and diacylglycerols are fatty acid monoesters and diesters of glycerol, respectively. These partial glycerides are important intermediates in metabolism. Moreover, sn-1,2-diacylglycerols are important in animal tissues where they function as signaling molecules in many cellular processes. Triacylglycerols are fatty acid triesters of glycerol. They are accumulated as storage products and are the major components of most natural fats and oils.

Glycerol-derived ethers

Alkyl ethers and alk-1-enyl ethers (or plasmalogens) are two general types of glycerol ethers. Mono- and dialkyl ethers have been reported to occur naturally. Examples include butyl alcohol (sn-1-Octadecylglycerol) and chymyl alcohol (sn-1,0-hexadecyl alcohol) as monoalkyl ethers and diphytanoylglycerol (sn-2,3-di-0-tetramethylhexadecylglycerol) as a diacyl ether. Although trialkyl ethers have not yet been found in nature, they have been synthesized with various combinations of saturated and unsaturated chains. In addition, monacyl and diacyl derivatives of alkyl ethers are reported for some natural sources. Similar to alkyl forms, the mono- and dialk-1-enyl ethers of glycerol have been identified in natural samples, whereas no trialk-1-enyl ethers have been isolated so far. A cyclated (mono- and diacyl derivatives) alk-1-enyl ethers (or neutral plasmalogens) have been also reported (2).

Glycerophospholipids

The structure of glycerophospholipids is characterized by a 1,2-diacyl-3-phospho-sn-glycerol, or phosphatidyl moiety, and a variable headgroup linked to the phosphate. Major phosphoglycerides found in nature are phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylglycerol (PG), phosphatidylinosline, phosphatidylinositol (PI), and diphaspho-
lipids with a high proportion (up to 70%) in the outer monolayer. PG is an only phospholipid present in significant quantities in (3).

release of N-acylethanolamines after phospholipase D action involved into the endocannabinoid signalling system through may be present in significant amounts. These compounds are

phospho-(3 to contain acylphosphatidylglycerol (1,2-diacyl-

sn)

3-

trans-

Fig. 1

PE (trivial name "cephalin") also has a net neutral charge (Fig. 1). PE is widespread and usually the second most abundant phospholipid in animal and plant membranes. It is also the main lipid component of microbial membranes. In animal tissues, phosphatidylethanolamine may exist in diacyl, alkyacyl and alkkenylacyl forms. Moreover, animal phosphatidylethanolamine usually contains higher levels of arachidonic and docosahexaenoic acids in comparison with the other zwitterionic phospholipid, PC. The partly methylated derivatives of PE (phosphatidyln-methyl-ethanolamine, phosphatidyl-N-dimethyl-ethanolamine) are found in small amounts in many organisms. These derivatives are metabolic intermediates in the conversion of PE into PC. In some tissues, N-acylated derivatives of PE may be present in significant amounts. These compounds are involved into the endocannabinoid signalling system through release of N-acylphosphatidylethanolamines after phospholipase D action (3).

PG is negatively charged (Fig. 1). It is the major phosphoglyceride in photosynthetic tissues and many bacteria. In plants, PG is an only phospholipid present in significant quantities in the thylakoid membranes where it can comprise 10% of the total lipids with a high proportion (up to 70%) in the outer monolayer. A n-4 fatty acid, δ5-trans-hexadecenoic acid (16:1(9)), is found in all eukaryotic photosynthetic organisms, especially extenifying the sn-2 position of PG (4). It is interesting to note that the stereochemical configuration of a double bond and its Δ2 position are very unusual for natural fatty acids. PG-16:1(3) is thought to play an essential role in photosynthetic membranes.

Although PG is only a minor phospholipid in animal tissues (1-2% of total phospholipids), it can be a second abundant phospholipid in some lung surfactants at up to 11% of the total (5).

For bacteria, PG is present in almost all types. In Esherichia coli, for example, PG accounts for 20% of its membrane lipids. The diacyl form of PG is more common in many bacteria, but some may contain the alkylacyl- and alkkenylacyl derivatives as predominant forms. Several prokaryotic species, including Salmonella typhimurium and E. coli, and parasitic protozoa, such as Trichomonas vaginalis and T. foetus, have been found to contain acylphosphatidylglycerol (1,2-diacyl-sn-glycero-3-phospho-(3-acyl)-sn-glycerol) in appreciable amounts (6). For example, Corynebacterium ammoniagenes contained about 30% of this lipid with oleate as a dominant fatty acid on the head group of glycerol (7). A fully acylated phosphatidylglycerol (bis-phosphatic acid or phosphatidyl(diacylglycerol) and its plasmalogen analogs have been also identified in a marine bacterium MB 45. In some bacteria, an amino acid (lysine, ornithine, arginine, or alanine) may be attached to the 3'-hydroxy of the base glycerol to form an O-amiinoacylphosphatidylglyceroI. Two other unusual derivatives of phosphatidylglycerol have been isolated from the primitive organisms, the Haloar-chea. They were identified as phosphatidylglycerol sulfate and phosphatidylglycerol phosphate methyl ester.

Diposphatidylglycerol (trivial name cardiolipin) has a unique dimeric structure with four acyl groups and two negative charges (Fig. 1). It is common in bacteria, and it can be found in the inner mitochondrial membranes of eukaryotes (i.e., those membranes that generate an electrochemical potential for substrate transport and ATP synthesis).

Phosphatidylserine also has a net negative charge. It is a widespread but minor lipid in eukaryotes, accounting usually for less than 10% of the total phospholipids. Its greatest con-centration has been noted for myelin from brain tissue. Phos-phatidylserine is concentrated in the inner monolayer of the plasma membrane and the other cellular membranes (Fig. 1).

Phosphatidylinositol is another widespread and minor lipid with a negative charge. It is an important lipid, both as a membrane constituent and in various phosphorylated forms as key molecules in signalling processes in eukaryotes (Fig. 1). The phosphatidylinositol phosphates are found with phosphates attached at any position of the inositol ring. However, PI-4-phosphate, PI-4,5-bisphosphate, and their 3-phosphates are the most important. PI also forms part of the glycophosphatidylinositol (GPI) anchor for certain surface proteins.

The acyl structure diversity

Monacyl derivatives of phosphoglycerides, lysy-derivatives, are present in small amounts in most tissues, but their occurrence in large levels usually indicates lipid degradation before or during lipid extraction. Only cereals grains contain lysophosphatidylcholine and lysophosphatidylethanolamine as the ma-jor phospholipids (as starch inclusion compounds). Moreover, lysosphatidyglycerols, especially lysophosphatic acid, are impor-tant signaling molecules (8).

Plasmalogens are monacyl monoalk-1-enyl ether forms of phospholipids. The most common forms of plasmalogens are the choline, ethanolamine, and serine derivatives. They are present in most animal tissues, especially in the mammalian brain. Plasmalogens are structural components of membranes. It has been proposed that plasmalogens protect membranes against oxidative stress (9).

Platelet-activating factor or 1-alkyl-2-acetyl-sn-glycero-3-phosphocholine is an ether analog of phosphatidylcholine. This biologically active lipid is of great current interest. Initially, it was found to affect aggregation of platelets and to induce a hyper-tensive response at very low concentrations. Recent research has revealed its role as a mediator of inflammation and of other physiologic effects on many different types of cells.

A rhodobacteria contain large amounts of unique lipids, which are based on 2,3-dialkyl-3-phosphoglycerides (DPG) and 2,3-dialkyl-4-phosphoglycerides (DAGP). DPG is the major phospholipid and DAGP is the major phosphoglyceride in these organisms. DPG and DAGP are present in large levels usually indicates lipid degradation before or during lipid extraction. Only cereals grains contain lysophosphatidylcholine and lysophosphatidylethanolamine as the ma-jor phospholipids (as starch inclusion compounds). Moreover, lysosphatidyglycerols, especially lysophosphatic acid, are impor-tant signaling molecules (8).

Glycosylglycerides

Glycosylglycerides are characterized by a 1,2-diacyl-sn-glycerol moiety with a monosaccharide attached at the sn-3 position of the glycerol backbone. In photosynthetic bacteria, cyanobacteria, algae, and higher plants, glycosylglycerides (glycolipids) are located predominantly in photosynthetic membranes. The major plastid lipids, galactosylglycerides, are neutral lipids. They contain one or two galactose molecules linked to the sn-3 position of the glycerol that corresponds to 1,2-diacyl-3-O-β-D-galactopyranosyl-sn-glycerol (or monogalactosyldiacylglycerol, MGDG) and 1,2-diacyl-3-O-(1→4)-β-D-galactopyranosyl-sn-glycerol (or digalactosyldiacylglycerol, DGDG) (Fig. 2). MGDG and DGDG are present at 40–55% and 15–35% of the total lipids in thylakoid membranes, respectively. A characteristic feature of these lipids is a very high content of polyunsaturated fatty acids. In addition to these main galactolipids, trigalactosyldiacylglycerols and tetragalactosyldiacylglycerols as well as other homologs with many different sugar combinations (e.g., mannosylglycerols and diglucosyldiacylglycerols with the diglucosyl residue that is linked through a β-1→2 linkage (as in kojibiose) and a galactosyldiacylglycerol have been isolated from some bacterial species. Monomannosyldiacylglycerols have been reported for bacteria, algae, and higher plants (11, 12). For example, in eubacteria, glycosylglycerols with one to three glycosyl units linked to sn-1,2-diacylglycerol were most common, but others with up to five glycosyl units have been also found. Monogalactosyldiacylglycerols and diglucosyldiacylglycerols with the diglucosyl moiety that have an α-1→2 linkage (as in kohioside) and a galactosyldiacylglycerol have been isolated from some Streptococcus species. Monomannosyldiacylglycerols and digalactosyldiacylglycerols have been reported for Micrococcus luteus. In Bacillus megaterium, N-acetylgalactosamine has been found linked to a diacylglycerol. In glycolipids present in some bacteria, a glycerophosphate group is linked to a carbohydrate moiety (11).

Various glycosylglycerols and galactosylglycerides have been also isolated in small amounts from animal tissues (13).

The galactoglycerolipids usually contain a single galactose residue that is linked through a β-glycosidic link between the C-1 of galactose and the C-3 of glycerol. The glycoacylglycerides that have been reported may contain up to eight glucose residues. Moreover, alkylacyl and diacyl lipids as well as sulfated forms have been identified (13).

Another class of glycosylglycerides, which is present in appreciable amounts in both photosynthetic and in nonphotosynthetic species, is the plant sulfolipid sulfoquinovosyldiacylglycerol, or 1,2-diacyl-3-O-(6-deoxy-6-sulfoglucopyranosyl)-sn-glycerol (SQDG) (Fig. 2). This lipid is unusual because of its sulfonic acid linkage. It consists of monogalactosyldiacylglycerol with a sulfonic acid in position 6 of the monosaccharide moiety. The sulfoglycosidic moiety (6-deoxy-6-sulfoglucoside) is described as sulfoquinovosyl. The sulfonic residue carries a full negative charge at physiologic pH. In the unicellular alga Chlamydomonas reinhardtii, an acylated derivative of this sulfolipid, 2-O-acyl-sulfoquinovosyldiacylglycerol has been found. Sulfoquinovosylglycerol has been isolated from the marine red alga Gracilaria verrucosa. For a review of algal lipids, see Reference 12.

In addition to sulfoquinovosyldiacylglycerol, the marine diatom Nitzschia alba has been found to contain a sulfonium analog of phosphatidylcholine, phosphatidylsulfatene (14). This lipid has two methyly groups attached to the sulphur atom, and it substitutes completely for phosphatidylcholine in Nitzschia alba. In other marine diatoms and algae, both lipids have been found (15).

Several lipids conjugated to taurine (2-amino ethylsulfonic acid, H2NCH2CH2SO3H) have been reported for many organisms. So, membrane lipids of certain bacteria and algae contain a taurine linked to diacylglycerol. In a seawater bacterium Hyphomonas jannaschiana, which is unique because of an absence of phospholipids, a taurglycolipid, 1,2-diacylglycerol-3-glucuronylglycerol has been described as sulfoquinovosyl. The sulfonic residue carries a full negative charge at physiologic pH. In the unicellular alga Chlamydomonas reinhardtii, an acylated derivative of this sulfolipid, 2-O-acyl-sulfoquinovosyldiacylglycerol has been found. Sulfoquinovosylglycerol has been isolated from the marine red alga Gracilaria verrucosa. For a review of algal lipids, see Reference 12.

Sulfoquinovosylglycerol has been isolated from the marine red alga Gracilaria verrucosa. For a review of algal lipids, see Reference 12.
has been isolated from extremely halophilic bacteria (11), and a glycolipid sulfate, 2,3,6′-tetraacetyl-α,α-tetrahalose-2′-sulfate has been isolated from Mycobacterium tuberculosis (16). For a review on the isolation, characterization, and biochemistry of taurolipids, see Reference 17.

**Betaine lipids**

Betaine lipids contain a betaine moiety as a polar group linked to the sn-3 position of glycerol by an ether bond. No phosphorus or carbohydrate group exists in betaine lipids. Three types of betaine lipids have been identified: 1,2-diacylglycerol-3-0-4′-(N,N,N-trimethyl)homoserine (DGTS), 1,2-diacylglycerol-3-0-2′-(hydroxymethyl)-(N,N,N-trimethyl)-β-alanine (DGTA), and 1,2-diacylglycerol-3-0-carboxy-(hydroxymethyl)-choline (DGCC) (Fig. 3) (18). These betaine lipids are all zwitterionic at pH 7 because they have a positively charged trimethylammonium group and a negatively charged carboxyl group (Fig. 3). Betaine lipids are not found in higher plants, either gymnosperms or angiosperms, but they are distributed widely in photosynthetic bacteria, algae, ferns, bryophytes, lichens, some fungi, and protozoans. Based on an obvious structural similarity between betaine lipids and phosphatidylcholine and on their taxonomic distribution (namely, their reciprocal relationship in many species), it has been suggested that betaine lipids, especially DGTS, are more primitive lipids evolutionarily that, in the lower plants, play the same functions in membranes that PC does in higher plants and animals (19).

**Diol Lipids**

Diol lipids have been reported only recently when techniques for their structure elucidation were developed. Small quantities of diol lipids, such as diaclylpropane-1,3-diol, diesters of butane-1,3-diol, and butane-1,4-diol are found in mammalian and fish liver, mammalian adipose tissues, egg yolk, corn seed, and yeast (20). From Actinomyces olivaceus, mixed acyl- and alk-1-enyl derivatives of simple diols have been isolated (21). An acylated diol phospholipid has been produced by the yeast Lypomyces starkeyi when grown on propane-1,2-diol (22).

**Sphingolipids**

Sphingolipids are lipids that contain sphingosine (trans-D-erythro-1,3-dihydroxy-2-amino-4-octadecene) or a related CH₂ OOCR' CH R"COO CH₂ O CH₂ CH₂ CH₂ N(CH₃)₃ COO⁻ 1,2-diacylglycerol-3-0-4′-(N,N,N-trimethyl)-homoserine (DGTS) CH₃-DOCOR' R"COO-CH₂-O-CH₂-O-CH₂-O-N(CH₃)₃ COO⁻ 1,2-diacylglycerol-3-0-2′-(hydroxymethyl)-(N,N,N-trimethyl)-β-alanine (DGTA) CH₃-DOCOR' R"COO-CH₂-O-CH₂-O-CH₂-O-N(CH₃)₃ COO⁻ 1,2-diacylglycerol-3-0-carboxy-(hydroxymethyl)-choline (DGCC)

Figure 3 Betaine lipids.

Sphingomyelin

Figure 4 Sphingomyelin.
aminoglycerolipids are a group of very complex lipids with a range of diverse functions. It has recently become apparent that sphingolipids are involved in many human diseases including diabetes, cancers, neurologic syndromes, infections, and diseases of the cardiovascular and respiratory systems (23). Moreover, an increased interest in these molecules results from the involvement of sphingolipids in the segregation/compartmentalization of membranes by self-organizing functional lipid microdomains, known as lipid rafts. Sphingolipids are located exclusively in the outer (exoplasmic) leaflet of the plasma membrane bilayer. In contrast, raft glycosphingolipids largely prefer the inner (cytoplasmic) leaflet, and cholesterol is most likely abundant in both leaflets. The lipid raft model is based on the assumption that sphingomyelin and other sphingolipids together with cholesterol are not distributed evenly in the plasma membrane, but rather they assemble to specific microdomains or raft. They act to compartmentalize and to separate membrane proteins with different biochemical functions. It is believed that up to 50% of the plasma membrane may consist of such rafts, and rafts formation has been shown to be crucial in modulation of signaling events in cells (24).

Sphingophospholipids and glycosphingolipid phospholipids

Sphingomyelin (or ceramide phosphorylcholine) is the most common lipid in this class, and is the phosphorylcholine ester of an N-acylsphingosine (or ceramide) (Fig. 4). It is a major lipid in certain membranes in animal tissues. Although it is usually lower in concentration than phosphatidylcholine, it can comprise about 50% of the lipids in certain tissues. Sphingomyelin replaces phosphatidylcholine in erythrocytes of most mammalian animals entirely. Sphingomyelin is probably absent from microorganisms and plants.

In the plasma of the newborn pig and infant, 3-O-acyl-D-erythro-sphingomyelin has been detected. In this lipid, position 3 of the sphingosine residue is esterified by an additional fatty acid.

In addition, lypo-sphingomyelins and sphingosines phosphorylcholine have been reported to be present in tissues in small amounts. They are involved in some signaling processes in the cell in a manner similar to sphingosine-1-phosphate (25, 26). Sphingosine-1-phosphate has been found in insects, yeasts, and plants; its function as an important cellular messenger has been shown in many studies. It regulates calcium mobilization inside the cell as well as cell growth and proliferation in response to several stress factors. Ceramide, phosphorylinositol, or myo-inositol (1,0)-phosphoryl (1,0)-ceramide, the sphingolipid analog of phosphatidyl myoinositol, is a major component of sphingolipids in yeasts (e.g., Saccharomyces cerevisiae). In these organisms, two other related inositol-containing sphingolipids, mannosyl-Ceramide and mannosylinositolphosphorylceramide, have been also found. Ceramide phosphorylethanolamine, the sphingolipid analogue of phosphatidylethanolamine, has been reported for the first time in the h outfly, Musca domestica. Shortly after, it was identified in the bacteria Bacteroides ruminicola and B. melanogenicus as well as in some protozoa, snails, marine bivalves, insects, chicken liver, and rat liver (27). In recent studies, this lipid has been isolated from three species of oomycete plant pathogens (28) and from several species of Sphingobacterium (29).

Ceramide phosphorylglycerols are known as membrane components in anaerobic bacteria of the genus Bacteroides and in the oral pathogen Porphyromonas gingivalis (30). A sphingoid analog of phosphatidic acid, ceramide-1-phosphate, has recently emerged as potent bioactive agent. Recent studies defined new biologic functions for this lipid related to control of numerous aspects of cell physiology, which include cell survival and mammalian inflammatory responses (26).

The first glycolipids identified in some plants were glycosphingolipids with a phytosphingosine and/or dehydro sphingosine backbone that contains both inositol and sphingosine. They have been named “phytosphingolsphingolipids” and more than 20 molecular forms have been identified with glucuronic acid, glucosamine, and many other carbohydrate moieties. The analysis of such compounds has been discussed thoroughly in (31).

From the bacterium Sphingobacterium spiritivorum, ceramide phosphorylmannose has been recently reported for the first time. A rhizobacteria has been shown to contain various phosphoglycolipids (11).

A another type of glycosphingolipid phospholipids are glycosphin golipids that are phosphorylated even more (i.e., where the ceramide is linked directly to sugar moieties not via phosphate group). The earthworm, Pheretima hilgendorfi, has been shown to contain such lipids, namely cholinephosphoryl-6Gal-1-Cer and cholinephosphoryl-6Gal-1-Der. In addition, triglycosylphosphorylporphospholipids with either a terminal mannose or a galactose linked to phosphorylcholine were also present in this species. Some filamentous fungi contain glycosphin golipids (e.g., phosphocholine-containing glycosyl inositolphosphorylceramides) (30).

Ceramides

Ceramides are formed by attachment of a fatty acid (linked by an amide bond) to the amino group of sphingosine or other related amino alcohol. The most commonly found sphingosyl alcohols are D-erythro-sphinganine (dihydrosphingosine, sphinganine), D-erythro-sphingosine (sphingosine, 4-sphingenine), C2D-dihydrosphingosine (icosahexanin), and 4-hydroxy-D-erythro-sphinganine (phytosphingosine, 4-hydroxydihydrosphingosine). A thorough ceramides are found usually at trace levels in tissues, they play important biologic roles (1). Moreover, they are synthesized as the key intermediates in the biosynthesis of sphingolipids, in which glycosylceramide is a key precursor of complex oligoglycolipids (Table 1).

Cerebrosides

Cerebrosides are glycosides of N-acyl long-chain bases (ceramides). Galactosyl and glucose are the monosaccharides usually found. Galactosylceramide is the principal glycosphin golipid in brain tissue (2). In general, galactosylceramides are present in all nervous tissues, and account for up to 2%
and 2-hydroxynervonic (\(-\text{OH} \ C_{24}:1\)) (2).

\(\alpha\)-OH \ C_{24}:0\), also present. Typical fatty acids reported are behenic (C\(_{22}:0\)), through the amino group. In addition, odd chain fatty acids may 2-hydroxy fatty acids, which are linked to the sphingosine base moiety, plasmal-o-galactosylceramide, has been identified (32).

Ceramide with a long-chain cyclic acetal at the carbohydrate residues linked to a ceramide base) are important components of tissues in small amounts. In the equine brain, a galactosyl-ceramide with 1-

Most compounds are located on the plasma membrane facing into the extracellular space. The structure of carbohydrate units may determine the function of oligoglycosphingolipids, and one of most important of these is in the immune defense system (33). In plants, two series of oligoglycosylceramides with either mannosyl or galactosyl residues are synthesized by elongation of glucosylceramide. They are located in the endoplasmic reticulum, Golgi, tonoplast, and plasma membranes. Their functions in plants are poorly understood (34).

**Gangliosides**

Gangliosides are glycosphingolipids that contain a oligoglycosylceramide to which a sialic acid (\(\alpha\)-D-N-acetylneuraminic acid) residue is attached via glycosidic linkages to one or more of the monosaccharide units (i.e., via the hydroxyl group on position 2) or to another sialic acid residue. The level of these lipids is around 6% of total lipids in the brain tissues. Neuronal membranes contain 10-12 gangliosides of the total lipid content (20-25% of the outer layer). They are also present at low levels in all animal tissues but not found outside of the animal kingdom.

Gangliosides are involved in control of cell growth and differentiation as well as cell interactions (33). They also play a key role in the immune defense systems. Many reactions are mediated through the location of these molecules in membrane rafts.

**Glycosphingolipid sulfates**

Glycosphingolipids with a sulfate ester group attached to the sugar moiety are termed glycosphingolipid sulfates (sulfatides or sulfoglycosphingolipids). The distribution of these compounds in mammalian tissues as well as their fatty acid composition and base composition are usually similar to those of cerebrosides. 3'-Sulfo-galactosylceramide is an example of one of the more abundant glycolipid compounds of brain myelin. It has been also found in many other organs, especially in the

of the dry weight of gray matter and 12% of white matter. Oligodendrocytes contain large amounts of these lipids.

Glucosylceramides are considered as characteristic components of plants but also found in low amounts in animal tissues, such as spleen, nervous tissues, and erythrocytes. In plants, they are abundant in photosynthetic tissues (31). From nonphotosynthetic tissues, monoglycosylceramides that contain a \(\beta\)-D-mannopyranosyl residue have been isolated.

In addition, fucosylceramide has been reported in a colon carcinoma, a xylose-containing ceramide was identified in an avian salt gland, and glycosylceramides with mannose and glucuronic or galacturonic acids as sugar moieties have been isolated from some microorganisms. \(\alpha\)-Acylated (with fatty acids in various positions of the sugar moiety) glucosylceramides and galactosylceramides have been also found in brain tissues in small amounts. In the equine brain, a galactosylceramide with a long-chain cyclic acetal at the carbohydrate moiety, plasmal-o-galactosylceramide, has been identified (32).

Galactosylceramides usually contain large amounts of 2-hydroxy fatty acids, which are linked to the sphingosine base through the amino group. In addition, odd chain fatty acids may also present. Typical fatty acids reported are behenic (C\(_{22}:0\)), \(\alpha\)-Acylated (with fatty acids in various positions of the sugar moiety) glucosylceramides and galactosylceramides have been also found in brain tissues in small amounts. In the equine brain, a galactosylceramide with a long-chain cyclic acetal at the carbohydrate moiety, plasmal-o-galactosylceramide, has been identified (32).

*Roman numerals show sugar positions in the root structure.

In general, hundreds of different neutral oligoglycosphin-golipids have been identified, and each mammalian organ has a characteristic pattern of neutral ceramides with kidney, lung, spleen, and blood that contain large amounts. In erythrocytes, for example, megaglycolipids with up to 50 sugar groups are present, but triglycosylceramides to pentaglycosylceramides are usually more abundant.
kidney. In addition to these "classic" sulfatides, a whole series of sulfatides in organisms that range from mycobacteria to mammals have now been characterized. These include sulfolactosyloceramide and other sulfatides derived from oligosaccharides of the globo series and gangliosides isolated from human kidney, and the ganglioside sulfatides isolated from echinoderms (35).

**Phosphonolipids**

Phosphonolipids are analogs of various phospholipids, which consist of aminoethylphosphonic acid residues, have been found in nature. The aminoethylphosphonic acid moiety may be linked through a phosphorus-carbon bond to either a ceramide or diacylglycerol backbone in phosphonolipids. Ceramide aminoethylphosphonate (or ceramide ciliatine) was the first phosphonolipid analog of sphingosylphosphatides, and has been identified in sea anemones (Fig. 5). Lately, it has also been detected in several mollusks, protists, bacteria, and bovine brain tissue together with its N-methyl derivative. In some bacterial species, phosphonolipids with a 1-hydroxy-2-aminoethane residue linked to the phosphorus moiety have been also detected. Phosphonoglycosphingolipids such as 6-O-(aminoethylphosphono)galactosylceramide (Fig. 5) and its N-methyl analog, have been isolated from some marine invertebrates. The role and biochemical functions of these lipids are still unknown.

The phosphonate form of phosphatidylethanolamine, 1,2-diacyl-sn-glycerol-3-(2'-aminoethyl)phosphonate (Fig. 5), is present in several species of protists as well as in bovine tissues and in human aorta. Its alkylacyl and alkenylacyl forms have also been found. From the freshwater cyanobacteria *Aphanizomenon flos-aquae*, 2-acyloxyethylphosphonate (with unusual biosurfactant properties) has been isolated. Phosphonolipids have been reviewed in References 36 and 37.

**Lipid-Soluble Arsenic Compounds (Arsenolipids)**

Lipid-soluble arsenic compounds were first identified from marine organisms over 30 years ago. By now, more than 100 naturally occurring arsenolipids have been detected in a wide range of organisms, including lichens, fungi, freshwater and marine algae, invertebrates, fishes, plants, and animals (38). The level of accumulation of these lipids may vary from 1.5 to 33.8 µg/g dry weight. Some plants and hyper-accumulators contain more than 1 mmol As g⁻¹ dry weight. Many species of bacteria as well as most algae species examined seem to convert arsenic compounds into their methylated derivatives, such as trimethylarsine (39). Structures, distribution, the possible metabolism of arsenolipids, as well as analytical techniques used for their separation, identification, and quantification are thoroughly reviewed in Reference 38.

**Other Esters**

A group termed "other esters" includes a large variety of functionally diverse lipids. Wax esters are a typical example. The term "wax" is used commonly for esters of long-chain fatty acids with long-chain primary alcohols, but sometimes it is used for the entire mixture of lipids that contain waxes. Esters are present in both plants and animals where they form the water-repellent surface coating (e.g., skin surface of animals and the leaf cuticle). Esters of normal alcohols with monobranched or multibranched fatty acids have been found in the preen glands of birds (2). Complex waxes (in which either the fatty acid or the alcohol component or both has a complex structure) have been isolated from some bacteria. Dicesters...
of phthiocerols (C33–C35 branched-chain diols) with myco-

ceric acids (C29–C32 branched-chain acids) are examples of
these compounds that have been reported for Mycobacterium
spp. (40).

Two types of diester waxes are characteristic of animal
skin-surface lipids. In the first type, acyl derivatives of hydroxy
acids formed by reaction between the carboxyl group of a
fatty acid with the hydroxyl group of a hydroxy acid. In the
second type, waxes consist of an alkane α,β-diol in which both
hydroxyls are esterified with fatty acids (41).

Ester forms are found in the commonly occurring sterols
and vitamin alcohols, such as vitamin A, the D vitamins, and
vitamin E, as well as in carotenoids (flowers and green algae)
and terpenoids (rose petals). Various other esters have been
reported in different bacteria and yeasts where they may occur
as glycoside and amino acid derivatives. For more details, see
Reference 2.

Fatty Acids

Fatty acids are aliphatic monocarboxylic acids. Over 1000
fatty acids are known with different chain length, positions,
configurations, and types of unsaturation. A division of various
functional groups along the aliphatic chain brings more struc-
tural and functional diversity to this group.

Saturated fatty acids

In most natural lipids, straight- or normal-chain saturated com-
ponents (even-numbered) account for up to 10-40% of the total
fatty acids. Straight-chain fatty acids with 16 and 18 carbon
atoms are the most common naturally-occurring compounds in
animals and plants although odd-numbered and even-numbered
homologs from 2C to 36C carbon atoms have been reported for
natural samples (2). In general, fatty acids do not exist as free
fatty acids because their high affinity for many proteins.
Moreover, elevated levels of free (nonesterified) fatty acids are
usually artifacts of cell damage that allow lipases to breakdown
the endogenous acyl lipids. Table 2 shows examples of the most
important straight chain saturated fatty acids together with the
information on their distribution.

Lipids: Chemical Diversity of branched-chain fatty acids have been found, and branches other than methyl are present in microbial lipids. Two distinct types, which are often found in bacteria, are the iso-methyl branched fatty acids with the branch point on the penultimate carbon (one from the end) and anteiso-methyl branched fatty acids with the branch point on the ante-penultimate carbon atom (two from the end). Fatty acids with these structures and with 10 to more than 30 carbon atoms have been identified in some bacteria and in other microorganisms. However, branch points are also found in other positions. For example, 10-R-methyloctadecanoic acid (or tuberculostearic acid) (Fig. 6) is a characteristic of the tubercle bacillus and related species. A wide range of mono-methyl branched fatty acids occurs in some mammalian tissues with the uropygial (preen) gland of birds as a major source. In membranes, they have a function (as an alternative to double bonds) in increasing the fluidity of the lipid bilayer (1).

From Mycobacteria and related species, fatty acids with \( \beta \)-hydroxy-\( \alpha \)-alkyl branched structure and high molecular weight (60 to 88 carbons or more) have been isolated. These mycolic acids can contain a variety of functional groups, which include double bonds, cyclopropane rings, methoxy groups, epoxy groups, and keto groups depending on bacterium species.

Monoenoic (Monounsaturated) Fatty Acids

Straight- or normal-chain (even-numbered) monoenoic fatty acids (with one double bond) amount to a significant proportion of the total fatty acids in most natural lipids. The double bond is usually of the cis- or Z-configuration, but some fatty acids with trans- or E-double bonds are found. For example, a major fatty acid esterified to phosphatidylglycerol in the photosynthetic membranes of higher plants and algae is trans-3-hexadecenoic acid. Often the cis bond is present at the \( \Delta 9 \) position.

The most common monoenoines are straight-chain compounds with 16 or 18 carbon atoms. cis-9-Octadecenoic acid (the trivial name oleic acid) is one of the most abundant fatty acids in nature. Table 3 shows examples and the occurrence of the most abundant monoenoic fatty acids.

A cis-bond in a fatty acid introduces a kink (a 60° bend) in the acyl chain with a restriction in motion at that point. Very long chain (C22:1 and longer) cis-monoenoic acids have relatively high melting points, whereas the more common C18 monoenoines are usually liquid at room temperature (1, 2).

In addition to the normal ethylenic double bonds, some fatty acids possess acetylenic bonds. They have been found in rare seed oils and some moss species.

Methylene-interrupted polynsaturated acids

Significant amounts of polynsaturated fatty acids (PUFA) with methylene-interrupted (two or more double bonds of the cis-configuration separated by a single methylene group) are found in all higher organisms. In higher plants, the number of double bonds are usually two or three, but in algae and other lower plants as well as in animals there can be up to six (Table 4).

The n-6 and n-3 families are two principal families of polynsaturated fatty acids occurring in nature and derived biosynthetically from linoleic (9-cis, 12-cis-octadecadienoic or C18:2n-6) and α-linolenic (9-cis, 12-cis, 15-cis-octadecatrienoic or C18:3n-3) acids, respectively (Fig. 6). Both fatty acids are synthesized in plants that can insert double bonds at the ∆5, ∆12, and ∆15 positions in a C18 chain but not in animals (they can insert double bonds at the ∆9, but not at ∆12 and ∆15). Therefore, these two acids are essential dietary components. In animals, additional double bonds are inserted between the carboxyl group and the ∆9 position by ∆9 desaturase enzymes, and the chain can also be extended in two carbon units at the carboxyl end of the molecules by elongase enzymes.

In animal biology, long chain metabolites of linoleate and linolenate may be even more important. The functions of arachidonic (C20:4n-6), eicosapentaenoic (C20:5n-3), and docosahexaenoic (C22:6n-3) acids make them essential conditionally (12). They are signaling molecules and are involved in the regulation of gene expression. These C20 fatty acids are also precursors of eicosanoids, which include prostaglandins (e.g., PGE\textsubscript{2} and PGE\textsubscript{3} series), thromboxanes, leukotrienes, and lipoxins, which have a variety of important biologic properties. Polynsaturated fatty acids are found in most lipid classes, but they are especially important as acyl chains of the phos- pholipids where they contribute to the particular physical and biologic functional properties of the membranes (1, 2).

Bis- and polymethylene-interrupted acids

Fatty acids with bis- or polymethylene-interrupted double bonds, or a mixture of methylene- and polymethylene-separated unsaturation, are found in some plants and marine organisms. From sponges and other marine invertebrates, a wide range of such fatty acids, the demospongic acids, have been isolated. They have bis-methylene-interrupted cis-double bonds and chain lengths (both odd and even) that range from C16 to C34. Double bonds in positions 5 and 9 are usual, although additional bonds may be present in position 7 and/or 9 together with methyl branching.

Bis-methylene-interrupted acids with a ∆5 cis-double bond only are common in gymnosperms (conifers) with a typical example being pinolenic acid (5-cis, 9-cis, 12-cis-octade- catrienonic acid). This fatty acid has been found in several pine and larch species at the levels of 25–30% of total fatty acids. In angiosperms, 5-cis, 13-cis-docosadieioidenic acid (Fig. 6) was reported in the seed oil of meadowfoam (Limnanthes alba) (10%) of the total fatty acids). An analog of pinolenic acid with a trans double bond in position 5 (5t,9c,12c-18:3) was found to be the main fatty acid of the seed oil of Aquilegia vulgaris (columbine) (1, 2).

Conjugated fatty acids

Fatty acids with two or more conjugated double bonds are found in some plants and animals. In tissues of ruminant animals (and, hence, in meat and dairy products), fatty acids with conjugated diene system were detected as intermediates or by-products in the biodegradation of linoleic acid by microorganisms in the rumen. The main isomer, 9-cis, 11-trans-octadecadienic acid, may account for up to 1% of the total fatty acids of milk fat. 9-cis, 11-trans-15-cis-octadecatrienic acid, derived from α-linolenic acid, is present in ruminant tissues only in trace levels. This fatty acid has been shown to have several medical properties, especially anti-cancer and anti-atherosclerosis effects.

The only conjugated dienoic fatty acid isolated from plant sources (the seed oil of Chilopsis linearis) is reported to be trans-10, trans-12-octadecadienic acid. In contrast, fatty acids with conjugated triene systems have been detected in various plant species. Tung oil is the commercial source of the most widespread fatty acid from this group, 9-cis, 11-trans, 13-trans-octadecatrienic (ω-eleostearic) acid (1, 2).

As an example of conjugated tetraenes, a naturally occurring cis- (or ω) parinaric acid (C18:4 9c,11t,13t,15c), should be mentioned. This acid was isolated from the seeds of the M akita tree (Parinarium laurinum), which is a tropical rainforest tree indigenous to Fiji. It is also isolated from Impatiens spp. cis-Parinaric acid has been used to measure phospholipase activity, lipase activity, and as an indicator of lipid peroxidation.

Cyclic fatty acids

Cyclic fatty acids with a carbon ring alone or at the end of the alkyl chain occur naturally in plants, especially in certain seed oils and in microorganisms. Cyclopropane fatty acids are reported occasionally from marine animals and may be synthesized by symbiotic bacteria. In addition, a variety of carbocyclic structures are formed from methylene-interrupted polyenes during food processing.

The cyclopropane fatty acid, cis-11,12-methylene-octadecanoic acid, was reported first for Lactobacillus arabinosus and was given the trivial name lactobacillic acid. By now, fatty acids with a mid-chain cyclopropane group have been found in many bacterial species, including aerobic, anaerobic, Gram-negative,
and Gram-positive species. They comprise up to 35% of the membrane lipids depending on the culture conditions.

This type of fatty acid is usually found at low levels (around 1%) in plant oils that contain cyclopropene acids. Cyclopropene acids are characteristic for oils of the Malvaceae, Sterculiaceae, Bombacaceae, Tiliaceae, and Sapiodicaceae families with sterulic acid (9,10-methylenesuccinic-9-enoic acid) and malvacic acid (8,9-methyleneoctadec-8-enoic acid) as two major compounds. Sterulic acid is more abundant (about 50% of the total fatty acids in Sterculia foetida oil). 2-Hydroxysterculic acid may also be present in this oil as a possible intermediate in the biosynthesis of malvacic acid (through α-oxidation of sterulic acid).

A fatty acid with a terminal ring structure, 11-cyclohexylundecenoic acid, was first isolated as a minor component of butter fat. It is produced by bacteria in the rumen and may be later digested and accumulated by the host animals. Together with homologous fatty acids, it has been also reported for many bacterial species, especially for those isolated from the extreme environments (e.g., hot springs).

For example, in strains of the acidophilic and thermophilic species in significant amounts. Other epoxy acids include yeasts, algae, marine bacteria, and plants (seeds, leaves, and fruits). A particular role of these acids as scavengers of hydroxy and hydroperoxyl radicals has been suggested (1, 2).

Fatty acids with oxygen-containing functional groups

Several fatty acids and their metabolites have oxygen-containing functional groups, which are most commonly a hydroxyl, epoxidic, or a furan ring.

Ricinoleic acid (R-12-hydroxy-9 cis-octadecenoic acid) (Fig. 6) accounts for 80–90% of fatty acids in castor oil from Ricinus communis. It is found in other plant species and in the sclerotic of the endospore (Claviceps purpurea). Lesquerolic acid (R-14-hydroxy-11-cis-eicosenoic acid), which is a C20 homolog of ricinoleic acid, occurs in Lesquerella species (up to 70% of total fatty acids). Isoricinoleic acid (R-9-hydroxy-12 cis-octadecenoic acid, or 9-OH 18:2 12c) is a major acid in the Wrightia species. In plants, several C16 and C18 mono-, di-, and trihydroxy fatty acids are structural components of cutin (a polyester constituent of plant cuticle).

2-Hydroxy or ω-hydroxy acids have been shown to occur in sphingolipids, skin lipids, wool wax, bacterial cell wall lipids, and in some seed oils. 3-Hydroxy or ω-hydroxy acids have been shown to occur in plant oils. 3-Hydroxy acids are present in bacterial lipids. Vernolic acid (or cis-12,13-epoxy-octadec-9-enoic acid) was the first naturally occurring epoxy fatty acid isolated from the seed oil of Vernonia anthelmintica. It is also found in several Compositae species. In significant amounts. Other epoxy acids include coronoric acid (9,10-epoxy-12 cis-octadecenoic acid), which is found in some Compositae species, sunflower oil, and other oils.

A C20 homolog of vernolic acid is reported for talks of

Lipids constitute one of the main classes of molecules in biological systems. They are involved in numerous cellular functions either as individual molecules or as lipid aggregates with varying sizes and morphologies. For example, lipids are a crucial component of cellular membranes that surround and protect cells. Lipids comprise membrane domains that provide membrane proteins with a well-defined environment to carry out their functions. Lipids also interact specifically with some proteins, which render their functions possible. Lipids play the role of drugs and enzymes, and our skin and lung surfactant lining lung epithelial cells are composed largely of lipids. What is more, lipids are used in delivery vehicles to encompass drugs and other molecules. These functions and many others develop in part from lipids’ specific properties relevant on molecular scales and also from the assembly of lipids as fascinating structures observed over a multitude of scales beyond molecular size. Here, we discuss the functions of lipids and lipid structures together with their structural and dynamic properties, including examples and highlights of recent studies.

Lipids (see Fig. 1) constitute one of five classes of molecules that can be considered as crucial in biological systems. Together with proteins, nucleotides (DNA), carbohydrates, and water, lipids can be thought of as one of the basic building blocks of living systems.

For some reason, lipids cause a lot of emotions among the people. One often talks about “bad” and “good” fats, and in terms of health, this view is partly understandable. In a similar manner, it is common to talk about “bad” and “good” cholesterol; although in this case, most common people probably do not even know that only one type of cholesterol molecule exists, which is crucial for life. It is one of the most common and the most important lipids in eukaryotic cells. The “bad” and “good” cholesterols refer to the carrier particles (lipoproteins) that transport cholesterol molecules, and their effects on our health depend on the lipoprotein in question. Meanwhile, when a great deal of recent discussion has dealt with the genetic code and the proteomics of proteins, it seems that far less attention has been paid to the importance of lipids. In part, this attention is because no genes code lipids. Yet undoubtedly lipids are a crucial component of cells: They would not survive without lipids. It has been observed that polyunsaturated lipids that have several double bonds in their hydrocarbon chains are involved in the functioning of the eye, and DHA (perhaps the most important polyunsaturated fatty acid) is vital for normal brain development for infants and for the maintenance of normal brain function throughout life. Furthermore, we all appreciate the importance of lipids as a major source of energy, which may even be critical for survival under extreme conditions. In summary, lipids and fat are good. Those who love good food, such as sushi and fish in general, probably appreciate this view.

Appreciating the importance of lipids in a variety of biologically important cases, one is tempted to understand how they actually function and how that is affected by the structures of their assemblies. The answers to these questions are far from being resolved, but we do have some insight into the related issues. What is remarkable and deserves to be stressed here is that lipids are characterized by fascinating structures over a multitude of scales, which range from the size of individual molecules to the sizes of colloidal systems that comprise large amounts of lipid molecules. Lipids are the main component of lipoproteins that carry cholesterol, vesicles that transport molecules inside them, cell membranes that surround cells, lung surfactant that keeps us alive by allowing us to consume oxygen, and skin that protects us from the outside. Beautiful examples of the...

Of these lipids, PyrPC is a pyrene-linked lipid probe and DPGALA is a glycolipid. The first four lipids are represented by a united-atom description, and the last two lipids are represented by a full-atom description.

Figure 1

Functions of lipids
No strict definition exists for the term "lipid" that is generally accepted. In a broad sense, lipids are compounds of low or intermediate molecular weight with a substantial proportion of hydrocarbons (1). Lipids have also been defined as "fatty acids and their derivatives, and substances related biosynthetically or functionally to these compounds" (4). Sometimes, it is also expected that molecules considered as lipids have some biological function. Many molecules based on fatty acids are lipids, but some vitamins and hormones are based on fatty acids as well. They serve many functions in living organisms, and the broad scope of these functions is truly fascinating.

The lipid membrane provides shelter for membrane proteins to do their functions. However, instead of working alone, membrane proteins such as ion channels work together with the membrane, such that the lipid composition around the protein actually affects the activation and the functioning of the protein. This idea is largely the essence of the lipid raft model (8), which highlights the importance of lipids in a variety of cellular functions. It has been observed, for example, that rhodopsin, which is the light sensitive membrane protein, favors interactions with polyunsaturated lipids (9).
Lipids are the main component in lipoproteins known as carriers of cholesterol (2). HDL (high-density lipoprotein, which is the "good" cholesterol) transports cholesterol and its esters from cells to liver for recirculation, whereas LDL (low-density lipoprotein, which is the "bad" cholesterol) carries cholesterol and cholesterol esters to the cells. The ratio of the two carrier particles partly determines one's risk for diseases such as atherosclerosis, although the understanding and the overall view of the related issues is still incomplete in many ways.

Some lipid species serve as second messengers that pass on signals and information in the cell, such as in programmed cell death in which a lipid known as ceramide has been proposed to be the messenger (10). The same lipid is often found in hair conditioners. Lipids also play the role of enzymes, receptors, and drugs, and our skin is largely composed of lipids. In a similar manner, a major amount of molecules that comprise the pulmonary surfactant, which is a thin liquid film that lines lung epithelial cells, are saturated lipids (11) characterized by a lack of double bonds in the chains. The lung surfactant stabilizes the alveoli during expiration, when lungs undergo compression, and reduces the re-expansion work during inhalation. Lipids are also widely used for storing energy in forms of triglycerides, and recently, disorder in the lipid spectrum of cells has been related to, for example, atherosclerosis and major psychiatric diseases. As for applications, lipids are used by nature as novel micro-encapsulation devices—which is an exciting application nowadays used for drug and gene delivery (12).

Scales of lipid systems

Temperature scales

The relevant temperature range for functions that deal with lipids is the physiologic temperature, which is about 330 K. The phase behavior of lipid systems should then be considered with respect to this value. Particular attention is usually paid to the main transition temperature \( T_{\text{m}} \) defined for a one-component lipid bilayer (see Fig 2). A bove \( T_{\text{m}} \), one finds a fluid (liquid-disordered) phase characterized by a lack of translational order in the bilayer plane and weak ordering of the lipid hydrocarbon chains. Below \( T_{\text{m}} \) in the gel phase, in turn, the lipids in the membrane plane position themselves to follow hexagonal packing, besides which the hydrocarbon chains are strongly ordered (all-trans) and tilted with respect to the membrane normal direction. These transitions in lipid conformational and translational order can be characterized readily by order parameters such as the second-order Legendre polynomial and the in-plane structure factor (13, 14). The second-order Legendre polynomial is used often because it can be exploited to provide insight into the orientation of lipid hydrocarbon chains, their tilt as well as the orientation of a lipid head group, and it can be accessed rather easily through simulations as well as experiments (nuclear magnetic resonance (NMR), see below). The main transition temperature varies from one lipid to another and is largest for lipids with saturated and long chains. For example, for a dipalmitoylphosphatidylcholine (DPPC) bilayer, it is 314.5 K. For comparison, for polyunsaturated lipids typical main transition temperatures are below 273 K. In a similar manner, other lipid systems such as droplets of triglycerides have distinctly different phases, usually crystalline at low temperatures and fluid above the transition point. For most of the physiologically important lipids \( T_{\text{m}} \) is below 310 K, which implies that the physiologically more important phase is the fluid phase.

However, natural membranes are not one-component bilayers but rather are comprised of a variety of different lipid components. This matter is discussed below in more detail. Consequently, the presence of many lipid types develops a formation of membrane domains with varying composition, and hence the main phase transition temperature is not well defined for a many-component membrane. Of particular interest are membranes with a large concentration of cholesterol, because cholesterol drives the formation of a new phase. The liquid-ordered phase (3), as it is commonly called, is characterized by a lack of translational order in the membrane plane, like in a fluid phase, and by a strong conformational order among the lipid hydrocarbon chains, which in turn is reminiscent to the gel phase. Currently, it is thought that the liquid-ordered phase and cholesterol in particular play a prominent role in the functions of lipid rafts, which are strongly ordered membrane domains involved in a variety of cellular functions such as signal transduction and protein sorting; see below for additional discussion. However, despite their significant ordering, rafts are essentially fluid-like membrane domains, which highlight the importance of fluidity for membrane functions under physiologic conditions.

Length scales

To understand cellular functions that deal with single-molecule properties, we must achieve deeper knowledge about the structure and the molecular organization of lipid membranes on the nanometer scale. This knowledge is particularly important in the context of membrane proteins, because studies indicate that some membrane proteins favor certain specific lipids in their vicinity (9). Recent crystallographic studies of membrane protein-tein structures have also revealed how lipids may be an integral part of the protein structure (15). However, as biological functions take place over a multitude of scales, one must also understand how structures and functions at larger scales emerge from corresponding ones at smaller scales. For example, membrane protein functions can be regulated by the (large-scale) elastic properties of membranes (16). Also, lipid aggregates such as micelles and vesicles are involved in intracellular transport and range in size from a few nanometers to micrometers; the size of a cell is typically about 30 micrometers. Therefore, no length scale would be specific to lipid structures.

Time scales

Time scales of dynamic processes in lipid systems are wide and range from picoseconds to hours or even months. Examples are discussed below. Here, we just refer to rotational motions as the fastest dynamical events and cell death as the slowest event. What is relevant to stress here is the lack of any specific time scale.

In summary, lipids play a prominent role in numerous cellular functions. Yet lipids and the structures composed of lipids are not characterized by any specific length or time scale. However, just like soft matter in general, there is one specific scale in

common: the well defined energy scale given by the thermal energy $kT$.

**Lipids in Various Forms**

The classification of lipids is largely arbitrary. It can be based on water solubility (hydration) or swelling of a lipid system at the air-water interface, for example. Here, we approach lipids in terms of increasing complexity and focus on those lipids that are found mostly in cells, see Fig. 1. A more thorough discussion of the topic is given by Hauser and Poupart (1) and Larson (4).

**From fats to fatty acids and lipids**

Fats are easy to recognize on the basis of our every-day experience. Usually, they are considered as frozen oils and used in cooking (17). The main component of a fat is a hydrocarbon moiety that is typically a long hydrocarbon chain, with a varying number of carbon atoms attached to each other through single (saturated) or double (unsaturated) bonds. Depending on the number of double bonds, the chains are called monounsaturated (one double bond), diunsaturated (two), or polyunsaturated (more than two). Fatty acids are obtained by attaching a carboxyl group at the end of a chain. Although hydrocarbons do not dissolve readily in water, fatty acids dissolve more easily because of the hydrophilic –COOH group. Yet fatty acids are not found free in the cell often. The rather few exceptions include the intercellular transport of fatty acids inside lipoproteins and the chemical reactions such as hydrolysis because of enzymes acting on lipids, in which a lipid is broken down into smaller pieces (one of them is a hydrocarbon chain). Fatty acids are linked more commonly to a chemical group that acts as the backbone of complex lipids. One of the most general groups is glycerol, which can form ester bonds in up to three positions. By doing so, one can form nonpolar lipids such as tri-acylglycerols (frequently also called triglycerides)
with three ester bonds and di-acyl glycerols with two ester linkages. Triglycerides are the major components of dietary fats and a common hydrophobic storage means of fat. They are also transported between cells via lipoproteins. Di-acyl glycerols function as second messengers in signal transduction.

Another common backbone for fatty acids is sphingosine, which is a long-chain amine. Through an amide linkage, it is bound to a fatty acid, which forms the ceramide found often in skin and hair conditioners. As mentioned above, ceramide is also one of the signaling molecules involved in processes such as apoptosis, which is the programmed cell death.

**Polar lipids**

The above molecules are nonpolar and therefore hydrophobic. The polarity of lipids can be promoted by binding polar groups to glycerol- or sphingosine-based molecules. For example, the vacant –OH group in the glycerol moiety of di-acyl glycerols can be linked to a polar group such as phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylserine (PS), phosphatidylglycerol (PG), or phosphatidylinositol (PI). PC and PE groups are neutral and zwitterionic, whereas PS, PG, and PI are anionic. Using glycerol as a backbone, one obtains glycerophospholipids, in which one of the above polar moieties usually is acting as the head group. The best known exception is cardiolipin, in which two glycerophospholipids, which start from the phosphate group, are linked to one another through a glycerol group. Such a dimeric anionic lipid has usually four hydrocarbon chains. In a manner similar to glycerophospholipids, the free –OH group in ceramide (as the end group of sphingosine) can be linked to one of these head groups and one obtains sphingophospholipids. A common lipid of this group is sphingomyelin with a PC moiety as the head group.

One of the most complex classes of lipids in terms of their head group is glycolipids. Glycosylglycerolipids are di-acylglycerols linked to a monosaccharide or a disaccharide such as galactose or lactose, respectively. In turn, glycosphingolipids are sphingolipids with a carbohydrate head group; the most common types are cerebrosides and gangliosides based on ceramide as the fundamental structure. Another subclass complementing the above ones is lipopolysaccharides. The complexity of glycolipids is caused not only by their structural diversity, but also by the stereo-chemistry that plays a major role in their properties. Carbohydrates in general are characterized by the lack of a well-defined structure-function relationship, which means that the details do matter and often turn out to be very important. For example, recent studies have shown that glycolipid bilayers with either a galactose or glucose head group yield substantially different membrane properties. Yet galactose and glucose differ only in chirality. Nonetheless, the most fascinating and complex lipid type is sterols. They have a rigid steroid ring structure, which is a simple hydroxyl group as their polar head and a short flexible tail at the other end of the molecule. Of the many sterols found, two sterols exist whose significance in cells is above the others. Cholesterol is abundant in eukaryotic cells, and ergosterol is abundant in fungi. The reasons why nature has chosen these two specific sterols are not well understood. One is tempted to think that the properties of all sterols should be similar, because the structural differences between them are seemingly negligible. However, it has turned out that the details do matter. For example, adding just one double bond to the structure of cholesterol changes its membrane properties substantially (19). Consequently, cholesterol is the sterol in eukaryotic cells, and cholesterol esters are the form of cholesterol by which it is transported in lipoproteins.

**Lipid composition of biological membranes and lipoproteins**

The composition of lipids varies markedly in a cell, and biomembranes and lipoproteins provide crisp examples about the diversity of different lipids. In the plasma membrane of animals (1), the amount of cholesterol is usually around 20-30 mol%. The rest of the lipids are mainly PC, PE, and sphingomyelin (SM) lipids, with smaller amounts of PS, PI, and glycolipids. These lipids are distributed asymmetrically across the membrane, because most cholesterol, PC, and glycolipids are located in the extracellular (outer) leaflet, whereas PS and PE lipids are located mainly in the intracellular (inner) monolayer. The lipid composition can be highly different in other organelles, however, as is the case in mitochondria (1), in which the mitochondrial membrane is composed of two (inner and outer) membranes. There, the amounts of cholesterol, SM, and PS are negligible; most lipids are PC and PE. The major difference compared with plasma membrane is the concentration of cardiolipins. They are actually found only in bacterial and in mitochondrial membranes, where their numbers are significant; even in mitochondria they are located mainly on the inner membrane.

In lipoproteins, one finds essentially the same types of lipids but with somewhat different concentrations. In order of decreasing numbers, low density lipoproteins contain (2) mainly cholesterol esters, (unesterified) cholesterol, phosphatidylcho- lines, SM, triglycerides, and lyso-PC, and smaller numbers of PE, PI, and ceramide. In HDLs, one finds the same lipid types but in a different order, as HDLs are abundant in phospholipids and are complemented by cholesterol esters, cholesterol, and triglycerides. Besides their head group, also other features differentiate lipids from one another. Among phospholipids, which is the main group of lipids in cells, about 10% are charged. Except for sphingomyelin, which is cationic, all other charged lipids are anionic. What is even more striking is the diversity of unsaturation and chain length. The number of double bonds per hydrocarbon chain ranges from zero to six, and the chain length ranges typically from 14 to 22 carbons per chain. Usually the sn-2 chain in a glycerophospholipid is unsaturated, whereas the sn-1 chain is saturated, and these two chains may be asymmetric in terms of chain length. Furthermore, in addition to ester lipids, ether lipids such as plasmalogens exist, in which the hydrocarbon chain is linked to glycerol by an ether bond instead of an ester bond. For example, ether lipids act in cell signaling.

The above examples highlight the extraordinary diversity of lipids. On a cellular level, any single membrane may contain more than 100 different lipid species, each assumed to have some particular function. Because nature always has a reason,
Methods Commonly Applied to Lipid Systems

An extensive toolbox is often applied to lipid systems. Here, let us discuss some of the most important techniques, considering both experimental as well as computational ones. Although the description here is inevitably brief, it hopefully provides some flavor to the techniques in question.

Experimental techniques

One of the most versatile methods for studies of lipid systems is NMR (13, 20). In NMR, an applied magnetic field is used together with an alternating electromagnetic field to probe changes in molecular alignment. NMR can provide detailed information on the topology, the dynamics, and the structure of molecules. In the context of lipids, it allows determination of the orientation of a lipid or a group of atoms in a lipid, such as the head group region or a single C-H bond in a hydrocarbon chain. The latter in particular is often used to determine the ordering of lipid hydrocarbon chains by selective deuteration of acyl chains, as it provides one with a solid understanding of fluidity inside a membrane. As for dynamics, NMR is commonly employed to explore the rotational motion of atom groups in lipids and the diffusion of lipids in the plane of a membrane.

Small angle X-ray scattering (SAXS) (13, 21) is used increasingly in biological sciences to determine dynamic structures of various molecular systems. The X-ray sources with high intensity allow the observation of weak scattering features that are associated with the internal structures of molecules studied. In the context of lipids, SAXS is often used to measure lipid system structures and their phase behavior.

Differential scanning calorimetry (DSC) (22) is based on measuring changes in heat capacity because the temperature of a system is varied monotonically. As heat capacity is a thermodynamic response function, it is expected to exhibit critical behavior close to a phase transition boundary, which in turn can be detected by DSC. Consequently, DSC is a common way to detect phase behavior.

Considering techniques that allow the imaging of lipid surfaces, scanning probe microscopes such as the atomic force microscope (AFM) (13, 23) have become very appealing. The AFM allows measurements of native lipid samples under physiologic-like conditions and while biological processes are underway. It is hence often used to determine lipid membrane structures, structural defects in membranes, domain formation, and even the behavior of lipid rafts with high nanometer-scale lateral resolution.

Another appealing technique used often to image lipid structures is fluorescence microscopy and imaging (24). By using fluorescent probes attached covalently to lipid molecules, the fluorescence microscopy provides a wealth of spatially resolved information of individual lipid aggregates instead of averaging over a large number of them, see Fig. 3. Hence, fluorescent probes provide detailed information of structure as well as dynamics, and this information is often exploited to investigate phenomena such as trafficking and membrane dynamics in the spirit of single-particle tracking and single-molecule detection (14, 25). The downside is that probes inevitably perturb the system (26, 27), thus their use and the interpretation of the results warrant particular care.

Computational modeling

Unlike simulations of proteins and protein complexes, modeling and simulations of lipid systems is relatively “easy” in the sense that lipid molecules and (smallest) lipid aggregates are reasonably small, and the time scales related to many processes that take place in lipid systems are of the order of nanoseconds. Consequently, even atomistic modeling of lipid aggregates is feasible for reasonably complex systems. Here, we discuss briefly the three main levels of modeling associated with lipids.

Quantum-mechanical (QM) modeling

QM methods (28) are crucial in studies of processes in which one must account for electronic degrees of freedom, such as the action of sphingomyelinase acting on sphingomyelin. Such enzymes hydrolyze lipids, which cuts them into pieces. To describe the hydrolysis process fully, one should treat the action center in a QM manner. The problem is that QM techniques are feasible only to small scales, typical system sizes are a few hundred atoms and time scales range up to tens of picoseconds. Obviously, these scales are short compared with most biologically relevant processes. Consequently, QM techniques are often bridged to classical simulations in a manner in which the region of interest (such as the action center) is described in a QM fashion, whereas the rest of the system follows classical equations of motion using molecular mechanics (MM) force fields. Such QM/MM methods have gained increasing popularity in the field, but their wider use is limited to difficulties of treating the interface accurately between QM and classical regions. However, recent studies have shown that the QM/MM techniques work well, and the prospects for broader applications are promising (29).

Classical atomistic simulations

The most popular technique to deal with lipid systems has by far been classical molecular dynamics (MD) (28, 30). In MD, all interactions are classic, and the time evolution of the system is described by integrating Newton’s equations of motion. The particles can represent atoms or clusters of atoms; the most typical choice is the full-atom description in which all atoms including hydrogens are described explicitly, and the united-atom description in which each methyl and methylene group is described by a single particle. The particle-particle interactions are usually determined from QM calculations and tuned even more in an iterative manner by fitting system properties to experiments until simulation results and experimental data match sufficiently well. Usually, the largest system sizes are hundreds...
of thousands of atoms over hundreds of nanoseconds, which renders possible studies of various relevant processes. Examples are presented below. However, considering a practical example for a lipid membrane, the largest systems considered to date have been about $20 \text{ nm} \times 20 \text{ nm}$ in size in the membrane plane, which is rather small compared with typical membrane domain sizes. This finding implies that atomistic MD simulations currently are not the method of choice for many-component membrane systems, in which time scales of mixing and domain formation are far beyond the limits of atomistic simulations. To reach such scales, efficient ways are needed to treat the dynamics or the models that are simpler than the atomistic ones. The first idea can be conducted by, for example, Monte Carlo simulations (28, 30, 31). Instead of integrating the equations of motion in a deterministic manner, one employs random noise to evolve the system from one configuration to another in a random fashion. Despite the fact that Monte Carlo simulations (usually conducted with the Metropolis scheme) do not yield natural dynamics, they gauge equilibrium properties that are not functions of time. What is more, the Monte Carlo approach allows the use of nonphysical moves, which usually provides a major speed-up, hence facilitating studies of very large systems. The second idea to deal with simplified (coarse grained) models is more common, however, because it allows one to consider dynamic quantities and nonequilibrium properties.

Coarse-grained models

The key idea of coarse-grained (CG) models (32, 33) is to get rid of all details that are not relevant for the properties one is interested in. Replacing CH$_2$ groups by a united-atom particle can be considered coarse graining. In a similar fashion, one can replace several (say, four) methyl groups in a lipid hydrocarbon chain by a coarse-grained particle. Because the number of interacting beads is reduced, the computational burden decreases as well, which allows one to consider larger systems and time scales. This strategy is used more and more often in simulations of lipid systems, and the results have been very encouraging. The main challenges associated with CG models are the choice of the coarse-grained molecular description, for which one can employ systematic techniques such as self-organizing maps (34) together with plain intuition, and the choice of the interactions used in the CG model. For the latter issue, several approaches have been proposed. Perhaps the most promising approach is presented by Marrink et al. (35, 36), who used thermodynamic quantities such as solvation free energies to determine interaction strengths for different molecular groups. Another means to improve coarse graining is to get rid of the solvent (37, 38). This solvent-free approach can provide a major speed-up for dynamics, although it also has obvious limitations because of the absence of full hydrodynamics.
Structure of Lipid Membranes and Importance of Cholesterol

One of the main functions of lipids is to serve as the main structural components of cell membranes (7). Membranes resemble thin elastic sheets with a total thickness of about 5 nm. The membrane is composed of two lipid monolayers. The lipids in a membrane typically include two nonpolar and hydrophobic (water hating) acyl chains and one polar head group next to the head group, which in turn is usually polar and hydrophilic (water loving) and therefore can form hydrogen bonds with neighboring water molecules. This "schizophrenic" nature of lipid molecules causes them to self-assemble as closed objects such as liposomes, such that the head groups face water molecules while the hydrophobic hydrocarbon chains are protected from the water phase.

The essential structure of membranes is captured by the single-component lipid bilayer shown in Fig. 2. Although this view is a highly simplified description of an actual biological membrane, it readily demonstrates the importance of lipids on membrane structure and dynamics. Native biological membranes found in living systems are composed of lipids in terms of a lipid bilayer; although in those cases, it is not a single-component but rather a many-component membrane that consists of hundreds of different types of lipids that differ from one another in several ways such as size, unsaturation level, chemical composition in the polar head group region, number of hydrocarbon chains, and charge. The bilayer in native membranes also acts as a soft fluid-like environment for integral and peripheral proteins embedded in or attached peripherally to the membrane. In addition, the membrane proteins are involved in a dynamic rubber-like network known as the cytoskeleton attached to the inner surface of the membrane. The cytoskeleton moves the cell, gives even more rigidity to the membrane, and also allows the membrane to adjust its shape to varying nonspherical shapes. Moving on, also the outer leaflet of the membrane is covered by a network, which in this case is made of carbohydrates. The glycocalyx network, as it is called, is involved in cell–cell recognition and adhesion to other cells, among other functions.

In eukaryotic cells, one of the most important, or even the most important, lipid is cholesterol. Cholesterol constitutes about 30–40 mol% of the plasma membrane, and in the ocular lens membrane, its amount can be as large as about 80 mol%. Therefore, the role of cholesterol deserves the particular attention discussed below.

Influence of cholesterol

Cholesterol affects a large variety of membrane properties in animal cells (39). It is involved in modifying dynamical membrane properties by reducing passive permeability, slowing down the lateral diffusion of molecules in fluid-like membranes, and speeding up diffusion in gel-like membranes. It also affects bilayer properties by condensing the bilayer, which changes its elastic properties and promotes the order of phospholipid acyl chains in the hydrophobic membrane core. In this manner, cholesterol develops the formation of the liquid-ordered phase (3), which is characterized by significant conformational order in the lipid hydrocarbon chain region and the absence of translational long-range order in the membrane plane. Through the formation of the liquid-ordered phase, cholesterol governs membrane fluidity and is associated with membrane domain formation, in particular the formation of lipid rafts (8). The role of cholesterol in rafts perhaps best underlines the biological importance of cholesterol, see below for discussion. What is more, cholesterol seems to have a unique structure-function relationship because many cells do not do well without cholesterol. For example, desmosterol, which differs from cholesterol only by one double bond in the short hydrocarbon tail, cannot substitute for cholesterol (19).

The ordering capability of cholesterol is illustrated by Fig. 4, which shows the effect of increasing cholesterol concentration on the ordering of lipid hydrocarbon chains in a fluid DPPC bilayer (39). In the absence of cholesterol, the NMR order parameter, $S_{zz}$, indicates reasonable conformational order close to the membrane-water interface, and monotonically decreasing order toward membrane center. For increasing cholesterol concentration, the conformational order increases significantly. For the largest cholesterol concentration of 50 mol%, the order parameter is close to its maximal value of 0.5, in which case the chain would be in a full-trans conformation standing along the membrane normal direction. The enhanced ordering of hydrocarbon chains because of increasing cholesterol concentration is coupled to stronger packing, which in turn reduces the amount of free volume and changes the shape and size distributions.
of free volume pockets inside the membrane (40). It is readily clear why cholesterol plays such a strong role in many dynamic membrane processes. Yet the biological relevance of cholesterol in cells is related largely to lipid rafts.

Lipid rafts

In 1997, Simons and Ikonen (8) proposed that strongly ordered membrane domains rich in cholesterol and sphingolipids would be involved in a variety of cellular processes such as signal transduction, protein sorting, and programmed cell death. Ever since, the research that focuses on lipid rafts (see Fig. 5, as they are commonly called, has been very intense (41). Although the studies have demonstrated the role of rafts in numerous processes, the definition and the structure of rafts are still under debate. The uncertainties regarding the structure of rafts is largely caused by the small length and time scales, because the sizes of rafts seem to range from a few nanometers to hundreds of nanometers, and the time scales are short because of...
the transient nature of rafts. These conditions pose a challenge to gauge raft systems through experiments, thus the precise understanding of the structure within rafts has remained limited. Recent atom-scale simulations have complemented experiments and have shed some light on the matter (42). As Fig. 6 shows, cholesterol strongly orders the lipids in its vicinity, which condenses the membrane. The interplay of cholesterol with sphingolipids develops domains that are distinctly highly packed, which in turn slows down the lateral diffusion rate substantially compared with other membranes with large amounts of cholesterol. Cholesterol plays a role in the lateral pressure profile that acts on proteins embedded in a membrane. Recent simulations have shown that lipid rafts have distinctly different pressure profiles compared with other membrane systems, and that the contribution of the pressure profile for the free energy barrier for membrane protein activation (using a model of MscL, as an example) can be considerable compared with the total free energy barrier (42). All together, the results highlight the distinct nature of rafts and the importance of cholesterol in membranes overall. However, whereas the understanding of rafts and their role in cellular functions has made considerable progress during the last decade, major gaps remain to be covered by a combination of novel experimental and theoretical efforts.

Dynamics of Lipid Systems

The dynamics of lipids and lipid aggregates is driven mainly by thermal fluctuations through $k_BT$. This finding is truly fascinating because it implies that nature uses random walks in essentially all dynamic processes: The diffusion of lipids in membranes is a random walk, the growth of microtubulin follows a random-walk line pattern, and the (passive) diffusion inside a cell overall is caused by the thermal forces that act on lipid systems (43). To complement thermal diffusion, active dynamic processes occur in which the chemical energy contained in ATP is converted into mechanical work done by motor proteins. These active processes are also involved partly in the dynamics of lipids, such as in the one-dimensional diffusion of motor proteins that drag cellular cargo inside a lipid droplet along a tubulin. However, we focus here on the passive dynamic processes driven by thermal energy.

Considering dynamic processes in fluid membranes as an example and starting from the fastest dynamical processes, one may first consider rotational diffusion of individual carbon-hydrogen bonds in CH$_2$ groups in lipid hydrocarbon chains. The time scale of these rotational motions is on the order of picoseconds. The rotational motion of whole lipids around their principal axes of rotation is a slower process and usually takes place over a scale of nanoseconds. Lateral diffusion, in turn, involves diffusion of matter and hence longer time scales. This time scale is characterized by the diffusion length $L = (2dDt)^{1/2}$, where $d$ is the dimensionality, $D$ is the diffusion coefficient (≈10$^{-10}$ cm$^2$/s in fluid membranes), and $t$ is the time scale considered for diffusion. On average, a lipid in a fluid membrane diffuses over a distance of its own size (≈0.8 nm) in about 15-20 ms. The mixing of different lipid components and domain formation requires longer times and depends on the length scale. A smearing a membrane domain with a radius of 100 nm, an individual lipid would cross this length on average in about 250 microseconds. In a similar manner, assuming a roughly constant diffusion coefficient in all regions in a membrane, the average time scale for diffusion from one point in a plasma membrane (surrounding the cell) to the other side of the cell would be about a minute. One minute is this a lot? No. It is vanishingly small compared with the time scales of many cellular functions or, say, protein folding. Diffusion over cellular scales along the membrane plane is an efficient means to transport molecules, and for a cell this comes for free. No ATP is wasted. Instead, thermal fluctuations drive the motion.

All dynamic events are not so rapid, however. Lipid flip-flop, in which a lipid translocates from one leaflet to another in a membrane, is usually a profoundly slow process and occurs in a time scale of minutes or even hours. As for the longest time scale associated with biological lipid systems, the typical life time of a cell ranges from a few days to several months, which depends on the tissue type.

The above estimates are for fluid-like systems. In gel-like systems with features of frozen order, the time scales are much longer. For example, the lateral diffusion coefficient in a gel-like one-component membrane is about 10$^{-12}$-10$^{-13}$ cm$^2$/s (43), whereas in a fluid membrane it is usually $\approx$10$^{-7}$ cm$^2$/s. In a similar manner, the diffusion of matter inside lipid droplets is a much slower process compared with lipid interfaces caused by entanglement effects, as the situation is largely similar to a polymer melt. This effect is the case inside LDL. It has been estimated that the diffusion coefficient for cholesterol esters inside LDL particles is roughly 10$^{-8}$ cm$^2$/s (44) and is intermediate to diffusion in fluid- and gel-like membranes. Overall, the mechanisms associated with dynamic processes in lipid systems are complex and are understood rather poorly, although the combination of experiments and computer simulations has improved the situation recently. As an example, let us consider a more concrete situation, the formation of pores in a cell membrane and its significance for cellular functions.

Pore formation in lipid membranes

Transient water pores in cellular membranes are involved in several relevant processes, such as maintenance of osmotic balance, drug and antibody delivery into cells, and ion transport across the membrane. Understanding ion transport across membranes is especially important, because membranes strive to maintain a cationic electrochemical gradient used for ATP synthesis. Yet, ions leak through lipid membranes, and understanding the mechanisms associated with ion leakage would allow one to control membrane properties better in related applications.

Figure 7 illustrates the complexity of transient pore formation (45) under conditions that closely resemble physiologic conditions. The initial ion concentration imbalance across the membrane develops a strong local electric field that induces the formation of a pore. The pore formation starts with the creation of a single water defect in terms of a chain of water molecules, which spans the entire membrane. The defect then expands within less than 1 ms through redistribution of lipid head groups.
Influence of Probes

Often, experimental studies of lipid systems are based on spectroscopic approaches, which in turn frequently employ probes for enhancement of sensitivity and resolution. For example, in NMR, hydrogen atoms of lipids are replaced with deuterium, and in fluorescence spectroscopy and imaging, native lipid molecules are replaced with lipids in which one or more hydrocarbon chains is linked covalently to a fluorescent marker such as pyrene or diphenylhexatriene. Fluorescent markers allow one to follow numerous cellular processes in real time, such as intracellular trafficking of molecules and formation of domains within a biomembrane, see Fig. 3. The downside is that the probes tend to perturb their environment and affect the thermodynamic state of the system. Experiments have shown, for example, that probes may change the main transition temperature of a lipid membrane, and that the dynamics of probes may deviate considerably from the dynamics of corresponding native molecules (see discussion in Reference 27). Therefore, we wish to pose several questions. What is the range of perturbations induced by the probe? How significant are these perturbations actually?

Figure B shows a plot of a fluid-like DPPC bilayer, in which a small fraction of the lipids are replaced by a pyrene-containing PyPC probe, see Fig. 1 (26). The study has demonstrated that the perturbations in the vicinity of the probe are substantial, as the conformational order parameter \( S_{CD} \) of lipid hydrocarbon chains close to the probe may change as much as about 100%. However, what is also found is the short range of perturbations, because the perturbations are negligible beyond a distance of about 1.5 nm. In practice, this finding implies that about 20–30 lipid molecules are affected by the marker, but the global properties averaged across the membrane are affected only little.

This brief example highlights the possible problems associated with using fluorescent probes and antibodies and with interpreting the results obtained through probes. However, fluorescent labels are one of the most appealing means to follow a variety of intriguing dynamic processes in biological matter. Although there is a reason to be cautious, there is even more reason to develop better probes that mimic the properties of native molecules as closely as possible.

Acknowledgments

We wish to thank our collaborators whose contribution for the results presented here has been crucial. Additionally, Jarmila Repakova, Empu Salonen, Tomasz Rog, Ole Mouritsen, and Luis Bagatolli are thanked for help with illustrations.

Lipids constitute a diverse and important group of biomolecules. Most lipids can behave as lyotropic liquid crystals. In the presence of water, they self-assemble in a variety of phases with different structure and geometry. The lipid polymorphic and mesomorphic behavior, i.e., their ability to form various ordered, crystalline, gel, or liquid-crystalline phases as a function of water content, temperature, and composition, is one of the most intriguing features of lipid-water systems. The mutual transformations between these phases and their physiologic implications are the subject of this article.

**Biologic Background**

Lipids have varied biologic roles: in energy storage and fat digestion, as enzyme cofactors, electron carriers, light-absorbing pigments, intracellular messengers, hormones, constituents of the pulmonary surfactant and the skin stratum corneum, and so forth. However, the issue of their phase behavior in water is particularly relevant and most often has been discussed in relation to their major structural function—as building blocks of the biologic membranes. The major discovery in the field of biologic membranes is undoubtedly the finding that the biomembrane is a liquid-crystalline lipid bilayer with embedded proteins (1–3). This so-called fluid-mosaic model (1) has been the central paradigm in membrane biology for more than three decades and has been very successful in rationalizing a large body of experimental observations. The model includes two references to the lipid phase state—liquid crystalline and bilayer—both of which are of vital importance for the proper membrane functioning. The liquid-crystalline phases can form in stacks with interbilayer aqueous spaces typically ~1–2 nm and thus build up the best-known lipid phase—the lamellar liquid-crystalline phase Lα. However, in addition to the Lα phase, the membrane lipids also can form a large variety of other phases (subgel, gel, cubic, hexagonal, and micellar). All these phases are interrelated and transform into each other via different kinds of phase transitions. On the temperature scale, the existence range of the Lα phase typically is limited from above by lamellar–nonlamellar transitions into cubic, hexagonal, and micellar phases and limited from below by fluid-solid transitions into gel and subgel phases. A remarkable property of the lipid dispersions from a biologic viewpoint is that the transition temperatures that limit the stability ranges of the different phases can be altered by tens of degrees by varying the composition of the lipid-water system. The possibility of modulating the lipid phase behavior in very broad limits by varying the lipid composition seems to represent the basis of important regulatory mechanisms involved in the biomembrane responses to external stimuli, such as changes in the environmental conditions, and the basis for the regulation of various membrane-associated processes (see the sections that follow).
Nonlamellar lipid phases and biologic membranes

Several classes of lipids common for the biomembranes can form inverted nonlamellar phases under physiologic conditions (4). The principle ones are phosphatidylethanolamines and monogalactosyldiglycerides. Also, cardiolipins and phosphatidic acids can form inverted phases in the presence of divalent cations, and phosphatidylserines and phosphatidic acids both form inverted phases at low pH. Moreover, biomembrane lipid extracts and membrane-mimicking lipid compositions form nonlamellar phases if heated above physiologic temperatures, dehydrated, or treated with divalent cations (5–7).

Recent developments show that the ability of lipids to form nonlamellar structures seems to be a prerequisite for important membrane-associated cell processes (5). It has been demonstrated, for example, that prokaryotic organisms maintain a delicately adjusted balance between lamellar-forming and nonlamellar-forming lipids (6). Growing evidence suggests that nonlamellar-forming membrane lipids play essential roles in many aspects of membrane functioning. Short-lived nonbilyayer structures are supposed to mediate the processes of fusion and fission, and long-lived bilyayer structures with a small radius of curvature occur in some types of biologic membranes (e.g., endoplasmic reticulum, inner mitochondrial membrane, and prolamellar bodies). Membrane phase transitions take place in the course of some cellular processes (8–11). For example, the action of anesthetic agents is believed to correlate with a lamellar-cubic transition in membranes (12). The prolamellar bodies in the etioplasts of dark-grown seedlings are organized into a cubic lipid phase; they undergo a light-induced phase transition to a lamellar phase—the thylakoid membranes of chloroplasts. Cubic patterns have been inferred from the electron micrographs of many cytomembranes (13, 14). Thus, the study of the roles played by membrane lipids, the functional lipidomics (see Lipidomics), is becoming increasingly important in membrane biology.

Modulation of membrane protein activity

A biologic reason for the abundance of nonlamellar lipids in membranes is that they possess the ability to modulate the activities of membrane proteins (15, 16). It has been recognized that membranes exist in a state of curvature frustration, which may be sufficiently large to have significant effect on certain membrane-associated cell processes (5). It shows the close relation between fusion and the transition from lamellar into bilayer cubic and hexagonal nonlamellar phases if heated above physiologic temperatures, dehydrated, or treated with divalent cations (5–7).

Lipid rafts

Nonuniform lipid distribution in membranes: lipid rafts

Growing awareness regarding the nonuniform lateral and transmembrane organization of lipids in membranes (9, 27, 28) has given rise to new developments of the fluid-mosaic biomembrane model (5). A remarkable recent advance is the widely discussed formation of membrane rafts, which presents a specific case of a lipid demixing transition (29) (see Lipid rafts). Rafts are microdomains, enriched in certain kinds of lipids such as cholesterol, sphingomyelin, saturated glycerophospholipids, and glycosphingolipids, that reside in the so-called liquid-ordered phase, which is immiscible with the regular liquid-crystalline (disordered) phase. Whereas the in vivo evidence of lipid rafts...
still remains a controversial topic, the liquid-ordered mi-
crodomain and the cases of liquid-liquid immiscibility have attracted much attention both as novel features in the membrane models and for their potential importance in phe-
nomena such as membrane signaling and differential trafficking of various membrane components.

Membrane adaptation and protection in extreme external conditions

External temperature variations, for example, seasonal variations, pose a severe challenge for the maintenance of normal physio-
logic activity in poikilothermic organisms, which cannot regu-
late body temperature and in plants and bacteria. The dominant hypothesis that accounts for acquired protection to low tempera-
ture damage relates to membrane lipid composition. Cold condi-
tioning generally leads to an increased proportion of unsaturated fatty acids in the major phospholipid classes. A consequence of increased chain saturation strongly reduces the gel-liquid-
crystalline phase transition temperature of lipids (see the section entitled "Gel-liquid-crystalline phase transition"). This phenomenon, in the context of unsaturated fatty acids serving as an adaptation mechanism that allows the membrane to maintain its physiologic behavior at low temperatures, high salinity, and dehydration, is attained by means of synthesis of water-soluble compounds. Low-molecular compounds with various chemical structures—saccharides, polyols, and amino acids—are known to be natural protectors and osmoregulators. It is important to note that all protectors modulate the membrane phase behav-
ior in a virtually identical way. Despite their different chemical structures, all natural cryo- and hypotonic protectors are kosmotropic agents (water-structure makers) that have been shown to stabi-
"Lung surfactant"

Lung surfactant forms a layer at the surface of lung alveoli, thereby preventing alveolar collapse. The alveolar surfactant consists of about 90% lipids, mainly phospholipids and cholesterol. After secretion from the epithelial cells, the surfactant lipids form lamellar bodies with spherically concen-
tric bilayers. During their release into the alveolar space, lamellar bodies swell, reorganize, and transform into a charac-
teristic cross-hatched structure termed tubular myelin. It exhibits complex topology, fitting an infinite periodic surface with a tetragonal structure (39). This structure supplies lipids to the surface, thus regulating the surface tension of lung alveoli.

Phase Transitions in Lipid-Water Systems

Lipid phase nomenclature

Lipid polymorphic and mesomorphic phases generally are characterized by their 1) symmetry in one, two, or three dimensions, 2) hydrocarbon chain ordering and specific chain arrangements in the ordered gel and crystalline phases, and 3) type (normal or inverted) for the curved mesomorphic phases. For four decades, the nomenclature introduced by Luzzati (40) has been used to designate lipid phases. Because of the rapid growth of the number of new lipid phases identified in the 1980s and 1990s, the introduction of new simplified notation has been attempted as part of the Lipid Data Bank project (41), but still the Luzzati scheme is used mostly in the literature. In the latter scheme, lattice periodicity is characterized by uppercase Latin letters: L for a one-dimensional lamellar lattice; H for a two-dimensional hexagonal lattice; P for a two-dimensional oblique or rectangular lattice; T, R, and Q for the three-dimensional rectangular, rhombohedral, and cubic lattices, with space groups specified according to the International Tables (42). A lowercase Greek or Latin subscript is used as a descriptor for the chain conformation: α for disordered (liquid crystalline), β for ordered (gel), γ for ordered tilted, and C for crystalline (subgel). Roman numerals are used to designate the aggregate type: I for the oil-in-water (normal) type, and II for the water-in-oil (inverted) type.

Phase transition types

Temperature and water content are primary variables in the lipid-water systems, responsible for their thermotropic and lyotropic phase behavior, respectively.
Lamellar crystalline (subgel) L₃ phase transforms into a lamellar gel L₂ phase at a higher temperature, the latter phase undergoes a melting transition into the lamellar liquid-crystalline L₁ phase. With an additional increase of temperature, a series of mesomorphic phase transitions follow the sequence: bilayer cubic Q₃II ↔ inverse hexagonal H₁II ↔ micellar cubic Q₃MI ↔ micellar M₁II. Some lipids can form two or more modifications of a given phase, for example, gel phases of different structures (interdigitated, noninterdigitated, tilted, rippled, etc., see Fig. 1-II j, k, l, etc., see Fig. 3a) and mesomorphic cubic phases of different topology (in P₃m, P₃m, etc., see Fig. 3b I, j, k, and l). Intermediate lipid phases have been reported as well, for example, the liquid-ordered phase has attracted much attention in recent years because of its relevance to the functional lipid rafts in membranes (29) (see lipid rafts).

From a biologic viewpoint, of greatest interest are the transitions that involve the physiologically important lamellar liquid-crystalline phase, namely, the gel—liquid-crystalline (melting) transition, and the lamellar—nonlamellar mesomorphic transitions.

**Gel—liquid-crystalline phase transition**

The lamellar gel—lamellar liquid-crystalline (L₃ → L₁) phase transition, frequently also referred to as (chain-)melting, order—disorder, solid—fluid, or main transition, is the major energetic event in the lipid bilayers and takes place with a large enthalpy change. It is associated with rotameric disordering of the hydrocarbon chains, increased headgroup hydration, and increased intermolecular entropy (45). The energy required to expand the hydrocarbon chain region against attractive van der Waals interactions (volume expansion) and to increase the bilayer area (increased hydrophobic exposure at the polar—apolar interface) contributes to the large transition enthalpy change.

The melting gel—liquid-crystalline transitions in fully hydrated lipids are accompanied by large increases in lipid surface area (~25%) and specific volume (~4%). In calorimetric measurements they manifest as sharp, narrow, high-heat capacity peaks with an enthalpy of ~20–40 kJ/mol (46, 47). A too, large volume fluctuations give rise to a strong increase of the isothermal bilayer compressibility at the melting transition temperature (48).

Because of a dramatic increase of the bending elasticity, large bilayer undulations (anomalous swelling) have been observed at the melting transition (49). The temperature of the chain-melting transition is determined largely by the hydrocarbon chains. The longer and more saturated they are, the higher the transition temperature (Fig. 3c). A summary of the phase transition temperatures of the major membrane lipid classes with different chain lengths is given in Table 1 (33, 46, 52, 55, 56). Most membrane lipids have two different hydrocarbon chains, usually one saturated and one unsaturated; most common are the glycerophospholipids with a saturated sn-1 chain typically 16–18 carbon atoms long and an unsaturated sn-2 chain typically 18–20 carbon atoms long.

The gel—liquid-crystalline (L₃ → L₁) transition temperatures of mixed-chain phosphatidylcholines are summarized in Table 2.
Figure 3  Dependence of the phase transitions temperature on lipid chemical structure and aqueous phase composition: (a) hydrocarbon chain length dependence of the $L_{\beta} - L_{\alpha}$ (black squares) and $L_{\alpha} - H_{\text{II}}$ (open circles) phase transition temperatures in saturated diacyl phosphatidylethanolamines (53, 73); (b) dependence of the $L_{\beta} - L_{\alpha}$ (black squares) and $L_{\alpha} - H_{\text{II}}$ (open circles) phase transition temperatures on the degree of N-methylation of the polar headgroup of ditetradecylphosphatidylethanolamine (reproduced with permission from (73); copyright (1983) American Chemical Society); (c) dependence of the $L_{\beta} - L_{\alpha}$ phase transition temperature on the double-bond position for dioctadecenoyl phosphatidylcholine bilayers (58); (d) dependence of the phase transition temperatures of dihexadecyl phosphatidylethanolamine on the concentration of sucrose (open squares) and NaSCN (full circles) (reproduced from (33) with kind permission of Springer Science and Business Media); (e) pH dependence of the chain-melting transition temperature of dimyristoylglycerophospholipid bilayers (superscripts give the lipid charge; abbreviations as in Table 1; MPA, methylphosphatidic acid) (reproduced with permission from (67)); (f) pH dependence of the gel-fluid (circles) and lamellar-hexagonal (squares) phase transition temperatures of didodecylphosphatidylethanolamine; the dashed line indicates the appearance of additional lines in the region of the lamellar-hexagonal transition (reproduced with permission from (68); copyright (1983) American Chemical Society).

It is evident from these data that altering the lipid chain length and unsaturation modulates the lipid phase state in very broad limits and therefore provides the basis of a mechanism for membrane adaptation to large fluctuations in the environmental temperature (see the section entitled "Membrane adaptation and protection in extreme external conditions").

**Formation of nonlamellar phases in membrane lipids**

Dispersions of double-chain nonlamellar membrane lipids most frequently display a lamellar-inverted hexagonal, $L_{\alpha} - H_{\text{II}}$, phase transition. In some instances, they also can form inverted phases of cubic symmetry. The membrane elastic energy plays an important role in lamellar–nonlamellar transformations (15, 23).

The $L_{\alpha} - H_{\text{II}}$ transition may be considered a result of competition between the spontaneous tendency of the lipid layers to bend and the resulting hydrocarbon chain packing strain; thus, membranes exist in a state of frustrated curvature stress (17). Respectively, the $L_{\alpha} - H_{\text{II}}$ transition is believed to be driven by the relaxation of the curvature of the lipid monolayers toward their spontaneous curvature. Conversely to the $L_{\beta} - L_{\alpha}$ transition, the $L_{\alpha} - H_{\text{II}}$ transition temperature decreases with the hydrocarbon chain length increase (Fig. 3a). At sufficiently long chains,
Lipids, Phase Transitions of

Table 1 Gel — liquid-crystalline and lamellar — nonlamellar phase transition temperatures [°C] of fully hydrated lipids as a function of the lipid polar head group and hydrocarbon chain length (33, 46, 52, 55, 56).

the Lc phase is eliminated completely, and direct Lc-H II tran-
sitions take place on heating. Such direct transitions have been
observed for diacyl PEs of 22-carbon chains and monogly-
cosyldiacylglycerols of 19-20 carbon chains (Table 5). With
long-chain glycolipids, a direct Lc-H II transition even is ob-
served in which both the Lc and Lp phases are eliminated from
the phase sequence. Interestingly, intermediate phases miss-
ing on heating may intervene in the cooling phase sequence (see the section entitled “Reversibility of the phase transitions”;

Table 3.

Among the seven cubic phases so far identified in lipids, of

WILEY ENCYCLOPEDIA OF CHEMICAL BIOLOGY © 2008, John Wiley & Sons, Inc.
these transitions typically are rather slow. The slow formation, hysteretic behavior, and extended metastability ranges of the cubic phases create significant difficulties in their study and applications.

Inverted micellar cubic phases have been observed mainly in mixtures of double-chain polar lipids with fatty acids or diacylglycerols but also in some single-component dispersions of glycolipids (61). The most frequently observed inverted micellar cubic phase in lipids is of space group $Q^{227}(Fd	ilde{3}m)$. For medium-chain lipids ($\geq 16$ C atoms), it typically forms via an $H-II-Q-II$ transition; however, the $L_\beta$ gel phase of dC19-xylopyranosyl has been found to melt directly into the $Fd	ilde{3}m$ cubic phase (62).

Polymorphic transitions between solid lipid phases

At temperatures below the main transition, a basic equilibrium structure is the subgel (crystalline) $L_c$ phase. Its formation usually requires prolonged low-temperature incubation. In addition to the $L_c$ phase, many intermediate stable, metastable, and transient lamellar gel structures are adopted by different lipid classes—with perpendicular or tilted chains with respect to the bilayer plane, with fully interdigitated, partially interdigitated, or noninterdigitated chains, rippled bilayers with various ripple periods, and so forth. (Fig. 1). Several polymorphic phase transitions between these structures have been reported. Well-known examples of polymorphic transitions are the subtransition ($L_c-L_\beta$) and the pretransition ($L_\beta-L_\beta'$) in phosphatidylcholines (33). Recently, a polymorphic transition that included rapid, reversible transformation of the usual gel phase into a metastable, more ordered gel phase with orthorhombic hydrocarbon chain-packing (so-called Y-transition) was reported to represent a common pathway of the bilayer transformation into a subgel (crystalline) $L_c$ phase (62).

Reversibility of the phase transitions: formation of metastable phases

Because of long relaxation times, especially in the transition vicinity, lipid phase transitions often are not reversible and end up with the formation of metastable phases, which replace the equilibrium phases in cooling scans. The metastable phases can be very long-lived and display no spontaneous conversion to the ground state in sensible time scales. Many rate-limiting factors have been suggested as physical reasons that lead to the formation of metastable phases: long hydration/dehydration times, slow reformation of hydrogen-bond networks, restricted molecular motion in the low-temperature solid–solid transformations, relative stability of the interfaces between solid and fluid domains, large spatial rearrangements in lamellar–nonlamellar transitions, low rate of appearance of critical-size nuclei of the nascent phase, and arrestment in local free-energy minima. A comparison between heating and cooling phase sequences observed in aqueous dispersions of lipids shows the frequent occurrence of additional, metastable phases, which only form in a cooling direction (Table 3).
Phase transitions in lipid mixtures: phase diagrams

Composition is another important variable that strongly modulates the lipid phase behavior. The phase properties of a lipid mixture are best presented by means of a temperature-composition phase diagram. Such diagrams may be constructed by using various experimental techniques (63); a most appropriate one is the differential scanning calorimetry. In addition to being non-perturbing, it also has the advantage of recording not only the temperature but also the enthalpy of the phase transitions.

Various types of lipid phase diagrams reported in the literature are shown in Fig. 5 (64–73). The lens-like diagram in Fig. 5a is characteristic for lipid mixtures that are completely miscible in both gel and liquid-crystalline phases. To display such complete miscibility, the two components must be very similar structurally. This kind of diagram is typical for lipid species with the same headgroup, differing by not more than two methylene groups in their hydrocarbon chains, such as the DMPC/DPPC binary (Fig. 5a). A usual complication of the lens-type diagram is the frequently occurring solid-state miscibility gap, where the mixture separates into two solid phases of different composition. In mixtures of lipids with sufficiently different structures, the miscibility gap may overlap with the region of the solid–liquid-crystalline phase coexistence and give rise to eutectic (Fig. 5b) or peritectic phase diagrams (Fig. 5d), in which single three-phase points exist. Horizontal solidus lines, reporting for such kind of behavior, have been observed for numerous lipid mixtures. Miscibility gaps also may occur in the liquid-crystalline phase of certain lipid mixtures. A phase diagram with a liquid-liquid immiscibility region is the
**Lipids, Phase Transitions of**

Monotropic phase diagram shown in Fig. 5e with a monotropic triple point of coexistence of one solid and two liquid phases. Deviations from ideal mixing may occur not only with a tendency for clustering of the like molecules and eventually leading to phase separation but also when contacts between unlike molecules are preferred - when the nearest-neighbor pairs tend to be made up of unlike molecules (a "chessboard" arrangement). Such mixtures often display phase diagrams with an upper isocencentration (azeotropic) point, such as the DPPC/palmitic acid diagram shown in Fig. 5g. Except for the phosphatidylycholine/cholesterol acid mixtures, phase diagrams with an upper isocencentration point are typical for mixtures that contain a charged lipid. An example of a phase diagram with a lower isocencentration point is shown in Fig. 5f.

The DPPC/cholesterol phase diagram in Fig. 5h contains a critical point. It is related to the existence of a peculiar, liquid ordered (lo) phase in the mixtures, which is believed to be the prototype of the lipid rafts (see Lipid rafts).

**Figs. 5I–L** illustrate the phase behavior in lipids/water mixtures. A quenched phase diagrams of monoglycerols of various chain length and saturation show the effect of molecular geometry on the lipid phase behavior. Increasing the chain length from C16 to C20 introduces cubic and hexagonal phases between the lamellar liquid-crystalline and the liquid L2 phase (72). In the unsaturated C18:1 glyceryl monostearate, two cubic phases, Ia3d (I) and Pn3m (D), and the inverted hexagonal HII phase form (73) (Fig. 5I).

Ternary phase diagrams are another important tool for the characterization of the phase properties of complex lipid mixtures. This kind of diagram has proven especially useful recently in the analysis of domains in model systems. Ternary mixtures of one phospholipid that has a relatively high melting temperature and another phospholipid that has a relatively low melting temperature together with cholesterol are viewed as useful models for the outer leaflet of animal-cell plasma membranes. An example of a ternary phase diagram is shown in Fig. 6 (74). It illustrates the rich phase behavior displayed by ternary lipid mixtures represented in this particular case by four regions of two-phase coexistence and one region of three-phase coexistence.

**Role of the aqueous phase composition**

**The Hofmeister Effect**

The interactions of the lipid polar groups with water have an important contribution to the energy balance of a given phase. The relatively high hydration, typical for the membrane lipids, is responsible in particular for their ability to form liquid-crystalline bilayers separated by aqueous spaces. Many lipid phase transitions take place with large changes in the lipid surface area and consequently in the amount of bound water. The lipid hydration is determined by the chemical structure of the polar groups, but it is essential to note that in fully hydrated systems with water in excess, the extent of the polar group hydration depends also on the state of the bulk water. On the other side, various low-molecular solutes are known for their ability to modulate strongly the bulk water structure: "water-structure makers" (kosmotropes) and "water-structure breakers" (chaotropes). It thus turns possible that, even without direct interaction with the lipid polar heads, solutes largely can modulate the properties of the lipid-water interface and hence the lipid phase behavior. Changes in the aqueous phase composition can shift substantially the temperature regions of stability of the different lipid phases and induce or suppress the formation of certain phases. Indirect solute effects of such kind on the interfacial properties, generally termed the Hofmeister effect, have been found in many lipid-water phases (34). Any studies on the nature of the Hofmeister effect indicate that it results from an interplay of electrostatics, dispersion forces, thermal motion, fluctuations, hydration, polarizability, ion size effects, and the impact of interfacial water (75, 76).

According to their effect on the lipid phase transitions, the Hofmeister solutes fall into two categories: 1) chaotropic solutes that favor the formation of the lamellar liquid-crystalline phase Lα, at the expense of the neighboring HII and Lβ phases and 2) kosmotropic solutes that favor the formation of the HII and Lβ phase at the expense of the Lα phase. Their effects are described correctly by an equation of the Clapeyron–Clausius type between phase transition temperature and solute concentration (34). The sign and magnitude of the transition shifts induced by the different solutes depend on the solute ability to distribute unevenly between interlamellar and free water. Kosmotropic solutes tend to minimize the area of the lipid-water contact. They suppress the Lα phase, as it has the largest surface area in contact with water. At a high enough concentration of kosmotropic solutes, the latter phase may disappear completely from the phase diagram. This disappearance is precisely what is seen with sucrose, trehalose, proline, and some salts and is consistent with the opposite effect caused by chaotropic solutes (Fig. 3d). The addition of chaotropic solutes also can induce the appearance...
Effect of pH
Changes in pH modulate the lipid phase behavior as a con-
sequence of protonation/deprotonation of the head group,
which results in a change of the surface charge of the mem-
brane (77). They also modify the surface polarity and hydration. Typ-
ical protonation decreases lipid hydration and increases the
main transition temperature (53). The effects of pH titration on
the chain-melting transition temperature $T_m$ of dimyristoyl
phospholipids is illustrated in Fig. 3e which shows that sin-
gle protonation increases the melting transition temperature
about 5–15°C.

The shifts of the lamellar-hexagonal transition during lita-
rations are greater and in the opposite direction relative to changes
of $T_m$. Thus, for didodecyl PE, the lamellar-hexagonal transi-
tion decreases by 43°C during phosphate protonation (pK$_a$ = 1.9)
and by 50°C during amine protonation (pK$_a$ = 3.9), whereas for
$T_m$ these shifts are 6°C and 15°C, respectively, in the opposite
direction (Fig. 3f) (54).

Tools and Techniques
From the analysis of the data in the LIPIDAT database (41),
more than 150 different methods and method modifications have
been used to collect data related to the lipid phase transitions.
Almost 90% of the data is accounted for by less than 10 meth-
ods. Differential scanning calorimetry strongly dominates the
field with two thirds of all phase transition records. From the
other experimental techniques, various fluorescent methods ac-
count for ~10% of the information records. X-ray diffraction,
nuclear magnetic resonance (NMR), Raman spectroscopy, elec-
tron spin resonance (ESR), infrared (IR) spectroscopy, and po-
nuclear magnetic resonance (NMR), Raman spectroscopy, elec-
tron spin resonance (ESR), infrared (IR) spectroscopy, and po-
larizing microscopy each contribute to about or less than 2–3% of
the chain-melting transition temperature

Alkaloids are highly diverse groups of natural products related only by the presence of a basic nitrogen atom located at some position in the molecule. Even among biosynthetically related classes of alkaloids, the chemical structures are often highly divergent. Although some classes of natural products have a recognizable biochemical paradigm that is centrally applied throughout the pathway, for example, the "assembly line" logic of polyketide biosynthesis (2), the biosynthetic pathways of alkaloids are as diverse as the structures. It is difficult to predict the biochemistry of a given alkaloid based solely on precedent, which makes alkaloid biosynthesis a challenging, but rewarding, area of study.

Biologic Background

Hundreds of alkaloid biosynthetic pathways have been studied by chemical strategies, such as isotopic labeling experiments (2, 3). However, modern molecular biology and genetic methodologies have facilitated the identification of alkaloid biosynthetic enzymes. This article focuses on pathways for which a significant amount of genetic and enzymatic information has been obtained. Although plant alkaloid natural products are produced by insects, plants, fungi, and bacteria, this article focuses on four major classes of plant alkaloids: the isoquinoline alkaloids, the terpenoid indole alkaloids, the tropane alkaloids, and the purine alkaloids.

In general, plant biosynthetic pathways are understood poorly when compared with prokaryotic and fungal metabolic pathways. A major reason for this poor understanding is that genes that express complete plant pathways typically are not clustered together on the genome. Therefore, each plant enzyme often is isolated individually and cloned independently. However, several enzymes involved in plant alkaloid biosynthesis have been cloned successfully, and many more enzymes have been purified from alkaloid-producing plants or cell lines (4–6). Identification and study of the biosynthetic enzymes has a significant impact on the understanding of the biochemistry of the pathway. Furthermore, genetic information also can be used to understand the complicated localization patterns and regulation of plant pathways. This article focuses on the biochemistry responsible for the construction of plant alkaloids and summarizes the biosynthetic genes that have been identified to date. Some of these pathways have been the subject of metabolic engineering studies; the results of these studies are mentioned here also. An excellent, more detailed review that covers the biochemistry and genetics of plant alkaloid biosynthesis up until the late 1990s is available also (7).

Isoquinoline Alkaloids

The isoquinoline alkaloids include the analgesics morphine and codeine as well as the antibiotic berberine (Fig. 1a). Morphine and codeine are two of the most important analgesics used in medicine, and plants remain the main commercial source of the alkaloids (8). Development of plant cell cultures of *Eschscholzia californica*, *Papaver somniferum*, and *Coptis japonica* has aided in the isolation and cloning of many enzymes involved in the biosynthesis of isoquinoline alkaloids (9).

Early steps of isoquinoline biosynthesis

Isoquinoline biosynthesis begins with the substrates dopamine and p-hydroxyphenylacetaldehyde (Fig. 1b). Dopamine is made from tyrosine by hydroxylation and decarboxylation. Enzymes that catalyze the hydroxylation and decarboxylation steps in either order exist in the plant, and the predominant pathway...
Alkaloid Biosynthesis

Figure 1  (a) Representative isoquinoline alkaloids. (b) Early biosynthetic steps of the isoquinoline pathway yield the biosynthetic intermediate (S)-reticuline, the central biosynthetic intermediate for all isoquinoline alkaloids. (c) Berberine and sanguinarine biosynthesis pathways. (d) Morphine biosynthesis. NCS, norcoclaurine synthase; 6-OMT, norcoclaurine 6-O-methyltransferase; CNMT, coclaurine N-methyltransferase (Cyp80B); NMTC, N-methylcoclaurine 3′-hydroxylase; 4′-OMT, 3′-hydroxy-N-methylcoclaurine 4′-O-methyltransferase; BBE, berberine bridge enzyme; SOMT, scoulerine 9-O-methyltransferase; CS, canadine synthase; TBO, tetrahydroprotoberberine oxidase; CHS, cheilanthifoline synthase; SYS, stylopine synthase; NMT, N-methyltransferase; NMSH, N-methylstylopine hydroxylase; P6H, protopine 6-hydroxylase; DHPO, dihydrobenzophenanthridine oxidase; RO, reticuline oxidase; DHR, dihydroreticulium ion reductase; STS, salutaridine synthase; SaR, salutaridine reductase; SaAT, salutaridinol acetyltransferase; COR, codeinone reductase.

for formation of dopamine from tyrosine is not clear. The second substrate, p-hydroxyphenylacetaldehyde, is generated by transamination and decarboxylation of tyrosine (10, 11). Condensation of dopamine and p-hydroxyphenylacetaldehyde is catalyzed by norcoclaurine synthase to form (S)-norcoclaurine (Fig. 1b). Two norcoclaurine synthases with completely unrelated sequences were cloned (Thalictrum flavum and C. japonica) and heterologously expressed in E. coli (12–14). One is homologous to iron-dependent dioxygenases, whereas the other is homologous to a pathogenesis-related protein. Undoubtedly, future experiments will shed light on the mechanism of these enzymes and on how two such widely divergent sequences can catalyze the same reaction.

One of the hydroxyl groups of (S)-norcoclaurine is methylated by a S-adenosyl methionine-(SAM)-dependent O-methyltransferase to yield (S)-coclaurine. This enzyme has been cloned, and the heterologously expressed enzyme exhibited the expected activity (15–17). The resulting intermediate is
then N-methylated to yield N-methylcoclaurine, an enzyme that has been cloned recently (18, 19). N-methylcoclaurine, in turn, is hydroxylated by a P450-dependent enzyme (CYP80B), N-methylcoclaurine (S)-hydroxylase, that has been cloned (20, 21). The 4′ hydroxyl group then is methylated by the enzyme 3’-hydroxy-N-methylcoclaurine 4′-O-methyltransferase (4′-OMT) to yield (S)-reticuline, the common biosynthetic intermediate for the berberine, benzocistanthidinone, and morphinan alkaloids (Fig. 1c). The gene for this methyl transferase also has been identified (15, 22). These gene sequences also were used to identify the corresponding T. flavum genes that encode the biosynthetic enzymes for reticuline from a cDNA library (23). At this point, the biosynthetic pathway then branches to yield the different structural classes of isoquinoline alkaloids.

Berberine biosynthesis

(S)-reticuline is converted to (S)-scoulerine by the action of a well-characterized flavin-dependent enzyme, berberine bridge enzyme (Fig. 1c). This enzyme has been cloned from several plant species, and the mechanism of this enzyme has been studied extensively (24–28). (S)-scoulerine is then O-methylated by scoulerine 9-O-methyltransferase to yield (S)-tetrahydrocolumbamine. Heterologous expression of this gene in E. coli yielded an enzyme that had the expected substrate specificity (29). A variety of O-methyl transferases also have been cloned from Thalictrum tuberosum (30). The substrate-specific cytochrome P450 oxidase canadine synthase (31) that generates the methylene dioxy bridge of (S)-canadine has been cloned recently (32). The final step of berberine biosynthesis is catalyzed by a substrate-specific oxidase, tetrahydrocolumbamine dehydrogenase, the sequence of which has not been identified yet (33).

Overproduction of berberine in C. japonica cell suspension culture with a high producing cell line (34) with reported productivity of berberine reaching 7 g/L (35). This overproduction is one of the first demonstrations of production of a benzylisoquinoline alkaloid in cell culture at levels necessary for economic production. This cell line has facilitated greatly the identification of the biosynthetic enzymes.

Sanguinarine biosynthesis

The biosynthesis of the highly oxidized benzocistanthidinone alkaloid sanguinarine is produced in a variety of plants and competes with morphine production in opium poppy. The pathway to sanguinarine has been elucidated at the enzymatic level (Fig. 1c) (36). Sanguinarine biosynthesis starts from (S)-scoulerine, as in berberine biosynthesis. Methyleneoxy bridge formation then is catalyzed by the P450 chelanthidine synthase (37). A second P450 enzyme, stylopine synthase, catalyzes the formation of the second methylenedioxy bridge of stylopine (37). Stylopine synthase from E. californica has been cloned recently (38). Stylopine then is N-methylated by (S)-tetrahydroprotoberberine cis-N-methyltransferase to yield (S)-cis-N-methylstylopine, an enzyme that has been cloned recently from opium poppy (39). A third P450 enzyme, (S)-cis-N-methylstylopine hydroxylase, then forms protopine. Protopine is hydroxylated by a fourth P450 enzyme, protopine 6-hydroxylase, to yield an intermediate that rearranges to dihydrosanguinarine (40). This intermediate also serves as the precursor to the benzocistanthidinone alkaloid macraine (Fig. 1a). The copper-dependent oxidase dihydrobenzocistanthidinone oxidase, which has been purified (41, 42), then catalyzes the formation of sanguinarine from dihydrosanguinarine.

Additional enzymes from other benzocistanthidinone alkaloids have been cloned. For example, an O-methyl transferase implicated in palmistine biosynthesis has been cloned recently (43).

Morphine biosynthesis

The later steps of morphine biosynthesis have been investigated in P. somniferum cells and tissue. Notably, in morphine biosynthesis, (S)-reticuline is converted to (R)-reticuline, thereby epimerizing the stereocenter generated by norcoclaurine synthase at the start of the pathway (Fig. 1d). (S)-reticuline is converted to (R)-reticuline through a 1,2-dehydroreticuline intermediate. Dehydroreticuline synthase catalyzes the oxidation of (S)-reticuline to 1,2-dehydroreticuline ion (44). This enzyme has not been cloned yet but has been purified partially and shown to be membrane-associated. This intermediate then is reduced by dehydroreticuline reductase, an NADPH-dependent enzyme that stereoselectively transfers a hydride to dehydroreticuline ion to yield (R)-reticuline. This enzyme has not been characterized, but it has been cloned yet (45).

Next, the key carbon–carbon bond of the morphinan alkaloid is formed by the cytochrome P450 enzyme salutaridinol synthase. Astonishingly, this enzyme has been detected in different palms and plants (46), but the sequence has not been identified (46). The keto moiety of the resulting product, salutaridinol, then is stereoselectively reduced by the NADPH-dependent salutaridinol reductase to form salutaridinol. The enzyme has been purified (47), and a recent transcript analysis profile of P. somniferum has resulted in the identification of the clone (48). Salutaridinol acetyltransferase, also cloned, then transfers an acetyl group from acetyl-CoA to the newly formed hydroxyl group, which results in the formation of salutaridinol-N-7-acetate (49). This modification sets up the molecule to undergo a spontaneous reaction in which the acetate can act as a leaving group. The resulting product, thebaine, then is demethylated by an as yet uncharacterized enzyme to yield neopine, which exists in equilibrium with its tautomer codeinone. The NADPH-dependent codeinone reductase reduces codeinone to codeine and has been cloned (50, 51). Finally, codeine is demethylated by an uncharacterized enzyme to yield morphine.

The localization of isoquinoline biosynthesis has been investigated at the cellular level in intact poppy plants by using in situ RNA hybridization and immunofluorescence microscopy. The localization of 4′-OMT (reticuline biosynthesis), berberine bridge enzyme (sanguinarine biosynthesis), salutaridinol acetyltransferase (morphine biosynthesis), and codeinone reductase (morphine biosynthesis) has been probed. 4′-OMT and salutaridinol acetyltransferase are localized to parenchyma cells, whereas codeinone reductase is localized to laticifer cells in...
sections of capsule (fruit) and stem from poppy plants. Berberine bridge enzyme is found in parenchyma cells in roots. Therefore, this study suggests that two cell types are involved in isoquinoline biosynthesis in poppy and that intercellular transport is required for isoquinoline alkaloid biosynthesis (52). A further study, however, implicates a single cell type (sieve elements and their companion cells) in isoquinoline alkaloid biosynthesis (53, 54). Therefore, it is not clear whether transport of pathway intermediates is required for alkaloid biosynthesis or whether the entire pathway can be performed in one cell type. Localization of enzymes in alkaloid biosynthesis is difficult, and, undoubtedly, future studies will provide more insight into the trafficking involved in plant secondary metabolism.

Metabolic engineering of morphine biosynthesis

In attempts to accumulate thebaine and decrease production of morphine (a precursor to the recreational drug heroin), codeinone reductase in opium poppy plant was downregulated by using RNAi (8). Silencing of codeinone reductase results in the accumulation of (S)-reticuline but not the substrate codeinone or other compounds on the pathway from (S)-reticuline to codeine. However, overexpression of codeinone reductase in opium poppy plants did result, in fact, in an increase in morphine and other morphinan alkaloids, such as morphine, codeine, and thebaine, compared with control plants (55). Gene expression levels in low morphine-producing poppy plants have been analyzed also (56). Silencing of berberine bridge enzyme in opium poppy plants also resulted in a change in alkaloid profile in the plant latex (57).

The cytochrome P450 responsible for the oxidation of (S)-N-methylcoclaurine to (S)-3′-hydroxy-N-methylcoclaurine has been overexpressed in opium poppy plants, and morphinan alkaloid production in the latex is increased subsequently to 4.5 times the level in wild-type plants (58). A diastereomeric, suppression of this enzyme resulted in a decrease in morphinan alkaloids to 16% of the wild-type level. Notably, analysis of a variety of biosynthetic gene transcript levels in these experiments supports the hypothesis that this P450 enzyme plays a regulatory role in the biosynthesis of benzylisoquinoline alkaloids. Collectively, these studies highlight that the complex metabolic networks found in plants are not redirected easily or predictably in all cases.

Terpenoid Indole Alkaloids

The terpenoid indole alkaloids have a variety of chemical structures and a wealth of biologic activities (Fig. 2b) (59, 60). Terpenoid indole alkaloids are used as anticancer, antimalarial, and antiarrhythmic agents. Although many biosynthetic genes from this pathway remain unidentified, recent studies have correlated terpenoid indole alkaloid production with the transcript profiles of Catharanthus roseus cell cultures (61).

Early steps of terpenoid indole alkaloid biosynthesis

All terpenoid indole alkaloids are derived from tryptophan and the indole terepne secologanin (Fig. 2a). Tryptophan decarboxylase, a pyridoxal-dependent enzyme, converts tryptophan to tryptamine (62, 63). The enzyme strictosidine synthase catalyzes a stereospecific Pictet–Spengler condensation between tryptamine and secologanin to yield strictosidine. Strictosidine synthase (64) has been cloned from the plants C. roseus (65), Rauwolfia serpentina (66), and, recently, Ophiorrhiza pumila (67). A crystal structure of strictosidine synthase from R. serpentina has been reported (68, 69), and the substrate specificity of the enzyme can be modulated (70). Strictosidine then is deglycosylated by a dedicated β-glucosidase, which converts it to a reactive hemiacetal intermediate (71–73). This hemiacetal opens to form a dialdehyde intermediate, which then forms dehydrogeniisschizine. The end form of dehydrogeniisschizine undergoes a conjugate addition to produce the heterocyclic amine catharanthine (74–76). A variety of rearrangements subsequently act on dehydrogeniisschizine to yield a diversity of indole alkaloid products (77).

Ajmaline biosynthesis

The biosynthetic pathway for ajmaline in R. serpentina is one of the best-characterized terpenoid indole alkaloid pathways. Much of this progress has been detailed in a recent extensive review (78). Like all other terpenoid indole alkaloids, ajmaline, an antiarrhythmic drug with potent sodium channel-blocking properties (79), is derived from dehydrogeniisschizine (Fig. 2c).

A membrane-protein fraction of an R. serpentina extract transforms labeled strictosidine (80, 81) into saragpane-type alkaloids. The enzyme activity is dependent on NADPH and molecular oxygen, which suggests that saragpane bridge enzyme may be a cytochrome P450 enzyme. Polyneuridine aldehyde esterase hydrolyzes the polyneuridine aldehyde methyl ester, which generates an acid that decarboxylates to yield epi-vellosamine. This enzyme has been cloned from a Rauwolfia cDNA library, heterologously expressed in E. coli, and subjected to detailed mechanistic studies (82, 83).

In the next step of the ajmaline pathway, vinorine synthase transforms the saragpane alkaloid epi-vellosamine to the ajmaline alkaloid vinorine (84). Vinorine synthase also has been purified from Rauwolfia cell culture, subjected to protein sequencing, and cloned from a cDNA library (85, 86). The enzyme, which seems to be an acetyl transferase homolog, has been expressed heterologously in E. coli. Crystallization and site-directed mutagenesis studies of this protein have led to a proposed mechanism (87). Vinorine hydroxylase hydroxylates vinorine to form vomicline (88). Vinorine hydroxylase seems to be a P450 enzyme that requires an NADPH-dependent reductase. This enzyme is labile and has not been cloned yet. Next, the indolenine bond is reduced by an NADPH-dependent reductase to yield 1,2-dihydropomilene. A second enzyme, 1,2-dihydropomilene reductase, then reduces this product to...
Alkaloid Biosynthesis

Figure 2  (a) Representative terpenoid indole alkaloids. (d) Ajmalicine and tetrahydroalstonine biosynthesis. (e) Vindoline biosynthesis from tabersonine. TDC, tryptophan decarboxylase; STR, strictosidine synthase; SGS, strictosidine glucosidase; SB, sarpagan bridge enzyme; PNAE, polyneuridine aldehyde reductase; VS, vinorine synthase; VH, vinorine hydroxylase; VR, vomilenine reductase; DHVR, dihydrovomilenine reductase; AAE, 17-O-acetyl-ajmalanesterase; NMT, norajmaline-N-methyltransferase; T16H, tabersonine-16-hydroxylase; HTOM, 16-hydroxytabersonine-16-O-methyltransferase; NMt, N-methyltransferase; DH, dihydrovomilenine-O-methyltransferase.

Acetylnorajmaline. Partial protein sequences have been obtained for both of the purified reductases. Although several putative clones that encode these proteins have been isolated, the activity of these clones has not been verified yet (89, 90). An acetylersterase then hydrolyzes the acetyl link of acetyl norajmaline to yield norajmaline. This esterase has been purified from R. serpentina cell suspension cultures, and a full-length clone has been isolated from a cDNA library. Expression of the gene in tobacco leaves successfully yielded protein with the expected enzymatic activity (91). In the final step of ajmaline biosynthesis, an N-methyl transferase introduces a methyl group at the indole nitrogen of norajmaline. Although this enzymatic activity has been detected in crude cell extracts, the enzyme has not been characterized additionally (92).
Figure 2 (continued)

**Ajmalicine and tetrahydroalstonine**

Ajmalicine (raubasine) affects smooth muscle function and is used to help prevent strokes (93), and tetrahydroalstonine exhibits antipsychotic properties (Fig. 2d) (94). These compounds are found in a variety of plants, including *C. roseus* and *R. serpentina*. A partially purified NADPH-dependent reductase isolated from a tetrahydroalstonine that produces a *C. roseus* cell line was shown to catalyze the conversion of cathenamine, a spontaneous reaction product that results after strictosidine deglycosylation, to tetrahydroalstonine in vitro (95). A second *C. roseus* cell line contains an additional reductase that produces ajmalicine. Labeling studies performed with crude *C. roseus* cell extracts in the presence of D2O or NADPD support a mechanism in which the reductase acts on the iminium form of cathenamine (96).

**Vindoline**

Vindoline, an aspidosperma-type alkaloid produced by *C. roseus*, is a key precursor for vinblastine, an anticancer drug that is the most important pharmaceutical product of *C. roseus*. Vindoline, like ajmalicine and ajmaline, is produced from deglycosylated strictosidine. Deglycosylated strictosidine is converted to tabersonine through a series of biochemical steps for which no enzymatic information exists. More details are known about...
the six steps that catalyze the elaboration of tabersonine to vindoline (Fig. 2e) (97). Tabersonine-16-hydroxylase, a cytochrome P450, hydroxylates tabersonine to 16-hydroxy-tabersonine in the first step of this sequence and has been cloned (98, 99). The newly formed hydroxyl group is methylated by a SAM-dependent O-methyl transferase to yield 16-methoxy-tabersonine; this enzyme (16-hydroxytabersonine-16-O-methyltransferase) has been purified but not cloned (100). In the next step, hydration of a double bond by an uncharacterized enzyme produces 16-methoxy-2,3-dihydro-3-hydroxytabersonine. Transfer of a methyl group to the indole nitrogen by an N-methyl transferase yields desacetoxyvindoline. This methyl transferase activity has been detected only in differentiated plants, not in plant cell cultures (101). The resulting intermediate, desacetylvindoline, is produced by the oxoglutarate-dependent dioxygenase enzyme desacetylvindoline 4-hydroxylase. This enzyme has been cloned and is absent from plant cell cultures (102). In the last step, desacetylvindoline is acetylated by desacetylvindoline O-acetyl transferase. This enzyme, also absent from nondifferentiated plant material, has been cloned successfully (103).

As in morphine biosynthesis, the knowledge of the enzyme sequences allows a more detailed understanding of the localization of the enzymes (104). Strictosidine synthase (Fig. 2b) seems to be localized to the vacuole (105), and strictosidine glucosidase is believed to be associated with the membrane of the endoplasmic reticulum (73, 106). Tabersonine-16-hydroxylase is associated with the endoplasmic reticulum membrane (98); N-methyl transferase activity is believed to be associated with the thylakoid, a structure located within the chloroplast (101, 107); and vindoline-4-hydroxylase and desacetylvindoline O-acetyltransferase are believed to be localized to the cytosol (Fig. 2e) (107, 108). Overall, extensive subcellular trafficking of biosynthetic intermediates is required for vindoline biosynthesis. Aside from subcellular compartmentalization, specific cell types are required for the biosynthesis of some terpenoid alkaloids. Several enzymes involved in the early stages of secologanin biosynthesis seem to be localized to the phloem parenchyma, as evidenced by immunocytocchemistry and in situ RNA hybridization studies (109). However, additional studies have suggested that these genes also are observed in the epidermis and laticifers (110). Studies of the localization of vindoline biosynthetic enzymes by using immunocytocchemistry and in situ RNA hybridization strongly suggest that the mid-part of the vindoline pathway (tryptophan decarboxylase, strictosidine synthase, and tabersonine-16-hydroxylase) takes place in epidermal cells of leaves and stems. However, the later steps catalyzed by desacetylvindoline 4-hydroxylase and desacetylvindoline O-acetyltransferase take place in specialized cells, the laticifers, and idioblasts (109–112). As with isoquinoline alkaloid biosynthesis, deconvolution of the enzyme localization patterns remains a challenging endeavor.

Vinblastine

Vinblastine is a highly effective antitumor agent currently used clinically against leukemia, Hodgkin’s lymphoma, and other cancers. (113, 114). Vinblastine is derived from dimerization of vindoline and another terpenoid indole alkaloid, catharanthine.
Arabidopsis

Interestingly, expression of a transcription factor from Arabidopsis thaliana in C. roseus leaves has been demonstrated to convert vindoline and catharanthine to anhydrovinblastine in vitro (122, 123). Because the dimerization of these C. roseus alkaloids also can be catalyzed by peroxidase from horseradish in reasonable yields (124), it is interesting to speculate that anhydrovinblastine may be a by-product of isolation; after lysis of the plant material, nonspecific peroxidases are released from the vacuole and may act on vindoline and catharanthine.

Metabolic engineering of terpenoid indole alkaloids

Strictosidine synthase and tryptophan decarboxylase have been overexpressed in C. roseus cell cultures (125, 126). Generally, overexpression of tryptophan decarboxylase does not seem to have a significant impact on alkaloid production, although overexpression of strictosidine synthase does seem to improve alkaloid yields. Overexpression of tryptophan and secolagenin biosynthetic enzymes in C. roseus hairy root cultures resulted in modest increases in terpenoid indole alkaloid production (127, 128). Secologanin biosynthesis seems to be the rate-limiting factor in alkaloid production (129). Precursor-directed biosynthesis experiments with a variety of tryptamine analogs suggest that the biosynthetic pathway can be used to produce alkaloid derivatives (130). Strictosidine synthase and strictosidine glucosidase enzymes also have been expressed successfully heterologously in yeast (131); however, efforts to express heterologously terpenoid indole alkaloids currently are limited because the majority of the biosynthetic genes remain uncloned.

Transcription factors that upregulate strictosidine synthase (132), as well as a transcription factor that coordinate upregulates expression of several terpenoid indole alkaloid biosynthetic genes, have been found (133). Several zinc finger proteins that act as transcriptional repressors to tryptophan decarboxylase and strictosidine synthase also have been identified (134). Manipulation of these transcription factors may allow tight control of the regulation of terpenoid indole alkaloid production. Interestingly, expression of a transcription factor from Arabidopsis thaliana in C. roseus cell cultures results in an increase in alkaloid production (135).

Tropane Alkaloids

The tropane alkaloids hyoscyamine and scopolamine (Fig. 3a) function as acetylcholine receptor antagonists and are used clinically as parasympatholytics. The illegal drug cocaine also is a tropane alkaloid. The tropane alkaloids are biosynthesized primarily in plants of the family Solanaceae, which includes Hyoscyamus, Duboisia, Atropa, and Scopolia (136, 137). Nicotine, although perhaps not apparent immediately from its structure, is related biosynthetically to the tropane alkaloids.

Tropane alkaloid biosynthesis has been studied at the biochemical level, and several enzymes from the biosynthetic pathway have been isolated and cloned, although the pathway has not been elucidated completely at the genetic level (Fig. 3b). L-Arginine is converted to the nonproteogenic amino acid L-ornithine by the urease enzyme arginase. Ornithine decarboxylase then decarboxylates ornithine to yield the diamine putrescine. In Hyoscyamus, Duboisia, and Atropa, putrescine serves as the common precursor for the tropane alkaloids. Putrescine is N-methylated by a SAM-dependent methyltransferase that has been cloned to yield N-methylputrescine (139, 140). Putrescine N-methyltransferase now has been cloned from a variety of plant species (141–143), and site-directed mutagenesis and homology modeling models have led to insights into the structure function relationships of this enzyme (144). N-methylputrescine then is oxidized by a diamine oxidase to form 4-methylaminobutanal, which then spontaneously cyclizes to form the N-methyl-D-putrescine ion (144, 145). This enzyme, which recently has been cloned, seems to be a cooper-dependent amine oxidase (146, 147). Immunoprecipitation experiments suggest that this enzyme associates with the enzyme S-adenosylhomocysteine hydrolase (148). The pyrrolinium ion then is converted to the tropane skeleton by yet uncharacterized enzymes (Fig. 3b). Although no enzymatic information is available, chemical labeling studies have indicated that an acetate-derived moiety condenses with the pyrrolinium ion; one possible mechanism is shown in Fig. 3b (136). Tropamine then is reduced via an NADPH-dependent reductase to tropine that has been cloned from Hyoscyamus niger (149, 150). All tropane-producing plants seem to contain two tropine reductases, which create a branch point in the pathway. Tropine reductase I yields the tropane skeleton (Fig. 3b), whereas tropine reductase II yields the opposite stereocenter, pseudotropine (151). Tropamine is converted to scopalamine or hyoscymamine, whereas the TRI I product pseudotropine leads to callyclavine (152). These two tropine reductases have been crystallized, and site-directed mutagenesis studies indicate that the stereoselectivity of the enzymes can be switched (153, 154). The biosynthesis of scopalamine is the best characterized of the tropane alkaloids. After action by tropine reductase I, tropine is condensed with phenyllactate through the action of a P450 enzyme to form littorine (155). The phenyllactate moiety is believed to derive from an intermediate involved in phenylalanine metabolism (156). Littorine then undergoes rearrangement to form hyoscyamine. The enzyme that catalyzes this rearrangement, which has been purified partially, seems to proceed via a radical mechanism using S-adenosylmethionine as the source of an adenosyl radical (157). L-Labeling studies have been used to examine the mechanism of rearrangement (136, 157–159). Hyoscymamine is converted to the hydroxylation of hyoscymamine to 6β-hydroxyhyoscymamine as well as the epoxidation to scopolamine (Fig. 3b) (160, 161).
Alkaloid Biosynthesis

Figure 3. (a) Representative tropane and nicotine alkaloids. (b) Tropane biosynthesis. ODC, ornithine decarboxylase; PMT, putrescine N-methyltransferase; MPO, diamine oxidase; TR1, tropinone reductase 1; H6H, hyoscyamine 6b-hydroxylase.

H6H, which has been cloned and expressed heterologously (162), is a nonheme, iron-dependent, oxoglutarate-dependent protein. It seems that the epoxidation reaction occurs much more slowly than the hydroxylation reaction. The tropane alkaloids seem to be formed in the roots and then transported to the aerial parts of the plant (163).

Metabolic engineering of tropane alkaloids

Atropa belladonna plants have been transformed with an H6H clone from H. niger. A. belladonna normally produces high levels of hyoscyamine, the precursor for the more pharmaceutically valuable alkaloid scopolamine. However, after transformation with the H6H gene, transgenic A. belladonna plants were shown to accumulate scopolamine almost exclusively (164). Additionally, the levels of tropane alkaloid production in a variety of hairy root cultures were altered by overexpression of methyltransferase putrescine-N-methyltransferase and H6H. Overexpression of both of these enzymes in a hairy root cell culture resulted in significant increases in scopolamine production (164, 165). Fluorinated phenyllactic acid substrates could be incorporated into the pathway (166), and several substrates derived from putrescine analogs were turned over by the enzymes of several Solonaceae species (167).

Purine Alkaloids

Caffeine biosynthesis

Caffeine, a purine alkaloid, is one of the most widely known natural products. Caffeine is ingested as a natural component of coffee, tea, and cocoa, and the impact of caffeine on human health has been studied extensively. The biosynthetic pathway of caffeine has been elucidated recently on the genetic level. Caffeine biosynthesis has been studied most widely in the plant species Coffea (coffee) and Camellia (tea) (168, 169).

Xanthosine, which is derived from purine metabolites, is the first committed intermediate in caffeine biosynthesis (Fig. 4). Xanthosine can be formed from de novo purine biosynthesis, S-adenosylmethionine (SAM) cofactor, the adenylate pool, and the guanylate pool (169). De novo purine biosynthesis and the
The biosynthesis of caffeine begins with the methylation of xanthosine to yield N-methylxanthine by the enzyme xanthosine N-methyltransferase (XMT) (also called 7-methylxanthosine synthase) (171-173). N-methylxanthine is converted to N-methylxanthine by methylxanthine nucleosidase, an enzyme that has not been cloned yet (174). N-methylxanthine is converted to theobromine by 7-methylxanthine-N-methyltransferase (MXMT) (also called theobromine synthase), a second N-methyltransferase (171, 175). Theobromine is converted to caffeine by 7-methylxanthine-N-methyltransferase (2XMT) (also called caffeine synthase) (171).

Coffee and tea plants seem to contain a variety of N-methyltransferase enzymes that have varying substrate specificity (168, 169). For example, a caffeine synthase enzyme isolated from tea leaves catalyzes both the N-methylation of N-methylxanthine and theobromine (176). The substrate specificity of the methyltransferases can be changed by site-directed mutagenesis (177), and the crystal structure of two of the methyltransferases has been reported recently (178).

Metabolic engineering of caffeine biosynthesis

Caffeine may act as a natural insecticide in plants. When the three N-methyltransferase genes were overexpressed in tobacco, the resulting increase in caffeine production improved the tolerance of the plants to certain pests (179). Conversely, coffee beans with low caffeine levels would be valuable commercially, given the demand for decaffeinated coffee. Because of the discovery of these N-methyltransferase genes, genetically engineered coffee plants with reduced caffeine content now can be constructed (180, 181). For example, a 70% reduction in caffeine content in engineered coffee plants with reduced caffeine content now can be constructed (180, 181). For example, a 70% reduction in caffeine content in engineered coffee plants with reduced caffeine content now can be constructed (180, 181). For example, a 70% reduction in caffeine content in engineered coffee plants with reduced caffeine content now can be constructed (180, 181).

Chlorophylls and carotenoids are essential pigments of photosynthesis, in which they have complementary functions for capturing light and transducing it to biochemical energy and for protecting against its deleterious effects. Carotenoids are also present in most other organisms where they have, besides photoprotection, a variety of other functions. Typical structures of both types of pigments are reviewed in this article as well as their functions, chemical properties, spectroscopy, biosynthesis, and applications.

Photons contain, by biologic standards, relatively high energies (120–300 kJ/mol). In photosynthesis, this energy is captured collectively by hundreds of pigment molecules (chlorophyll, carotenoids, and biliproteins) that are organized in light-harvesting complexes (LHCs). The excitation energy is then funneled with high quantum efficiencies to reaction centers (RCs), where few specialized chlorophylls initiate the charge separation across the photosynthetic membrane. The resulting electrochemical potential is used by a vectorial electron/proton transport chain to generate energy-rich compounds (adenosine triphosphate, reduced nicotinamide adenine dinucleotide) that are used eventually to reduce atmospheric carbon dioxide to carbohydrates (see the section entitled "Photosynthesis").

Chlorophylls (Chls) and carotenoids (Cars) are the two indispensable pigments of photosynthesis, where they have complementary functions. Chls are key pigments for the productive functions of photosynthesis, which includes light harvesting and primary energy transduction of light into an electrochemical gradient. The combination of intense light absorption and long excited state lifetimes renders them, however, highly phototoxic and potentially damaging. This finding may be the reason that only few examples exist where Chl (derivatives) have been found in nonphotosynthetic tissue and organisms and, generally, in low concentrations. Chls and their precursors are also involved in intracellular communication and regulation. Cars have essential light-protective functions in all photosynthetic organisms and in many nonphotosynthetic organisms. Cars are functionally more diverse, however. In photosynthetics, they can function in a productive way by light harvesting. They contribute to the coloration of flowers, their derivatives are photosensory pigments (rhodopsin), they are involved in the alternative photosynthesis of halobacteria that is based on \( \text{H}^+ \)-pumping, they act as hormones in plants (abscisic acid) and animal (retinoic acid), and they act as volatile defensive or attractive principles in plants. This short review is focused on the biochemistry and biophysics of Chls and Cars in photosynthesis, and it will provide a short outline of applications.

In the dynamic natural light environment, the combination of Chls and Cars allows photosynthetic organisms to maintain the balance between efficiently competing for light and damage by an overdose of light. Photosynthesis based on these two pigments has conquered nearly all habitats on earth where light is available, even at very low levels. It has produced the atmospheric oxygen we breathe, and it fixes \( 5 \times 10^{11} \) tons of carbon annually. The greening and de-greening of the vegetation in temperate zones, because of the biosynthesis of Chls in spring and their degradation in fall, is probably the most obvious life process on earth, which is visible clearly from outer space (1).

Chls and Cars both absorb light very strongly. In the LHC, these absorptions cover, in combination, most of the visible and the near-infrared spectral range (350–1050 nm). The two groups of pigments differ, however, by more than three orders of magnitudes in their excited state lifetimes: Those of the Chls live for several nanoseconds (\( 10^{-9} \) s), and those of most Cars live for only few picoseconds (\( 10^{-12} \) s). This finding has major consequences for their potential functions. The short lifetimes of the Cars suffice only for an efficient transfer in the LHC over very short distances, whereas the much longer lifetimes of Chls allow for transfer over tens of nanometers. Only the latter are also involved in charge separation. However, the short lifetimes of Cars with relatively excited state energies are favorable for light protection, where Cars are indispensable. Whenever, under varying light (cloud cover, leaf movements) and physiologic conditions (water, temperature), the energy cannot be transformed rapidly in a productive way; high-energy side-products can be formed that can lead to severe damage sunburn. Cars are involved in minimizing this damage at several levels. Excess energy is drained from the Chls and converted into heat, triplet states of Chls are quenched, and reactive oxygen species (ROS) are quenched as well, in particular singlet
Chlorophylls and Carotenoids, Chemistry of oxygen. The widespread occurrence of photosynthesis in many habitats and its evolution over more than $3 \times 10^9$ years led to considerable variations of the photosynthetic apparatus, which includes the pigments. The variety within the two pigment classes and the principally similar properties of the different pigments within each of the two groups will be reviewed.

Chlorophylls

Structures

The basic structure of Chls is the tetrapyrrolic porphyrin macrocycle with an attached isocyclic ring (Fig. 1). This structure has been termed "phytoporphyrin" by the IUPAC commission (2). The four nitrogens bind a magnesium ion ($\text{Mg}^{2+}$) as central metal. In rare cases, it is replaced by $\text{Zn}^{2+}$, and it is missing in the pheophytins that are present in type II reaction centers. Three spectrally distinct types of Chls can be distinguished by the degree of unsaturation of the macrocycle; they are shown in Fig. 1. It is fully unsaturated in the phytoporphyrin type Chls, hydrogenated in ring D in the phytochlorins, and hydrogenated in ring B in the phytobacteriochlorins. The red-most absorption band ($Q_x$) becomes increasingly intense and red-shifted with increasing saturation (Fig. 2). Green plants, green algae, cyanobacteria, and green photosynthetic bacteria contain mainly chlorin-type Chls. Bacteriochlorin-type Chls abound in the purple photosynthetic bacteria and heliobacteria, and the porphyrin-type Chls is found in brown algae and dinoflagellates (Table 1). The Chls vary even more in their peripheral substituents (Fig. 1). In most Chls, the C-17 propionic acid side chain is esterified by a long-chain alcohol, which is mainly the C20 terpenoid alcohol.
phytochlorin-type Chls that absorb at wavelengths ing energetics of water splitting, their reaction centers contain totrophs, viz. organisms that generate oxygen from water, can such as bacteria contain Chls at higher energies. Plants, red and green algae, and cyanobacteria Therefore, their light-harvesting systems also need to absorb bands in the blue spectral region where light in clear waters prevails. Plants, red and green algae, and cyanobacteria contain Chls a and b, few cyanobacteria contain Chl d. Brown algae and dinoflagellates, contain, in addition, Chls of the c-type. They absorb in the “green gap” where all other Chls absorb only weakly (Fig. 2) and they have particularly intense absorption bands in the blue spectral region where light in clear waters prevails.

RCs contain few, more specialized Chls (Fig. 1 and Table 1, see References 3 and 4). They form a chain of pigments across the membrane, over which in a stepwise fashion electrons are transferred from the primary donor, which is a pair of Chls located on the periplasmic side of the membrane, to the acceptors on the cytoplasmic side. Two types of reaction centers can be distinguished. In type I, the primary donor is a heterodimer composed of one molecule of Chl a or d (oxygentic photosynthesis) or BCHl g (an oxygentic Photosynthesis), and one molecule of the respective C-13P-epimer (Chl′ a, d, BCHl ′ g). The electron acceptors of the type I RC are Chls a (or d) in oxygentic photosynthesis and Chls like Bacteriochlorin a in an oxogentic Photosynthesis. In type II reaction centers, the primary donor is Chl a or d (oxygentic photosynthesis), or BCHl a or b (an oxygentic Photosynthesis): The same pigments also act as primary acceptors, whereas the Mg-free phaeophytin a and bacteriopheophytin a (or b), respectively, act as secondary acceptors.

Because of their long excited-state lifetimes, chlorophyll derivatives are rare outside phototropic organisms. However, some chlorophyll-like pigments perform other functions in nature: Certain deep-sea fish use Chls as visual pigments; in the marine worm, Bonellia viridis, a chlorophyll-like derivative acts as a sex determinant; and in certain tunicates, the tunichlorins may be involved in nonphotosynthetic electron transport (5).

Spectroscopy

The spectral properties of Chls are described by the four-orbital model (6–8). It predicts four major absorptions termed Q_x, Q_y, Q_b, and Q_a, in the near ultraviolet (NIR), visible (Vis), and NIR spectral regions that are often accompanied by vibrational side bands at higher energies of the 0–0 transition. The band intensities vary among the Chls, however, and they partly overlap so that the four bands are observed only in the bacteriochlorophyll structures, viz. BCHls a, b, g. The type of spectrum is determined mainly by the degree of unsaturation of the tetrapyrrole macrocycle (Fig. 2). In the fully unsaturated Chl c that contains a phytophorphyin macroyclic system, the B-bands around 400 nm are very intense and overlap, the Q_a-band around 620 nm is weak, and Q_b-band is even weaker and discernible only with special techniques. In phytochlorin-type Chls (Chl a, b, d, BCHl c, d, e), the B-bands are reduced in intensity and still overlap, the Q_a-band is increased to nearly equal intensity and red-shifted to ~660 nm, and the Q_b-band is only weak. In the phytobacteriochlorin-type Chls (BChl a, b, g), the B-bands are blue-shifted to ~400 nm and are well separated, the Q_a-band is even more increased in intensity and red-shifted to ~750 nm, and the Q_b-band has gained intensity and becomes clearly visible around 570 nm. By these spectral characteristics, the chlorophyll type of any given pigment can be determined readily from the spectra and other details can be detected, such as substitution pattern, ligation to the central metal (e.g., by the protein), or aggregation (see below).

Chls dissolved in organic solvents have long-lived excited states (10−5 s). Therefore, they are highly fluorescent and have significant intersystem crossing to the triplet state, which generates phosphorescence and, under aerobic conditions can generate highly toxic ROS like singlet oxygen. Chlorophyll solutions bleach rapidly by attack of the pigment by these ROS, and photooxidize cosolutes. Excess Chls or precursor porphyrins are phototoxic, their biosynthesis is controlled tightly, and deregu- lation is a way of herbicidal action (9–12). Chlporphyrin injected into animals lead to severe “sunburn” and destruction of tissue.

*Ala, antenna pigment; R, reaction center pigment. Major pigments bold caps, minor pigments in lowercase, and pigments present in few species in italics.
Chlorophyll and Carotenoids, Chemistry of

This effect is used in photodynamic therapy of cancer and other diseases (PDT) (12, 13).

Chls aggregate readily both in nonpolar solvents and in water. Aggregates have generally red-shifted absorption of the \( Q_y \)-band, and the excited state lifetimes (and thereby fluorescence and phosphorescence) are reduced drastically because of rapid conversion of the excitation energy into heat by intermolecular conversion (IC). Formation of such aggregates is probably responsible for “concentration quenching.” In both cases, one mechanism of preventing quenching seems to be the presence of “traps,” such as radicals. In large aggregates in which the excitation is highly delocalized over many pigment molecules, this mechanism reads generally to deexcitation that becomes more efficient with aggregate size. Exceptions are the aggregates of BChls \( c, d \), and \( e \) present in chlorosomes of green and brown bacteria, which are fluorescent.

Aggregation is also observed in photosynthetic pigment-protein complexes, where it may be considered a major organizing force. In addition to the red-shifted absorption, an additional red shift exists of all bands and is brought about by the protein environment. Both bands are most pronounced in the phytobacteriochlorin-type BChls. In photosynthetic systems, these aggregates show much less IC. In the antenna systems, an important function of the protein is to block (and control) deexcitation channels of Chl-aggregates in a manner still unresolved mechanistically. Isolated LHCs, which contain most (>99%) Chls of the photosynthetic apparatus therefore show high fluorescence. Light-harvesting Chls are coupled to those in the RC, such that now the excitation energy of the former is transferred efficiently to the latter. The RCs show only little fluorescence at moderate light intensities, here “photochemical quenching” by the uppermost indicator antenna system (BChls). To study the absorption bands of the RC, one needs to demetallate the BChls. To the best of our knowledge, the complete RC of green algae has not yet been isolated. It is not clear whether the RCs are a direct continuation of the antenna systems, or whether there is an additional reaction center. It is clear from a comparison of the BChls of different organisms that the arrangement of the pigments in the chlorosomes of purple bacteria is significantly different from the arrangement in the LHC of green bacteria, the chlorosomes, coordinating properties of the central Mg\(^{2+}\), and the ligation of special peripheral substituents combine to form large aggregates of BChls \( c, d \), and \( e \) that are nearly devoid of protein. Free valences of the central Mg\(^{2+}\) are also critical for interactions with the proteins in photosynthetic complexes. By coordinating to suitable amino acid side chains (e.g., histidine, methionine, and glutamate) or backbone C=O-groups, they are positioned optimally for efficient energy or electron transfer. Most (B)Chls have a single extra ligand; in this case, two isomers can be formed in which binding occurs to the (inequivalent) upper or lower face of the molecule (Fig. 1).

The esterifying alcohol, in most cases phyto (Fig. 1), comprises about 1/3 of the mass of Chls, yet its influence on the chemistry (and function) is still poorly understood. With the exception of the nonesterified Chls \( c, d \), it renders Chls amphiphilic, and is important both in aggregation in polar environments, and in the positioning of Chls in photosynthetic complexes. Variations of the alcohol are frequent in phototrophic bacteria, in particular in the chlorosomal membrane, where they contribute to formation of the fluorescent BChl \( c, d \), and \( e \) aggregates that are unique for these pigments (16).

**Metabolism**

The first dedicated intermediate in CN biosynthesis (17) is 5-aminolevulinic acid (ALA), which is the common precursor of all tetrapyrroles. It can be formed either in a single step from succinyl-CoA and glycine (C\(_5\)-pathway) or from glutamic acid (C\(_4\)-pathway) via an intermediate (Glu-IRNA\(^{\text{7p}}\)) that is generally involved in protein synthesis. Some photosynthetic bacteria (purple bacteria) use the C\(_4\)-pathway for BCHN formation; most other organisms use the C\(_5\)-pathway. In the second stage, which is ubiquitous for all natural tetrapyrroles, four ALA react to yield a pyrrole (porphobilinogen). Four of those then condense to a linear tetrapyrrole and then cyclize in a remarkable reaction in which one of the pyrroles is flipped, to the cyclic tetrapyrrole skeleton (uroporphyrinogen III). The next step involves a series of decarboxylations and oxidations to yield protoporphyrin. The latter is the first of a series of increasingly colored and phototoxic products, therefore, the organisms regulate the levels of ALA tightly to avoid any over production of protoporphyrin. Any deprotonation of this process, as well as mutations of the enzymes, may result in severe damage and often death (9–11).
The next stage, which is dedicated to Chls, is the insertion of Mg, the esterification at the C-13 propionic acid side chain, and its cyclization to yield protochlorophyllide. The biosynthesis of the phytoporphyrin-type Chls c is practically complete at this stage and requires only peripheral modifications. For the phycobobilin-type Chls, ring D is reduced either by the light-dependent protochlorophyllide-reductase (DPOR), or by the light-dependent LPOR. In angiosperms, only the latter is present; therefore, they require light for Chl biosynthesis. Subsequent reactions at the periphery, including esterification with an activated long-chain alcohol derived from the isopenoid pathway, complete the reaction sequence to the phycobobilin-type Chls. In the phycobilliprotein-type c BChls, ring B is reduced, too, by an enzyme that is homologous to DPOR, which is followed again by peripheral modifications.

Because of the high phototoxicity of Chls, their degradation is tightly controlled. It has been studied in detail only for Chls a and b, where it involves early on the (light-independent) opening of the macrocycle to yield the much less phototoxic open chain tetrapyrroles (bilins), which are modified over several stages and eventually are degraded to monocyclic compounds (14, 15). Very little is known on the degradation of the other Chls.

Applications

The best source for Chl a is the cyanobacterium Spirulina platensis, which is available commercially. Chl a/b mixtures can be obtained from all green plants. All other Chls are less readily accessible, which limits their applications. Several Chl derivatives are used as dyes for food colorants (Cu-chlorophyllin) and cosmetics. The “chlorophyll” used for the “chlorophyll” ink is a complex mixture of degradation products. More recently, (B)Chl derivatives have gained increasing interest as photosensitizers in photodynamic therapy of cancer, these compounds include pigments in which the isocyclic ring is opened and/or the central metal has been removed or replaced (e.g., by Pd(II)) to increase phototoxicity (12, 13).

Carotenoids

Structures

Most Cars are tetraterpenes that contain 6–15 conjugated double bonds. Two C20–units (originally geranyl-geraniol) are joined tail-to-tail to a chain of 32 carbon atoms bearing 8 methyl side-chains (see Reference 18 for nomenclature, and lycopene tail-to-tail to a chain of 32 carbon atoms bearing 8 methyl a similar fashion but starting from two C15-units (farnesol). In addition, a family of triterpenic Cars exists that are generated in acylation, and shortening or extension of the carbon skeleton. In oxygen-containing functional groups and their glycosylation or ble bonds, cyclization at one or both ends, the introduction of (18), including isomerization and rearrangement of the double bonds, cyclization at one or both ends, the introduction of oxygen-containing functional groups and their glycosylation or acylation, and shortening or extension of the carbon skeleton. In addition, a family of triterpenic Cars exists that are generated in a similar fashion but starting from two C30–units (farnesol). In combination, these modifications account for the more than 800 isomers. The number and the structural variations of Cars reflect a variety of functions. The modifications seem to be particularly far-reaching in Cars dedicated to light harvesting, as exemplified by peridinin; a highly modified C35 pigment from algae (Fig. 3).

Furthermore, many carotenoid metabolites exist that have distinct functions. One such example shown in Fig. 3 is retinal, the chromophore of visual pigments (rhodopsins) and the light-driven proton pump, bacteriorhodopsin. Other examples are the plant hormone, abscisic acid, or volatile compounds that contribute to the fragrance of roses, for example.

Occurrence and Functions

Car functions are as diverse as their structures. In contrast to the Chls, they are not defined to photosynthetic organisms but are rather ubiquitous in living organisms. However, animals (including humans) cannot synthesize them but rely on dietary supplies, for example of vitamin A.

The essential and indispensable function of Cars in photosynthesis is the protection of the photosynthetic apparatus. Variations of light quality (color) and intensity in the natural environment often lead to overload of the photosynthetic machinery. Whenever energy transfer in the light-harvesting systems is disturbed, or the RC cannot cope with the input from the LHC, the Cars are the prime protectants from toxic long-lived excited states of the Chls and the subsequently formed ROS (see above). This task is achieved by three major reaction mechanisms. The first is direct photoprotection: Cars have several “forbidden” states that can accept excess singlet excitations from Chls; this energy is subsequently converted rapidly into heat by IC (19). The second mechanism is quenching of Chl triplets by triplet energy transfer to the low-lying Car triplets that can no longer generate ROS. Even if ROS are formed by Chl photosensitization, Cars can detoxify them for example by energy transfer from singlet oxygen or by addition of ROS to the double bond system. All these processes require very close distances between the donor (excited Chls, ROS) and the energy-accepting Car. Therefore, all photosynthetic Chl proteins contain Cars, and they are always in contact with the Chls, as is revealed by several X-ray structures of photosynthetic complexes (20). Specialized Cars are found in the RC and in all Chl-containing LHCP. In the latter, the effective Cars in protection seem to be positioned strategically at critical sites where the energy is funneled to the RC.

Because ROS attack is an important defense mechanism against infections in animals, Cars have functions in bacteria that protect them against the immune system. Many bacteria synthesize Cars for their protection, and many virulent forms of Cars are colored by deep Colors.

Carotenoids also protect simply by their function as nonphototoxic light filters. They remove, by virtue of their high absorption, near ultraviolet and blue light region, and they degrade their excitation energy rapidly to heat by IC. Certain algae tolerant to extreme light stress contain droplets of pure Cars. Many nonphotosynthetic organisms synthesize Cars when subjected to increasing light intensities. As nonphototoxic pigments, Cars often function as “safe” colorants in nature. Examples are colors of flowers used for attracting and for communicating with

...pollinating animals, mainly insects, or examples of crustaceans that blend into the marine background.
A rather function in photosynthetic organisms is light harvest-
ing in the “green gap” (470–600 nm) where Chls absorb only poorly. Because of rapid IC, most Cars transfer energy only with low efficiency to Chls. However, particularly in microal-
geae and phototrophic bacteria they can contribute prominently to photosynthesis despite their general protective function. Two factors are important to this function. One is the evolution of Cars in which the excited state lifetime is somewhat increased, and therefore IC is reduced. The two most abundant Cars, fucox-
anthin and peridinin, have lifetimes that reach 100 ps (22). The second factor is, again, a location of such Cars close enough to Chls that energy transfer becomes sufficiently effective within the short excited state lifetimes (electron exchange mechanism). Plants and some algae use, e.g., in the so-called violaxanthin cy-
cle) subtle structural modifications to manipulate Cars such that light-harvesting Cars are converted into protecting pigments, and vice versa, in response to the light supply and the status of the photosynthetic apparatus (22). The mechanism of this switch is still unclear.

Last are Car precursors for important metabolites. Only three examples shall be given. The first example is retinal (Fig. 3), which is the chromophore of the visual pigment rhodopsin (23) and is derived from β-carotene. Because the latter cannot be synthesized by mammals, they need it to be supplied as provitamin A. Retinal derivatives are also required for other regulatory functions. The second example is abscisic acid (Fig. 3), which is the plant hormone involved in the shedding of leaves in fall and in fruit ripening: it is derived from violaxanthin. Finally, certain fragrances of roses are not synthesized directly, but they are breakdown products of the flowers’ Cars.

Spectroscopy

Carotenoids are conjugated linear polyenes with 6–15 double bonds. The optical spectra of such pigments are characterized by some unusual features (Fig. 4, 19). First, the lowest energy S0 – S1 transition located in the red to NIR spectral range is “opti-
cally forbidden” for conventional one-photon excitation or emis-
sion; therefore, the related absorption and fluorescence are ex-
tremely weak. Theoretically, this is true only for C2-symmetric polyenes; but in practice, even highly asymmetric Cars like peridinin have negligible S0 absorption. Second, the most in-
tense absorption, which is responsible for the yellow-orange color of most Cars, is a series of closely spaced, sometimes overlapping bands in the 400–550 nm range. They belong to vibrational sub-bands of an S0 – S0 absorption that are gen-
erally well resolved, but they can be broadened to a degree that they appear only as a single, broad band. With an increas-
ing number of conjugated double bonds, these absorptions are shifted, in an asymptotic fashion, to the red. Third, at least two other transitions of intermediate energy exist, which are again forbidden and therefore are very weak. Fourth, cis-carotenoids show an additional band that is typically located 100–150 nm below to the blue of the main absorption. Last, the triplet states have comparably low energy. Cars with >7 double bonds it lies below 1250 nm, which is the energy required to generate sin-
glet oxygen. The “forbidden” bands and the triplet state(s) are fundamen-
tally important for the biologic functions of Cars (see abo-

above). Car triplets can quench singlet oxygen efficiently by a spin-allowed singlet-triplet exchange reaction. The “forbidden” states are important in singlet energy transfer with other Cars and, in particular, Chls. They can be reached only indirectly (e.g., after absorption into the energy-rich major absorption band and subsequent IC) or by energy transfer from neighboring pig-
ments like Chls, but thereby contribute to energy transfer and dissipation. The fluorescence of Cars is generally negligible even from the optically allowed S0 state because of rapid IC to the lower lying forbidden states. Generally, lifetimes are a few picoseconds, and even in extreme cases they reach only 100 ps, which corresponds to fluorescence yields of ~1%.

When incorporated into proteins, the spectral properties of Cars can be modified considerably. Generally, the bands are sharpened and red-shifted, and they can become strongly op-
tically highly even for achiral Cars because of twisting of the long-chain molecule. The red shifts are in the range of ~10 nm, but they can be much larger. Spectacular cases are the color change of astaxanthin from orange to green when it is bound in the crustacean protein, α-astaxanthin, and its reversion when the protein is denatured by boiling, or the red shift of retinals in rhodopsins.

Chemical Properties

The basic hydrocarbon skeleton of Cars is very hydrophobic, and almost all Cars are insoluble in water and soluble in nonpo-
lar solvents. Solubility is increased by polar functional groups and conjugation to sugars (glycosylation) (Fig. 3), but truly water-soluble Cars are very rare. The conjugated double-bond system is moderately stable chemically. It is subject to rear-
rangements, in particular in the light, and to additions (e.g., of oxygen). The chemical properties of the highly modified Cars are determined by their particular functional groups, which in some Cars are labile. A frequent example is the epoxy-group present e.g., in violaxanthin, diadinoxanthin, fucoxanthin or peridinin. With the latter two representing >75% of the total Cars. Because of the diversity of structures and substituents, the reader is referred to specialized treatments of carotenoid chemistry (see “Further Reading” section).
Metabolism

Carotenoids are terpenoids, which are derived from oligomerization of activated isoprene. It can be synthesized either by the mevalonate pathway from acetyl-Coenzyme A, or via the recently discovered deoxyxylulose pathway (24). The latter seems to be the pathway that leads to Cars in most photosynthetic organisms. Both pathways result in two isomers: isopentenyl pyrophosphate and dimethylallyl pyrophosphate. One molecule of the latter is condensed by prenyl transferases in a head-to-tail fashion sequentially with three molecules of isopentenyl pyrophosphate. The resulting geranylgeranyl pyrophosphate (GGPP) constitutes an important branching point in terpenoid metabolism that leads to Chls via esterification with the tetrapyrrolic chlorophyllides (see above), to longer isoprenoids via additional condensation with isopentenyl pyrophosphate, and in particular to Cars (25), beginning with a tail-to-tail condensation of two molecules of GGPP by the first dedicated enzyme, phytoene synthase. The resulting phytoene is still uncolored because it has only three conjugated double bonds (Fig. 3). Dehydrogenation by phytoene-desaturase still uncolored because it has only three conjugated double bonds (Fig. 3). Dehydrogenation by phytoene-desaturase via phytolpheine to lycopene is common to most known Cars. C30 molecules are derived, in an analogous fashion, from tail-to-tail condensation of two C15 units (farnesol-pyrophosphate) and subsequent dehydrogenations. A variety of enzymes is responsible for additional structural modifications, which includes cyclases to form the end-rings characteristic of many Cars, oxygenases to introduce OH groups which can be additionally modified, isomerases and (de)hydrogenases to modify the double-bond system, and many others, which provide the structural diversity of Cars.

Applications

The use of Cars as food colorants is of considerable economic importance. This task can be done directly, but is generally done indirectly by supplying Cars or carotenoid-rich algae as food additives to fish (salmon) or poultry (chicken eggs). In cosmetics, Cars are used as sunscreens. Provitamin A (β-carotene) is a dietary supplement that is given directly but more frequently is given indirectly, for example as milk supplement. Natural sources for Cars are algae like Hematococcus, plants like carrots, or genetically manipulated bacteria. Industrial scale synthetic methods have been developed.

Whereas plants and certain microorganisms can generate all required coenzymes from CO₂ or simple organic precursors, animals must obtain precursors (designated as vitamins) for a major fraction of their coenzymes from nutritional sources. Still, most vitamins must be converted into the actual coenzymes by reactions catalyzed by animal enzymes. The structures and biosynthetic pathways of some coenzymes are characterized by extraordinary complexity. Enzymes for coenzyme biosynthesis have frequently low catalytic rates, and some of them catalyze reactions with highly unusual mechanisms.

Many coenzymes (cofactors) involved in human and animal metabolism were discovered in the first half of the twentieth century, and their isolation and structure elucidation were hailed as milestones as shown by the impressive number of Nobel prizes awarded for research in that area. Studies on coenzyme biosynthesis were typically initiated in the second half of the twentieth century and have generated a massive body of literature that continues to grow rapidly because the area still involves many incompletely resolved problems. In parallel, numerous novel coenzymes were discovered relatively recently by studies of microorganisms. In this article, the terms “cofactor” and “coenzyme” are used as synonyms.

Cofactor biosynthesis is a very broad and multifaceted topic. This article summarizes basic concepts of major cofactors. Detailed status reports on the biosynthesis of individual coenzymes can be found in excellent recent reviews that are quoted (1).
Vitamin B12 from nutritional sources must then be converted to coenzyme B12 by mammalian enzymes. Ultimately, the biosynthesis of vitamin B12 requires five enzymes, albeit of vital importance, which are involved in fatty acid and amino acid metabolism (6). Notably, because plants do not generate corrinoids, animals depend on bacteria for their supply of vitamin B12 (which may be obtained in recycled form via nutrients such as milk and meat) (7).

Some coenzymes develop by very complex pathways and/or reactions. Whereas tetrahydrobiopterin is biosynthesized from GTP via just three enzyme-catalyzed steps (2), some coenzyme biosynthetic pathways are characterized by enormous complexity. Thus, the biosynthesis of vitamin B12 requires a sequence of a deamination and reduction can proceed in a common theme, for example, in the biosynthesis of vitamin B12, a sequence of a deamination and reduction can proceed in different order. In other cases, entirely different reactions afford a given intermediate, for example in the case of nicotinic acid biosynthesis. A further example is the biosynthesis of isoprenoid building blocks and their downstream products, in which the existence of a second pathway besides the classic mevalonate pathway had been ignored until recently. Notably, higher plants use both isoprenoid pathways but for different final products.

### Specific Biosynthetic Pathways

**Biosynthesis of iron/sulfur clusters**

Iron/sulfur clusters are inorganic cofactors that are used in all cells (10). They comprise S\(^{2-}\)  ions and iron ions in the +2 or +3 state (Fig. 2). Iron/sulfur clusters are essential cofactors for numerous redox and nonredox enzymes, alone or in tandem with organic cofactors such as flavocoenzymes and/or pyridine nucleotides. The simplest structural type is the rhombic [2Fe-2S] cluster (3), [3Fe-4S] (4) and [4Fe-4S] (5) clusters are characterized by distorted cubic symmetry (10, 11). Clusters can form aggregates, and other metal ions can replace iron ions or can be present additionally.

Whereas many cognate apoenzymes can be reconstituted with iron/sulfur clusters by simple and essentially alchemistic procedures using Fe\(^{2+}\) and sulfide ions under anaerobic conditions, a highly complex enzymatic machinery is used in vivo for the synthesis of iron/sulfur clusters and their transfer to the target enzymes. Sulfide ions required for cluster synthesis are obtained from cysteine (1) via a persulfide of a protein-bound cysteine residue (2); pyridoxal phosphate is required for the formation of the persulfide intermediate (Fig. 1) (12).

In eukaryotes, the formation of iron/sulfur clusters proceeds inside mitochondria (13). The mitochondrial enzymes are orthologs of the subcellular isc proteins and are characterized
by very slow rates of evolution. Iron/sulfur clusters are initially assembled on Isc protein (prokaryotic) or Isu protein (eukaryotic) that serves as a scaffold. They can be exported to the cytoplasm in which they can become part of cytoplasmic enzymes by the assistance of proteins that serve as iron chaperones.

The persulfide intermediate 2 can also serve as a sulfur source for the biosynthesis of thiamine (6), lipoic acid (7), molybdopterin (8), and biotin (9) (Fig. 1).

Tetrapyrroles

A large and structurally complex family of coenzymes, including various hemes, chlorophylls, corrinoids (including coenzyme B12) and the archeal coenzyme F430, is characterized by their macrocyclic tetrapyrrole structure (14, 15). These coenzymes contain a metal ion (Fe, Mg, Co, or Ni) at the center of the tetrapyrrole macrocycle, which is specifically introduced by enzyme catalysis. These compounds are all derived from δ-aminolevulinic acid (12) that can be biosynthesized by two independent pathways, one that is, from glycine (11) and succinyl-CoA (10) in animals and some bacteria (e.g., Rhodobacter) or from glutamyl-tRNA (13) in plants, many eubacteria, and archaebacteria (Fig. 2) (16, 17). Two molecules of δ-aminolevulinic acid (12) are condensed under formation of porphobilinogen (14). Oligomerization of porphobilinogen affords hydroxymethylbilane (15), in which all pyrrole rings share the same orientation of their substituents. Ring D is then inverted by a rearrangement that affords uroporphyrinogen III (16) (3). Side-chain modification and the incorporation of iron by ferrochelatase (18) afford the various hemes, chlorophylls, corrinoids (including coenzyme B12) and the archaeal coenzyme F430 by a series of enzyme reactions that occur in the human host (7).

A family of coenzymes biosynthesized from GTP: tetrahydrofolate, tetrahydrobiopterin, flavocoenzymes, molybdopterin

Several coenzymes comprising a pyrimidine ring motif are derived from GTP (22) (Fig. 3). Specifically, this group comprises two members of the B vitamin group, riboflavin (vitamin B2) (24) and folic acid/tetrahydrofolate (33). Two other members of the group, tetrahydrobiopterin (32) and molybdopterin (8), are biosynthesized de novo in animals and do not have vitamin status (20, 21).

The first committed step in the biosyntheses of these compounds is the hydrolytic opening of the imidazole ring of GTP, which affords a diaminopyrimidine-type intermediate. In the biosynthetic pathways of folate, tetrahydrobiopterin, and methanopterin (34), the respective diaminopyrimidine intermediate undergoes ring closure by means of an intramolecular condensation that involves parts of the ribose side chains of GTP, which affords a 2-amino-4-pteridinone compound (29).

The 4-aminobenzoate moiety of tetrahydrofolic acid is obtained from the shikimate ring pathway of aromatic amino acid biosynthesis via chorismate. Interestingly, apicomplexan protozoa may have conserved the complex shikimate pathway for the single purpose to generate 4-aminobenzoate as a tetrahydrofolic acid precursor, whereas aromatic amino acids are obtained from external sources.

The formation of intermediate 27 (compound 2) in the biosynthesis of molybdopterin (8) proceeds a rearrangement that...
involves the ribose side chain as well as C-8 of GTP for the formation of the tetracyclic ring system.

The carbocyclic moiety of vitamin B2 is assembled from two molecules of a deoxytetrolose phosphate (22). The carbocyclic moiety of the deazaflavin-type coenzymes (36) is provided by the tyrosine precursor, 4-hydroxyphenylpyruvate.

Notably, the GTP cyclohydrolases that catalyze the first committed step in the pathways of tetrahydrofolate biosynthesis in plants and microorganisms and of tetrahydrobiopterin in animals are orthologs.

**Thiamine pyrophosphate**

The biosynthesis of thiamine pyrophosphate (46) in microorganisms and plants is characterized by extraordinary complexity (21, 23). Animals are dependent on nutritional sources but can convert unphosphorylated thiamine (that is not an intermediate of the bacterial biosynthetic pathway) into thiamine pyrophosphate in two steps.

In bacteria, the pyrimidine precursor (38) is derived from 5-aminoimidazole ribotide (39), an intermediate of the basic branch of the bacterial biosynthetic pathway into thiamine pyrophosphate in two steps.

In bacteria, the pyrimidine precursor (38) is derived from 5-aminoimidazole ribotide (39), an intermediate of the basic branch of the bacterial biosynthetic pathway into thiamine pyrophosphate in two steps.

In yeasts, a totally unrelated reaction sequence uses carbon atoms from vitamin B6 (39) that are indicated by roman letters in Fig. 4 for the assembly of the thiamine precursor (38), whereas the nitrogen atoms and one additional carbon atom are introduced from histidine (40).

In bacteria, the thiazole moiety (42) of thiamine is derived from 1-deoxy-D-xylulose 5-phosphate (43) that can also serve as a precursor for pyridoxal in many eubacteria (Fig. 5) and for isoprenoids via the nonmevalonate pathway (cf. isoprenoid cofactors). The sulfur atom is derived from the persulfide that also serves as precursor for iron-sulfur clusters and for biotin (6) and thiooctanoate (7). C2 and N3 of the thiazole moiety of thiamine have been reported to stem from tyrosine in Escherichia coli and from glycine in Bacillus subtilis, respectively. Yeasts use ADP-ribulose (44) derived from NAD as precursor (24).

In plants, little is known about the basic building blocks and the reactions involved in thiamine biosynthesis. An early study with chloroplasts of spinach indicated that 1-deoxy-D-xylulose 5-phosphate, tyrosine, and cysteine act as precursors for the thiazole moiety in analogy to the pathway in E. coli. More recently, it has been shown that a homolog of the THIC protein that converts 5-aminoimidazole ribotide into (38) is essential (25). These results suggest that the plant pathway is similar to the pathway in prokaryotes but not to that in yeast.

**Pyridoxal phosphate**

In many eubacteria, 1-deoxy-D-xylulose phosphate (43) serves as a common precursor for the biosynthesis of vitamins B6 and...

B3 and for the biosynthesis of isoprenoids via the nonmevalonate pathway. Condensation of 43 with 3-amino-1-hydroxyacetone phosphate (47) (biosynthesized from D-erythrose 4-phosphate) affords pyridoxine 5′-phosphate (48, Fig. 5A). A sequence of elimination, tautomerization, and water addition precedes cyclization via an aldol condensation (26, 27). Then, pyridoxine 5′-phosphate can be converted into pyridoxal 5′-phosphate (39) by oxidation with molecular oxygen.

A more recently discovered second pathway starts from ribulose 5-phosphate (49) that is condensed with ammonia and glyceraldehyde phosphate or its isomerization product dihydroxyacetone phosphate (50), which affords pyridoxal 5′-phosphate in a single enzyme-catalyzed reaction step (Fig. 5B) (28, 29). This pathway seems to be widely distributed: it is used in plants (30) and has also been shown to proceed in fungi, archaea, and most eubacteria.

In mammals, dietary vitamin forms, including pyridoxal, pyridoxol, and pyridoxamine, can all be converted to the respective coenzyme forms by phosphorylation.

Pyridine nucleotides

Animals and yeasts can synthesize nicotinamide from tryptophan via hydroxyanthranilic acid (52) and quinolinic acid (53, Fig. 6A) (31), but the biosynthetic capacity of humans is limited. On a diet that is low in tryptophan, the combined contributions of endogenous synthesis and nutritional supply of precursors, such as nicotinic acid, nicotinamide, and nicotinamide riboside, may be insufficient, which results in cutaneous manifestation of niacin deficiency under the clinical picture of pellagra. Exogenous supply of nicotinamide riboside was shown to promote NAD+−dependent Sir2 function and to extend life-span in yeast without calorie restriction (32).

Bacteria and plants use aspartate (54) and dihydroxyacetone phosphate (50) as precursors for the biosynthesis of nicotinamide via quinolinic acid (53, Fig. 6B) (33). The transformation of precursors into NAD (56) and NADP (57) follow the same pathway in all organisms. A ribosyl phosphate residue can be transferred to biosynthetic quinolinic acid.

or to preformed nicotinamide affording 55 (or its amide) that is converted to NAD by adenylation. Subsequent phosphorylation yields NADP.

Pantothenate

Pantothenate (also designated vitamin B5, 64, Fig. 7) is biosynthesized de novo in plants and many microorganisms but must be obtained from nutritional sources by animals (20, 34). The branched carboxylic acid 63 is obtained from α-ketoisovalerate (62), which is an intermediate of valine biosynthesis, via 62. β-Alanine (60) is obtained by decarboxylation of aspartate (54) in microorganisms. Plants and yeasts can biosynthesize β-alanine from spermine (58) (35). An additional pathway to 60 starting from uracil (59) has been reported in plants, where the downstream steps that lead to pantothenate are understood incompletely.

Organisms of all biological kingdoms convert 64 into the cysteamine derivative phosphopantetheine (65) using L-cysteine as substrate. 65 is converted to coenzyme A (66) by attachment of an adenosine moiety via a pyrophosphate linker and phosphorylation of the ribose moiety. Phosphopantetheine can be attached covalently to serine residues of acyl carrier proteins that are parts of fatty acid synthases and polyketide synthases.

Vitamin C

Whereas most mammals can synthesize ascorbic acid (vitamin C, 75) from D-glucose 1-phosphate (67) via the pathway shown in Fig. 8B, humans and guinea pigs lack the last enzyme of that
Cofactor Biosynthesis

pathway and are therefore dependent on nutritional sources (36, 37). Plants use the pathway shown in Fig. 8A that has been elucidated relatively recently (38, 39). Yeasts produce and use a five-carbon analog, which is called erythroascorbic acid, instead of ascorbate. The biosynthetic pathway of erythroascorbic acid involves the oxidation of D-arabinose to D-arabino-1,4-lactone, which is then oxidized to erythroascorbic acid.

Pyroloquinoline quinone

Pyroloquinoline quinone (77, Fig. 9, PQQ) serves as cofactor of bacterial oxidoreductases (40). The heated debate whether PQQ has vitamin character for animals is still inconclusive (41-43). PQQ is derived from a peptide precursor that contains conserved glutamate (13) and tyrosine (76) residues. All carbon and nitrogen atoms of the precursor amino acids are incorporated into the product (44). Gene clusters involved in this pathway have been studied in considerable detail. The X-ray structure of the enzyme that catalyzes the final reaction step has been determined, and reaction mechanisms have been proposed on that basis (45). However, details of the biosynthetic pathway are still incompletely understood.

Biotin

Biotin (vitamin H, 6, Figs. 1 and 10) acts as cofactor of carboxylases. It can be produced in bacteria, plants, and some fungi (46). The biosynthetic pathway involves four steps that start from alanine (78) and pimeloyl-CoA (79). Carboxylation and cyclization of 81 affords diethiobiotin (82), which is then converted into biotin (6) by the iron/sulfur protein, biotin synthase, in an unusual radical mechanism (47).

Isoprenoid cofactors

Isoprenoids are one of the largest classes of natural products that comprise at least 35,000 reported members (48). Many of these compounds play crucial roles in human metabolism as hormones, vitamins (vitamins A, D, E and K), quinine-type cofactors of respiratory chain enzymes (ubiquinone), membrane constituents, and functionally important side chains of signal cascade proteins (Fig. 11). Chlorophyll (17, Fig. 2) and heme a (18) have isoprenoid side chains. Whereas vitamin E (99) and vitamin A or its biosynthetic precursor, β-carotene, must be obtained by animals from dietary sources, many other isoprenoids, including the quinone type coenzyme Q family (where individual representatives differ by the length of their side chains), can be synthesized de novo by vertebrates. 3-Hydroxy-3-methylglutaryl-CoA reductase, the enzyme that catalyzes the conversion of (S)-3-hydroxy-3-methylglutaryl-CoA (84) to mevalonate (85), is one of the most important drug targets for the prevention of cardiovascular disease (see below) (49, 50).

All isoprenoids are biosynthesized from two isomeric 5-carbon compounds, isopentenyl diphosphate (IPP, 86) and dimethylallyl diphosphate (DMAPP, 87) (Fig. 11). The mammalian pathway for the biosynthesis of these key biosynthetic precursors from three acetyl-CoA units (83) via mevalonate (85) had been elucidated in the 1950s (51). In the wake of that pioneering work, it became established dogma that all terpenoids are invariably of mevalonate origin, even in the face of significant aberrant findings.
The existence of a second pathway that affords IPP and DMAPP was discovered in the 1990s. The details of that nonmevalonate pathway were then established in rapid sequence by the combination of isotope studies, comparative genomics, and enzymology (52). The delayed discovery of the nonmevalonate pathway can serve as paradigm for pitfalls in the elucidation of biosynthetic pathways.

The mevalonate pathway starts with a sequence of two Claisen condensations that afford (S)-3-hydroxy-3-methylglutaryl-CoA (84) from three acetyl-CoA moieties. The pathway affords IPP that can be converted into DMAPP by isomerization. The first committed intermediate of the nonmevalonate pathway is 2C-methyl-D-erythritol 4-phosphate (90) obtained from 1-deoxy-D-xylulose 5-phosphate (43), which is a compound also involved in the biosynthesis of vitamins B1 (46, cf. Fig. 4) and B2 (39, cf. Fig. 3), by rearrangement and subsequent reduction. Three enzyme-catalyzed steps are required to convert the compound into the cognate cyclic diphosphate 91 that is then converted reductively into a mixture of IPP and DMAPP by the consecutive action of two iron/sulfur proteins.

It is now firmly established that green plants use both isoprenoid biosynthesis pathways (52). More specifically, sterols and triterpenes are generated in the cytoplasm via the mevalonate pathway, whereas isopentenyl diphosphate and isopentenyl pyrophosphates are generated in plastids via the nonmevalonate pathway. These assignments are not absolute because there is a level of crosstalk between the compartments.

Oligomerization of isoprenoids under elimination of pyrophosphate affords the precursors for the biosynthesis of monoterpenes, sesquiterpenes, diterpenes, triterpenes, and tetraterpenes (93). Long-chain oligomer pyrophosphates also supply the side chains of vitamin E (99, α-tocopherol, Fig. 11), heme a (138), chlorophyll (17, Fig. 2), and the quinone type co-factors, including vitamin K (menaquinone, 98) and coenzyme Q10 (ubiquinone, 97). The quinone moieties are derived from hydroxybenzoate that is synthesized from tyrosine in animals or from chorismate in microorganisms (53, 54).

The tetraterpene, β-carotene (95), is biosynthesized in microorganisms and in the chloroplasts of higher plants where it serves as an important component of the light-harvesting apparatus. In plants, the isoprenoid precursor units of carotenoids are predominantly of nonmevalonate origin. In vertebrates, β-carotene serves as provitamin A that can be converted into the vitamin retinol (96) by oxidative cleavage. Whereas vitamin A functions as a component of retinal photoreceptors and in signal transmission in vertebrates, it is also involved in bacterial photosynthesis, in which it serves as prosthetic group in a light-driven proton pump. The halobacterial proton pump and

Humans can generate vitamin D₃ (cholecalciferol) by endogenous biosynthesis but require dietary sources under certain environmental conditions. More specifically, 94 that can be obtained via the endogenous mevalonate pathway can be photochemically converted into provitamin D in light-exposed skin areas. The transformation requires ultraviolet light. At higher geographical latitudes, light exposure of the skin can be a limiting factor. The fact that skin pigmentation retards the photochemical formation of vitamin D may have acted as a selective factor that favored pale skin when modern humans migrated to areas with higher geographic latitude.

Biosynthesis of archaeal coenzymes

Archaea bacteria that were discovered only during recent decades are now recognized as a third kingdom of life besides eubacteria and eukaryotes. An important subgroup of archaea can generate energy by conversion of carbon dioxide or low molecular weight organic acids into methane. The pathway of methanogenesis has been shown to implicate several unique coenzymes (55). Specifically, 5-deaza-8-hydroxy-10-ribosylisoalloxazine (factor
clusters (12). Use a pyrosulfide protein precursor that is also used for the coenzymes (thiamine (18) or pyridoxal phosphate). A tetrapyrrole-type coenzyme F430 (5) was named on basis of its absorption maximum at 430 nm. The nickel-chelating factor is biosynthesized via the porphyrin biosynthetic pathway (Fig. 2) (19). For the handling of one-carbon fragments that play a central role in their metabolism, methanogenic bacteria use methanopterin (34, Fig. 3). The tetrahydropterine system that serves as the business end of the methanopterin coenzyme family is structurally similar to tetrahydrofolate, and the biosynthetic pathway starting from GTP is similar to that of tetrahydrofolate (Fig. 3). The ribitylaniline moiety is derived from ribose and from the shikimate pathway via 4-amino-phenylpyruvate (56, 57). In contrast to the coenzymes limited to methanogenic bacteria and are also found in streptococci, those of the riboflavin biosynthetic pathway, which affords the benzenoid moiety, are derived from the shikimate pathway via 4-hydroxyphenylpyruvate (56, 57).

Some coenzymes serve as biosynthetic precursors that afford structural parts of other coenzymes. Thus, the benzenoid moiety of the flavo coenzyme FMN serves as a precursor for the lower ligand 26 of the central cobalt ion in vitamin B12 (20, Fig. 3). Pyridoxal and NAD are used as precursors for the biosynthesis of thiamine in yeast (Fig. 4) (23, 24).

Branching of pathways is relevant in several cases. Thus, intermediates of the porphyrin biosynthetic pathway serve as precursors for chlorophyll (12, Fig. 2) and for the central ring systems of vitamin B12 (20, Fig. 2) (17). 3-D-xylyl-5-phosphate (43) serves as an intermediate for the biosynthesis of pyridoxal phosphate (17, Fig. 3), for the terpenoid precursor IPP (86) via the nonmevalonate pathway (Fig. 11), and for the thialeole moiety of thiamine pyrophosphate (46, Fig. 4). 7,8-Dihydrobiopterin triphosphate (29, Fig. 3) serves as an intermediate in the biosynthetic pathways of tetrahydrofolate (33) and tetrahydrobiopterin (31). The closely related compound 7,8-dihydroneopterin triphosphate is the precursor of the archaean cofactor, tetrahydromethanopterin (34) (58). A common pyrimidine-type intermediate (23) serves as the precursor for flavin and deazaflavin coenzymes. Various sulfur-containing coenzymes (lipoic acid (7), biotin (6), Fig. 1) use a pyrosulfide protein precursor that is also used for the biosynthesis of inorganic sulfide as a precursor for iron/sulfur clusters (12).

**Coenzymes as biosynthetic precursors**

Several coenzymes are involved in the biosynthesis of their own precursors. Thus, thiamine is the cofactor of the enzyme that converts 1-deoxy-D-xylulose 5-phosphate (43) to tetrahydrofolate derivatives as coenzymes (cofactors) (Fig. 3). When a given coenzyme is involved in its own biosynthesis, we are faced with a “hen and egg” problem, namely how the biosynthesis could have evolved in the absence of the crucially required final product. The answers to this question must remain speculative. The final product may have been formed via an alternative biosynthetic pathway that has been abandoned in later phases of evolution or that may persist in certain organisms but remains to be discovered. Alternatively, the coenzyme under study may have been accessible by a prebiotic sequence of spontaneous reactions. An interesting example in this respect is the biosynthesis of flavin coenzymes, in which several reaction steps can proceed without enzyme catalysis despite their mechanistic complexity.

In terms of coenzyme evolution, it is also noteworthy that the biosynthesis of a given coenzyme frequently requires the cooperation of other coenzymes. For example, the biosynthesis of riboflavin (24) requires tetrahydrofolate (33) for the biosynthesis of GTP, which serves as a precursor (Fig. 3). Pyridoxal 5′-phosphate is required for the biosynthesis of the activated pyrosulfide type protein (2) that serves as the common precursor for iron/sulfur clusters and various sulfur-containing organic coenzymes (Fig. 1).

Covalent coenzymes

Whereas many coenzymes form noncovalent complexes with their respective apoenzymes, various flavoenzymes are characterized by covalently bound FMN (25) or FAD (Fig. 3). Covalent linkage involves the position 8 of the riboflavin or the benzenoid carbon atom of the flavin and a cysteine or histidine residue of the protein. The covalent CN or CS bond can be formed by autoxidation of the noncovalent apoenzyme/coenzyme precursor complex as shown in detail for nicotine oxidase (59). Biotin (6, Fig. 10) and lipoic acid (7, Fig. 1) are attached enzymatically to apoenzymes via carboxamide linkage to specific lysine residues (60, 61). The pantotheryl moiety (64, Fig. 7) can also be linked covalently to proteins via amide linkage (62). Covalently bound heme is involved in heme M (63) and heme L-catalyzed reactions (64, 65). Several covalently bound coenzymes, including pyruvyl, methylidene imidazolone, topaquinone, and tryptophan tryptophyl quinone-type prosthetic groups are generated by posttranslational modification (66).

Cellular topology of coenzyme biosynthesis in eukaryotes

In bacteria, coenzyme biosynthesis is located in the cytoplasm. In eukaryotic cells, organelles play important roles in the biosynthesis of certain cofactors. For example, certain steps of iron-sulfur cluster biosynthesis proceed in mitochondria (10, 13). In plants, some steps of the biosynthesis of tetrahydrofolate, biotin, and lipoate proceed in mitochondria (7, 15), whereas the biosynthesis of vitamin B2 is operative in plastids (67). In apicomplexan protozoa, enzymes in mitochondria, in the apicoplast (an organelle that is believed to have a common evolutionary origin with chloroplasts) and in the cytoplasmic
that results from mutations of phenylalanine hydroxylase has also been advocated for certain patients with classic phenylketonuria. In fact, the relatively large number of patients with classic phenylketonuria may provide an economic incentive for the development of a biotechnological process for the bulk production of the coenzyme.

Deficiencies of enzymes involved in the transformation of the vitamin pantothenic acid (64) into the cognate coenzyme forms (66, Fig. 7) result in severe developmental and neurological deficits that affect few human patients (34, 72). Therapy with megadoses of pantothenic acid has been advocated, but their efficiency has yet to be demonstrated by stringent clinical studies (73).

Genetic defects of molybdopterin biosynthesis (Fig. 3) also result in severe neurologic and developmental deficits (74). Genetic defects in the biosynthesis of the quinine-type coenzyme Q10 (97, Fig. 11) can result in encephalopathy, myopathy, and renal disease (53).

Inherited defects or porphyric biosynthetic enzymes can cause the accumulation of pathway intermediates that cannot be converted anymore with sufficient velocity. Various genetic forms of porphyria have been reported and result in liver toxicity, neurological damage and photosensitivity (75). Aquired forms of porphyria can be caused by a variety of toxic and pharmacologic agents.

The absorption of vitamin B12 (20) requires a glycoprotein-designated intrinsic factor that is secreted by the gastric mucosa. A acquired failure to produce the intrinsic factor results in a complex disease that can present with hematological (macrocytotic anemia and pernicious anemia), neurological, or psychiatric symptoms or a combination thereof. Prior to the discovery of vitamin B12, pernicious anemia was lethal. Initial treatment was based on the consumption of large amounts of uncooked liver. If diagnosed timely, the disease can now be cured easily by the parenteral administration of vitamin B12. Notably, the liver can store large amounts of the vitamin.

### Cofactor Biosynthesis

#### Three-dimensional structures of coenzyme biosynthesis enzymes

The rapid technological progress in X-ray crystallography has enabled the structural analysis of numerous enzymes involved in coenzyme biosynthesis. Complete sets of structures that cover all enzymes of a given pathway are available in certain cases such as riboflavin, tetrahydrobiopterin, and folic acid biosynthesis. Structures of orthologs from different taxonomic groups have been reported in certain cases. X-ray structures of enzymes in complex with substrates, products, and analogs of substrates, products, or intermediates have been essential for the elucidation of the reaction mechanisms. Structures of some coenzyme biosynthesis enzymes have been obtained by NMR-structure analysis.

Enzymes that are addressed by major drugs have been studied in particular detail. Thus, well above one hundred structures have been reported for dihydrofolate reductases from a variety of organisms, including major pathogens such as Mycobacterium tuberculosis, which is the causative agent of tuberculosis, and of Plasmodium falciparum, which is the most important of the Plasmodium spp. that causes malaria. The interaction of mammalian dihydrofolate reductases with inhibitors that are used as cytostatic agents and/or immunosuppressants is also documented extensively by X-ray structures.

The rapidly growing number of three-dimensional coenzyme biosynthesis enzyme structures in the public domain and the cognate publications are best addressed via the internet server of Mycobacterium tuberculosis (76). The factor binds the vitamin and enables its subsequent transport across the ileal mucosa. Acquired failure to produce the intrinsic factor results in a complex disease that can present with hematological (macrocystotic anemia and pernicious anemia), neurological, or psychiatric symptoms or a combination thereof. Prior to the discovery of vitamin B12, pernicious anemia was lethal. Initial treatment was based on the consumption of large amounts of uncooked liver. If diagnosed timely, the disease can now be cured easily by the parenteral administration of vitamin B12. Notably, the liver can store large amounts of the vitamin.

#### Medical Aspects

**Genetic deficiency of coenzyme biosynthesis**

Genetic defects have been reported for the biosynthesis of several coenzymes in humans. Typically, these rare anomalies cause severe neurological deficits that become apparent at birth or in early childhood.

Specifically, the deficiency of certain enzymes of tetrahydrobiopterin biosynthesis (GTP cyclohydrolase I, pyruvoyltetrahydrobiopterin synthase, [Fig. 3](#)) result in severe neurological and developmental deficits designated as atypical phenylketonuria. The condition can be treated with some success by the oral application of synthetic tetrahydrobiopterin in large amounts. More recently, tetrahydrobiopterin therapy has also been advocated for certain patients with classic phenylketonuria that results from mutations of phenylalanine hydroxylase (71). This therapeutic approach is based on the concept that the function of certain defective phenylalanine hydroxylases can be bolstered by increased amounts of the cognate coenzyme tetrahydrobiopterin. In fact, the relatively large number of patients with classic phenylketonuria may provide an economic incentive for the development of a biotechnological process for the bulk production of the coenzyme.

Genetic defects of molybdopterin biosynthesis (Fig. 3) also result in severe neurologic and developmental deficits (74). Genetic defects in the biosynthesis of the quinine-type coenzyme Q10 (97, Fig. 11) can result in encephalopathy, myopathy, and renal disease (53).

Inherited defects or porphyric biosynthetic enzymes can cause the accumulation of pathway intermediates that cannot be converted anymore with sufficient velocity. Various genetic forms of porphyria have been reported and result in liver toxicity, neurological damage and photosensitivity (75). Aquired forms of porphyria can be caused by a variety of toxic and pharmacologic agents.

The absorption of vitamin B12 (20) requires a glycoprotein-designated intrinsic factor that is secreted by the gastric mucosa. A acquired failure to produce the intrinsic factor results in a complex disease that can present with hematological (macrocystotic anemia and pernicious anemia), neurological, or psychiatric symptoms or a combination thereof. Prior to the discovery of vitamin B12, pernicious anemia was lethal. Initial treatment was based on the consumption of large amounts of uncooked liver. If diagnosed timely, the disease can now be cured easily by the parenteral administration of vitamin B12. Notably, the liver can store large amounts of the vitamin.

#### Coenzyme biosynthesis enzymes as anti-infective drug targets

Enzymes involved in coenzyme biosynthesis represent targets for anti-infective agents (77). The sulfonamides that were discovered in the 1930s were the first group of synthetic agents for anti-infective agents (77). The sulfonamides that were discovered in the 1930s were the first group of synthetic agents with a broad spectrum of activity against pathogenic bacteria and protozoa. Their mode of action, via inhibition of dihydrofolate synthetase in the biosynthetic pathway of tetrahydrofolate biosynthesis (Fig. 3), was elucidated only much later. Subsequent studies on compounds with antifolate activity afforded inhibitors of dihydrofolate reductase, which is the en-zyne in that pathway that catalyzes the formation of tetrahydrofolate from dihydrofolate in organisms that synthesize the coenzyme de novo and from folate in organisms that rely on dietary sources. Trimethoprim, which is an inhibitor of dihy-drofolate reductase that is required for the use of nutritional folate and dihydrofolate as well as for the metabolic recycling
of tetrahydrofolate coenzymes) became a widely used antimicrobial agent that is typically applied in combination with a sulfonamide.

Fosmidomycin, initially discovered as a product of Streptomyces lavendulae with antibacterial and herbicide activity, was recently shown to act via the inhibition of IspC protein that catalyzes the first committed step in the nonmevalonate pathway of isoprenoid biosynthesis that is absent in humans (43 → 90, Fig. 11). Based on these findings, the compound is now under clinical evaluation as an antimalarial drug (78).

In principle, other coenzyme biosynthetic pathways that occur in pathogenic bacteria but not in humans should qualify as anti-infective drug targets with a favorable toxicity profile. Novel anti-infective principles would be highly desirable in light of the rapid spread of resistant pathogens.

Coenzyme biosynthesis as a target for cytostatic agents

The development of the sulfonamides as antibacterial and antiparasitic agents had preceded the discovery of its metabolic target in the biosynthesis of tetrahydrofolate (that was per se unknown in the 1930s) (Fig. 3). The discovery of the vitamin in the 1940s triggered a wave of research directed at additional inhibitors of its biosynthesis. This work resulted in the discovery of methotrexate that is widely used as a cytostatic agent predominantly for hematological malignancy, and also an immunosuppressive agent used in the therapy of autoimmune disease such as Crohn’s disease (79).

Drug interaction with coenzyme biosynthesis pathways

Mevastatin is an inhibitor of 3-hydroxy-3-methylglutaryl-CoA reductase (Fig. 11, 84 → 85) that was isolated from Penicillium citrinum in 1971. A group of structurally related compounds designated as statins is now widely used for the prevention and treatment of cardiovascular disease (80). Statins exert their desired effects via the lowering of low-density lipoprotein and probably also via reduced prenylation of small G-proteins of the Ras protein family that are involved in proinflammatory signaling. The highly pleiotrophic mevalonate pathway is the source of numerous other highly important metabolites including coenzyme Q10 (97). However, a recent review concludes that the suppression of coenzyme Q10 biosynthesis, which can be expected as a side result of statin therapy, is not a significant cause of rhabdomyolysis, a dreaded side effect of statin therapy (81).

Modulation of vitamin D biosynthesis by environmental factors

Fair-skinned humans face a dilemma because ultraviolet light exposure carries the risks of carcinogenesis and skin aging, whereas insufficient ultraviolet light carries the risk of vitamin D deficiency (94, Fig. 13). Insufficiency. The case is unique in so far as an endogenous biosynthetic pathway is subject to regulation by external lifestyle factors such as ultraviolet exposure and the use of chemical and physical sunscreens. Recent studies indicate that vitamin D deficiency is widespread in the human population and is a risk factor for a wide variety of conditions, including cancer and autoimmune disease (82). The dilemma of ultraviolet protection and vitamin D sufficiency can clearly be addressed easily by vitamin D supplements.

Biotechnology

Harnessing biosynthetic pathways for vitamin production

Certain vitamins that serve as coenzymes (vitamin C) or as precursors of coenzymes (all B group vitamins and certain carotenoids) are commercially produced in bulk amounts, which are used for human nutrition and animal husbandry, as antioxidants (vitamins C and E) and food colorants (vitamin B12, carotenoids). Only a fraction of technically manufactured vitamins is used for inclusion in drugs.

Vitamin B12 is produced exclusively by bacterial fermentation technology. The chemical synthesis of vitamin B12 has been suspended during the past two decades by fermentation processes using bacteria and yeasts. Carotene, various other carotenoids and vitamin A are produced by chemical synthesis, but a variety of biotechnological processes have been also been explored for their production. Notably, vitamin A deficiency continues to be a major cause for acquired blindness in developmental countries, although vitamin A and β-carotene, which serves as a provitamin, can be produced at modest cost and in virtually unlimited quantity by existing technology. At least certain steps of the various technical vitamins production are also conducted by fermentation. For various other vitamins, biotechnological production may become competitive in the future.

Lantibiotics are a unique class of antimicrobial peptides produced by Gram-positive bacteria. They are synthesized ribosomally as precursor peptides and undergo extensive posttranslational modification to attain their biologically active structures. These modifications include dehydration of serine and threonine residues that produce dehydroalanines and dehydrobutyrines, followed by intramolecular addition of cysteine thiols to the unsaturated amino acids. The lantibiotic biosynthetic machinery displays low substrate specificity both in vivo and in vitro, which allows for the engineering of novel lantibiotics. The polycyclic peptides exert their biological activity through several modes of action including the sequestration of the cell wall precursor lipid II and pore formation in bacterial membranes. Because of their high potency, several commercial applications of lantibiotics are being developed.

Biological Background

The prototypical lantibiotic, nisin, was discovered in 1928 for its antibacterial properties and has been used as a preservative in dairy products since the 1950s (1). Nisin and other lantibiotics exhibit nanomolar efficacy against many Gram-positive strains of bacteria (2), which include methicillin resistant Staphylococcus aureus, vancomycin resistant enterococci, and oxacillin resistant bacteria. On the other hand, some lantibiotics function as morphogenetic peptides rather than antibiotics and are important for spore formation in streptomycetes (3). Since the structural elucidation of nisin in the early 1970s, extensive research efforts have been directed at understanding the biosynthesis and mode of action of various lantibiotics.

Molecular structures

Lantibiotics are synthesized ribosomally as precursor peptides with an amino-terminal leader sequence and a carboxy-terminal structural region. The structural region undergoes extensive posttranslational modification catalyzed by enzymes unique to lantibiotic biosynthesis. After structural region modification, the unaltered leader sequence is removed by a protease, which results in the biologically active species.

Lantibiotics contain several unusual amino acids, including the thioether lanthionine (Lan) linkage and its methyl substituted analog methyl-lanthionine (MeLan) (Fig. 1a) that unifies all members of the class and accounts for their family name. In addition to Lan, lantibiotics commonly contain 2,3-dehydroalanine (Dha) and (Z)-2,3-dehydrobutyryne (Dhb). In all, no less than 15 different posttranslational modifications have been documented in lantibiotics (for a selection see Fig. 1a), and up to 58% of their amino acids are modified. These extensive structural alterations overcome the constraints imposed by the use of 20 amino acids in ribosomally synthesized peptides. Some less common, posttranslationally crafted residues in lantibiotics are β-hydroxy aspartate, lysinoalanine, aminovinyl cysteine (AviCys), D-alanine, 2-oxobutyrate, 2-oxopropionate, and 2-hydroxypropionate. The presence of these unusual residues is thought to be important for the biological activity of lantibiotics.

Currently, the lantibiotic family contains more than 50 members with varying structures, properties, and biological activities (Fig. 1b). Depending on the ring topology of mature lantibiotics, they may have an elongated three-dimensional structure.

(e.g., nisin), a globular conformation (e.g., cinnamycin), or have both regions of linearity and of globular nature (e.g., lacticin 481). The thioether linkages are thought to confer stability and enhance activity by locking the mature lantibiotics in their biochemically active form and by decreasing the susceptibility to protease-mediated degradation. The mature species vary widely in size, shape, charge, and biological activity. They have been classified by groupings named after a representative member (e.g., the nisin, lacticin 481, and cinnamycin subgroups) (4). Members of each group share a high degree of sequence homology, biosynthetic machinery, and also have similar biological activities. A unique group of lantibiotics is the two-component systems such as lacticin 3147 (Fig. 2a) that are composed of two posttranslationally modified peptides that act in synergy to exert their bactericidal activity.

**Mode of action**

Nisin displays several biological activities including inhibition of cell wall biosynthesis, disruption of the cell membrane, and inhibition of spore outgrowth. Nisin is able to disrupt cell wall biosynthesis by binding to the essential peptidoglycan precursor lipid II (Fig. 2a) (2). Based on studies with fluorescently labeled nisin, the molecule not only binds lipid II, but also removes it from its functional location in the cell (7). Mutagenesis studies have demonstrated that the A and B rings of nisin are essential for binding to lipid II (5), and a nuclear magnetic resonance (NMR) structure of a 1:1 nisin-lipid II analog complex has revealed that the mechanism of molecular recognition involves hydrogen bonding interactions between the lipid II pyrophosphate moiety and the nisin amide linkages in the A and B-rings (Fig. 2b) (6). After binding to lipid II at the membrane surface, the C-terminus of nisin inserts perpendicularly into the membrane (Fig. 2c). Mutagenesis studies have also shown that the C and D rings of nisin as well as a hinge region are important for pore formation (8). This hinge region, which is composed of three residues that link the C and D rings (A200, M201, and Ly22), gives nisin the conformational flexibility necessary to traverse the lipid bilayer. The mechanism of bacterial spore outgrowth inhibition is less defined, but it is thought to involve the electrophilic nature of Dha5 (9).

The mode of action of the two-component lantibiotic lacticin 3147 also involves binding to lipid II and pore formation, but it requires two posttranslationally modified peptides to act in synergy to affect their bactericidal properties. In a recent model, lacticin 3147 A2 was proposed to first bind lipid II, which causes a change in its conformation such that lacticin 3147 A2 is recruited to the cell surface. Interaction of A2 then promotes deeper insertion into the membrane and pore formation (10). Other lantibiotics, like mersacidin, also bind lipid II but do not form pores. They are thought to prevent the transglycosylation step of cell wall biosynthesis by preventing action of the transglycosylation enzyme on lipid II. This inhibition is achieved by binding to the disaccharide pyrophosphate region of the peptidoglycan precursor (11). Vancomycin also prevents cell wall biosynthesis by binding to the D-Ala-D-Ala moiety of lipid II. Considering their different binding sites, it is not surprising that alteration of the D-Ala-D-Ala structure in vancomycin-resistant bacterial strains does not affect the efficacy of mersacidin (11). Thus, mersacidin represents a promising antibiotic candidate with the potential of treating multi-drug resistant bacterial infections.

**Lantibiotic Biosynthesis**

The genes that encode lantibiotics and their biosynthetic machinery are designated generically by the locus symbol lan, with a more specific annotation for each family member. The lanA gene encodes the precursor peptide LanA, the lanE gene for the nisin precursor, LctA for the lacticin 481 prepeptide, and so on. The lanBCDMPTXY genes encode for various modification enzymes, the lanKROX genes produce regulatory proteins, and the lanEG1 genes provide immunity proteins. Typically, a subset of these genes is present in a given biosynthetic gene cluster. The cluster for nisin is shown in Fig. 3a as a representative example.

**Enzymatic dehydration and cyclization**

The unsubstituted residues Dha and Dib are formed by dehydration of serine and threonine residues, respectively, and the thioether linkages Lys and MeLys are generated by intramolecular Michael-type addition of cysteine thiol(s) to the unsubstituted sites (e.g., Fig. 3b). These modifications can be performed by either two separate enzymes (LanB and LanC) in class I lantibiotics or a single bifunctional enzyme (LanM) in class II lantibiotics. Typically, proteolysis of the leader sequence is performed by a dedicated protease, either a LanP serine protease (class I) or the cysteine protease domain of a LanT protein (class II). The lanB genes encode large (~1000 residues) predominantly hydrophilic dehydratases that may be membrane associated. To date, the dehydratase activity of a LanB protein has not been reconstituted in vitro and little is known about the mechanism of catalysis of this group of enzymes.

The lanC genes encode smaller (~400 residues), zinc metalloenzymes that catalyze cysteine thiol addition to unsaturated amino acids to form the lanthionine and methyllanthionine residues in a regiospecific, stereoselective, and chemoselective manner (Fig. 3b). The first experimental evidence for the role of LanC proteins in lantibiotic biosynthesis was the accumulation of dehydrated NisA in strains that lack the NisC protein (14). In 2006, the crystal structure of NisC was solved, and its cyclase activity was reconstituted in vitro (15). Its active site contains a single zinc atom with one histidine and two cysteine...
Figure 2. Mode of action of the prototypical lantibiotic nisin. (a) The peptidoglycan precursor lipid II is composed of an N-acetylmuramic acid disaccharide (GlcNAc-MurNAc) that is attached to a membrane anchor of 11 isoprene units via a pyrophosphate moiety. A pentapeptide is linked to the muramic acid. Transglycosylase and transpeptidase enzymes polymerize multiple lipid II molecules and crosslink their pentapeptide groups, respectively, to generate the peptidoglycan. (b) The NMR solution structure of the 1:1 complex of nisin and a lipid II derivative in DMSO (6). (c) The amino-terminus of nisin binds the pyrophosphate of lipid II, whereas the carboxy-terminus inserts into the bacterial membrane. Four lipid II and eight nisin molecules compose a stable pore, although the arrangement of the molecules within each pore is unknown (5).

ligands as well as a coordinated water molecule. A cysteine thiol of the substrate is thought to displace this water molecule, followed by deprotonation to generate a thiolate that then attacks the beta-carbon of a Dha or Dhb residue, which results in an enolate that is prototated stereoselectively to provide the D-configuration at the alpha-carbon (Fig. 3c).

Class II lantibiotic gene clusters (e.g., lacticin 481) do not contain lanBC genes, but instead contain a lanM gene that encodes a large bifunctional LanM protein (∼115–120 kDa) that catalyzes both dehydration and cyclization (Fig. 4). The C-termini of LanM proteins share a low degree of sequence identity with LanC proteins, which include the zinc binding ligands, but have no homology to LanB proteins. Both the dehydratase and cyclase activities of lacticin 481 synthetase (LctM) and haloduracin synthetase (HalM) were reconstituted recently in vitro (16, 17).

Other modifications

Another common posttranslational modification found in mature lantibiotics is a C-terminal AviCys (Fig. 1a). This residue is formed by EpiD in epidermin (18). Currently, not much is known about the enzymes that catalyze formation of other unique lantibiotic residues. The cinnamycin gene cluster was cloned recently (19), which set the stage for studies to determine which gene products are responsible for lysinoalanine and beta-hydroxy aspartate formation.

Proteolysis and export

After posttranslational modification of the precursor peptide, the unmodified leader sequence is cleaved by a protease to reveal the biologically active compound. Depending on the lantibiotic, this cleavage occurs either just prior to or after transport outside the cell. For most class I lantibiotics, the cleavage reaction is...
Lantibiotics, Biosynthesis and Mode of Action of

Figure 3 (a) The nisin biosynthetic gene cluster. (b) Posttranslational modifications during the biosynthesis of nisin. Dehydration of serine and threonine residues in the structural region of the precursor peptide NisA is performed by the dehydratase NisB. Then, the (Me)LaN rings are installed by the cyclase NisC. After secretion, the unmodified leader sequence is removed by the serine protease NisP, which generates the biologically active species. (c) The proposed cyclization mechanism for NisC.

catalyzed by a LanP serine-type protease. Many LanP proteases contain a presequence, which indicates they themselves may be secreted and therefore act after the modified precursor peptide has been exported. NisP is required for nisin maturation because strains that lack the nisP gene but contain all other nisin biosynthetic machinery produce fully modified but biologically inactive nisin with the leader peptide still attached (20). For all lantibiotics investigated to date, removal of the leader sequence is required for biological activity.

Lantibiotics are secreted out of the cell by the LanT ATP-binding cassette transporters. These enzymes are transmembrane, homodimeric proteins that use the energy of ATP hydrolysis to secrete either the mature lantibiotic or a fully modified precursor peptide with the leader sequence still attached. A second type of LanT transporter is found in the biosynthetic machinery of class II lantibiotics, whose precursor peptides contain a "double-glycine" type cleavage site (21). These bifunctional LanT proteins contain an N-terminal proteolytic domain in addition to the membrane-spanning portion and C-terminal ATP-binding cassette. Cleavage occurs C-terminal to the G(−2)G/A(−1) motif at the junction between leader and structural region, and it is thought to take place concomitant with export.

Chemical Tools and Techniques

Because lantibiotics are gene-encoded antimicrobials, genetic, molecular biology, and protein chemistry techniques have been used traditionally to explore their structure and biosynthesis. These approaches include gene deletions and disruptions, and
Lantibiotics, Biosynthesis and Mode of Action of

in vivo and in vitro site-directed mutagenesis. The following sections will detail more recent tools used in various aspects of lantibiotic research with an emphasis on chemical biology techniques.

Discovery

Until recently, the discovery of new lantibiotics relied on the painstaking isolation and purification of compounds that exhibited bactericidal activity from the producer strains. Characterization of those isolates by amino acid analysis, and in some cases determination of their structure by NMR spectroscopy would classify them as a lantibiotic. More recently, the advent of bioinformatics has provided another avenue to discover new lantibiotics by scanning the ever-increasing number of fully sequenced genomes for genes homologous to known lantibiotic producing genes. The two-component lantibiotic haloduracin was discovered in this way (17, 22).

Structure determination

Over the years, several techniques have been developed to elucidate the structure of a new lantibiotic. The extensive post-translational modifications limit Edman degradation to a stretch of amino acids from the N-terminus to the first modification. Various chemical derivatization techniques have been used to aid in the resolution of the sequence and to reveal the position of the posttranslationally modified residues. Originally, these techniques relied on treatment with ethanethiol under highly basic conditions that resulted in the incorporation of dehydroamino acids and dehydrated residues already present in the parent structure. More recently, the structural determination of the LtnA1 and LtnA2 peptides of lacticin 3147 was aided by a novel method that involves nickel boride (Ni2B), an in situ generated hydrogenation and desulfurization catalyst (23). First, the N-terminal 2-oxobutyryl residue and the Dhb at position 2 of LtnA2 (see Fig. 3b) were removed by treatment with 1,2-diaminobenzene in aqueous acetic acid. Subsequent treatment with Ni2B in the presence of NaBD4 in CD3OD/D2O resulted in the incorporation of a single deuterium at the β-carbon of each residue that was involved in a (methyl)lanthionine linkage. Deuterium atoms are introduced at both the α- and β-carbon of dehydro amino acids, which allows distinction between (Me)Lan and Dha/Dhb that was not possible with the ethanethiol method. Both approaches are unable to determine the thioether ring topology, however, and modern NMR techniques and in some select cases tandem mass spectrometry have been used for this task. It should be noted that the thioether linkages restrict the use of tandem mass spectrometry methods to linear stretches of amino acids within the lantibiotics, because fragmentation within a ring does not result in fragment peptides (17). However, when tandem MS techniques are used in combination with site-directed mutagenesis to remove one or more rings from the parent structure, it offers a highly valuable approach to establish ring topology and requires much less material than NMR studies (16). None of these techniques can establish the stereochromy of the methyl/lanthionines with absolute confidence.
Lantibiotics, Biosynthesis and Mode of Action of

Figure 4  Posttranslational modifications in the biosynthesis of the class II lantibiotic lacticin 481. Both the dehydration and the cyclization events are catalyzed by the bifunctional protein LctM. The unmodified leader sequence is removed by the cysteine protease domain of LctT concomitant with transport of the mature lantibiotic outside the cell.

In early studies, this stereochemistry was established for a select few lantibiotics by comparison to chemically synthesized standards in combination with gas chromatography using chiral stationary phases. The stereochemistry determined in these early studies is assumed to be the same for lantibiotics that were discovered and characterized subsequently, but for most members this supposition has not been confirmed experimentally.

Mode of action

Chemical approaches have also contributed to the current understanding of the mode of action of lantibiotics. Prior to the discovery that nisin and other lantibiotics bind to lipid II, biophysical techniques, such as analysis of efflux of analytes from liposomes and other vesicles, as well as electrophysiology studies had established that many lantibiotics punch holes into membranes (4). More recently, NMR studies have elucidated the details of the molecular recognition used by nisin to sequester lipid II (8), and modification of nisin with fluorescent markers using synthetic chemistry showed that nisin removes lipid II from its functional location in the cell (7). Conversely, fluorescent labeling of lipid II showed that after initial docking of nisin with lipid II a higher order structure is assembled consisting of 4 lipid II molecules and 8 nisin molecules that make up the pores in the bacterial membranes (6).

Biomimetic studies

Several biomimetic studies involving the nonenzymatic, intramolecular cyclization of synthetic peptides that contain dehydroamino acids and unprotected cysteine residues have been used to investigate the cyclization step of lantibiotic biosynthesis. Short peptides that contain a single Dha or Dtb residue and a free cysteine undergo stereoselective cyclization to produce the naturally occurring isomers of (Me)Lan (24–26). These results indicate that the peptides have an innate propensity for Si-face attack on the dehydro amino acids and Re-face protonation of enolates to give the D-configuration at the u-carbons. This selectivity has a kinetic origin and is not caused by thermodynamic control (27). An attempt to prepare biomimetically the nisin A-ring (Lan) and B-ring (MeLan) was unsuccessful because of the much higher reactivity of dehydroalanines compared with dehydrobutyrines (27). Collectively, these studies show that although enzymatic control may not be required for the stereoselectivity of (Me)Lan formation, it is absolutely essential to govern the regioselectivity.

Mechanistic studies on the biosynthetic enzymes

The in vitro reconstitution of the enzymatic activities of LctM, NisC, and EpiD has paved the way to detailed mechanistic studies. The dehydration reaction catalyzed by the bifunctional LctM requires ATP for phosphorylation of the serine and the threonine residues that undergo dehydration (28). Usually, the phosphorylated intermediate is not observed with the wild-type substrate, but incorporation of certain nonproteinogenic amino acids into the substrate peptide by using expressed protein ligation resulted in the accumulation of phosphorylated peptides. Preparation of authentic phosphorylated substrate by ligation of synthetic phosphopeptides to a recombinant truncated LctA peptide that carries a C-terminal thioester confirmed that LctM catalyzes the elimination of the phosphate group to generate dehydro amino acids (28). Furthermore, high resolution Fourier transform mass spectrometric analysis of the dehydration reaction has shown that...
the dehydration reaction takes place by a processive mechanism (29). Mechanistic investigations of the EpiD enzyme that catalyzes the oxidative decarboxylation of the C-terminal cysteine in epidermin biosynthesis to produce the AviCys structure revealed that a (Z)-enethiol is generated that presumably adds to an unsaturated residue in a reaction catalyzed by EpiC (18).

Lantibiotic engineering

The cloning of the gene clusters involved in the biosynthesis of many lantibiotics laid the foundation for genetic protein engineering aimed at in vivo production of novel compounds with potentially interesting properties. Many studies have indicated the feasibility of changing the molecular structures of lantibiotics by mutagenesis of the prelantibiotic genes (30). In these investigations, not only the biosynthetic machinery, but also the immunity factors had to be considered to generate successful expression systems. Collectively, these studies have demonstrated the low substrate specificity of the biosynthetic enzymes involved. Disadvantages of reprogramming the structures of lantibiotics through in vivo engineering include a limited structural and functional space that can be sampled through mutagenesis and the potential for breakdown of immunity of the producing strain in cases where more active compounds are actually generated. The in vitro reconstitution of the complete biosynthetic pathways for lacticin 481 and haloduracin has provided the opportunity to explore the substrate specificity of their biosynthetic machinery in more detail. Using the expressed protein ligation technology, a series of Ser and Thr analogs embedded in the substrate peptide have been probed as potential substrates for the dehydration reaction, which demonstrates that the dehydration domain of lacticin 481 synthase has remarkable substrate promiscuity (31). Similarly, the cyclization domain was shown to tolerate Cys analogs such as selenocysteine and to convert them into the unnatural occurring (Me)Cys crosslinks (32). In addition to tolerating changes in the structure of the posttranslationalally modified amino acids, the enzyme also displays remarkable substrate promiscuity with respect to the position of the dehydrated residues as well as substitutions with nonproteinogenic amino acids at nonmodified positions. Similarly, the oxidative decarboxylase EpiD exhibits a very broad substrate scope (33). These investigations demonstrate that the engineering of novel structures by using the biosynthetic enzymes has great promise.

The Future of Lantibiotics

Many questions still remain with respect to both the biosynthesis and the mode of action of lantibiotics. Whereas the targets of the nisin, mersacidin, and cinnamycin groups are now known, the mechanism of action of many other lantibiotics (e.g., lacticin 481, Pep5, and sublancin) is still unclear. Similarly, the biosynthetic pathways still hold many unresolved questions, which include the molecular recognition that allows the synthetases their high level of substrate promiscuity and at the same time provides exquisite control of the regioselectivity of cyclization. Similarly, the biosynthetic enzymes for the majority of the 15 currently known posttranslational modifications in lantibiotics have not yet been identified, with the rate of discovery of new lantibiotics and new modifications exceeding the characterization of new biosynthetic enzymes.

Currently, the most common commercial application for lantibiotics is as a preservative in the food industry to combat foodborne pathogens and spoilage bacteria, but many other uses are under active investigation. Duramycin has been shown to increase chloride transport in nasal epithelial cells of cystic fibrosis patients (33), which in turn increases the fluidity of mucus in the lungs and airway and decreases the patient’s susceptibility to infections. Furthermore, several lantibiotics have shown potent activities against multidrug-resistant pathogenic bacterial strains. Combined with the development of new techniques to alter the structures of the lantibiotics, the future will likely see detailed SAR studies that may result in improved variants.

Oceans provide enormous and diverse habitats for marine life. The distinct feature of marine life is the domination of invertebrates, which account for more than 95% of marine animals. Most marine invertebrates are sessile and soft-bodied and lack obvious physical defenses. Instead, they have evolved to defend by chemical means against predation and overgrowth by other fouling organisms. In fact, their secondary metabolites have unusual structural features and potent biologic activities, many of which are not found in terrestrial natural products. This review focuses on bioactive metabolites isolated mainly from marine invertebrates with a special emphasis on the uniqueness of marine natural products.

The world’s oceans cover more than 70% of the earth’s surface and represent greater than 95% of the biosphere. Species ranging from 3 to 100 million are estimated to inhabit in the oceans. All but 1 of the 35 principal phyla in the animal kingdom are represented in aquatic environments; 8 phyla are exclusively aquatic. Most of them are sessile and soft-bodied organisms, most of which have evolved by chemical means to defend against predators and overgrowth by competing species. As expected, a variety of bioactive metabolites were found in marine invertebrates (see a series of reviews on marine natural products published in Natural Product Reports since 1984).

Bergmann’s revolutionary discovery of arabinose-containing nucleosides [e.g., spongouridine (1)] from the Caribbean marine sponge Cryptotheca crypta was a driving force for the birth of a new research field, Marine Natural Products Chemistry, in the early 1970s (1, 2). Nearly 18,000 new compounds, including polyketides, peptides, alkaloids, terpenoids, shikimic acid derivatives, sugars, and a multitude of mixed biogenesis metabolites, have been discovered during the last 40 years according to MarinLit (University of Canterbury, New Zealand). Many marine natural products have structural features previously unreported from terrestrial sources (3). Halogenated, especially brominated, and sulfated compounds are often encountered as marine natural products. Arsenic compounds, in particular arsenobetaines and arsenosugars, are distributed widely in marine algae and invertebrates. Recently, the first polyarsonic organic compound from Nature, arsenicin A (2), was reported from the sponge Echinostallina bargibanti (4). Also, several highly bioactive compounds with interesting modes of action have been discovered from marine invertebrates. A considerable percentage of these compounds was suggested or found to be derived from microorganisms. Indeed, certain bi-valves and c pajean fish become poisonous by feeding toxic dinoflagellates or herbivorous c pajean fish (5), whereas some cytotoxic metabolites of sponges and tunicates are produced by symbiotic microorganisms (6).

This review describes bioactive compounds isolated from marine algae and invertebrates with an emphasis on their uniqueness. Because of limited space, metabolites from bacteria, cyanobacteria, and fungi cannot be included, although some from cyanobacterial and endosymbiotic bacterial origins are described (some reviews on metabolites of marine bacteria, cyanobacteria, and fungi are provided in the “Further Reading” section). Structures and bioactivities are described for compounds that represent natural product classes, but steroids and carotenoids are not included.

Polyketides and Fatty Acid Derivatives

A diverse array of polyketide metabolites are found in marine organisms, which range from simple oxylipins to highly complex polyethers and macrolides. Particularly intriguing are “ladder-shaped” polyethers of dinoflagellate origin and sponge macrolides.

Fatty acid derivatives

Oxylipins, which are a major metabolite of fatty acids, are observed regularly in seaweeds and opisthobrachs that feed on seaweeds. Aplydilactone (3), which is an unusual oxylipin isolated from the sea hare Aplysia kurodai, activates phospholipase A₂ (7). More than 50 halogenated C₁₅ acetogenins, which are derived from fatty acids, have been isolated from red algae of the genus Laurencia; laurenin (4) was first isolated from L. nipponica (8). These compounds were reported to be antifeeding and insecticidal. Certain species of soft corals...
are known to contain prostanoids, of which the most intriguing are punaglandins (punaglandin 1 [(9), the first halogenated protaglandins isolated from the soft coral Telesto riei (3). They are antiviral and cytotoxic.

Fatty acid-derived cyclic peroxides are often found in marine sponges of the genus Plakortis; the first example was chondrin (6). 1,2-Dioxygen and 1,2-dioxolane carboxylates were also discovered from Plakortis sponges (9). These cyclic oxides show a wide range of biologic activities, for example, antimicrobial, cytotoxic, and antimalarial activities.

In addition, a variety of bioactive fatty acid derivatives have been isolated from marine organisms, including glyceroceramides (10). Perhaps the most unusual example is a highly chlorinated sulfolipid (11) isolated from the mussel Mytilus galloprovincialis (10).

Polycyclic lipids

The most prominent source of marine polycyclic lipids are sponges (11). Although the chain lengths vary from C14 to C49, likely they are to be derived from C16 fatty acids. Polypropionates show a wide range of bioactivities, including antimicrobial, cytotoxic, antiviral, and enzyme inhibitory.

Corticatic acid A (8), which is a C16 polypropionate carboxylic acid isolated from Petrosia corticata, is not only antimicrobial, but also it inhibits geranylgeranytransferase I (12).

Polyketides

Linear polyacetylenes are found frequently in marine sponges of the order Haplosclerida (11). Although the chain lengths vary from C4 to C24, likely they are to be derived from C18 fatty acids. Polyacetylenes show a wide range of bioactivities, including antimicrobial, cytotoxic, antiviral, and enzyme inhibitory.

Corticatic acid A (8), which is a C16 polypropionate carboxylic acid isolated from Petrosia corticata, is not only antimicrobial, but also it inhibits geranylgeranytransferase I (12).

Polycyclic lipids

The most prominent source of marine polycyclic lipids are sponges (11). Although the chain lengths vary from C14 to C49, likely they are to be derived from C16 fatty acids. Polypropionates show a wide range of bioactivities, including antimicrobial, cytotoxic, antiviral, and enzyme inhibitory.

Corticatic acid A (8), which is a C16 polypropionate carboxylic acid isolated from Petrosia corticata, is not only antimicrobial, but also it inhibits geranylgeranytransferase I (12).

Polyacetylenes show a wide range of bioactivities, including antimicrobial, cytotoxic, antiviral, and enzyme inhibitory.

Corticatic acid A (8), which is a C16 polypropionate carboxylic acid isolated from Petrosia corticata, is not only antimicrobial, but also it inhibits geranylgeranytransferase I (12).

Polyketides

Dinoflagellates of the genus Amphidinium produce highly oxygenated, long-chain polyketides named amphidinolins (amphidinol 3 [(20)), that are highly antifungal and hemolytic (5). Polyacetylenes (13) are another class of highly unusual polyketide polyethers originally isolated from Irish seaweed that contains a polyether compound, namely highly antifungal gambieric acid (9). Isolated from Siphonaria grisea, whereas such unusual pyrrole-containing metabolites as siphonarin A (10) were isolated from S. zelandica. Marine polypropionates not only play defensive roles in mollusks, but also they show antimicrobial, antiviral, and cytotoxic activities.

Polyethers

Dinoflagellates are unique, aquatic photosynthesizing eukaryotes, that are classified in the kingdom Protoctista. They produce a variety of unusual polyketides with potent bioactivities (14).

The most unique metabolites are “ladder-shaped” polyethers: brevetoxin B (11), which was isolated from Gymnodinium breve (current). Karenia brevis is the first example of this group, and more than 15 brevetoxins have been isolated from the same source. Ciguatoxin (12) is a causative agent of ciguatera, a fish poisoning in subtropical and tropical regions, first isolated from a moray eel. It was later found to be originated from the dinoflagellate Gambierdiscus toxicus that contains a more complex polyether, maitotoxin (13), which is also involved in DSP (14). G. toxicus produces a variety of polyether compounds, namely highly antifungal gambieric acid (14). Maitotoxin, which is the most toxic natural product (LD50 value of 50 mg/kg in mice), increases membrane permeability to Ca2+, but the detailed mechanism remains unknown. Ciguatoxin is also highly toxic (1/10 potency of maitotoxin) and activates voltage-gated Na+ channels, whereas brevetoxins are much less toxic, although their mode of action is similar to that of ciguatoxin.

A different class of “ladder-shaped” polyethers, yesositoxins [e.g., yesostoxin 1 (25)], was isolated from toxic scallops; again its producer is the dinoflagellate Proteroceratium reticulatum (5). The mode of action seems to be different from that of brevetoxins and ciguatoxins.

The sponge Halichondria okadai contains a polyether metabolite named okadac acid (16) that was also isolated as a causative agent of diarrheal shellfish poisoning, and also isolated from mussels and other bivalves (14). However, the real producers are dinoflagellates of the genus Dinophysis. It is a potent cancer promoter that was found to be caused by inhibition of protein phosphatases 1 and 2A at nanomolar levels. Pectenotoxins are also involved in DSP and are produced by Dinophysis spp.; pectenotoxin 2 (17) inhibits actin polymerization (14).

Azaspiracids (azaspiracid-1 (18)) are another class of highly unusual polyketide polyethers originally isolated from Irish seaweed that contains azaspiracid shellfish poisoning (5). They are produced by the dinoflagellate Protoperidinium crassipes. A similar class of polyether toxins named pinnatoxins (pinnatoxin A (19)) were reported from the bivalve Pina pectinata; a closely related species P. attenuata is known to cause food poisoning in China. Pinnatoxins are likely of dinoflagellate origin and activate Ca2+ channels (15).

Open-chain polyketides

Dinoflagellates of the genus Amphidinium produce highly oxygenated, long-chain polyketides named amphidinolins (amphidinol 3 (20)), that are highly antifungal and hemolytic (5). Polyacetylenes (13) are another class of highly unusual polyketide polyethers originally isolated from Irish seaweed that contains a polyether compound, namely highly antifungal gambieric acid (9). Isolated from Siphonaria grisea, whereas such unusual pyrrole-containing metabolites as siphonarin A (10) were isolated from S. zelandica. Marine polypropionates not only play defensive roles in mollusks, but also they show antimicrobial, antiviral, and cytotoxic activities.

Pectenotoxins are also involved in DSP and are produced by Dinophysis spp.; pectenotoxin 2 (17) inhibits actin polymerization (14).

Azaspiracids (azaspiracid-1 (18)) are another class of highly unusual polyketide polyethers originally isolated from Irish seaweed that contains azaspiracid shellfish poisoning (5). They are produced by the dinoflagellate Protoperidinium crassipes. A similar class of polyether toxins named pinnatoxins (pinnatoxin A (19)) were reported from the bivalve Pina pectinata; a closely related species P. attenuata is known to cause food poisoning in China. Pinnatoxins are likely of dinoflagellate origin and activate Ca2+ channels (15).
its primary target is G-actin. Recently, it was discovered from cyanobacteria, although its eubacterial origin was predicted (6). Another class of macrolides that inhibit actin polymerization is the tris-oxazole-containing macrolides, namely kabiramides and mycalicides (1). Kabiramide C (26) was isolated from eggmasses of a nudibranch of the genus Hexabranchus, whereas mycalicides are of sponge origin, which indicates kabiramides were sequestered by nudibranchs from sponges. These macrolides are potently antifungal and cytotoxic. They bind G-actin in a molar ratio of 1:1, which thereby inhibits actin polymerization. Similar macrolides named alyponines were isolated from the sea hare Aplysia kurodai; alyponine A (27) shows remarkable antitumor activity (T/C > 500% at 0.08 mg/kg against P388 leukemia cells) as well as a similar mode of action to that of kabiramides (7). Presumably, alyponines are of cyanobacterial origin.

Halichondrin B (28), which is a polyether macrolide isolated from H. okadai, shows promising antitumor activity and has entered phase I clinical trials (2, 15). It inhibits polymerization of tubulin by binding to the colchicine domain. The macrocyclic portion seems to be essential for the activity (2). Halichondrins have been found in several species of sponges, which indicates their microbial origin (6). Spongistatins/hyrtiostatins/cinachyrolide A [spongistatin-1 (29)] are highly unusual, 35-membered macrolides isolated from several sponges (3). They inhibit growth of tumor cells at sub-nM levels by binding to the vinca domain of tubulin. Their low yields and occurrence in several different sponges suggest their microbial origin. Spirastrellolide B (30) was reported recently as an antimitotic agent from the sponge Spirastrella coccinea. It is actually a potent and selective inhibitor of protein phosphatase 2A (12).
Peloruside A (31), which is a 16-membered, highly oxidized macrolide from the sponge Mycale hentschelii, induces tubulin polymerization (2). 13-Deoxytedanolide (32) isolated from Japanese sponges of the genus Mycale shows promising antitumor activity. It inhibits protein synthesis by binding to a 70 S large subunit of eukaryotic ribosome (17).

Bryostatins are medicinally important macrolides discovered from the cosmopolitan bryozoan Bugula neritina (2). Twenty bryostatins, which all possess a 20-membered ring, are known to date. Bryostatin 1 (33) showed good antitumor activity; it selectively modulates protein kinase C (12).
Phorboxazole A (34) is an unusual oxazole-containing macrolide isolated from a sponge Phorbas sp. (18). It is highly antifungal and cytostatic.

Salicylihalamide A (35) is a salicylic acid-containing macrolide enamide isolated from a sponge Haliclona sp., and it inhibits V-ATPases at a low nM concentration. Members of this family have been isolated from sponges, tunicates, and bacteria (12).

PKS/NRPS metabolites
Bengamides were isolated originally as anthelmintic agents from a sponge Jaspis sp. Later, bengamide A (36) was found to inhibit growth of tumor cells as well as methionine aminopeptidases (2).

Marine natural products of the pederin class (mycalamides, onnamides, and theopederins) isolated from sponges are mixed biogenesis metabolites of polyketide synthase and nonribosomal synthase (1). In fact, biosynthesis gene clusters of this class have been cloned recently using metagenomic techniques from the marine sponge Theonella swinhoei (6). These compounds are...
potently cytotoxic; theopederin A (37) inhibits protein synthesis in a similar mode of action to that of 13-deoxytedanolide.

Calyculin A (38) is an extraordinary metabolite composed of C28 fatty acid and two γ-amino acids isolated from the sponge *Discodermia calyx*. It is not only highly antifungal and antitumor but also a potent cancer promoter that was found to be caused by potent inhibition of protein phosphatases 1 and 2A (1). More than 15 calyculin derivatives were isolated from several marine sponges, which indicates the involvement of symbiotic microorganisms in the production of calyculins (6).

Pateamine (39) is a macrolide isolated from a marine sponge *Mycale* sp. Its potent cytotoxicity is attributed to inhibition of transcriptional initiation (19).

### Aromatic polyketides and enediyne

Aromatic polyketides are rare metabolites in marine invertebrates. Naphthoquinone and anthraquinone derivatives were reported as echinoderm pigments in the earlier stage of marine natural products research. The most interesting aromatic polyketides are the pentacyclic polyketides of the halenaquinone/halenaquinol class. Halenaquinone (40) was first isolated from the sponge *Xestospongia exigua*. Compounds of this class show a variety of biologic activities, which include inhibition of tyrosine kinase (12, 19).

Only two groups of enediyne have been found from marine organisms; namenamycin (41) was first isolated from the *Fijian tunicate* *Polysyncraton lithostrotum*, whereas shishijimicins A (42)–C, β-carboline-containing enediyne, were isolated from the Japanese tunicate *Didemnum proliferum*, along with 41, which
thus suggests the involvement of symbiotic microorganisms in their production (1). As expected, these compounds inhibited growth of tumor cells at pM levels.

**Nonribosomal Peptides and Amino Acid Derivatives**

In addition to ribosomal peptides, some of which exhibit interesting bioactivities as is the case of conotoxins, marine organisms, in particular, sponges and tunicates contain a wide variety of nonribosomal peptides, many of which contain unusual or unprecedented amino acids. It should be noted that these peptides show a range of biological activities.

**Amino acid derivatives**

Microalgae and macroalgae often contain UV-absorbing amino acids collectively dubbed "mycosporines." Mycosporine-glycine (43) is most widely distributed in marine organisms that use it for protection from UV irradiation. Domoic acid (44) is not only a helminthic agent originally isolated from a red alga, but also it is a causative agent of amnesic shellfish poisoning (14). It is a potent agonist of glutamate receptors. Dysiherbaine (45), which is a novel betaine isolated from the sponge Dysidea herbacea, is a potent non-NMDA-type agonist with very high affinity for kainate receptors (20).
Giroline (46), which is a potent cytotoxin isolated from the sponge Pseudaxinyssa cantharella, inhibits protein synthesis (2).

**Bromotyrosine derivatives**

Bromotyrosine-derived metabolites are often encountered in marine sponges of the families Aplysinidae and Pseudoceratidae, in particular Pseudoceratina (= Psammaplysilla) purpurea. They show a variety of biological activities, which include antimicrobial, enzyme inhibitory, and antifouling activities. Psammaplysin A (47) is antimicrobial, cytotoxic, and antifouling, whereas psammaplin A (48) is an inhibitor of histone deacetylase (2). The marine sponge Ianthella basta synthesizes at least 25 bastadins that are linear or cyclic peptides composed of four bromotyrosine residues [bastadin 5 (49)] and show antimicrobial, cytotoxic, and enzyme inhibitory activities as well as interaction with Ca²⁺ channels (21).

**Linear peptides**

Sponges and tunicates frequently contain unusual linear and cyclic peptides; those from the former source were reviewed in 1993 and 2002 (22, 23). To avoid duplication, this review focuses on bioactive peptides isolated from other sources and new findings. Gymnanjamide (50) is the first described peptide from a hydroid (24). This pentapeptide from Gymnanium regae contains three previously unknown amino acids. Although modestly cytotoxic, its structure is reminiscent of dolastatin 10 (33), which is a powerful antibitin agent of the sea hare Dolabella auricularia (2). Actually, dolastatins are of cyanobacterial origin. Dysinosin A (52) is a novel inhibitor of factor VIIa and thrombin, which was isolated from a new genus and species of an Australian sponge of the family Dysideidae (12). Perhaps the most intriguing linear peptide is polytheonamide B (53), which is a potent cytotoxin discovered from T. swinhoei.
(25). It is composed of 48 amino acid residues, most of which are unusual amino acids. More significantly, it has the sequence of alternating D- and L-amino acids.

Cyclic peptides

Most cyclic peptides have been isolated from sponges and tunicates. Azumamides A (54) through E, which are cyclic tetrapeptides isolated from the sponge *Mycale laevis*, are the most recent addition to the list of cyclic peptides. They strongly inhibit histone deacetylase (12). Dolastatin 11 (55), which is a cyclic depsipeptide isolated from *D. auricularia*, stabilizes actin filaments as in the case of jaspakinolide/jaspamide. Kahalalide F (56) is a cyclic depsipeptide isolated from the sacoglossan mollusk *Elysia rufescens*. It shows promising antitumor activity and has entered Phase II clinical trials, but its mode of action is not clear (2). Dolastatins and kahalalides likely are sequestered by the mollusks from cyanobacterial diets. A scidean peptide often contain thiazole/thiazoline and oxazole/oxazoline amino acids as represented by patellamide A (57) isolated from *Lisoclinum patella* (3). These cyclic peptides show cytotoxic activity. Probably the most well-known ascidian peptide is didemnin B (58) isolated from *Trididemnum solidum*. This depsipeptide showed remarkable antitumor activity and entered clinical trials, but it was dropped because of side effects (2). It inhibits protein synthesis. Aplidine (dehydrodidemnin B) (59) isolated from *Aplidium albicans* is more promising as an anticancer drug, although it shows multiple modes of action (2).

Marine organisms produce a wide range of alkaloids with potent bioactivities, which include such specific classes as 3-alkylpiperidine, guanidine, indole, polyanine, pyridoacridine, and pyrrole-imidazole alkaloids. Their biological activities vary from antimicrobial to neurological.

3-alkylpiperidines

A variety of 3-alkylpiperidine-derived compounds have been obtained from sponges belonging to five families of the order Haplosclerida (26). They show a range of bioactivities, for example, cytotoxic, antimalarial, and antifouling. It is likely that 3-alkylpiperidines are produced by sponge cells but not by symbiotic microorganisms.

The first 3-alkylpiperidine derivative reported is halitoxin (60), which was isolated from Haliclona sp. Similar polymeric alkylpyridines are also known from several sponges. In addition to the polymers, various types of metabolites of 3-alkylpyridines or 3-alkylpiperidines have been isolated, namely, macrocyclic bis-3-alkylpiperidine [telomerase-inhibitory cyclostellettamine A (61)] (12). Bis-quinolizadine [petrosin A (62)] and bis-1-oxaquinolizadine macrocycles [xestospongin C (63)] isolated from Petrosia seriata and Xestospongia spp., respectively, also belong to this group. The former is ichthyotoxic, whereas the latter is a potent vasodilator as well as an inhibitor of IP3 receptor. Halicyclamine (64), which was isolated from Haliclona sp., is another group of macrocyclic bis-3-alkylpiperidines, whereas sarain A (65), which was isolated from Reniera sarai, has a more complex polycyclic core. These compounds are moderately cytotoxic.

The most well-known group of 3-alkylpiperidine alkaloids is the manzamines. Manzamine A (66), which is the first member of this group, was isolated from an Okinawan Haliclona sp. More than 20 manzamines have been isolated from sponges of eight different genera. Manzamine A is highly cytotoxic,
antituberculosis, and antimalarial, but its mode of action remains unknown (27).

**Pyrrole-imidazoles**

The pyrrole-imidazole alkaloids are found exclusively in marine sponges, in particular in the families Agelasidae, Axinellidae, and Halichondridae (28). Oroidin (67), which was discovered from *Agelas oroides*, is the building block of about 100 metabolites of this family, which can be divided into those derived from different modes of cyclization, for example, (-)-dibromophakelin (68) isolated from *Phakellia flabellate* and ageladine A (69) from *Agelas nakamurai*, and those derived from different modes of dimerization, namely sceptrin (70), which is isolated from *Agelas sceptrum*, palau’amine (71) from *Stylotella aurantium* and massadine (72) from *Stylissa massa*. Quite recently, a dimer of massadine (oridin tetramer) named stylissadine A was isolated from *Stylissa caribica*. The pyrrole-imidazole alkaloids show a range of bioactivities, which include antimicrobial, cytotoxic, antagonistic to receptors, immunosuppressive, enzyme inhibitory, and antifouling.

**Pyridoacridines and related alkaloids**

Pyridoacridines are highly colored polycyclic alkaloids mainly isolated from sponges and tunicates (29). They are divided into four groups, the simplest of which is styelsamine D (73), which was isolated from the ascidian *Eusynstyela latericius*. The pentacyclic pyridoacridines are also classified into two groups as represented by amphimedine (74), which was isolated from a sponge *Amphimedon* sp., and ascididemin (75), which was isolated from a tunicate *Didemnum* sp., respectively. Dercitin (76) is a thiazole-containing pentacyclic alkaloid isolated from a sponge *Dercitus* sp., whereas cyclodercitin (77), which was
isolated from a sponge Stelletta sp., is a member of the hex acyclic group. The most complex octacyclic pyridoacridines are represented by eudistone A (79), which was isolated from Eudistoma sp.

Alkaloids related to pyridoacridines are known also from sponges and tunicates. Discornin B (79), which is the first marine pyridoquinoline alkaloid, was isolated from the sponge Latruncula cf. bocagai. More than 20 alkaloids of this class are known at present (30). A different example of this family is batzelline A (80) from a deepsea sponge of the genus Bathylamella and wakayin (81) from an ascidian Clavelina sp.

Many pyridoalkaloids show a wide range of biological activities, namely antimicrobial, antiviral, antiparasitic, insecticidal, antitumor, and enzyme inhibitory (12, 29, 30).

Indole alkaloids

Highly substituted pyrroles are often found in sponges, ascidians, and mollusks (30). Lamellarins A (82–D) are the first metabolites of this group that were reported from a mollusk Lamellaria sp., followed by the discovery of more than 50 alkaloids of this class from sponges and ascidians. Polycitone A (83) was isolated from a tunicate Polycitor sp., whereas storniine A (84) was isolated from a sponge of the genus Cistella. The most recent addition to this class is dictyodendrins A (85) through E isolated as telomerase inhibitors from the sponge Dicytostelidella serpulaforma (12). Various bioactivities have been reported for lamellarins and related compounds, which include antitumor, antiviral, and enzyme inhibitory.

Indole alkaloids

Many indole-containing metabolites have been reported from marine organisms, some of which were already mentioned. This section focuses on important indole-containing substances that belong to structural classes not mentioned above. These alkaloids show antimicrobial, antiparasitic, antitumor, and enzyme inhibitory activities (27). Dragmacidin (86) is a novel bis-indole isolated from a deepsea sponge Dragmacidon sp., whereas another deepsea sponge Spongosorites ruetzleri contains a similar bis-indole, topsentin (87).

β-carboline-containing metabolites are known from sponges and tunicates. Eudistomins were the first β-carboline alkaloid isolated from marine organisms. Eudistomin K (88), which is a novel oxahexitrione ring containing β-carboline, was isolated from the tunicate Eudistoma olivaceum, whereas a guanidine-containing grossularine 1 (89) was from the tunicate Dendrosoma grossularia (27).

Physisostigmine alkaloids are often contained in bryozoans. The highly unusual constituent is secureine A (90) isolated from Sarcinifustra secernifrons from the North Sea. Another interesting physisostigmine is urochordamine A (91) isolated as a larval settlement inducer from the ascidian Ciona savignyi (30). Neosurugatoxin (92), which is a causative agent of “ivory shellfish poisoning” isolated from the gastropod Babylonia japonica, is a reversible nicotinic acetylcholine antagonist (14). Its bacterial origin has been suggested. Finally, diazonamide A (93) is a highly unusual cytotoxic metabolite of the tunicate Dialeana angulata. It inhibits tubulin polymerization (2).

Guanidine alkaloids

Many guanidine-containing compounds have been reported from diverse marine organisms (31). No doubt exists that the most well-known guanidine alkaloid is tetrodotoxin (94), which is a causative agent of puffer fish poisoning (14). It is highly toxic because of inhibition of voltage-gated Na⁺ channels. Production of tetrodotoxin by bacteria of such genera as Pseudalteromonas and Vibrio was reported. Similarly, saxitoxin (95) causes paralytic shellfish poisoning. Bivalves accumulate the toxin in dinoflagellates, for example, Alexandrium catenella, A. tamarense, and Gymnodinium catenatum. Its mode of action is similar to that of tetrodotoxin. More than 30 saxitoxin derivatives are known to date.

Pillomycolin A (96) is a novel polycyclic guanidine alkaloid isolated from the sponge Piliocaulis spiculifer (31). It is highly cytotoxic, antifungal, and antiviral. The related alkaloids were reported from the Mediterranean sponge Crambe crambe that also contains other types of guanidine alkaloids such as...
crambescin A (97). Batzelladines are a similar class of alkaloids isolated from a sponge Batzella sp.; batzelladine A (98) shows anti-HIV activity.

Variolin B (99), which is a pyrido[3,4-d]pyrimidine alkaloid isolated from the sponge Kirkpatrickia variafoxa, is strongly cytotoxic, antifungal, and antiviral (30). It inhibits cyclin-dependent kinases (12).

**Polyamine alkaloids**

Stellettadine A (100), which is isolated from a sponge Stelleta sp., represents the first polyamine alkaloid with an arcaine backbone (32). Similar alkaloids (e.g., stellettazole A (101)) are also known from the same source. These compounds show larval settlement-inducing, antifungal, and enzyme inhibitory activities. Isoquatenated polyamines are encountered occasionally as metabolites of soft corals as represented by sinulamide (102), which inhibits H,K-ATPase (12).

**Quinolines and isoquinolines**

Aaptamine (103), which is a cytotoxic benzonaphthyridine alkaloid isolated from the sponge Aaptos aaptos, induces differentiation in chronic leukemia cells (33). Schulzeine A (104) is a novel dihydroquinoline alkaloid isolated from the sponge Penares schulzei that inhibits glycosidases (12).

Sponges and tunicates contain tetrahydroisoquinoline alkaloids (30). Renieramycin A (105) from a sponge Reniera sp.
represents the first example of this particular class of alkaloids isolated from marine organisms. Ecteinascidins, in particular ecteinascidin 743 (106), which was isolated from the tunicate Ecteinascidia turbinata, are promising as anticancer leads. Ecteinascidin 743 cleaves DNA chains and is in clinical trials (2).

Quinolizidines and indolizidines

Only a few compounds of these classes of alkaloids have been reported from marine organisms. Clavepictine B (107), which was isolated from the ascidian Clavelina picta, is marginally cytotoxic. Stellettamine A (108), which is an indolizidine derivative from a sponge Stelletta sp., is antifungal and cytotoxic. It also inhibits calmodulin (12). Lepadiformine (109), which has a similar structural feature isolated from the tunicate Clavelina inoluccensis, inhibits K+ channels (33).

Steroidal alkaloids

Steroidal alkaloids belong to a rare class of marine natural products. Plakinamine A (110), which is an antimicrobial metabolite from a sponge Plakina sp., is the first steroidal alkaloid isolated from marine organisms. Cephalostatins and ritterazines are unprecedented dimeric steroidal alkaloids isolated from the hemichordate Cephalodiscus grichristii and the tunicate Ritterella tokioka, respectively (1, 30). They are specific to marine metabolites. Cephalostatin 1 (111) and ritterazine B (112) are
Marine Natural Products, Chemical Diversity of

highly cytotoxic, but their mode of action remains to be elucidated.

Although unlikely steroids or triterpenoids, zoanthamines found in zoanthids of the genus Zoanthus should be mentioned here. Zoanthamine (113) represents the first example of 10 metabolites of this class. Norzoanthamine has been best studied and found to suppress the production of IL-6 (15).

Terpenoids

Although those similar to terrestrial terpenoids are found commonly in marine organism, in particular in algae, several terpenoids with new or modified skeletons have been isolated frequently from algae, sponges, and crinidarians. Halogenated terpenoids are often contained in algae, whereas sulfated terpenoids and steroids are distributed widely in sponges.

Monoterpenoids and Sesquiterpenoids

Red algae contain highly halogenated monoterpenoids such as 114, which is an antifeeding constituent isolated from Plumaria cartilagineum (34, 35).

Several halogenated sesquiterpenes with various skeletal types were reported from red algae of the genus Laurencia, for example, elatol (115), which is a chamigrane sesquiterpene that has antifeeding and antifouling activities from L. obtusa. A series of linear and cyclic sesquiterpenes with an 1,4-diacyctobybutadiene functionality [e.g. caulerpenyne (116)] have been isolated as antifeeding agents from green algae of
the order Caulerpales (35). Coelenterates are a rich source of sesquiterpenes of 20 skeletal types, which include \( \Delta^{9(12)} \)-capnellane (117), an antifeeding metabolite isolated from Capsella imbricata (36).

Sponges produce furanosesquiterpenes of various skeletal types, such as furodysinin (118) from Dysidea herbacea and nakafuran-8 (119) from D. etheria, the latter of which is an antifeeding. Similarly, mixed shikimate-mevalonate metabolites are often encountered as sponge metabolites; the first example is avarol (120), which was isolated from Dysidea avara. Several related compounds have been isolated from dictyoceratid sponges. They show a wide range of bioactivities, for example, antimicrobial, antitumor, anti-inflammatory, and enzyme inhibitory.

Diterpenoids

Brown algae are rich in diterpenoids, which can be classified into three groups, namely "xenicanes," "extended sesquiterpenes," and "dolabellanes," which are represented by dictyotadial (121) from Dictyota crenulata, spatul (122) from Spatoglossum schmittii, and amijidictyol (123) from Dictyota linearis, respectively.
These terpenes are involved in chemical defense. Red algae contain brominated diterpenes of several established skeletal types. Spongian diterpenes are a chemical marker for dictyoceratid and dendroceratid sponges (37). The first example of a spongian diterpene is isoagatholactone (124) isolated from Spongia officinalis. In addition to those possessing a basic spongian skeleton, a wide variety of rearranged spongian diterpenoids have been reported, which include gracillin B (125) from Spongionella gracilis. Many spongian diterpenes are antimicrobial and cytotoxic.

Again, soft corals and gorgonians are a rich source of diterpenoids of 19 structural classes, some of which are specific to them (35, 36). Besides tobacco plants, cembranoid diterpenes are limited to soft corals. Lophotoxin (126) isolated from sea whips of the genus Lophogorgia is a sodium channel inhibitor (3). Xenicin (127) from the soft coral Xenia elongata and briarein A (128) from the gorgonian Briareum asbestinum represent non-cembranolide diterpenes. Diterpenoids of these classes show antimicrobial, cytotoxic, and insecticidal activities.
Pseudopterosin A (129), which is a diterpene glycoside isolated from the sea whip Pseudopterogorgia elisabethae, shows anti-inflammatory activity by inhibiting release of leukotriene B\(_2\) from leukocytes (2, 35). A more interesting class of diterpenes includes sarcodictyn A (130) and eleutherobin (131), which were isolated from the soft corals Sarcodictyon roseum and Eleutherobia sp., respectively. These diterpenoids show potent cytotoxicity by stabilizing microtubules (2, 35).

Ageladine A (132), which is a 9-methyladenine derivative of a diterpene isolated from a sponge Agelas sp., is antimicrobial and inhibitory against Na, K-ATPase (12). A novel, chlorinated diterpenoid, chlorolissoclimide (133), which was isolated from the ascidian Lissoclinum forskali, inhibits eukaryotic protein synthesis (38).

Isocyanoterpenes and related terpenoids

Isocyanide-containing natural products are rare; they have been reported only from cyanobacteria, Penicillium fungi, marine sponges, and nudibranchs (35, 39). Sesquiterpenoid and diterpenoid isocyanides are found in a limited species of sponges and nudibranchs that prey on these sponges. Axisonitrile-1 (134) isolated from the sponge Axinella cannabina is the first isocyanide-containing marine natural product. Isocyanopupukeanane (135) was isolated originally from the nudibranch Phylidia verrucosa and later from a sponge Ciocalypta sp. Kalihinol A (136) and 7,20-diisocyanoadocane (137) were isolated from the sponges Acanthella carvenosa and Adocia sp., respectively.
respectively. Isocyanoterpenes are often accompanied by thio-
cyanates, isothiocyanates, and formamides. These terpenoids
display a wide range of bioactivities, which include antimicro-
bial, cytotoxic, ichthyotoxic, antifouling, and antimalarial. The
carbonimidic dichloride group is considered to be equivalent
to isocyanide, and the first sesquiterpenoid that contains this
moiety was isolated from the sponge *Pseudoaxinyssa pitys.*

Terpenoids that contain carbonimidic dichloride show similar
bioactivities to those of isocyanide counterparts.

**Sesterterpenoids, triterpenoids, and steroids**

Variabilin (**139**), which is a C25 tetronic acid isolated from
the sponge *Ircinia variabilis,* represents the class of furano-

Several unusual polysaccharides have been isolated from sponges (34). Bioactivities include antimicrobial, cytotoxic, antimalarial, and antitumor.

Mannolide (140) is perhaps the most well-known marine sesquiterpene isolated from the sponge *Luffariella variabilis* (40). A number of sesquiterpene glycosides have been isolated from the sponge *Axinella infundibula* (12). It resembles bacterial 13-deoxytedanolide, a marine sponge-derived antitumor macroclide, which is the first natural product inhibitor of cdc25A (12). Mycaperoxide A (143), which is a norsesterepene peroxy isolated from *Mycale* sp., showed promising antimalarial activity (9).

Probably one of the most interesting marine triterpenoids is the squareni-14,18-diene derived polyethers found in red algae of the genus *Laurencia*. Among the nearly 30 metabolites of this class, thyrone (141), which has been isolated recently as a potent telomerase inhibiter from *Axinella infundibula* (12). Mucaperoxide A (143), which represents the first example of this class. A dicuslate-2 (141) is a member of the triterpenoid hydroquinone sulfates isolated from an ascidian (aka Ascidia) sp. that is the only known natural product inhibitor of kinase (12, 19).

Didemneketal C (147) is an unusual heptaprenoid isolated from an ascidian *Didemnum sp.*; its methanolysis product, didemnaketale B (148), inhibited HIV-1 protease (12).

**Sugars**

Several unusual polysaccharides have been isolated from sponges (11), among which the most unusual is asirennolide A (149), which has been isolated recently as a potent telomerase inhibitor from *Axinella infundibula* (12). It resembles bacterial lipopolysaccharides.

Natural Products, Common Biological Targets for
Natural Products: an Overview
The carbon skeleton of isoprenoids is derived from the branched C_5 skeleton of isoprene. Isopentenyl diphosphate and dimethylallyl diphosphate represent the biologic equivalents of isoprene. From research on cholesterol biosynthesis in liver tissues and on ergosterol in yeast, mevalonate was accepted as the universal precursor of isoprenoids. However this assertion is inaccurate. Incorporation of labeled acetate and glucose isotopomers into bacterial isoprenoids and into diterpenes of ginkgo embryos indicated fortuitously the existence of an alternative mevalonate-independent route. Its full elucidation required experiments using ^13C- and ^2H-labeled precursors followed by extensive nuclear magnetic resonance analyses as well as a combination of biochemical and molecular biology methods. These additional studies revealed a complete set of novel unsuspected enzymes.

Isoprenoids represent the largest family of natural products, with an exceptional structural diversity. Isoprenoids are present in all living organisms. This group includes essential metabolites, such as sterols of the eukaryotic plasma membranes, prenyl chains of the quinones and carotenoids from electron transport chains, and carotenoids from the photosynthetic apparatus in the plant chloroplasts, or in the phototrophic bacteria. Isoprenoids also include secondary metabolites of a more restricted distribution and with a less obvious physiologic significance. Their carbon skeleton can be derived from the combination of C_5 subunits with the branched skeleton of isoprene.

Steps for the Formation of Isoprene Units

The biologic precursors of isoprene units are isopentenyl diphosphate and dimethylallyl diphosphate. These precursors can be obtained by two different metabolic pathways: the mevalonate (MVA) pathway, which was the first one to be elucidated, and the long overlooked methylerythritol phosphate (MEP) pathway.

Mevalonate (MVA) pathway

Labeling experiments, performed mainly with liver tissues and yeast, elucidated the biosynthesis of cholesterol and ergosterol, leading to the discovery of the mevalonate pathway leading to IPP and DMAPP. In this pathway, isoprene units are derived, like fatty acids, from acetyl-coenzyme A. The key intermediate is mevalonate, which results from the reduction of hydroxymethylglutaryl-coenzyme A catalyzed by the HMG-CoA reductase, and represents the committed step of the pathway. Confirmation of this pathway was obtained for the biosynthesis of plant sterols, triterpenes, and sesquiterpenes.

Discrepancies with the MVA pathway and the discovery of an alternative route: the MEP pathway

The MVA pathway was accepted as the unique biosynthetic pathway for the formation of all isoprenoids in all living organisms. Discrepancies with this general assertion appeared, however, as early as the 1950s. For instance, ^14C-labeled MVA was not incorporated into chloroplast isoprenoids (e.g., carotenoids and phytol from chlorophylls; Fig. 6), whereas it was well incorporated into phytosterols synthesized in the cytoplasm. Unexpected labeling patterns were found in the prenyl chain of ubiquinone. In Escherichia coli at incorporation of ^14C-labeled acetate, finally, the labeling pattern in an isoprene unit from the sesquiterpenic pentalenene series from a Streptomyces species at incorporation of uniformly labeled acetate led to the discovery of the mevalonate pathway leading to IPP and DMAPP. In this pathway, isoprene units are derived, like fatty acids, from acetyl-coenzyme A. The key intermediate is mevalonate, which results from the reduction of hydroxymethylglutaryl-coenzyme A catalyzed by the HMG-CoA reductase, and represents the committed step of the pathway. Confirmation of this pathway was obtained for the biosynthesis of plant sterols, triterpenes, and sesquiterpenes.
Methylerythritol Phosphate Pathway for the Formation of Isoprene Units

Figure 1 | Mevalonate pathway for the biosynthesis of isopentenyl diphosphate 7 and dimethylallyl diphosphate 8.

Figure 2 | Methylerythritol phosphate 12 pathway for the biosynthesis of isopentenyl diphosphate 7 and dimethylallyl diphosphate 8.

Labeled [U-13C6]glucose was not in accord with what was expected from the MVA pathway.

The discovery of an alternative mevalonate-independent route to isoprene units was a fortuitous, nonprogrammed, and non-programmable side product of two independent biosynthetic investigations: on triterpenoids of the hopane series 20 in bacteria (1) and on diterpenes of the ginkgolide 26 and bilobalide series in the higher plant Ginkgo biloba (3). In this pathway (Fig. 2), isoprene units are derived directly from carbohydrate metabolism, with pyruvate 9 and glyceraldehyde 3-phosphate 10 as starting materials and with MEP 12 as the committed intermediate.

Significance of the MEP pathway

The MEP pathway remained overlooked for nearly 40 years. The MEP pathway is present in most eubacteria, including pathogens and opportunistic pathogens, as shown first by biochemical evidence and later by comparison of gene sequences. It is present in all phototrophic organisms, but its presence is restricted to the chloroplasts; the MVA pathway operates in the cytoplasm. It is also found in phylogenetically related nonphotosynthetic taxa, such as the Plasmodium spp., which are the parasites responsible for malaria possessing apicoplasts (plastid-derived organelles).
The MEP pathway revealed a set of seven novel enzymes that correspond to unannotated genes with unprecedented reaction mechanisms, especially the last two enzymes (GCP and LytB). These two enzymes are characterized by a Fe/S cluster, which catalyzes the conversion of a 1,2-diol derivative into an olefin and the conversion of an allylic alcohol into an olefin.

The MEP Pathway

Several aspects of the MEP pathway reaction sequence are unexpected, including the conversion of two highly oxidized carbohydrate derivatives, pyruvate 9 and glyceraldehyde phosphate 10 (GAP), into two monounsaturated alcohol diphosphates, IPP 11 and DMAPP 12. 1-deoxy-D-xylulose 5-phosphate (DXP), the first C5 Intermediate and DXP Synthase

The first step of the MEP pathway is to form DXP 11, by the DXP synthase (DXS) from pyruvate 9 and GAP 10 (2). This reaction could be postulated from the knowledge of the origin of the carbon atoms in isoprene units. Incorporation of deuterium-labeled isotopomers into the prenyl chain of ubiquinone 22 and menaquinone 23 (Fig. 6) from E. coli provided the first evidence for the involvement of deoxyxylulose (DX) in isoprenoid biosynthesis. This observation was extended to plant isoprenoids in plant systems. Free DX is usually well incorporated into the MEP pathway, with the perulose being phosphorylated by a nonspecific xylulose kinase in bacteria as well as in plants (4). The DXS gene of this enzyme was observed directly, but synthetic methylerythrose phosphate 18 derived from the synthetic ME. Free ME added to the culture medium was later confirmed by the incorporation of DX isotopomers with multiple labeling into the prenyl chains of the quinones 22 and 23 (Fig. 6) in E. coli or phytol 24 from Catharanthus roseus cell cultures (2). This reaction was first written as an acid-catalyzed rearrangement of an α-ketol (Fig. 4a), followed by the NADPH-dependent reduction of the resulting carbonyl derivative. An analogy was made between the corresponding reaction found in the biosynthesis of branched chain amino-acids. A 2-C-methyl-d-erythritol 4-phosphate 12 derivative is the product of this rearrangement. Deuterium-labeled free 2-C-methyl-d-erythritol (ME) was incorporated into the prenyl chain of ubiquinone and menaquinone from wild-type E. coli, but with a much lower yield than DX. This result suggests its correlation with the biosynthesis of isoprene units. In E. coli mutants with a dxs deletion, this deletion was rescued by the addition of synthetic deuterated ME to the culture medium. Incorporation was quantitative, as all isoprene units were derived from the synthetic ME. Free ME added to the culture medium is used only by a few bacteria. In Salmonella enterica, the sorbitol phosphotransferase system is responsible for the phosphorylation and transport of free ME. An analysis of E. coli mutants auxotrophic to ME enables the identification of the DXP reducto-isomerase gene (dxr). As expected, this enzyme catalyzes the rearrangement of DXP into methylenetetrahydrofolate 4-phosphate 18 (Fig. 4) and catalyzes the concomitant NADPH-dependent reduction of the intermediate α-diketone into MEP. The enzyme requires a divalent cation, such as Mg$^{2+}$ or Mn$^{2+}$. The postulated alpha-ketol intermediate 18 has never been observed directly, but synthetic methylenetetrahydrofolate 18 is converted by DXX into DXP in the presence of NADP$^+$ and into MEP in the presence of NADPH. The addition of NADPH
and DXP follows an ordered mechanism with NADPH binding before DXP. The stereochemistry of the reduction step is known. The pro-5 hydrogen of NADPH is transferred onto the re face of the aldehyde intermediate (6). 1-Fluoro DXP is a poor substrate of DXR. Although no definitive conclusion could be drawn from this conversion, a careful kinetic analysis of the conversion of this substrate analog suggests an alternative retro-aldol/aldol reaction for the rearrangement step (Fig. 4(a)) which was confirmed by the secondary isotope effects observed upon incubation of DXP with deuterium labeling at C-3 or C-4 (8).

Fosmidomycin (Fig. 4) and its analogs are strong inhibitors of the MEP pathway, and they inhibit strongly the DXR. According to the X-ray structure of the E. coli DXR, which crystallizes in the presence of fosmidomycin, the antibiotic acts as an analog of the DXP substrate rather than as an analog of the intermediate methylerythrose phosphate (9).

From methylerythritol phosphate to methylerythritol cyclodiphosphate

No obvious indications were available to identify the next steps after the formation of MEP (2, 10, 11). The incubation of synthetic trimethyl-labeled MEP with a crude cell-free system from E. coli and with a cocktail of all plausible cofactors and the analysis of the radioactive metabolites suggested the formation of a ME/nucleotide adduct, which could not be characterized fully.

A systematic search in gene libraries for a gene encoding an enzyme that uses a polyol phosphate and a nucleotide triphosphate as substrates led to the acsi gene from H. hemophilus influenzae encoding an enzyme coupling ribitol 5-phosphate with cytidine 5’-triphosphate (CTP) and yielding the 5’-diphosphocytidyl adduct of ribitol. This gene presented high homologies with the unannotated ygbP gene from E. coli. The corresponding protein was tested in the presence of MEP 12 and nucleotide triphosphates, with the most efficient one being CTP, and catalyzed the formation of the 4-diphosphocytidyl adduct of ME (Fig. 2). In E. coli, the ygbP gene was accompanied by two additional genes, ycbB and ygbR, which together constitute a small cluster. In fact, these two genes coded for the next two enzymes of the pathway. The YcbR protein catalyzed the ATP-dependent phosphorylation of the tertiary hydroxy group of 4-diphosphocytidyl MEP 13 yielding 4-diphosphocytidyl MEP 2-phosphate 14. The YgbP protein converted the latter intermediate into ME cyclodiphosphate 15 with the elimination of cytidine 5'-monophosphate (Fig. 2). Interestingly, in many bacteria, the ygbP and the ygbR genes yield a fusion protein, which corresponds to a bifunctional enzyme catalyzing the two steps, which are performed by two distinct enzymes in E. coli or in plants (12).

From ME Cyclodiphosphate to IPP and DMAPP

In the conversion of MEP 12 into ME cyclodiphosphate 15, the oxidation state of the C5 branched carbon skeleton does not change. The main modification is the introduction of a good leaving group at C-2 on the ME skeleton, which implies that the additional steps include elimination and reduction to afford the unsaturated alcohol diphosphates, IPP and DMAPP, from a tetrol derivative, which is unprecedented in enzyme reactions. Only two additional genes, gcpE and lytB, accompanied all above-mentioned genes of the MEP pathway, making them candidates for the catalysis of the final steps. The amino acid sequence of the two proteins encoded by the gcpE and lytB genes reveals the signature of [Fe₄S₄] proteins, i.e., with three conserved cysteines involved in the fixation of the cluster in the active sites (2, 13). Most of these proteins are oxygen...
Methylerythritol Phosphate Pathway for the Formation of Isoprene Units

\[

\]

**Figure 5** Origin of carbon atoms from glucose in the isoprene units of (a) the hopanoids of *Zymomonas mobilis*, (b) the diterpenoids of *Ginkgo biloba*.

**Figure 6** Isoprenoids from bacteria (bacteriohopanepolyol, 20; pentenolactones, 21; ubiquinone, 22; menaquinone, 23) and from higher plants (phytol, 24; β-carotene, 25; ginkgolide, 26; sterols, 27).

Sensitive, and enzyme tests must be performed under an inert argon atmosphere. GcpE converts ME cyclodiphosphate 15 into 4-hydroxy DMAPP 16, which is in turn converted into IPP 7 and DMAPP 8 in an estimated 5:1 ratio (**Fig. 2**). The first reaction corresponds with the conversion of a diol derivative into an olefin; the [Fe₄S₄] cluster in a reduced state acts as an electron donor and probably acts as a Lewis acid for the elimination of the C-3 hydroxy group of ME cyclodiphosphate. The second reaction is the conversion of an allylic alcohol into an olefin. Again the reduced [Fe₄S₄] cluster of LytB is involved in a reductive one-electron transfer process and acts as a Lewis acid for the elimination of the C-4 hydroxy group of 4-hydroxy DMAPP 16 (**Fig. 2**).

Both GcpE and LytB must be associated with a reducing system to convert the oxidized [Fe₄S₄]²⁺ cluster into the active reduced [Fe₄S₄]⁺⁺ form (**Fig. 3**), which can be performed with the isolated enzymes from E. coli either by the biologic system flavodoxin/flavodoxin reductase/NADPH, by the semiquinone radical of 5-deazaflavin, or by dithionite. In cyanobacteria, and in plant chloroplasts where flavodoxin is absent, this reducing
role can be performed by ferredoxin as shown for the GcpE enzyme, the electron flow coming directly from photosynthesis in the light or from catabolic metabolism in the dark (14).

Elucidation of the MEP Pathway: Key Experiments

The first results from studies the MEP pathway were obtained from in vivo incorporation experiments of 13C labeled glucose isotopomers with bacteria or ginkgo embryos, which determined the origin of the carbon atoms of the isoprene units and which resulted in a reasonable biogenetic scheme. This step was followed by biochemical experiments that were designed to validate the aforementioned scheme and were led to the identification of enzymes, deoxyxylulose phosphate (DXP) and MEP, and the identification of enzymes, deoxyxylulose phosphate synthase (DXS) and DXP reducto-isomerase (DXR). Later steps were identified by using a combination of molecular biology and biochemical methods, including enzyme tests as mentioned in the previous paragraph. Most experiments were cited for the elucidation of the pathway. Three sets of key experiments are described in detail.

Incorporation of 13C-labeled glucose into the hopanoids of Zymomonas mobilis and into the diterpenoids of ginkgo embryos: the origin of carbon atoms in isoprene units

Incorporation studies of 13C-labeled precursors require extensive nuclear magnetic resonance (NMR) measurements. The signals of 13C-NMR-spectra of the analyzed metabolites must be assigned fully. The 13C-NMR spectra of the reference compound of natural abundance (1.1%) and of the labeled metabolite must be recorded in the same conditions. A comparison between the relative signal intensities of the two spectra indicates that the carbon atom is labeled and indicates the magnitude of the isotope enrichment.

The incorporation of 13C-labeled acetate into bacterial hopanoids (Fig. 6) revealed unambiguously a labeling pattern that was not compatible with the MVA pathway. The incorporation of 13C-labeled glucose isotopomers into the isoprene units of the hopanoids from the bacterium Zymomonas mobilis determined the origin of all the carbon atoms of the isoprene units (Fig. 5a, 1, 2). This bacterium uses glucose as a carbon and energy source via the Entner-Doudoroff pathway. It has a tricarboxylic acid cycle and does not convert pyruvate into glyceraldehyde phosphate. These metabolic peculiarities facilitated a retrobiosynthetic analysis of the labeling pattern, which suggested that the C5 isoprene skeleton was formed from a C2 moiety derived from pyruvate decarboxylation and from a C3 subunit derived from a triose phosphate. The incubation of doubly labeled (4,5-13C2)glucose showed that the coupling of the labeled carbon atoms was preserved in the isoprene units, which indicates that they were introduced together via a single precursor and suggests that an intramolecular rearrangement performed the insertion of the C2 pyruvate-derived subunit between the carbon atoms derived from C-4 and C-5 of glucose. This key experiment excluded the MVA pathway for the formation of the bacterial isoprene units and was the signature of an alternative biosynthetic route.

Similar experiments performed on ginkgo embryos also revealed an unexpected labeling pattern of the isoprene units of the diterpenoid skeletons. In this case, glucose is metabolized via glycolysis and a retrobiosynthetic analysis was in accordance with the formation of isoprene units from pyruvate and from a triose phosphate derivative (Fig. 5b) (3).

Incorporation of 2H-labeled deoxysylulose and methlyerythritol into terpenoids from bacteria and from plant plastids

The incorporation of 13C-labeled glucose isotopomers showed that a pyruvate and a triose phosphate derivative were the precursors of isoprene units in the alternative route. The triose phosphate derivative was identified as glyceraldehyde phosphate using E. coli mutants; each lacks a single enzyme of the triose phosphate metabolism (allowing the interconversion of pyruvate and glycerol) and grows either in the presence of no-labeled pyruvate and 13C-labeled glycerol or in the presence of a 13C-labeled pyruvate and nonlabeled glycerol. These initial results led to the identification of the first two C2 intermediates of the pathway.

1-D-Deoxy-D-xylulose is a known natural product. It was first isolated from the fermentation broth of a Streptomyces and later shown to be a precursor of pyridoxol. Its structure can be deduced biogenetically from pyruvate and glyceraldehyde phosphate (Figs. 2 and 3). Two 2H-labeled DX isotopomers were synthesized chemically. They were incorporated efficiently into the prenyl chains of ubiquinone and menaquinone by wild-type E. coli, indicating that a DX derivative is an isoprenoid precursor (2, 3).

Free methlyerythritol is a widespread poliol in plants. The formation of the isoprene skeleton via the alternative route involves an intramolecular rearrangement. The branched carbon skeleton of ME can be deduced from the rearrangement of the straight chain DX (Fig. 4). Deuterium-labeled ME isotopomers were synthesized chemically and were incorporated into the prenyl chains of the E. coli quinones (2).

E. coli constructs using MVA for the identification of MEP pathway genes

Many isoprenoids are essential metabolites in living cells. Inhibition of their biosynthesis is lethal, which implies that any deletion or any major mutation of a gene of the MEP pathway will be lethal and must be rescued by another source of precursor for IPP and DMAPP. In E. coli, this can be performed by introducing the genes of the MVA pathway, which is absent in this bacterium (15).

For instance, the deletion of the ddx gene, which encodes the enzyme catalyzing the conversion of DXP into MEP, is lethal. This deletion can be rescued two ways by adding
synthetic ME, which is phosphorylated in vivo and enters the MEP pathway, or by introducing the genes of enzymes which allow the conversion of MVA into IPP. For this reason, these genes must be introduced in the construct, encoding, respectively, mevalonate kinase, phosphomevalonate kinase, and dihydrophosphomevalonate decarboxylase (Fig. 1).

This approach has been used to check that ggE and lyB are involved in the MEP pathway. These genes accompanied regularly the other known genes of the pathway in the completely sequenced bacterial genomes. The deletion of either of these genes was lethal, which indicates that they are essential but was rescued by the insertion of the three above-mentioned genes of the MVA pathway, indicating that they are involved in the biosynthesis of IPP and DMAPP (2).

Future Developments
Inhibition of the MEP pathway: toward novel antibacterial and antiparasitic drugs
The MEP pathway is the only pathway involved in the biosynthesis of essential isoprenoids in pathogenic bacteria and in parasites, and it is absent in animals and in humans. Therefore, any enzyme of this pathway is a potential target for a novel type of antimicrobial drugs (16, 17). This concept has been validated by the mode of action of fosmidomycin, a natural antibiotic that inhibits the second step of the MEP pathway catalyzed by the deoxyxylulose phosphate reducto-isomerase (DXR).

Overexpression of the MEP pathway: toward improved production of plant terpenoids of economic value
The MEP pathway is the starting material of major plant terpenoids of economic value, e.g., monoterpene s from essential oils, diterpenoids from pathogenic bacteria and in parasites, and it is absent in animals and in humans. Therefore, any enzyme of this pathway is a potential target for a novel type of antimicrobial drugs (16, 17). This concept has been validated by the mode of action of fosmidomycin, a natural antibiotic that inhibits the second step of the MEP pathway catalyzed by the deoxyxylulose phosphate reducto-isomerase (DXR).

Cross-talk between the MVA and the MEP pathway: A Novel Aspect for the Regulation of Terpenoid Biosynthesis in Plants
Finally, the dichotomy between the cytoplasmic mevalonate pathway and the plastidial MEP pathway is not strict. An exchange of metabolites occurs between the two compartments at the level of C5, C10, and C15 prenyl diphosphates. The inhibition of one pathway (e.g., by mevinolin for the MVA pathway or by fosmidomycin for the MEP pathway) can be complemented by the other route either partially, as in most tested plant systems, or even completely, in the case of the tobacco Bright yellow-2 cell cultures (20). In addition, a regulation of the two pathways by the nuclear cycle is suggested: the MEP pathway is activated in the presence of light and is activated by photosynthesis (21). Cross-talk and light regulation lead to new findings in the regulation of isoprenoid biosynthesis in plants.

Natural Products: An Overview
Jon Clardy and Michael A. Fischbach, Harvard Medical School, Massachusetts
doi: 10.1002/9780470048672.wecb377

Natural products, the remarkable collection of small molecules made by living organisms in an idiosyncratic manner, have made important contributions to organic chemistry, biology, and medicine. Although natural products contain a mother lode of molecular diversity, all of their structures reflect an evolutionary history and a biosynthetic production from a limited set of starting materials and reactions. The structures of natural products differ quantifiably from the small molecules usually found in the screening libraries used in high-throughput assays. Deeper structural analysis often reveals that natural products bind important biological targets with an exquisite degree of shape and charge complementarity. In addition, natural products often employ a variety of strategies to disguise reactive functional groups until they are needed. Biosynthetic pathways for natural products resemble those used to construct more common biomolecules; the main themes are reactions that couple monomers into larger molecules and the lavish use of redox chemistry not just to create skeletons but also to cross-link them and decorate them with oxygen-based functionality. Although the historic contributions of natural products to chemistry, biology, and medicine are clear, their current use, especially in drug discovery, seems less clear. However, efforts to explore new areas of biological diversity, mine genomes, and study the natural roles of natural products are rejuvenating natural products research and illuminating its future.

What are Natural Products?
"Natural product" is such a familiar term to most chemists and biologists that it is easy to forget that it describes a group of compounds with breathtaking molecular diversity and biological activity. Two natural products easily can seem to have little, if anything, in common, so what distinguishes natural products from other small molecules? In the past, describing a natural product was fairly straightforward: It was an organic molecule obtained from a living (or formerly living) organism that had a limited distribution in nature. Biosynthetic production and sporadic occurrence were the key defining features. But as we have learned more about natural products, this seemingly clear definition has become more ambiguous as illustrated by three molecules: tryptophan, psilocin, and serotonin (Fig. 1).

All prokaryotes and some eukaryotes biosynthesize tryptophan, and all organisms incorporate tryptophan into their proteins. Its widespread distribution excludes it from being a natural product, and it is usually called a primary metabolite. Psilocin, which is biosynthesized from tryptophan, is best known as the hallucinogenic principle of "magic mushrooms," and its limited distribution in a group of small mushrooms, not to mention its role in pre-Columbian religious rituals in Mexico, make it a...
classic natural product (2). Serotonin, which is also biosynthesized from tryptophan, is a well-known human neurotransmitter, and its regulation is an important therapeutic target for depression and other conditions. Serotonin and serotonin bind some of the same receptors in the human brain, although to very different effect (3). But many organisms, including bacteria and plants, make serotonin for various purposes, and its classification depends on context. In humans, it is a neurotransmitter; in barnacle larvae looking for a place to settle, it is a natural product (or settling pheromone); and the difference has more to do with the scientists conducting the study than the molecule being studied (4). Is there a fundamental difference between these three molecules that have very similar structures, share large parts of their biosynthetic pathways, and bind common cellular targets? In addition to the ambiguities introduced by the limited-distribution test, our increased understanding of natural products has made even "coming from a living organism" ambiguous. Is the product of a biosynthetic pathway reconstituted in a test tube rather than a living organism a natural product? If a pathway found in nature were altered in some way, say by introducing a different enzyme for one step, then does it still produce a natural product? If enzymes from many different pathways are combined, does that new pathway produce a natural product? It seems likely that in the future, the term "natural product" will embrace any small molecule produced by a (genetically encoded) biosynthetic pathway whether the pathway is common or rare in nature or even created in the laboratory.

Even the usual classifications of natural products by their producing organism—plant, microbial, and marine natural products are the major divisions—are breaking down under genetic infection and other conditions. Psilocin and serotonin bind some of the same receptors in the human brain, although to very different effect (3). But many organisms, including bacteria and plants, make serotonin for various purposes, and its classification depends on context. In humans, it is a neurotransmitter; in barnacle larvae looking for a place to settle, it is a natural product (or settling pheromone); and the difference has more to do with the scientists conducting the study than the molecule being studied (4). Is there a fundamental difference between these three molecules that have very similar structures, share large parts of their biosynthetic pathways, and bind common cellular targets? The Structures of Natural Products

At the most fundamental level, natural products differ from other small molecules because of their evolutionary history. Natural products—or, more accurately, the genes that produce them—have undergone countless rounds of alteration, selection, and amplification that have honed their biological activities to better fulfill evolutionary selection criteria. This evolutionary recycling of their structural features has created what one recent commentator described as "the extraordinary advantages of small molecule natural products as sources of agents, which interject themselves in a helpful way in various physiological processes" (9).

Synthetic molecules, especially those prepared by medicinal chemists, also have selection criteria, but they usually involve synthetic accessibility, drug-like properties, or elaborations on a successful model. Whereas natural products generate their molecular diversity from a relatively limited set of starting materials and reaction types, as will be discussed shortly, synthetic molecules can stem from much larger sets of starting materials and reactions. Several studies have compared natural products and synthetic molecules and concluded that natural products contain relatively more carbon, hydrogen, and oxygen and less nitrogen and other elements than synthetics (10). In contemporary synthetic molecules, drug-like properties (how they are absorbed, distributed, metabolized, and eliminated) are enhanced by having molecular weight cutoffs (500 daltons is popular), limited hydrogen bonding potential, and solubility criteria (11). Most natural products actually conform to these rules, but notable exceptions of clinically useful compounds that greatly exceed the molecular weight guideline and have greater water solubility than recommended can be found (Fig. 2).

For any small molecule to possess sufficient binding energy to be a potent ligand (a dissociation constant in the 10^-9 to 10^-4 M range), its structural features must organize the molecule's electrostatic, hydrogen-bonding, and hydrophobic interactions to complement those of its binding partner. Successful natural and synthetic molecules achieve these conformationally restricted structures in rather different ways. Natural products often achieve this rigidification by forming macrocycles, having polycyclic structures, and minimizing gauche interactions (Fig. 2). Synthetic molecules favor possessing aromatic rings and minimizing the number of rotatable bonds. Natural products generally have more sp3-hybridized carbons and sterogenic centers (Fig. 2). Morphin, a molecule with an ancient if occasionally troubled involvement with humans, illustrates the exquisite level of three-dimensional conformational control to project hydrophobic surfaces and hydrogen bonding partners in all directions that can be achieved by natural products. In more elaborate comparisons with many molecular parameters, natural products and synthetics occupy rather different regions of “chemical space.”

A less appreciated aspect of natural products is their extraordinary repertoire of strategies employed to carry out their biological roles. They are, for example, masters of disguising reactive functionality. Sometimes the disguise can be as simple as converting a reactive aldehyde into an intramolecular hemiacetal, but it can also involve much more elaborate schemes. Some spectacular examples of this “wolf in sheep’s clothing” approach can be found in a structurally diverse family of natural products called DNA-targeting agents. These molecules must move through a biological milieu—including the cell and nucleus—and clear membranes—with many molecules that are much more reactive than DNA—and then degrade DNA beyond easy repair. Calicheamicin initiates a complex set of reactions to carry out this destructive mission by unmasking a thiol, which undergoes an intramolecular conjugate addition, which sets up the aromatization of the enediyne fragment, which generates an aromatic diradical, which damages both DNA strands (Fig. 2). Although calicheamicin’s molecular gymnastics might seem unduly complicated, calicheamicin linked to an antibody that directs it to cancer cells has shown therapeutic efficacy as an anticancer agent in several clinical trials (13). Not all
DNA-targeting agents rely on masking their reactivity. CC-1065 uses shape complementarity with specific DNA sequences to enhance its reactivity to carry out a disabling alkylation (Fig. 2) (14). It accelerates the reaction in the appropriate biological context through the exquisite alignment of the reacting partners.

**Biosynthetic Pathways**

Biochemistry has revealed nature's two main themes in carrying out the chemistry of life: 1) coupling reactions that join similar (or identical) small molecules into the larger molecules needed to store information, form cellular structures, and carry out catalytic functions and 2) redox reactions such as the largely oxidative reactions our bodies use to get energy from small molecules and the largely reductive reactions our bodies use to build up small molecules. Not surprisingly, the biosynthesis of natural products reprises these two reaction types. Although many natural product biosynthetic pathways employ only one of these two themes—either coupling or redox chemistry—some use both. These two-stage pathways typically begin with the coupling-mediated assembly of a multimer followed by the redox-mediated maturation of the initially formed product. In these hybrid pathways, redox-mediated maturation reactions decorate the core structure assembled by the coupling pathway. Nature also uses redox reactions to build core structures, an approach rarely employed for the same purpose in laboratory synthesis. These general observations are expanded in the examples below.

**Coupling reactions**

A coupling reaction, broadly defined, joins two fragments with the accompanying loss of a small molecule (or ion). In one well-known coupling reaction, the nucleophilic amino group of one amino acid reacts with the electrophilic carboxyl carbon of a second amino acid to form an amide bond with the loss of water (Fig. 3). Proteins, RNA/DNA polymers, lipids, and polysaccharides are all produced by different monomer-joining coupling reactions. Major classes of natural products—terpenes, polysaccharides, nonribosomal peptides, and polyketides—are also produced by coupling reactions, most of which feature a phosphate in some form as the ejected fragment. The details of the coupling reaction for these different classes vary depending on the subunits to be joined and the nature of the ejected fragment. The ejected fragment is a good leaving group, meaning that the bonds being formed are stronger than those being broken, and its release provides an entropy compensation for joining the two substrates.

Terpenes are formed by coupling double-bond isomers of the same monomer, isopentenyl pyrophosphate (IPP), with loss of a pyrophosphate ion (15, 16). Three such coupling reactions join four IPPs, each with five carbon atoms, to make geranylgeranyl-pyrophosphate, the C20-precursor of diterpenes (Fig. 3). Linear terpene precursors, which differ only in the number of IPP units joined, can be assembled by a few polyprenyl synthase enzymes, as the monomers are identical and the only variable is how many monomers to link together. In subsequent steps, these linearpolyenes undergo cation-induced cyclizations to create the starting frameworks for terpenes and their derivatives.

The coupling reaction used to build polysaccharides, such as the sugar fragment in vancomycin (Fig. 2), from hexose and pentose monomers is conceptually similar to the terpene pathway, except the leaving group is a nucleoside diphosphate (a ribosylpyrophosphate) rather than inorganic pyrophosphate, and the sugars to be joined can have considerable variety. This variability in the substrates requires a larger set of coupling enzymes, or glycosyltransferases, each of which selects specific glycosyl donor and acceptor cosubstrates (17). Genomic analyses highlight the consequences of this increased specificity.
Streptomyces avermitilis, a bacterium with a completely sequenced genome (18, 19), has three times as many predicted glycosyltransferases than predicted polyphenyl synthases.

The amino acid monomers of nonribosomal peptides (20) like vancomycin (21) (Fig. 2) are also linked using a phosphate-displacing coupling reaction with an adenosine monophosphate (AMP) leaving group. Unlike terpene and polysaccharide biosynthesis, the overall coupling process has two distinct reactions connected by a stable intermediate (Fig. 3). In the first reaction, the aminoacyl-adenylate is transferred to a "carrier protein" to which it is tethered through an aminoacyl thioester bond, and in the second reaction, the amine of an aminoacyl co-substrate reacts with the thioester to form a peptide bond (22). Both reactions have good leaving groups—either AMP or a thiolate. This two-step process resembles the ribosomal assembly of peptides with the amino acid bound to a carrier protein by a thioester bond in the nonribosomal case or a tRNA by an ester bond in the ribosomal case. Tethering substrates to intermediate carrier protein domains may be required for proper directionality of chain assembly, a role that is fulfilled by elongation factors during ribosomal peptide synthesis.

Nonribosomal peptide synthetases (NRPSs) function similarly to the ribosome in a second way: They act processively to build a peptide chain. In both cases, the amine group of the incoming aminoacyl monomer attacks the (thio)ester bond that links the nascent peptide to its carrier, which translocates the chain while elongating it by one monomer (22).

The polyketides (23) form the only major class of natural products that has monomer couplings that do not involve the loss of phosphate; like the nonribosomal peptides, the monomer couplings use a thioester intermediate. These molecules, which have biosynthetic pathways much like those of fatty acids, are assembled from the alpha-carboxylated two- and three-carbon metabolites malonyl-CoA and methylmalonyl-CoA (22). In these monomers, the alpha-carboxyl group is a caged form of carbon dioxide, and decarboxylation yields a thioester enolate...
that attacks a downstream thiolster to form a carbon-carbon bond (Fig. 3). In this coupling reaction, decarboxylation not only provides the attacking nucleophile, but also it serves as the driving force for unidirectional assembly. Although the coupling reactions for polyketides and nonribosomal peptides differ, the enzymes that assemble them function by similar processive logic: The incoming monomer attacks the nascent chain, which translocates it while elongating it by one monomer. Unlike many of today’s software designers, nature prioritizes compatibility across platforms, which leads to numerous molecules that are formed by hybrid pathways, just like the lipoproteins, glycoproteins, and glycolipids from primary cellular pathways, hybrid natural products originate from variants of these chemically compatible coupling reactions in which a donor monomer of one type gets linked to an acceptor monomer of a different type. For example, vancomycin (Fig. 3) is a hybrid between a nonribosomal peptide and a polysaccharide in which the key bond is formed by a coupling enzyme that links the peptide residue 4-hydroxyphenylglycine to the hexose monomer UDP-glucose (24).

**Redox reactions**

Redox chemistry occurs in natural product biosynthesis in at least three ways: building core structures, cross-linking core structures, and adding functionality to core structures. Just as the coupling reactions in natural product pathways resemble those from macromolecular synthesis, redox transformations in natural product pathways have counterparts in primary metabolism, which indicates that the genes in natural product pathways and the genes in primary metabolic pathways have common ancestors. Examples to illustrate the distinctions between building cores, cross-linking cores, and decorating cores are discussed below.

Podophyllotoxin (Fig. 1) was the basis for a successful anticancer drug because of its ability to prevent tubulin polymerization, although etoposide, the successful drug developed from it, actually works by inhibiting topoisomerase II and thereby preventing DNA replication (23). Podophyllotoxin’s skeleton is assembled through a very common redox reaction, the one-electron oxidation of coniferyl alcohol and a coupling of two such radicals (26, 27) (Fig. 4). This basic structure then undergoes a reduction, aromatic and aliphatic hydroxylations, and modifications of its aromatic substituents to give podophyllotoxin (27). The initial one-electron oxidation of a phenolate anion is also used to build the skeleton of morphine (Figs. 2 and 4) (28).

An example of oxidative cross-linking takes place during vancomycin biosynthesis; three cytochrome P450 enzymes—which use the same heme cofactor as the cytochromes from the primary metabolic electron transport chain—cross-link aromatic rings in its scaffold to form its rigid Cup-like shape (29, 30). Cytochromes P450 that decorate cores with oxygen-based functionality are commonly found in biosynthetic pathways. For example, these enzymes hydroxylate the reduced polycyclic scaffold of the diterpene taxol and install functional groups that are required for target binding and increase its hydrophilicity (31).

**Modifying naturally occurring pathways**

The most frequently encountered natural product biosynthetic pathways—those producing polyketides, nonribosomal peptides, polysaccharides, and terpenes—are all highly “evolvable” because they have a biosynthetic logic that is highly susceptible to small changes and rearrangements. François Jacob, one of the fathers of molecular biology, described these changes as “molecular tinkering” to emphasize the way nature cobbles together a workable solution through small alterations and rearrangements of previously existing materials (32). The “evolvability” of natural product biosynthetic pathways takes on two forms: modularity, in the case of polyketides, nonribosomal peptides, and polysaccharides, and plasticity, in the case of terpenoids. Researchers have taken advantage of these same features to engineer new pathways that produce new products. As mentioned above, polyketides are assembled processively by logic that resembles ribosomal peptide synthesis. But a fundamental difference is found: Whereas the ribosome is a “factory on wheels” that translocates along an mRNA template, polyketide synthases (PKSs) are multidomain enzymatic assembly lines that function both as the template and the synthesizer. Like assembly lines in factories, PKSs are modular, and each module (a set of domains) adds a single monomer to the growing polyketide chain. Researchers have exploited this modularity to alter or replace modules in the PKS that produces the backbone of erythromycin and have generated a library of “programmed” derivatives that differ at specific positions (33). A complementary approach, in which a library of artificial two-module PKSs was constructed, led to the production of new polyketide fragments and set the stage for future efforts to construct “synthetic” polyketide pathways from a standard set of biosynthetic building blocks (34). The former approach resembles the mutational component of the evolutionary approach used by nature, and efforts to introduce the component of selection are likely to improve the future prospects of “synthetic” pathway construction.

The coupling reaction described above for terpene pathways results in a linear C9n chain, whereas terpenoid natural products have a staggering array of shapes and topologies. The cyclic skeletons characteristic of terpenes are formed from these methylated precursors by enzymes called terpene cyclases (35). Terpene pathways are plastic in two ways: Relatively few mutations in these cyclase enzymes can lead to skeletons of different topology, and the redox enzymes that add oxygen-based functionality to these skeletons are often promiscuous. By exploiting the plasticity of terpene cyclases, seven mutants of the gamma-humulene synthase have been designed in which 1-5 amino acid substitutions led to the production of seven new products with a wide range of topologies (36).

**The Future of Natural Products Chemistry**

Although the historical contributions of natural products to the development of chemistry, biology, and medicine are clear, their role in the future development of these fields is cloudy,
Natural products chemistry has, like most things, evolved in fits and starts—periods of rapid advances followed by consolidation. The periods of rapid advance have always been associated with the opening up of new ecological niches to natural products research. In recent times, the opening up of the marine environment to natural products research spurred a few decades of truly heroic natural product discoveries. Marine natural products such as halichondrin B and ecteinascidin 743, analogs of which are in anticancer trials, were identified (37). Today, the most impressive remaining frontiers are largely microbial, and exploring the marine environment with suitably modified microbiological techniques has led to an increasing flow of molecules that are both novel and potentially useful. One example is the proteasome inhibitor salinosporamide, which was isolated from the marine actinomycete Salinispora tropica CNB-440 (38–40). The recently sequenced genome of this organism reveals a wealth of new molecules, which highlights the potential of marine microenvironments as a source of molecular diversity and showcases the biosynthetic prowess of this new actinomycete genus (41). Likewise, the discoveries of new molecules like jamicamidamide (42) and curacin (43) demonstrate the promise of marine cyanobacteria as a source of natural products (44). Some of the most impressive molecular diversity may not be found in the ocean but in the soil beneath our feet. Myxobacteria, the source of the tubulin-binding anticancer drug epothilone (45), showcases the biosynthetic prowess of this new actinomycete genus (41). Likewise, the discoveries of new molecules like jamicamidamide (42) and curacin (43) demonstrate the promise of marine cyanobacteria as a source of natural products (44). Some of the most impressive molecular diversity may not be found in the ocean but in the soil beneath our feet. Myxobacteria, the source of the tubulin-binding anticancer drug epothilone (45),

**New geographical and phylogenetic niches**

On the negative side, most large pharmaceutical companies have either greatly reduced or completely oxidized their natural product drug discovery programs; but on the positive side, researchers are finding new ecological niches containing dramatically new natural products, developing methods to mine genomic sequences for new natural products, and discovering new ways to connect natural products with ecology (Fig. 5).

**Figure 5** Biosynthetic pathways. (a) In the terpenoid coupling reaction, isomers of isopentenyl pyrophosphate are joined with the loss of pyrophosphate, leading to a linear intermediate that is cyclized to a terpene skeleton, as shown for the diterpene taxol. (b) In the polysaccharide coupling reaction, the loss of carbon dioxide from a two or three-carbon monomer yields a thioester enolate that attacks a carrier protein-tethered intermediate, forming a carbon-carbon bond as shown for the polyketone precursor of enterocin. (c) In the first step of the nonribosomal peptide coupling reaction, an aminoacyl adenylate is transferred to a carrier protein or "thiolation" leading to a linear intermediate that is cyclized to a terpenoid skeleton, as shown for the diterpene taxol. (d) In the polyketide coupling reaction, the loss of carbon dioxide from a two or three-carbon monomer yields a thioester enolate that attacks a carrier protein-tethered intermediate, forming a carbon-carbon bond as shown for the polyketone precursor of enterocin.

**Genome mining**

The ability to connect natural products to the genes that produce them has had two important consequences. The first consequence was stimulating genetic and biochemical studies into natural product biosynthesis, which increased our knowledge of the inner workings of these pathways dramatically and set the stage for the modification of existing pathways and the construction of new pathways.

On the negative side, most large pharmaceutical companies have either greatly reduced or completely oxidized their natural product drug discovery programs; but on the positive side, researchers are finding new ecological niches containing dramatically new natural products, developing methods to mine genomic sequences for new natural products, and discovering new ways to connect natural products with ecology (Fig. 5).

**New geographical and phylogenetic niches**

Natural products chemistry has, like most things, evolved in fits and starts—periods of rapid advances followed by consolidation. The periods of rapid advance have always been associated with the opening up of new ecological niches to natural products research. In recent times, the opening up of the marine environment to natural products research spurred a few decades of truly heroic natural product discoveries. Marine natural products such as halichondrin B and ecteinascidin 743, analogs of which are in anticancer trials, were identified (37). Some of the most impressive molecular diversity may not be found in the ocean but in the soil beneath our feet. Myxobacteria, the source of the tubulin-binding anticancer drug epothilone (45), are proving to be one of the richest sources of new natural products (46, 47).

**Genome mining**

The ability to connect natural products to the genes that produce them has had two important consequences. The first consequence was stimulating genetic and biochemical studies into natural product biosynthesis, which increased our knowledge of the inner workings of these pathways dramatically and set the stage for the modification of existing pathways and the construction of new pathways.
The second consequence was to create a new approach to natural product discovery based on bioinformatics. Instead of screening culture extracts to identify hits in an assay, a function-based approach, a research group scanned the genome of a bacterial strain to identify loci that encode natural product biosynthetic genes, a sequence-based search, and then isolated a new natural product from one of these loci, ECO-02301 (48). This effort was notable not only because the new molecule was identified by genomics rather than by screening but also because bioinformatics played an important role in accelerating the process of structure elucidation. Given the rapidly decreasing cost of genome sequencing and the increasingly powerful ability of bioinformatic analysis to predict natural product structure from gene sequence, genomics and bioinformatics are likely to play a more prominent role in future natural product discovery efforts.

**Clues from ecology**

The potential of natural products to serve as human medicines has always been the major driver of natural products research, and the relentless emphasis on their roles in treating human diseases has had the effect of largely separating natural products from the biological contexts in which they evolved and functioned. We know much more about the unnatural uses of natural products than we do about their intended uses. For example, the number of articles retrieved by searching for “taxol and cancer” (∼9500) greatly exceeds the number retrieved by searching for “taxol and ecology” (three, two of which deal with the possible extinction of the taxol producer to make anticancer medications). Chemical ecology, the subfield of chemical biology that studies molecular interactions between organisms, places natural products in their evolutionary biological context, and natural products chemistry and chemical ecology have extensive overlaps. Both ecology and natural products chemistry are becoming increasingly focused on microbiology. As the great insect ecologist E. O. Wilson wrote in Naturalist, his autobiography, “If I could do it all over again and relive my vision in the twenty-first century, I would be a microbiologist” (49) As ecologists discover new types of microbes and study their roles in interspecies interactions...
interactions, natural products chemists will acquire the producers of fascinating new molecules. One example is the role of actinomycetous bacteria in maintaining an insect–fungus mutualism. Leafcutter ants, New World ants that strip foliage from plants, take the vegetation to large underground colonies where the partially chewed leaves are fed to a fungus (50). In this mutualistic relationship, the fungus eats the leaves, and the ants eat the fungus. Another fungus, which attacks the food fungus, poses a grave threat to the ant colony. A rts protect their food fungus in several ways, including carrying a symbiotic bacteria that produces a selective fungicide, a natural product that selectively kills the antagonistic but not the food fungus (51). Each of the 39 species of leafcutter ants has its own species of food fungus, its own species of antagonistic fungus, and its own symbiotic bacteria to make antifungal compounds with appropriate activity. It is likely that exploring this mutualistic relationship, and possibly even other insect-bacteria mutualisms, will lead to a deeper understanding of the roles of microbes in maintaining symbioses, new natural products and their biosynthetic pathways, and possibly even new compounds with therapeutic efficacy.

Chemical Ecology: An Overview
Plants contain numerous natural products (secondary metabolites) that may not participate directly in their growth and development but play an important role in ecological interactions with other organisms. Despite immense chemical diversity, which originates from simple carbohydrates produced because of photosynthesis, plant natural products are formed from only a few biosynthetic building blocks that consist of acetate, mevalonate, and shikimate. These basic building blocks undergo a variety of biosynthetic transformations and combinations that lead to numerous classes of plant natural products including, but not limited to, carbohydrates, fatty acids and their esters, aromatic polyketides (phenols and quinones), terpenoids and steroids, phenyl propanoids (lignans and lignin, coumarins, flavonoids, and isoflavonoids), and alkaloids.

Summarized in this article are representative members of these important classes of plant natural products with special emphasis on their chemical diversity. The article concludes with a brief discussion on recent methods for the maximization of chemical diversity and the production of natural products from plants.

The number of different plant species on the surface of the earth has been estimated to be over 250,000 (1, 2), and only a fraction of these have been investigated for their constituent natural products (3). Plants are known to produce over 100,000 natural products (4). However, according to Verpoorte (5) “extrapolations of the number of species studied and the number of compounds known suggests that, from all plant species, at least a million different compounds could be isolated”. The vast majority of these compounds, commonly referred to as secondary metabolites, does not seem to participate directly in the growth and development of plants (6). In their natural environments, plants coexist and interact with other organisms in a variety of ecosystems (7), and the possible roles that these natural products play in plants, especially in the context of ecological interactions, are being speculated about, appreciated, and debated (8, 9). Although the functional role that secondary metabolites play in the producing organism is a matter of controversy (10, 11), the chemical diversity of plant natural products is well recognized, and it has been suggested that the chemical diversity of plant natural products is far greater than their functional diversity (9, 10, 12, 13).

Two models exist to explain the abundant chemical diversity of plant natural products. In the first model, secondary metabolites produced by plants are believed to be involved in physiological responses during the interactions with their biotic and abiotic environments, especially as elements of their defense arsenals. In this model, the diversity of compounds produced by plants is explained by considering the great diversity of plant life strategies and the vast number of accompanying defense strategies (14–16). The second model is an evolutionary model that makes the assumption that potent biological activity is a rare property for any natural product to possess and therefore is of no value to the producer organism (8). This model, based on the Screening Hypothesis of Jones and Firn (10, 17, 18), suggests that organisms that make and “screen” many chemicals will have an increased likelihood of enhanced fitness simply because the greater the chemical diversity the greater the chances of producing the rare metabolites with useful and potent biological activities.

**Origin of Natural Products in Plants**

It is intriguing that despite the immense chemical diversity exhibited by them, plant natural products are derived from only a few building blocks: acetate (which contains two carbon atoms), mevalonate (which contains five carbon atoms), and shikimate (which contains nine carbon atoms). These building blocks are derived in turn from simple carbohydrates produced...
because of the light-catalyzed reduction of atmospheric carbon dioxide by higher (green) plants during photosynthesis. The products formed by the condensation of the above building blocks (small biosynthetic units) are additionally elaborated (“tailored” or “decorated”) by numerous enzyme-catalyzed reactions such as cyclization, elimination, rearrangement, reduction, oxidation, methylation, and so forth. Chemical diversity that results from these “decoration” reactions will be considered under each biosynthetic class of plant natural products.

Carbohydrates

Although not as structurally diverse as other classes of natural products, carbohydrates are among the most abundant chemical constituents of plants. All animals and most microorganisms depend on plant-derived carbohydrates for their nourishment and survival. Simple carbohydrates (aldoses and ketoses), the first formed products of photosynthesis, are used by plants to make their food reserves, as starter units for the synthesis of plant secondary metabolites, and to make sugar derivatives (glycosides) of products of secondary metabolism. Plant carbohydrates consist of monosaccharides (pentoses and hexoses), disaccharides, oligosaccharides, and polysaccharides. Monosaccharides of plant origin include the stereoisomeric forms of hexose sugars (D-glucose (A2), β-D-galactose (A2), β-D-mannose (A3), α-L-rhamnose (A4), β-D-xylose (A5), β-D-ribose (A7), and β-D-fructose (A8) (Fig. 1)). L-ascorbic acid (A9), commonly known as vitamin C and occurring in most fresh fruits and vegetables, is a monosaccharide derived from D-glucose. As the name implies, disaccharides are formed from two monosaccharide units and contain a C-C glycosidic bond. Among the common plant disaccharides, maltose (A10) and lactose (A11) contain respectively C(1)–O–C(4) and C(1)–O–C(4) links formed between two D-glucose (A2) units, whereas sucrose (A12) contains the C(1)–O–C(2) link formed between D-glucose (A2) and D-fructose (A8) units (Fig. 1). Polysaccharides that are polymeric monosaccharides perfom two major functional roles, namely, the food reserves and structural elements in plants. Amylose (A13), an example of a storage polysaccharide, is a linear polymer that contains 1000–2000 C(1)–C(4) linked glucopyranose units. Cellulose is an example of a structural polysaccharide composed of a linear chain of ca. 8000 residues of C(1)–C(4) linked glucopyranose units. It is noteworthy that cellulose, the main constituent in plant cell walls, is the most abundant organic material on earth.

Products of Acetate Pathway

The two-carbon precursor, acetyl coenzyme A (acetyl-CoA), is the initial substrate for synthesis of the carbon backbone of plant polyketides. As the name implies, polyketides are naturally occurring polymers of ketene (CH2=O) and contain alternating carbonyl and methylene groups derived from the acetate pathway. Polyketides and their derivatives are ubiquitous and are found in all organisms known to produce secondary metabolites. Because of their immense structural diversity, a unified classification of polyketides has yet to emerge (19). Plant polyketides are represented by two major classes of metabolites: fatty acids and aromatic compounds.

Fatty acids and their esters

Plants contain both saturated and unsaturated fatty acids mostly as esters of the trihydroxy alcohol, glycerol. As they are derived from the linear combination of acetate (C2) units, common fatty acids possess an even number of carbon atoms and contain a straight chain. Thus, fatty acids that contain an odd number of carbons are rare in nature. Over 300 fatty acids belonging to 18 structural classes occur in plants (20). Among these, the more common are saturated fatty acids that contain 16 or 18 carbon atoms such as lauric acid, myristic acid, palmitic acid, and stearic acid, and the unsaturated analogs of stearic acid, namely, oleic acid and linoleic acid. Oils produced by many plants constitute glycerol esters of both saturated and unsaturated fatty acids. The other classes of fatty acids are defined by the number and arrangement of double or triple bonds and various other functional groups.

Aromatic polyketides in plants

Aromatic natural products of polyketide origin are less prevalent in plants compared with microorganisms. The majority of the plant constituents that contain aromatic structures are known to arise from the shikimate pathway (see below). Unlike those derived from the shikimate pathway, aromatic products of the polyketide pathway invariably contain a meta oxygenation pattern because of their origin from the cyclization of polyketides. Phenolic compounds such as chrysophanol-anthrone (B1), and emodin-anthrone (B2), and the anthraquinones, aloes-emodin (B3) and emodin (B4) (Fig. 2), are products of the polyketide pathway and are found to occur in some plants of the genera Cassia (Leguminosae) (21), Rhamnus (Rhamnaceae) (22), and Aloe (Liliaceae) (23). The dimer of emodin-anthrone (B2), namely hypericin, (B5) is a constituent of the antidepressant herbal supplement, St. John’s wort (Hypericum perforatum, Hypericaceae) (24).

Products of Mevalonate Pathway

Mevalonic acid, a six-carbon building block, is made up from three molecules of the most basic two-carbon precursor, acetyl-CoA. The mevalonate pathway, which involves the intermediary of mevalonic acid, directs acetate into a series of natural products different from those derived directly from the acetate pathway and includes terpenoids and steroids. Terpenoids constitute the most chemically diverse and one of the largest groups of plant natural products, and therefore a detailed discussion on this group of natural products is warranted.

Most terpenoids are derived from mevalonic acid (MVA) through the universal precursor isopentenyl diphosphate (IPP) and its allylic isopentenyl diphosphate (DMAPP). Thus, the vast majority of terpenoids contain the basic structural residue 2-methylbutane, often less precisely referred to as isoprene units. These C5 hemiterpene units combine with

each other in a variety of ways leading to mono- (C10), sesqui- (C15), di- (C20), sester- (C25), tri- (C30), tetra- (C40), and poly- (C5n (n > 8)) terpenes. The primary products of condensation undergo more elaboration (reduction, oxidation, derivatization, etc.) and “decorations” that lead to terpenoid hydrocarbons, alcohols and their glycosides, ethers, aldehydes, ketones, and carboxylic acids and their esters, which makes terpenoids the most diverse class of plant natural products. It is noteworthy that over 40,000 different terpenoids have been isolated and characterized from natural sources including plants (25, 26).

WILEY ENCYCLOPEDIA OF CHEMICAL BIOLOGY © 2008, John Wiley & Sons, Inc.
Monoterpene precursors undergo a variety of cyclization and rearrangement reactions leading to diverse monoterpenes and bicyclic monoterpene derivatives that contain irregular monoterpene carbon skeletons and bicyclic monoterpenoids that consist of hydrocarbons, alcohols, and ketones. Compared with cyclopentane and cyclopropane analogs, cyclobutane and cyclohexane monoterpenoids that contain irregular monoterpene carbon skeletons are rare in nature. (+)-Trans-chrysanthemic acid (D1) and (+)-trans-pyrethric acid (D2) esters, which are known to occur in flower heads of Chrysanthemum cinerariifolium (Compositae), are two important examples of cyclocopropane monoterpenoids. Noteworthy examples of cyclobutane monoterpenoids are (15.25)-frangol (D3), which occurs in the roots of Artemisia frangrans (Asteraceae), and junonione (D4), which occurs in the fruits of the juicy tree (Juniperus communis, Cupressaceae) (Fig. 4).

To date about 200 cyclopentane monoterpenoids are known (32), and the majority of these in plants occur as iridoids and seco-iridoids that contain the iridane carbon skeleton fused to a six-membered oxygen heterocycle. The simplest iridoid, (+)-nepetalactone (D5), is a constituent of the volatile oil of Nepeta cataria (Labiatae), which is known to be a powerful cat attractant and stimulant. Other well-known plant-derived iridoids consist of a diverse array of valepotriates known to occur in the popular herbal supplement valerian (Valeriana officinalis, Valerianaceae). Most of these valepotriates, including (+)-valerian (D6), the constituent responsible for the tranquilizing properties of the valerian, contain several hydroxyl groups centered with the C3, C4, and C5 moieties of iridoids also occur as plant constituents. Important examples are (+)-aspiruloside (D7) with insect antifeedant activity in Asperula odorata (Galium odoratum, Rubiaceae) and many other plants and (+)-loganin (D8) from the fruits of Strychnos nux vomica (Loganiaceae). Although not as prevalent as iridoids, the seco-iridoids, (+) -oleuropin (D9), (+)-jasmonamide A (D10), and (+)-secologanin (D11), Fig. 4, have been isolated from many parts of the olive tree (Olea europaea, Oleaceae), Jasminum multiflorum (Oleaceae) and Strychnos nux vomica (Loganiaceae), respectively.

Cyclohexane monoterpenes are a chemically diverse group of monoterpenoids that occur in the plant kingdom mainly as hydrocarbons, alcohols, ketones, aromatic hydrocarbons, and carboxylic acids (Fig. 5). The saturated hydrocarbon trans-ρ-methane (E1) is a constituent of the oil of turpentine and the resin of pine (Pinaceae) trees. Its unsaturated analogs, namely (R)-(+)-limonene (E2) [present in oil of orange (Citrus aurantium) and mandarin (Citrus reticulata, Rutaceae) peel oil]; ω-terpine (E3) and terpinolene (E4) in some Citrus, Juniperus, Mentha and Pinus species; (R)-(-)- u-pheanthrene (E5) in Eucalyptus pheanthra (Myrtaceae); and (S)-(+)- p-phenanthrene (E6) in water fern Wateria (Phalangium aquilicum, Umbelliferae), are components of many plant volatile oils. The rich chemical diversity of cyclohexane monoterpenes is apparent from the natural occurrence of all four pairs of ρ-methane-3-ol enantiomers, for
example, (−)-menthol (E7) [a major component of peppermint (Mentha piperita, Labiatae) oil], (+)-neomenthol (E8) [a constituent of Japanese peppermint (Mentha arvensis) oil], and (−)-neoisomenthol (E9) in geranium (Pelargonium roseum, Geraniaceae) oil. The unsaturated versions of p-menthol, namely p-menthenol, exhibit extensive regioisomerism and are represented by (−)-pulegol (E10) (a constituent of several peppermint (Mentha gentilis and M. spirata, Labiatae) oils), (−)-isopulegol (E11) in Mentha arvensis (Labiatae), (−)-α-pinene (E12) in several Mentha and Eucalyptus species, (−)-α-terpineol (E13) in Artemisia, Eucalyptus, Juniperus, and Mentha species), and (−)-carveol (E14). Oxidation products of both saturated and unsaturated cyclohexane monoterpenoids also occur in nature. Of these, the most abundant in the plant kingdom are (−)-menthone (E15) in peppermint.
Figure 5 Chemical diversity of monocyclic cyclohexane and aromatic monoterpenes. (Mentha x piperita) oil), (−)-isopulegone (E16) (in oil of Mentha pulegium), (−)-piperitone (E17) (in Eucalyptus oil), and (−)-carvone (E18) (in ripe fruits of dill (Anethum graveolens, Umbelliferae) and caraway (Carum carvi, Umbelliferae)).

Aromatic versions of cyclohexane monoterpenes (benzenoid menthanes or cymenes) are also found in nature and are constituents of some plants frequently used as spices. The hydrocarbon p-cymene (E19) has been found to occur in the oils of cinnamon (Cinnamomum zeylanicum), cypress, eucalyptus, thyme, and turpentine, whereas m-cymene (E20) is a constituent of the oil of blackcurrant (Ribes nigrum, Saxifragaceae). The corresponding phenols, thymol (p-cymen-3-ol) (E21) and carvacrol (p-cymen-2-ol) (E22), have been found to occur in many plants. Thymol (E21) is a constituent of thyme (Thymus vulgaris, Labiatae) and Orthodon angustifolium (Labiatae). Carvacrol (E22) has been found to occur in oils of thyme, marjoram, origanum, and summer savoy.

A different chemical diversity of monoterpenes is apparent from the natural occurrence of their bicyclic analogs that bear cyclopropane (carane and thujane types), cyclobutane (pinane type), and cyclopentane (camphane/bornane, isocamphane and fenchone types) rings (Figs. 6 and 7). The carane type of bicyclic monoterpenoids in plants is represented by (−)-3-carene...
Figure 6  Bicyclic cyclopropane and cyclobutane monoterpenoids.

Figure 7  Bicyclic cyclopentane monoterpenoids.

(F1) that occurs in Pinus longifolia (Pinaceae) and the related carboxylic acid, (+)-chaminic acid (F2), in Chamaecyparis nootkatensis (Cupressaceae). Compared with caranes, the thujane type of monoterpenoids is more abundant in plants. The hydrocarbon analog (−)-3-thujene (F3) has been found to occur in the oils of coriander (Coriandrum sativum), Eucalyptus, and Thuja occidentalis (Cupressaceae). Its regiosomer, (+)-sabinene (F4), occurs in Juniperus sabina (Cupressaceae). The hydration product of (−)-3-thujene, namely (−)-thujol (F5), occurs in plants belonging to the genera Thuja, Artemisia, and...
chemically diverse group of terpenoids known in nature. Like acyclic sesquiterpenes, about 10,000 sesquiterpenoids are known (32), and in the plant kingdom they commonly occur as hydrocarbons, alcohols, aldehydes, ketones, carboxylic acids, lactones, and oxiranes. The acyclic sesquiterpene hydrocarbons are the most thoroughly studied sesquiterpenoids, occurring in a large number of species, and in the plant kingdom they commonly occur as hydrocarbons, alcohols, aldehydes, ketones, carboxylic acids, lactones, and oxiranes. The acyclic sesquiterpene hydrocarbons, which are the most chemically diverse group of sesquiterpenoids known in nature, are included in this review.

Sesquiterpenoids

The C15 terpenoids known as sesquiterpenoids are the most chemically diverse group of terpenoids known in nature. Like monoterpenoids, many sesquiterpenoids contribute to the flavor and fragrance of a variety of plants. To date about 10,000 sesquiterpenoids are known (32), and in the plant kingdom they commonly occur as hydrocarbons, alcohols, aldehydes, ketones, carboxylic acids, lactones, and oxiranes. The acyclic sesquiterpene hydrocarbons are the most thoroughly studied sesquiterpenoids, occurring in a large number of species, and in the plant kingdom they commonly occur as hydrocarbons, alcohols, aldehydes, ketones, carboxylic acids, lactones, and oxiranes. The acyclic sesquiterpene hydrocarbons, which are the most chemically diverse group of sesquiterpenoids known in nature, are included in this review.

Figure 8: Acyclic plant sesquiterpenoids and their derivatives.
Natural Products in Plants, Chemical Diversity of

Figure 9  Cyclization modes of farnesane skeleton that lead to diverse monocyclic and bicyclic sesquiterpenoids.

respectively. Some elemene-type sesquiterpenoids present in plants are represented by (−)-bicycloelemene (I8) from peppermint (Mentha piperita) and M. arvensis and β-elemenone (I9) from Commiphora abyssinica. The humulane type of monocyclic sesquiterpenes, which contain an 11-membered macrocyclic ring, is also found in plants and includes regioisomeric α- and β-humulenes (I10 and I11, respectively) from Lindera strychnifolia (Lauraceae), and (−)-humulol (I12), all of which are important constituents of the essential oils from clove (Caryoppylli flos, Caryophyllaceae), hops (Humulus lupulus, Cannabaceae), and ginger (Zingiber zerumbeticum, Zingiberaceae). Bicyclic sesquiterpenoids are formed because of two
carbon–carbon bonds, each linking two carbon atoms of the farnesane skeleton together.

**Diterpenoids**

The diterpenoids, which contain 20 carbon atoms, are represented by acyclic, monocyclic, bicyclic, tricyclic, and tetracyclic structures. Over 5,000 naturally occurring diterpenoids, many of which frequently occur in plant families Araliaceae, Asteraceae, Cistaceae, Cupressaceae, Euphorbiaceae, Leguminosae, Labiatae, and Pinaceae, are known (32). The acyclic diterpenoid alcohol phytol (J1) (Fig. 11) is a part of the structure of chlorophyll. A group of monocyclic diterpenoids with a 14-carbon macrocyclic ring called cembranes [e.g., cembrene A (J2)] also occurs in plants and is represented by over 100 members (32). Among the other cyclic diterpenoids, the most abundant in plants are the bicyclic labdanes [e.g., (−)-forskolin (J3)], tricyclic abietanes [e.g., abietic acid (J4)], and tetracyclic kauranes [e.g., (−)-kaurane (J5)], represented respectively by 500, 200, and 100 members (32). Baccatin III (J6), which is the diterpenoid part of the well-known anticancer drug paclitaxel...
Triterpenoids and steroids

Triterpenoids and steroids are groups of natural products that contain about 30 carbon atoms. They have a common origin, and their structures can be considered as being derived from that of squalene. Triterpenoids are found mostly in the plant kingdom, whereas steroids occur in plants, animals, and microorganisms. The chemical diversity of plant triterpenoids results from the ability of the C30 precursor, squalene, to undergo various modes of cyclization and subsequent "decoration" reactions. The plant triterpenoids belong to two main groups, the tetracyclic and pentacyclic. The tetracyclic triterpenoids, which consist of dammarane (K1) and tricyclane (K2) among others, are regarded by some authors as methylated steroids. The group of pentacyclic triterpenoids is by far the most diverse and is divided into five main groups: friedelane (K3), lupane (K4), ursane (K5), oleanane (K6), and houpe (K7). (Fig. 12). The steroids are modified triterpenoids that contain the tetracyclic ring system present in lanosterol. Chemical diversity represented by steroids depends mainly on the nature of the side chain attached to the steroid nucleus. Most prevalent in the plant kingdom is stigmastane (K8) and cycloartane (K9) classes of steroids (Fig. 12).

Triterpenoids and steroids frequently occur in many plant species as their glycosides called saponins (33). The chemical diversity of saponins is dependent therefore on both the nature of the 30-carbon moiety and the carbohydrate residue. Some saponins contain carbohydrate residues attached to several different positions of the aglycone (triterpenoid or the steroid) skeleton. Saponins are classified into 11 main structural classes based on the carbon skeletons of their aglycone moiety (33). In addition to their soap-like behavior in aqueous solution because of this combination of polar (carbohydrate) and nonpolar (aglycone) structural elements, saponins exhibit a diverse range of pharmacological and medicinal properties. Within the plant kingdom saponins are present in two major taxonomic classes, Magneliopsida (dicot) and Liliopsida (monocot) (33). Some important examples of saponins include glycyrrhizic acid (K10) from licorice and digitoxin (K11) from foxglove (Digitalis purpurea).

Products of Shikimate Pathway

The shikimate pathway links the metabolism of carbohydrates to the biosynthesis of aromatic natural products via aromatic amino acids. This pathway, which is found only in plants and microorganisms, provides a major route to aromatic and phenolic natural products in plants. To date, over 8,000 phenolic natural products are known, which accounts for about 40% of organic carbon circulating in the biosphere. Although the bulk of plant phenolics are components of cell wall structures, many phenolic natural products are known to play functional roles that are essential for the survival of plants.

It has been noted that the chemical diversity of plant phenolics is as vast as the plant diversity itself. Most plant phenolics are derived directly from the shikimic acid (simple benzoic acids), shikimate (phenylpropanoid) pathway, or a combination of shikimate and acetate (phenylpropanoid-acetate) pathways.

Products of each of these pathways undergo additional structural elaborations that result in a vast array of plant phenolics such as simple benzoic acid and cinnamic acid derivatives, monolignols, lignans and lignin, phenylpropanoids, coumarins, stilbenes, flavonoids, anthocyanidins, and isoflavonoids.

Benzoic acid derivatives

As apparent from their structures, many benzoic acid derivatives are directly formed from shikimic acid by dehydration, dehydrogenation, and enolization reactions. Gallic acid is a component of gallotannins common in some plants that are used in the tanning of animal hides to make leather. Astringency of some foods and beverages, especially coffee, tea, and wines, is because of their constituent tannins. Other benzoic acid derivatives that occur in plants include protocatechual acid, 4-hydroxybenzoic acid, and salicylic acid.

Cinnamic acid derivatives

Cinnamic acid and its derivatives found in plants originate from the aromatic amino acids L-phenylalanine and L-tyrosine by the elimination of ammonia. Some common natural cinnamic acid derivatives include p-coumaric acid, caffeic acid, ferulic acid, and sinapic acid.

Monolignols, lignans, and lignin

The alcohols formed from some cinnamic acid derivatives, namely p-coumaryl alcohol, coniferyl alcohol (L1), and sinapyl alcohol (L2), commonly known as monolignols, undergo dimerization reactions that yield lignans such as (+)-pinoresinol (L3), (-)-sesamin (L4), (-)-matairesinol (L5), and podophyllotoxin (L6). (Fig. 13). Several thousand lignans are found to occur in nature. Lignins, the structural components of plant cell walls, are polymers of monolignols and/or lignans.

Phenylpropenes

Phenylpropenes are derived from cinnamic acid and its derivatives by a series of reductions and other transformations. Cinnamaldehyde, the first product of the reduction of cinnamic acid, occurs in the bark of cinnamon (Cinnamomum zeylanicum, Lauraceae). Several hydrocarbon analogs are also known to occur in plants. Anethole is the main constituent of oils from anise (Pimpinella anisum, Umbelliferae), fennel (Foeniculum vulgare, Umbelliferae), and star anise (Illicium verum, Illiciaceae). Eugenol is a major constituent of cinnamon leaf, whereas myristicin occurs in nutmeg (Myristica fragrans, Myristicaceae).

Coumarins

Coumarins derive their name from their precursor, α-coumaric acid. They occur widely in plants both in the free form and as...
Triterpenoid and steroid skeletons common in plants and structures of some saponins. Glycosides and are commonly found in families such as the Umbelliferae and Rutaceae. The parent compound coumarin (M1) is found in sweet clover (Melilotus alba, Leguminosae) and its hydroxyl derivative umbelliferone (M2) has been isolated from several Ferula spp. (Umbelliferae). Coumarins with complex structures also occur in plants and are formed by incorporating additional carbons derived from the mevalonate pathway. Alkylation of umbelliferone (M2) with dimethylallyl diphosphate (DMAPP) leads to demethylsuberosin (M3), which undergoes cyclization yielding marmesin (M4), the precursor of naturally occurring furanocoumarins, psorolen (M5), and bergapten (M6) (Fig. 14).

Stilbenes, flavonoids, anthocyanidins, and isoflavonoids

In contrast to other plant phenolics, the basic carbon skeleton of stilbenes, flavonoids, anthocyanidins, and isoflavonoids
indole, and imidazole ring systems. Alkaloids are also known to originate from aromatic amino acids, tyrosine, phenylalanine, tryptophan, anthranilic acid, and histidine, and thus contain pyrrolidine, pyrrolizidine, piperidine, quinolizidine, indolizidine, pyridine, quinoline, isoquinoline, indole, and imidazole ring systems. Alkaloids are also known to originate from mixed biosynthetic pathways, the most important of which include terpenoid and steroidal alkaloids. A limited number of alkaloids that contain a purine ring (e.g. caffeine) also occur in plants. Of the large number and variety of plant alkaloids, only a few are considered here for the purpose of illustration of their chemical diversity.

**Alkaloids derived from aliphatic amino acids and nicotinic acid**

Alkaloids that contain pyrrolidine and pyrrolizidine ring systems are derived from the nonprotein amino acid, L-ornithine. Cocaine (N1) and L-3,4-dihydroxyphenylalanine (L-DOPA), the two important pyrrolidine alkaloids that contain a piperazine ring system, have been found to occur in coca (Erythroxylon coca, Erythroxylaceae) leaves and whole plant of the deadly nightshade (Atropa belladonna, Solanaceae). The hepatotoxic alkaloid senecionine (N2) contains a bicyclic pyrrolizidine skeleton derived from two molecules of L-ornithine. Piperidine alkaloids, for example, piperine (N3), and pseudopelletierine, are known to be derived from the amino acid, L-lysine. Piperine is responsible for the pungency of black pepper (Piper nigrum, Piperaceae), whereas pseudopelletierine is a constituent of the bark of pomegranate (Punica granatum, Puniceae). The bicyclic ring system in quinolizidine alkaloids such as (+)-sparteine (N4) in the broom plant (Cytisus scoparius, Leguminosae) is derived from two molecules of L-lysine in a manner similar to the L-ornithine-derived pyrrolizidine ring system. Indolizidine alkaloids derived from L-lysine via the cyclic amino acid, L-3-piperidone, contain fused six- and five-membered rings with a nitrogen atom at the ring fusion. An important example of an indolizidine alkaloid is swainsonine (N5), which occurs in the leguminous plant Swainsona canescens. Alkaloids that contain a pyridine ring also occur in the plant kingdom. Two common plant-derived pyridine alkaloids, nicotine (N6) and anabasine, both of which are found in tobacco (Nicotiana tabacum, Solanaceae), contain a pyridine and a pyrrolidine or a piperidine ring, respectively (Fig. 13).

**Alkaloids derived from aromatic amino acids**

Aromatic amino acids that originate from the shikimate pathway also act as precursors to many alkaloids. A alkaloids that contain a phenylethylamine moiety are derived from L-tyrosine or its oxidation product L-DOPA. Mescaline (N7), originating from the latter amino acid is known to occur in several cacti and is responsible for the hallucinogenic activity of peyote (Lophophora williamsii, Cactaceae). Lophocerine is a tetrahydroisoquinoline alkaloid derived from L-dopa, and found to occur in a different Lophophora species, L. schottii. Condensation of two phenylethyl units derived independently from the same or different aromatic amino acid(s) leads to a variety of benzyltetrahydroisoquinolines, which, with additional structural modifications, produce a diverse range of alkaloids. (-)-Reticuline occurring in several plant species of Amonoea is an important benzyltetrahydroisoquinoline alkaloid that acts as a precursor to several pharmacologically active.
alkaloids such as papaverine (N8), (+)-tubocurarine (N9), and morphine (N10). Papaverine and morphine are known to occur in opium (Papaver somniferum, Papaveraceae) and are responsible for its narcotic activity, whereas (+)-tubocurarine (N9) is a muscle relaxant obtained from the arrow poison of the South American Indians, curare (Chondrodendron tomentosum, Menispermaceae). Phenethylisoquinoline alkaloids are similar structurally to benzylisoquinolines but as the name implies contain a phenylethyl moiety instead of a benzyl moiety as the pendant aromatic ring. Both (S)-autumnaline and the cyclized analog colchicine (N11) belonging to this class have been found to occur in the seeds of autumn crocus (Colchicium autumnale, Liliaceae).

Maximization of Chemical Diversity and Production of Natural Products in Plants

As is apparent from the foregoing discussion, plants produce a huge array of natural products, many of which are specialized secondary metabolites associated with particular plant species and/or having to play important ecological roles. It is likely that for diversification and survival of the plant kingdom, individual plants had to develop the ability to perform in vivo combinatorial chemistry by mixing and matching and evolving the genes required for different secondary metabolite biosynthetic pathways (34, 35). With the elucidation of several secondary metabolic pathways in plants together with the advent of techniques for the introduction of genes into plants and the availability of an increasing number of genes, it has become possible to modulate and diversify secondary metabolite production in transgenic plants and plant cell cultures.

Two general approaches for the production of long-chain polyunsaturated fatty acids usually found in fish oil have been employed, both of which used 18 carbon fatty acids endogenous to plants as the starting substrates (36). Soybean and canola, the oilseed plants rich in omega-6 fatty acids, have been engineered to produce omega-3 polyunsaturated fatty acids such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) (37, 38). Chalcone synthase (CHS), the first plant natural product polyketide synthase (PKS) to be characterized at the molecular level (39), catalyzes the condensation of 4-coumaryl-CoA with three molecules of malonyl-CoA to afford naringenin chalcone, a precursor of the major classes of plant flavonoids. The cloning of a novel type III polyketide chalcone synthase (PCS) from aloe (Aloe arborescens, Liliaceae) rich in aromatic polyketides, especially quinones such as aloe-emodin and emodin, resulted in...
PCS-catalyzed condensation of five molecules of malonyl-CoA to produce 5,7-dihydroxy-2-methyl chromone new to this plant (40). Another novel Aloe arborescens type III PKS that produces two hitherto unknown aromatic octaketides, SEK4 and SEK4b, has recently been reported (41). The application of plant cell cultures for the production of the polyketide hypericin from St. John’s wort (Hypericum perforatum, Hypericaceae) has been investigated (42).

To date over 30 plant terpenoid synthases have been cloned as cDNAs, and many of these were found to encode enzymes of secondary metabolism (43). Isolation and analysis of six genomic clones encoding monoterpene (\((-\)-pinene and \((-\)-limonene), sesquiterpene (\(\alpha\)-\(\delta\)-selinene) and diterpene (abietadiene) synthases from Abies grandis, and a diterpene (taxadiene) synthase from Taxus brevifolia have been reported (44). Overexpression of a cotton farnesyl diphosphate synthase (FPPS) in transgenic Artemisia annua has resulted in 3- to 4-fold increase in the yield of the sesquiterpenoid anti-malarial drug, artemisinin, in hairy roots (45).

Plant cell culture, an environmentally friendly and renewable alternative for the production of plant natural products, has also been investigated to obtain taxane diterpenoids from Taxus sp. (46–48) and terpene indole alkaloids from the Madagascar periwinkle (Catharanthus roseus) (49). A recent study has provided evidence for the production of novel terpene indole alkaloids using both differentiated Catharanthus roseus (seedlings) and hairy root culture (50).

Natural products have played a vital role in the treatment of human ailments for thousands of years and continue to play a big role in the modern discovery of new agents for the treatment of diseases today. In certain therapeutic areas, natural products account for almost all key modern medicine used today. Many drugs are formulated and used directly as they are found in nature, some are derived directly from natural products by semisynthesis, and others are modeled after natural products. In this overview, examples of the pharmaceutically important natural products have been summarized.

Introduction

Natural product preparations have played a vital role in empiric treatment of ailments for thousands of years in many advanced civilizations and continue to play a significant role even today in various parts of the world. The use of plants and preparations derived from plants has been the basis for the sophisticated medical treatments in Chinese, Indian, and Egyptian civilizations for many thousands of years. These medical applications have been documented in the Chinese 萩经 (1100 BC), in the Indian Ayurveda (1000 BC), and in Egyptian medicine as early as 2900 BC. Plant preparations continued to be the basis of medical treatments in the ancient Western world as well. This knowledge migrated through Greece to Western Europe, including England, during the ancient period and led to its formal codification in the United Kingdom and to the publication of the London Pharmacopoeia in 1618.

The isolation of strychnine (1), morphine (2), atropine (3), colchicine (4), and quinine (5) in the early 1800s from the commonly used plants and their use for the treatment of certain ailments might constitute the early idea of "pure" compounds as drugs. E. Merck isolated and commercialized morphine (2) as the first pure natural product for the treatment of pain (1–3). Preparations of the Willow tree have been used as a painkiller for a long period in traditional medicine. Isolation of salicylic acid (6) as the active component followed by acetylation produced the semisynthetic product called "Aspirin" (7) that was commercialized by Bayer in 1899 for the treatment of arthritis and pain (4).

The World Health Organization estimates that herbal and traditional medicines, derived mostly from plants, constitute primary health care for ~89% of the world population even today. The compounds produced by plants play significant roles in the treatment of diseases for the rest of the 20% of populations that are fortunate to use modern medicine. About 50% of the most prescribed drugs in the United States consist of natural products or their semisynthetic derivatives, or they were modeled after natural products. "Curare," the crude extract from the South American plant, Chondodendron tomentosum, and the derived purified compound tubocurarine, has been used as anesthetic in surgery until recently. Purified digoxin, as well as the crude extracts that contain digitalis's glycosides from foxglove plant, Digitalis lanata, is used as cardiotoxic even today.

Drugs derived from microbial fermentations have played perhaps a bigger role in the modern drug discovery and have revolutionized the practice of medicine, which leads to saving human lives. Although the contribution of purified natural products as single agent drugs is significant in almost all therapies, their contribution in the treatment of bacterial infection is perhaps most critical (5). Natural products constitute drugs or leads to all but three classes of antibiotics. The discovery of microbial natural products-based antibiotics began with the serendipitous observation by Fleming in 1929 that bacterial growth was prevented by the growth of Penicillium notatum. Although this discovery was highly publicized and very important, it took over 10 years before the active material, penicillin, was purified and structurally elucidated by Florey and Chain in early 1940s. Subsequent commercialization was very quick, driven largely by the medical needs of World War II. Penicillin was one of the first broad-spectrum antibiotics that treated bacterial infection and saved millions of lives. Fleming, Florey, and Chain were awarded the Nobel Prize in 1945 for their efforts on penicillin. The success of penicillin led to unparalleled efforts by government, academia, and the pharmaceutical industry to focus drug-discovery efforts based on the newfound "microbial"
sources for the discovery of natural products beyond plants. However, initial efforts were mostly focused on the discovery of antibiotic compounds from fermentations of a variety of microorganisms of not only fungal origin but also soil-dwelling prokaryotes (e.g., Streptomyces spp.), which led to the discovery by 1962 of almost all novel classes of antibiotic scaffolds that are being used today. The antibiotic discovery effort was performed largely by Fleming’s method of detection of antibacterial activity on petri plates. Zones of inhibition of bacterial strains on agar plates were measured after applying whole broth or extracts obtained from microbial ferments (5). As newer biological assays and screening techniques became available in the 1960s, microbial sources, along with plant and marine sources, started to be used for screening against other therapeutic targets, which led to the discovery of leads and drugs in those areas. Examples of these discoveries will be discussed with the target area. As time progressed, improved technologies in biology and chemistry helped with the popularization of natural products; natural product extracts became part of the screening resource in most large pharmaceutical houses from 1960 through the 1980s until their de-emphasis in the early 1990s. Therefore, natural product extracts became popular sources for the screening against purified enzymes and receptors, an occurrence that led to the discovery of leads and drugs in those areas. Examples of these discoveries will be discussed with the target area. As time progressed, improved technologies in biology and chemistry helped with the popularization of natural products; natural product extracts became part of the screening resource in most large pharmaceutical houses from 1960 through the 1980s until their de-emphasis in the early 1990s. Therefore, natural product extracts became popular sources for the screening against purified enzymes and receptors, an occurrence that led to the identification of many nonantibiotic natural products that have revolutionized the practice of medicine, saved countless human lives, improved quality of life, and perhaps helped increase life expectancy for humans.

**Antibacterial Agents**

Natural products contribute to over 80% of all antibiotics that are in clinical practice today. Natural products contribute to all but three classes of antibiotics (3).

Penicillin was the first β-lactam and the first broad-spectrum antibiotic discovered that started the “Golden age” (1940–1962) of antibiotics. The structure of penicillin contains a thiazolidine ring that is fused to a β-lactam ring. The existence and stability of the β-lactam ring was highly controversial at the time despite the availability of a single crystal X-ray structure of one of the penicillins. Penicillin G (8) was the first penicillin that was clinically used. Penicillin G was converted easily by chemical or biochemical means to β-amino-penicillanic acid (9), which became the lead for the semisynthetic modifications that led to the synthesis of various penicillin derivatives. Some early derivatives (e.g., amoxicillin 10) are still in clinical use. Penicillin (general structure 11) bind to penicillin-binding proteins and inhibit the bacterial cell wall. Penicillins became targets of β-lactamases without having significant intrinsic antibacterial effectiveness of these compounds (11, 12). Cephalosporin C (12), a second class of β-lactam antibiotics, was first discovered from Cephalosporium acremonium, isolated from a sewer outfall of Sardinia, Italy in 1948. Although Cephalosporin C was less active than penicillin G, it was less prone to β-lactamase action and therefore attracted a lot of attention that led to the development of five generations of orally active clinical agents (e.g., cephalexin, 13 and general structure, 14, 5, 6).

Continued search for even better antibiotics led to the discovery of highly potent and broad-spectrum antibiotic thienamycin (15), the third class of the β-lactams, called carbapenems, in which the sulfur atom of the thiazolidine ring was replaced by a methylene group. Thienamycin was produced by Streptomyces cattleya (17). The primary amine group of thienamycin self-catalyzes the opening of the β-lactam ring, which leads to the concentration-dependent instability that poses a serious challenge for the fermentation-based production of the compound. The Merck group stabilized the compound by replacing the primary amine with an aminomethylideneamino group and synthesized imipenem (16) (8). They developed a highly efficient total synthesis that remains in commercial use today. Imipenem was approved for clinical use 23 years ago in 1985, but it remains one of the most important broad-spectrum hospital antibiotics in the market today. Like other β-lactams, several generations of carbapenems (general structure 17) have been approved for clinical use in recent years (9). As resistance to β-lactam antibiotics increased because of the expression of a variety of β-lactamases, many groups focused their efforts on discovering compounds that could be more reactive to β-lactamases without having significant intrinsic antibacterial activity of their own and pharmacokinetic properties that would be similar to β-lactam antibiotics. This focus led to the discoveries of clavulanic acid (18) and monobactam sulfazecins (19). Nature effectively stabilized the latter monobactam structure by the addition of a 4-thiulamic acid. The β-lactamase inhibitor clavulanic acid was combined with amoxicillin, which...
led to the development of a potent and successful antibacterial agent, Amoxicillin (10) (GSK, Surrey, UK) (10). Chemical modifications of the monobactam produced aztreonam (20), a clinical agent with a narrow spectrum but significantly improved activity against Gram-negative pathogens, particularly Pseudomonas aeruginosa (11).

Immediately after the discovery of penicillin, Waksman started efforts on soil-dwelling bacteria and discovered the first of the aminoglycosides, streptomycin (22) from Streptomyces griseus, in 1943 (6). Subsequently, a series of aminoglycosides was isolated. These aminoglycosides are potent broad-spectrum antibiotics and are potent inhibitors of protein synthesis. Unfortunately, nephrotoxicity limited their wider use, and they are used mainly for treatment of infections caused by Gram-negative bacteria. Continued efforts to screen prokaryotic organisms led to the discovery of the phenylpropanoids (chloramphenicol, 23) and tetracyclines. The latter is a major class of tetracyclic polyketides that were discovered from various species of Streptomyces spp. Although the parent tetracycline (22) was not used as an antibiotic to a great extent, the chloro derivative (Clotrimocycline 24), oxytetracycline (25), and minocycline (26) are clinical agents. This class of compound suffered from the selection for rapid resistance via efflux mechanism that limited their use (6). Recently, however, chemical modifications of the A-ring yielded compounds that overcame the efflux pump and lead to the development of tigecycline (27), as an effective broad-spectrum antibiotic (12).

Another large class of orally active protein synthesis inhibitor antibiotics that were produced by Streptomyces spp. is represented by 14-membered lactones generally called macrolides, exemplified by the first member, erythromycin (28) (6). Chemical modifications of this class of compounds led to many clinical agents such as the aza derivatives, azithromycin (29) and ketolide (telithromycin, 30) (13, 14). Mupirocin (pseudomonic acid, 31) is another protein synthesis inhibitor that was isolated from Pseudomonas fluorescens and is used only as a topical agent (6).

Vancomycin (32), a glycopeptide produced by Streptomyces orientalis, is a key Gram-positive antibiotic, originally discovered in 1954, and remains a critical antibiotic in clinical practice even today for the treatment of Gram-positive bacterial infections (6). Teicoplanin (33), a related glycopeptide produced by Streptomyces teicomyceticus, is a newer antibiotic that complements vancomycin in the clinic but is not effective against vancomycin-resistant bacteria. Ramoplanin (34) represents another glycopeptide that is larger in molecular size and structurally different from vancomycin and teicoplanin; it is in the late stages of clinical development for treatment of Gram-positive bacterial infections. Glycopeptides inhibit the bacterial cell wall. Daptomycin (35), a cyclic lipopeptide produced by Streptomyces roseosporus, is one of the newest members of antibiotics approved for the clinical practice as a broad-spectrum Gram-positive agent. It works by depolarization of the bacterial cell membrane (14). Streptogramins were discovered in the early 1960s but were used for humans only recently when a 70/30 mixture of dalfopristin (36) and quinupristin (37) with the trade name Synercid (King Pharmaceuticals, Bristol, N.J.) was developed for the treatment of drug-resistant Gram-positive bacterial infections (15).

Antibiotics from natural sources range from compounds with small molecular size (e.g., thienamycin) to large peptides (e.g.,
ramoplanin). They generally possess complex architectural scaffolds and densely deployed functional groups, which affords the maximal number of interactions with molecular targets and often leads to exquisite selectivity for killing pathogens versus the host. This function is nicely illustrated by vancomycin binding to its target. Vancomycin has five hydrogen bond contacts with the D-Ala-D-Ala terminal end of peptidoglycan. Resistant organisms modify the terminal D-Ala with D-lactate, which leads to loss of one hydrogen bond and a 1000-fold drop in binding affinity and loss of antibiotic activity (see Fig. 1).  

Antifungal Agents
Significant similarities in the fungal and mammalian cellular processes result in very few fungal-specific drug targets that lead to the development of only a few quality and safe antifungal agents. Amphotericin B (38), a natural product that consists of a polyene lactone, is a highly effective broad-spectrum antifungal agent unfortunately with a very limited safety margin. Recently, glucan synthesis was identified as a fungal-specific target that could be inhibited by a series of cyclic peptides called echinocandins, which were identified in the 1970s as having potent antifungal activities (16, 17). This identification provided impetus for the discovery and development of new related lipopeptides that led to the identification of pneumocandins from Glarea lozoyensis (e.g., pneumocandin Bo, 39). Chemical modifications at two sites of pneumocandin Bo led to the synthesis of caspofungin (40), which was the first in the class of glucan synthesis inhibitors; it is a "potent", highly effective, and safe antifungal agent approved for serious fungal infections in hospitals. Side chain replacements of the related cyclic peptide...
FR901379 (isolated from the fungus Coleophoma empetri) and echinocandin B (isolated from Aspergillus nidulans) led to two additional clinical agents of this class, micafungin (41) and anidulafungin (42), respectively. (16, 17)

**Antimalarials**

Quinine (5) isolated from Cinchona bark was one of the first antimalarials discovered, and it became a model for the discovery and development of some of the most successful antimalarial agents, chloroquine and its successors. However, the development of resistance by the malarial parasite *Plasmodium falciparum* for these drugs has rendered them ineffective. Artemisinin (43), a sesquiterpene peroxide originally isolated from a Chinese herb *Artemisia annua* in 1972 as an antimalarial agent, was chemically modified to a derivative, artemether (44), which is a very effective and widely used antimalarial agent (18). Unfortunately, limited supply of this plant-derived compound rendered it inaccessible for wider use. Recently, biosynthetic genes of artemisinin have been identified and successfully transfected to an heterologous host, *Escherichia coli*. This method has allowed the production of an intermediate, amorphadiene (45) and artemisinic acid (46), which could be
transformed chemically to artmether and potentially could relieve the strain of supply and could provide wider availability (19–21).

**Antivirals**

Most antiviral agents are based on nucleoside structures and have their origin from spongouridine (47) and spongothyminidine (48) that were isolated from marine sponges in the 1950s by Bergmann and his coworkers (22–24). These natural nucleosides possessed sugars other than ribose and deoxyribose and provided rationale for the substitution of the sugars in the antiviral nucleosides with various sugar mimics, including linear polar groups that led to the synthesis of Ara-A (49) and acyclovir (50). HIV protease inhibitors were developed from pepstatin (51), a pepsin inhibitor produced by various fungal species. Pepstatin possesses as the structural component statine a β-hydroxyγ-amino acid that mimics the transition-state intermediate of the hydrolytic reaction catalyzed by the proteases (25). This structure became the foundation for the rational peptidomimetics and design of all HIV protease inhibitors, for example, indinavir (Crixivan®, Merck & Co., Inc., Whitehouse Station, NJ; 52) and others (26).
Antipain Agents

Use of the opium poppy (Papaver somniferum) to ameliorate pain dates back thousands of years, and the active metabolite morphine (2) was isolated first from its extracts in 1806 followed by codeine (53) in 1832 (27, 28). Morphine and its derivatives are agonists of opiate receptors in the central nervous system and are some of the most effective pain relievers known and prescribed for postoperative pain. Morphine and codeine differ by substitution by methyl ether. Unfortunately, addictive properties of these compounds limit their use. Efforts have been made to reduce the addictive properties of morphine, which resulted in a semisynthetic derivative buprenorphine (54) (29). This compound is 25 to 50 times more potent than morphine with lower addictive potential and has been indicated for use by morphine addicts.

Conotoxins, a class of 10 to 35 amino acid-containing peptides produced by cone snails to intoxicate their prey, were isolated and characterized by Olivera and coworkers (30). They are a novel class of analgesics that helped identify the target and blocking of N-type Ca\(^{2+}\) channels. One compound, Ziconotide (55), was synthesized and developed as a treatment for severe chronic pain (31, 32).

The alkaloid epibatidine (56) was discovered from the skin of an Ecuadorian poison frog (Epipedobates tricolor), and its...
potent analgesic activity was demonstrated as early as in 1974 by Daly and coworkers (33–35). The paucity of the material delayed the structure elucidation and was only accomplished after the invention of newer and more sensitive NMR techniques in 1980s. Once the structure was elucidated as chloronicotine derivative, it was synthesized and was shown to antagonize nicotinic acetylcholine receptor, is about 50-fold more potent than morphine without addictive properties, and was under advanced clinical development until its discontinuance in 2003 (36–39).

Antineoplastic Agents

Natural products have played a much bigger role, perhaps second only to antibacterial agents, in the discovery and development of anticancer agents either directly as drugs or leads to drugs (48). In fact, they contribute 64% of all approved cancer drugs (3). Taxol® (paclitaxel) is unarguably the most successful anticancer drug in clinical use. It is a taxane diterpenoid that was isolated from the Pacific yew Taxus brevifolia in 1967 as a cytotoxic agent but not pursued as a development candidate until its novel mode of action was determined in 1979 as a stabilizer of microtubule assembly (49–52). The discovery of the mechanism of action led to the United States National Cancer Institute (NCI) committing significant resources to the large-scale production, eventual clinical development, and approval of Taxol® (paclitaxel) by U.S. Food and Drug Administration in 1992 for treatment of breast, lung, and ovarian cancer. Another important plant product, camptothecin (62), an alkaloid from Camptotheca acuminata, was discovered in 1966, also by the Wall and Wani group (53). The development of this compound was also hampered by the lack of knowledge of the mechanism of action and most importantly by its extremely poor water solubility. Determination of the mechanism of action as an inhibitor of topoisomerases-I led to significant efforts both by NCI and the pharmaceutical industry, which resulted in chemical modification of the structure, introduction of water-solubilizing groups (e.g., amino), and development of several derivatives as anticancer agents exemplified by topotecan (63) and irinotecan (64) (54, 55).

Alzheimer’s Agents

Galantamine (60) is a tetracyclic alkaloid that was isolated originally from G. nivalis and subsequently from Narcissus spp. (45). It was approved by trade name Reminyl® by Johnson & Johnson, New Brunswick, NJ for the treatment of Alzheimer’s disease. That galantamine, a selective inhibitor of acetylcholinesterase, was confirmed by X-ray structural characterization of galantamine bound to a plant acetylcholinesterase (46, 47).
compounds bind to tubulin and inhibit cell division by inhibiting mitosis; they were perhaps the best-known anticancer agents before Taxol. Chemical modifications of vinblastine led to the clinical agents vinorelbine (66) and vindesine (67) (48 one, 59–61). Podophyllotoxin (68) was isolated from various species of the genus Podophyllum spp. as an anticancer agent. Chemical modifications of the naturally occurring epimer, epipodophyllotoxin (69), led to the synthesis and development of etoposide (70) and teniposide (71) as clinical agents (48, 54, 62–65).

Combretastatin A4 phosphate (72) is a phosphate prodrug of combretastatin A4, a cis-dilene, isolated from Combretum caffrum (66). Combretastatin A4 is one of the many combretastatins that inhibits tubulin polymerization (67), shows efficacy against solid tumor, is a vascular targeting agent that blocks the blood supply to solid tumors, and is in Phase III clinical development for the treatment of various types of tumors as a vascular targeting agent (68–71).

Microbial sources have been a very rich source for cancer chemotherapeutic agents. Of particular note is the Streptomyces spp., which has been responsible for the production of many approved anticancer agents that are in clinical practice. These agents are represented by highly diverse structural classes exemplified by the anthracycline family (e.g., doxorubicin, 73) (72–74), actinomycin family (e.g., dactinomycin, 74), glycopeptides family (e.g., bleomycins A2 and B2, 75 and 76), and mitomycin family (e.g., mitomycin C, 77) (72, 76). All these compounds specifically interact with DNA for their mode of action.

Staurosporine (78) produced by Streptomyces spp. is a potent inhibitor of protein kinase C (77–79). This compound inhibits many other kinases with almost equal potency and has become a great tool for the study of kinases. Lack of selectivity for protein kinase C has significantly hampered the development of this compound. Recently, however, several compounds derived from this lead have entered into the clinic for potential treatment of cancer. These include 7-deoxystaurosporine (79) and CGP41251 (80, 81). CGP41251 shows multiple modes of action including inhibition of angiogenesis in vivo.

Microbial sources other than Streptomyces spp. have also provided highly interesting and structurally diverse compounds. Discovery of epothilones from myxobacterial strains by a German group (82) and the Merck group (83, 84) constitute a breakthrough discovery. The Merck group used an assay that mimicked Taxol at the active site for the screening of natural products that led to the isolation of epothilones A (81) and B (82). The discovery of a unique structural class, interfering biological activity, and clinically proven mode of action drew significant attention from the scientific community and led to a variety of approaches, including combinatorial biosynthesis, chemical modifications, and total synthesis, that permitted preparation of many derivatives with improved potency and drug-like properties. A series of these compounds have entered human clinical trials, and many are in the late stages of development. Epothilone discovery and development has been recently reviewed (85).

Recent pursuit of marine microbial sources led to the isolation of salinosporamide A (83). It is a β-lactone produced by the marine bacteria Salinispora tropica and is a proteasome inhibitor (86). Mechanistically, it works by specific covalent modification of the target. This compound has entered human clinical development for treatment of multiple myeloma (87–89).

Although use of marine microbial sources for the discovery of natural products is a somewhat recent phenomenon, marine natural products from higher species have contributed tremendously to the discovery of novel architecturally complex compounds as anticancer agent leads with one, Ecteinascidin 743, now approved in the European Union for treatment of sarcoma. The discovery of natural products derived from marine sources exploded in the 1970s not only because of increased...
level of NCI funding but also because of technological advancements in the techniques for collection of specimens, chemical isolation, and structural elucidation of low amounts of compounds initially isolated. Because of the fear of a limited supply of marine sources for large-scale production, marine natural products have remained the exclusive purview of academia except for a small Spanish pharmaceutical company, PharmaMar, which collaborates closely with academia and governments. Bryostatins are among the most interesting marine natural products known. They were isolated from the bryozoan Bugula neritina. They are a series of polyketide macro lactones represented here by the major congener bryostatin I (84), which is a modulator of protein kinase C, and has been subjected to several human clinical trials (90, 91). Recently, combination studies have been recommended for Phase I and Phase II trials, mainly under the auspices of the NCI. Modeling studies along with a diligent chemical design approach has led to the synthesis of a simplified analog (85) that has been shown to be equally active as bryostatin I in most in vitro studies (92, 93). This compound stands a better chance of being produced at larger scale by total synthesis.

Dolastatins are a class of peptides comprised of mostly nonribosomal amino acids. They were isolated from a sea hare Dolabella auricularia (94). Dolastatin-10 (86) is one of the most potent and the best-studied members (95, 96). It exerts antitumor effect by inhibiting tubulin polymerization and binds at the vinca alkaloid binding site (97, 98). Dolastatin-10 has been studied in Phase II human clinical trials but was discontinued because of lack of efficacy (99). Auristatin PE (77), a synthetic analog, seems to be more promising and is being studied in Phase II human trials (100).

Discodermolide (88) was isolated from Discodermia disso-
lute by using a P388 cell line toxicity bioassay; later it was determined that it stabilized microtubule assembly better than Taxol® and it drew a lot of attention as an anticancer agent (101, 102). Its development, like that of many other complex marine natural products, was hampered because of the lack of ample supply of the material required for the clinical studies. In this case, the supply problem was overcome by the synthetic efforts of the Novartis process group. They synthesized it on a large enough scale to allow clinical studies. Unfortunately, its development seems to have been halted because of toxicity at Phase I (103, 104).

Several other novel, structurally and mechanistically diverse marine natural products have entered various preclinical and clinical studies. One of these products is ecteinascidin-743 (89), ET-743), isolated from the tunicate Ecteinascidia turbinata (105, 106) and recently approved for the treatment of sarcoma in the European Union as the first “direct-from-the-sea” drug. Total synthesis and methods developed during the total synthesis allowed the preparation of a simpler analog phthalascidin (90) with comparable activities (107–109).

Hemiasterlin (92), a tripeptide isolated from a sponge that was chemically modified to HTI-286 (92), which binds to the vinca binding site of tubulin, depolarizes microtubules; it entered into clinical development but was apparently dropped (110, 111).

One difficulty with the cytotoxic agents that are used for the treatment of cancer is the differentiation of cytotoxicity between target tumor cells and normal cells. In an innovative approach, the Wyeth group took advantage of a tumor cell-specific drug delivery mechanism of antibodies. They conjugated calicheam-
icin (93), perhaps the best described member of the ene-dyne
Immunosuppressant Agents

Natural products represent essentially all clinically used immunosuppressant agents. These agents collectively have made organ transplant possible. Cyclosporin (95) is an N-methyl cyclic peptide and originally was isolated from the fungus Trichoderma polyergus as an antifungal agent; almost immediately, the inhibition of T-cell proliferation and in vivo immunosuppressive properties were discovered and led to the development and approval of this molecule as a highly effective immunosuppressive agent (116–118). Natural products isolation of related compounds allowed the discovery of new congeners with reduced or no immunosuppressive activity in favor of antifungal and various other biological activities (e.g., antiparasitic activity) and asthma (119, 120). FK506 (96), a macrocyclic lactone, discovered from Streptomyces tunicatus (97) as an immunosuppressive agent (121–125), was approved for clinical use for organ transplant as Tacrolimus (98). Astel- las, Tokyo, Japan (126). Rapamycin (99), another macrocyclic lactone that is a very potent immunosuppressive agent, was approved as Sirolimus (100). Wyeth, Madison, NJ for clinical use for transplant rejection (127, 128). Rapamycin was isolated from Streptomyces hygroscopicus (129, 130). Mechanistically, all three of these compounds bind to their specific intracellular receptors, immunophilins, and the resulting complexes target the protein phosphatase, calcineurin (cyclosporin and FK506), and mammalian target of rapamycin (mTOR) to exert their immunosuppressive effects (131–133). Rapamycin and FK506 have played significant roles in studies of signal transduction and identification of various targets for other therapeutic applications, such as mTOR. Mycophenolic acid (101) originally was isolated from various species of Penicillium, and its antifungal activity has been known since 1932 (134). Mycophenolate was approved for acute rejection of kidney transplant (135, 136).

Cardiovascular Agents

The biggest impact made by natural products in the treatment of cardiovascular diseases is undoubtedly associated with the discovery of the first of the HMG CoA reductase inhibitors by enzyme-based screening of microbial extracts that led to the isolation (from Aspergillus terreus) and characterization of mevinolin (lovastatin 102), which binds to CD33 antigens expressed on the surface of leukemia blasts. Mylotarg (103), which is a homologue of compactin (300) that was discovered earlier (137, 138). These compounds possess a lipophilic hexahydrodecalin, a 2-methylbutanoate side chain, and a β-hydroxy-γ-lactone connected to the decalin unit with a two-carbon linker. These compounds are potent inhibitors of HMG CoA reductase, the rate-limiting enzyme of cholesterol biosynthesis, and inhibit the synthesis of cholesterol in the liver. Lovastatin (Mevacor®) Merck & Co., Inc., Whitehouse Station, NJ; was the first compound approved for lowering cholesterol in humans and became the cornerstone of all cholesterol-lowering agents generically called “statins.” The modification of 2-methylbutanoate to 2,2-dimethylbutanoate led to the semisynthetic derivative, simvastatin (Zocor®) Merck & Co., Inc., Whitehouse Station, NJ; 101), the second and more
effective agent approved for human use (139). Hydroxylation of compactin by biotransformation led to pravastatin (Pravachol™, BMS, NY) (139). The key pharmacophore of the statins is the \( \beta \)-hydroxy-\( \beta \)-lactone or open acid. As the importance and value of cholesterol lowering to human pathophysiology became clearer, the search for additional cholesterol-lowering agents became more prominent and led to the discovery and development of several other clinical agents. All these compounds retained nature’s gift of the pharmacophore, \( \beta \)-hydroxy-\( \beta \)-lactone (or open acid), with replacement of the decalin unit of the natural products with a variety of aromatic lipophilic groups that resulted in fluvastatin (105) (141), Cerivastatin (105, withdrawn from the clinic) (142), Rosuvastatin (105), and Pitavastatin (107). The statins have had tremendous impact in improvement of overall human health and quality of life because of the lowering of low-density lipoprotein (LDL) particles, which leads to a reduction in the incidence of coronary heart disease; arguably, they are the most successful class of medicines.

Ephedrine (108), isolated from the Chinese plant Ephedra sinica, was approved as one of the first bronchodilators and cardiovascular agents. This discovery led to a variety of such antihypertensive agents including \( \beta \)-blockers (4). An angiotensin-converting enzyme (ACE) converts angiotensin I to angiotensin II, and its inhibition has led to several very successful, clinically useful antihypertensive agents. Although these inhibitors are of synthetic origin, the original lead was modeled after a nonapeptide, teprotide (109). This peptide was isolated from snake (viper, Bothrops jararaca) venom by Ondetti et al. It had antihypertensive activity in the clinic by parenteral administration (138, 144, 145) but was devoid of oral activity. Ondetti and coworkers worked diligently, and, recognizing that ACE was a metallo-enzyme, they visualized the binding of a smaller snake-venom peptide SQ 20475 (110) with ACE; they modeled an acyl-proline with a sulfhydryl substitution at the zinc binding site, which led to the design and synthesis of captopril (111) as an orally active highly effective antihypertensive clinical agent. Additional application of the rational design by Patchett and coworkers led to the synthesis of enalapril (112) and other clinically relevant oral ACE inhibitors (138).

**Antiparasitic Agents**

Avermectins (113, 114) are a series of macrocyclic lactones that are broad-spectrum, highly potent, glutamate-gated, chloride channel-modulator antiparasitic agents produced by Streptomyces avermitilis (146, 147). Ivermectin, 23,24-dihydroavermectin \( B_1a/B_1b \) (115), was the first product approved in the mid-1980s for treatment of intestinal parasites in domesticated and farm animals, and it remains the standard of care (148, 149). The remarkable activity of ivermectin against Onchocerca volvulus, the causative parasite of onchocerciasis (river blindness), led to clinical development and the approval of Medizin™ Merck & Co., Inc., Whitehouse Station, NJ, for the treatment of such diseases. These parasitic diseases have debilitated millions of people in many countries in Africa and South America. Because Medizin™ is a very effective treatment, Merck is providing this drug free of cost to all people in need as a part of the “Medizin Donation Program,” which

Spinosyns were discovered from the fermentation broth of Saccharopolyspora spinosa by screening for mortality of blowfly larvae, and a mixture of spinosyns A (136) and D (137) was approved and used successfully as a crop protection and antiparasitic animal health agent. (151) Nodulisporic acids are an indole diterpenoid class discovered from various species of Nodulisporium as orally active antiflea and antitick agents for dogs and cats (152, 153). The most active of the series is nodulisporic acid A (138), which selectively modulates the activity of insect-specific glutamate-gated chloride channels (153).

Pharmaceutical Models

The roles played by natural products as models for design and development of pharmaceutical agents are too many to cover in this overview. A few examples are illustrated during the discussions of specific disease areas above. For example, a...

marine sponge-derived nucleoside was the precursor for various nucleoside-based antiviral agents, pepstatin for renin and HIV protease inhibitors, snake venom peptide for ACE inhibitors, lovastatin andcompactin for all statins, and ephedrine for many painkillers and β-blockers. Below are a few critical examples that have played a big role in defining leads for some therapeutic areas but have not resulted in a drug yet.

Asperlicin (119) was isolated from Aspergillus alliaceus as a weak cholecystokinin A receptor (CCK-A) antagonist by using CCK receptor binding screening assays (154). It is a competitive antagonist of CCK-A (but not CCK-B) but did not have sufficient potency or oral activity to qualify as a drug candidate. In a remarkable strategy, medicinal chemists simplified the molecule to a benzodiazepine core of asperlicin, which led to the synthesis of potent, safe, and orally active analogs (120 and 121) with selectivity for either CCK-A (120) or CCK-B (122) receptors. They entered human clinical trials but were abandoned because of lack of efficacy (155, 156). The benzodiazepine scaffold was coined as “privileged structures” by Evans et al (155). This discovery is a beautiful demonstration of how a natural product became a model for the CCK program and played a pivotal role in defining the entire field (138).

The second example is apicidin (122), which is a cyclic tetrapeptide isolated from a fungus Fusarium pallidoroseum by using an empiric antiprotozoal screen (157, 158). It showed potent inhibition of apicomplexan protozoa including the malarial parasite Plasmodium falciparum and coccidiosis parasite Eimeria spp. It was effective in vivo against reducing malaria parasite infection in a mouse model (157) and exhibited strong activity against tumor cell lines (159, 160). Cyclic tetrapeptides with a terminal epoxy-ketone were known to be effective cytotoxic agents before the discovery of apicidin, but the pharmacophore was associated with the epoxy-ketone group (e.g., Trapoxin B, 123) with covalent modification as a mode of action. Apicidin does not contain the epoxy-ketone but showed potent antitumor activity (161). The mode of action of apicidin was shown to be the inhibition of histone deacetylase (HDAC) (157). The amino-oxo-decanoic acid (L-Aoda) mimics the acetylated lysine residue and positions itself at the zinc-binding site of HDAC (162). Chemical modification of apicidin with retention of the ethyl or methyl ketone led to the synthesis of small dipeptides (e.g., 124) that retained the HDAC and tumor cell line inhibitory activities with significant reduction of inhibition of normal cells (161).
 discovery of the fatty acid synthesis inhibitor antibiotic platensimycin (125) (163, 164) and platencin (126) (165, 166). The former shows exquisite selectivity for FabF, whereas the latter compound is a balanced inhibitor of both condensing enzymes, FabF and FabH.

Polyketide Biosynthesis, Fungi

Thomas J. Simpson and Russell J. Cox, School of Chemistry,
University of Bristol, Bristol, United Kingdom
doi: 10.1002/9780470048672.wecb458

Fungi produce a wide variety of biologically active compounds. Among these compounds, the polyketides form a large and structurally diverse group. These compounds are synthesized by highly programmed, large iterative multifunctional proteins, which are called the polyketide synthases. This review describes the structure and biosynthesis of polyketide fungal metabolites and highlights recent work on the links between gene sequence, protein architecture, and biosynthetic programming for fungal polyketide synthases.

Polyketides have long been recognized as one of the most important classes of secondary metabolites (1). They occur in plants, bacteria, and marine organisms as well as in fungi. Fungal polyketides vary from the simplest monocyclic aromatic compounds, for example, orsellinic acid and 6-methylsalicylic acid (6-MSA) to polycyclic aromatics such as citrinin, alternariol, islandicin, deoxyherqueinone, and norsolorinic acid. Although initially associated with the formation of aromatic compounds, many polyketides are nonaromatic (e.g., the macroclide deco restrictine and the long-chain polyfunctional molecules exemplified by T-toxin and the decalin, lovastatin, and compactin). Many other metabolites consist of an aromatic ring attached to a more highly reduced moiety (e.g., zearalenone, dehydrocurvularin, and monocerin). A different diversity results from extensive oxidative metabolism of preformed polyketide structures (e.g., penicillic acid and patulin), which are formed from cleavage and rearrangement of 6-MSA and orsellinic acid, respectively, and indeed ring cleavage is a very common feature with the potent hepatotoxic B1 and orsellinic acid, respectively, and indeed ring cleavage is a very common feature with the potent hepatotoxic aflatoxin B1, being derived by extensive ring cleavages and rearrangements of norsolorinic acid. Other metabolites contain a polyketide-derived moiety as part of a larger molecule whose biosynthesis is other than polyketide. A classic example is mycophenolic acid, in which the branched carboxylic side chain is derived via a cleaved farnesyl moiety. Other compounds of mixed terpenoid-polyketide origin include the mycotoxin viridicatumtoxin. A gain the origins of the polyketide-derived moiety may be disguised as a result of extensive metabolism as observed in the meroterpenoid metabolites azidin, paraherquonin, which are all derived via 3,5-dimethylorsellinic acid. The xenovulenes are an interesting group where it has been shown that the cyclopentanone, benzimid, and troponol moieties all have a common biosynthetic origin via ring expansion and ring contraction of 3-methylcyclopentadiene. Other groups contain Krebs’ cycle intermediates, for example, the tetrone acid, carlsic acid, and the squalestatins (see below) or amino-acid derived moieties (e.g., fusarins).

Biological Properties

A further important feature of fungal polyketides is their vast range of biological activities both beneficial and harmful. Thus, griseofulvin was one of the first effective antifungal agents. Penicillin was discovered shortly after the penicillin, is also a powerful antibiotic, but unfortunately it proved too toxic for clinical use. Mycophenolic acid has been “rediscovered” as an immunosuppressive agent. The statins (e.g., lovastatin, which was discovered shortly after the penicillin, is also a powerful antibiotic, but unfortunately it proved too toxic for clinical use. Mycophenolic acid has been “rediscovered” as an immunosuppressive agent. The statins (e.g., lovastatin), although not themselves used in the field formed the basis for the development of the widely used methoxyacrylate group of antifungal agents and, of course the statins, as represented by lovastatin, are among the most widely prescribed drugs for control of cholesterol levels and associated heart disease. As a cursory inspection of their structures would suggest, the squalestatins (e.g., lovastatin), although not themselves used in the field formed the basis for the development of the widely used methoxyacrylate group of antifungal agents and, of course the statins, as represented by lovastatin, are among the most widely prescribed drugs for control of cholesterol levels and associated heart disease. As a cursory inspection of their structures would suggest, the squalestatins (e.g., lovastatin) are effective inhibitors of squalestatin synthase though their early promise as cholesterol-lowering clinical candidates declined because of inherent toxicity. They contain two separate polyketide chains linked to oxaloacetate. Overall, fungal metabolites and their pharmaceutical and agrochemical derivatives have total sales of many tens of billions of pounds annually. In addition to these beneficial effects, the large group of mycotoxins represented first and foremost by aflatoxin B1, 17 and others such as the fuminosins, zearalenone, citrinin, ochratoxins (e.g., T-toxin), are the cause of many problems in both animal and human health, and spoilage of both growing crops and stored foodstuffs through contamination by mycotoxin producing fungi is a cause of major economic losses worldwide.
Polyketide Biosynthesis, Fungi

**Biosynthesis**

Although diverse in structure, the class is defined by the common biosynthetic origin of the carbon atoms: These atoms are derived from the CoA thioesters of small carboxylic acids, such as acetate and malonate. As long ago as 1953, Birch realized that polyketide biosynthesis is related to fatty acid biosynthesis, and some of the earliest applications of radioisotopes to natural product biosynthesis were to fungal polyketide metabolites, where the ease of fermentation and isolation of metabolites in pure form, and relatively efficient uptake of simple labeled precursors facilitated the work. In more recent years, fungal metabolites in general, and polyketides in particular, were the focus of the rapidly expanding applications of stable isotope labeling being greatly facilitated by the contemporaneous development of Fourier Transform methods and their application to 13C NMR. The application of doubly 13C-labeled precursors with analysis of regiospecificity of labeling being greatly facilitated by the contemporary development of Fourier Transform methods and their application to 13C NMR. The application of doubly 13C-labeled precursors led to the concept of bond labeling, which allowed investigators the mode of cyclization of linear polyketide precursors into polycyclic molecules, bond fragmentation, and rearrangements processes to be detected for the first time through analysis of the resulting 13C-13C coupling patterns. This method was then rapidly followed by applications of isotope induced shifts in 13C NMR, which allowed indirect detection of -H and 13C labels and the use of direct 1H NMR. These new methods allowed stereochemistry and regiochemistry of labeling to be detected and in particular permissible levels of oxidation and reduction in otherwise undetectable biosynthetic intermediates to be determined. Along with similar work with bacterial polyketides, this method laid the basis for the ideas of the processive mode of polyketide biosynthesis to be established. It was a major step because it changed fundamentally the idea that polyketide chains were assembled in their entirety and then subjected to necessary reductive modifications to the simple, in retrospect, idea that these changes occur concomitant with chain elongation rather than post-elongation. Although it is still not uncommon for these classic “Birch” fully oxygenated polyketide intermediates to be invoked it is now evident that in most polyketide metabolites, these have no reality. The concept of processive polyketide assembly and modification brought polyketide biosynthesis even closer to the process of fatty acid biosynthesis in which full reductive processing in each cycle of chain condensation and elongation is the norm. The rapid developments in understanding of the molecular genetics of polyketide biosynthesis particularly in bacteria in the 1990s were fully consistent with the processive mode. Understanding of the genetics of fungal polyketide biosynthesis still lags behind that of bacterial polyketides and the remainder of this article will provide a brief overview of current understanding.

**Polyketide assembly**

The basic assembly cycle for both polyketide and fatty acid biosynthesis is shown in Fig. 1 in which a starter unit, normally acetate is transferred to the ketosynthase (KS) or condensing enzyme which catalyzes a deacylative condensation with malonate, bound after after malonyl transferase (MT) catalyzed malonylation to the acyl carrier protein (ACP). During fatty acid biosynthesis, the resulting β-ketoester is subjected to additional chemical processing while attached to the terminal thiol of the ACP: first, it is reduced by a β-ketoacyl reductase (KR) to a secondary alcohol which then undergoes a dehydrogenase (DH)-catalyzed dehydration to form an α,β-unsaturated thioester, and finally enoyl reduction (ER) yields a fully saturated thioester. Fungal PKSs employ all these reactions, but additionally the chain can be methylated, using a methyl group from S-adenosylmethionine (SAM). This reaction probably occurs after KS, which gives an α-methyl-β-ketoester. During the biosynthesis of palmitic acid (C16), there are seven cycles of these reactions. The final reaction of FAS is hydrolysis of the thioester by a dedicated thioesterase (TE). Apart from the capacity for C-methylation, fungal PKSs in common with other PKSs have the ability to use the condensation and reductive cycle in a highly controlled manner to produce polyketide intermediates in which no reductive modification has occurred to give a classic poly-β-ketoester, or more generally “reduced” or “processive” polyketide intermediates in which a complete spectrum of reduction and/or C-methylation has occurred in each condensation cycle as indicated in Fig. 1 for the squaerylactide tetraketide synthase (see below). Another variation is that a range of alternate starter units can be used (e.g., hexanoate in the case of norsolorinic acid or benzoate in the case of the streptomycins). Enzymology

The understanding of the relationship between FAS and PKS enzymes, the application of molecular genetics, and more latterly genomics, has greatly facilitated the discovery and understanding of polyketide synthases from diverse sources. The homology in catalytic function between FAS and PKS enzymes is preserved in their respective gene sequences. It is now clear that fungal PKSs belong to the class of Type 1 iterative synthases represented by mammalian FAS. Type 1 FAS proteins are large multifunctional proteins in which single (or occasionally two) peptides contain the sequences for KS, ACP, AT, KR, DH, ER, and TE activities—these catalytic functions are carried out by particular functional domains. Similarly, the genes for Type 1 FAS proteins are correspondingly large single open reading frames, and Type 1 PKSs consist of very large multifunctional proteins with individual functional domains. Thus, PKSs use much the same array of chemical reactions as FASs—but the key differences is that of programming: FASs have to control chain length (i.e., the number of extensions), but PKSs can additionally control starter unit selection and the extent of reduction during each condensation cycle. Fungal PKSs can program the extent of chain methylation and the off-loading mechanism. The issue of programming is key to understanding and exploiting PKSs. In the case of the bacterial modular polyketide synthases, each condensation cycle is catalyzed by a discrete module containing all the catalytic domains required. In this case, the program is explicit in the order and composition of the modules. However, for the iterative Type 1 fungal polyketide synthases, the programme is cryptic—encoded in the PKS itself.
Polyketide Biosynthesis, Fungi

Figure 1

Generic polyketide assembly pathway reactions catalyzed by iterative fungal polyketide synthases. The assembly sequence for the squalesatin tetraketide intermediate 37 is shown for illustration.

Fungal Polyketide Synthases

Fungi make some of the simplest and some of the most complex polyketides known (3). It is useful to consider a hierarchy of complexity when considering the structures of fungal polyketides, because the complexity in chemical structure is generated by enzymes and ultimately genes. The simplest structures are those such as orsellinic acid 1. Addition of an extra acetate gives a pentaketide such as 1,3,6,8-tetrahydroxynaphthalene, which is a compound widely distributed in fungi and which is involved in melanization—a key component of appressorium formation and invasion of plant cells by plant pathogens such as Magnaporthe grisea, Colletotrichum lagenarium, and others.

Additional complexity is represented by compounds such as 6-MSA acid 2, in which a single, programmed reduction reaction occurs during biosynthesis. More reduction is then observed in compounds such as T-toxin 19 produced by Cochliobolus heterostrophus and lovastatin 10 produced by Aspergillus terreus. In these compounds, many more carbon atoms are used and many more reduction and dehydration reactions occur. Additionally, in many cases (e.g. fusarin C 26), pendant methyl groups have been added from the S-methyl of methionine, catalyzed by a C-methyl transferase domain.

Linking PKS genes and compounds in fungi

The huge structural variety of fungal polyketides is caused by differences in programming of their PKS proteins—apparent increases in structural complexity are caused by increasing use and control of reductive, dehydrative, and methylating steps by the PKS. This increase must be because of differences in PKS protein sequence and structure. This fact has been exploited in the development of rapid methods for the cloning of fungal PKS genes associated with the biosynthesis of particular fungal polyketide types.

Bingle et al. (3) realized that these subtle protein sequence differences should be reflected in DNA sequence, and polymerase chain reaction (PCR) primers could be designed to amplify fragments of fungal PKS genes selectively from fungal genomic DNA (or cDNA). In early work in this area, they hypothesized that fungal polyketides could be grouped into two classes: nonreduced (NR) compounds such as orsellinic acid 1, norsolorinic acid 7, and 1,3,6,8-tetrahydroxynaphthalene, and partially reduced (PR) compounds, such as 6-MSA 2. At the time, very few fungal PKS genes were known, and based on very limited sets of sequences, they designed degenerate PCR primers that were complimentary to conserved DNA sequences in the KS domains in fungal PKS responsible for the biosynthesis of NR and PR compounds. Later, the same analysis was extended to the KS domains of highly reduced (HR) compounds, such as lovastatin 30 when DNA sequence data became available for the lovastatin nonaketide and diketide synthases (LNKS and LDKS, respectively) (4). The availability of these sequences also allowed the development of selective PCR primers for CMeT domains.

This sequence analysis has been significantly extended as genomic approaches have been applied to fungi recently (5). Full genome sequences have now been obtained for more than a dozen fungi. In each organism, many PKS genes have been discovered. For example, Aspergillus niger contains 34 PKS genes, so several hundred fungal PKS genes are known. Sequence comparison of all these new PKS genes, however, shows that the three classes of fungal PKS genes predicted by Bingle et al. (3) are the same three classes observed in the most recent sequence comparisons (5). Despite the fact that so many fungal PKS genes have been discovered, however, relatively few genes have been definitively linked to the biosynthesis of specific metabolites. Because the NR, PR, and HR nomenclature is useful for describing both the chemical products and their cognate genes, the state of knowledge of fungal PKS is reviewed in this way.

Fungal NR-PKS

The tetraketide orsellinic acid 1 is the simplest tetraketide, which requires no reductions during its biosynthesis. One of the first discovered fungal PKS, orsellinic acid synthase (OSAS)
was isolated from Penicillium marneffei in 1968. Despite the early work with the protein, however, the OSAS-encoding gene has not yet been discovered, and nothing is known of the catalytic domains or their organization. However, genes involved in the biosynthesis of several other nonreduced polyketides are now known, and a general pattern of domain organization has emerged. In all known cases, these genes encode Type I iterative PKS proteins. At the N-terminus, a domain is present that seems to mediate the loading of a starter unit (Fig. 2a). It seems that the starter unit can derive from either a dedicated FAS, another PKS, or an acyl CoA. The starter unit loading domain (SAT) is followed by typical KS and AT domains responsible for chain extension and malonate loading. Beyond the AT is a conserved domain known as the product template (PT) domain. This domain is followed by an ACP. Some NR-PKS seem to terminate after the ACP, but many feature a diverse range of different domains that include cyclases, methyl transferases, and reductases. Thus, it seems that these synthases are arranged with an N-terminal loading component; a central chain extension component that consists of KS, AT, PT and ACP domains; and a C-terminal processing component.

NR-PKS loading component

Feeding experiments with isotopically labeled precursors have shown that many NR fungal polyketides are formed by the use of “advanced” starter units. In the classic case of norsolorinic acid biosynthesis, it has long been known that hexanoate forms the starter unit. Differential specific incorporation of acetate into the early and late positions in compounds such as citrinin have shown that many NR fungal polyketides are formed by the use of advanced starter units. For example it is now known (8) that two PKS genes are involved in the biosynthesis of zearealenone (Fig. 2b). In one case of this is a NR-PKS (see below) and probably provides a highly reduced hexaketide as a starter unit. The second zearealenone PKS is a NR-PKS possessing an N-terminal SAT domain, which likely loads the hexaketide ready for three further extensions. Most NR-PKS seem to possess potential SAT domains whether they require an acetate starter unit or not. For example, polyketide synthases involved in the biosynthesis of YWA1 (WA) and tetrahydroxynaphthalene (THNS). In the case of THNS from C. lagenarium, in vitro experiments have implicated that the purified protein uses malonyl CoA as the starter unit. The THNS SAT domain may therefore be involved with loading and decarboxylation of malonate to use as a starter unit, much as the bacterial Type 2 KS, component does.

NR-PKS chain extension component

The extension components of NR polyketide synthases consist of KS, AT, PT, and ACP domains. Sequence analysis of PT domains (450–550 residues) from a range of NR-PKS in which the chemical products are known suggests that it is conceivable that the PT domain is involved in chain-length determination. Comparison of the PT domains from the Acremonium strictum strain PKS1, citrinin PKS, zearealenone PKS-B, NSAS, sterigmatocystin PKS, dothistromin PKS, THNS from C. lagenarium and Wagneria dermatitis, and WAS suggests that these domains group into clades that correspond with chain length (9). The citrinin, ASPK51, and zearealenone-B groups correspond to tetrahydroxynaphthalene synthases; the NSAS, sterigmatocystin, and dothistromin PKS are all octaketide synthases; the THNS are hexaketide synthases; and the WAS synthase (WAS) forms an outgroup, which is a heptaketide.

The domains found after the chain extension components at the C-terminus of fungal NR-PKS are highly variable. These components include putative Claisen-cyclase/thioesterases (CLC/TE), C-methyl transferases (C-MtT), reductases (R), and additional ACP domains. Recent work indicates that these processing components act after chain assembly to modify either a poly-keto or a cyclized intermediate.

CLC/TE domains

The first fungal NR PKS gene to be cloned was Aspergillus nidulans wa (encoding WAS). Limited domain analysis was carried out to determine the presence of KAS, AT, and ACP domains. Later, it was shown that wa also possesses a TE domain, which forms one of the most common processing components of NR PKS. The TE domain can either operate as a standard thioesterase or be involved in a cyclization-release mechanism. Fujii et al. (10) expressed A. nidulans wa (encoding...
Polyketide Biosynthesis, Fungi

**Figure 2.** (a) General architecture of NR PKS genes; proposed mechanism of WAS CLC domain, (b) the Monascus purpureus citrinin PksCT and A. strictum MOS synthases; and (d) domain architecture of A. terreus and P. patulum MSAS, and proposed mechanism of 6-MSA 2 and TAL 44.

WAS in Aspergillus oryzae. Initially, the expression strain produced the isocoumarin 38, which indicated that WAS is a heptaketide synthase (Fig. 2b). It was then realized that the expression construct used in this experiment had a deletion that resulted in the expressed WAS missing the final 67 amino acids of the C-terminal TE domain. When the complete was gene was expressed, however, the heptaketide naphthopyrone YWA139 was produced (10). A series of experiments that involve step-wise shortening of the C-terminus of WAS showed that deletion of as few as 32 amino acids resulted in production of the isocoumarin 38. Site-directed mutagenesis of a conserved serine and histidine in the C-terminal domain also resulted in a switch from naphthopyrone production to citreoisocoumarin production.

Isotopic feeding experiments using 13C-labeled acetate indicated the folding pattern shown in Fig. 2b for the naphthopyrone 39. Thus, both the isocoumarin 38 and the naphthopyrone 39 must result from the cyclization of the common intermediate 40. This finding suggests that the WAS chain extension component produces a heptaketide and catalyzes the cyclization and aromatization of the first ring. The C-terminal domain must therefore catalyze a second (Claisen) cyclization reaction to...
form. The involvement of conserved serine and histidine residues suggests involvement of the CLC-bound intermediate 43 shown in Fig. 2b. Thus, the TE domain has been renamed as C-MeT domain. No obvious catalytic machinery exists for off-loading the product. The DNA sequence of the KS domain is distin-
guished from those of the other domains in the PKS and seems not to require a TE/CLC domain. Some HR PKSs possess an ER domain, but those that do not lack a fully functional ER domain. The PKS often terminates with an ACP domain. No obvious catalytic machinery exists for off-loading the product. The DNA sequence of the KS domain is distin-
guished from those of the other domains in the PKS and seems not to require a TE/CLC domain. Some HR PKSs possess an ER domain, but those that do not lack a fully functional ER domain.

C-MeT domains

Few NR PKSs are known to possess C-methylation domains, although many known fungal nonreduced polyketides are C-methy-
lated, such as 3,5-dimethylorsellinic acid. A small group of NR PKSs have been identified in genome sequences (5), which feature a C-MeT domain located after the ACP (Fig. 2c). The first correlation between a gene sequence and a compound came from Monascus 3, in which the PKS involved in citrinin biosynthesis has been isolated (11). Here, the C-MeT domain must be programmed because it acts twice during polyketide biosynthesis when a probable methylated diketide starter unit is extended. It is not yet clear whether the C-MeT domain acts during extension, after chain extension but before aromatization, or after aromatization. 1,3-Di-hydroxynonamethoxan is known to tautomerase easily to keto forms, and it is conceivably that it could act as the nucleophile for the reaction with SAM.

R domains

Reductases are currently rare as part of the processing compo-
nent of NR PKS. Evidence for the role of these reductase domains has been obtained by the isolation of the PKS respon-
sible for the formation of the tetraketide component found in xenovulene A (xenovulene A). The PKS gene (MOS) was found to have SAT, KS, AT, C-MeT, and R domains (Fig. 2d), and heterolo-
gous expression of the gene in Aspergillus oryzae resulted in high yields of 3-methylorcinolactone 45. Although not described in the literature, sequence analysis of the citrinin PKS sequence discussed above shows that it also possesses a C-terminal thi- olester reductase domain.

Similar domains are known from NRPS systems in which reductase domains are sometimes used as chain release mecha-
nisms, which release an aldehyde or primary alcohol. In the case of MOS and citrinin biosynthesis the reductive release mecha-
nism makes good sense as this provides the products with C-1 at the correct oxidation state (Fig. 2c).

Fungal PR-PKS

The domain structure of PR PKSs is much closer to mammalian FAS, with an N-terminal KS followed by AT, and DH domains (Fig. 2b). A so-called “core” domain follows the DH, which is followed by a KR and the PKS terminates with an ACP do-
main. The domain structure differs considerably from the NR PKS—no SAT domain or PT domain exists, and the PKS ter-
minishes after the ACP and seems not to require a TE/CLC domain. No obvious catalytic machinery exists for off-loading the product. The DNA sequence of the KS domain is distin-
guished from those of the other domains in the PKS and seems not to require a TE/CLC domain. Some HR PKSs possess an ER domain, but those that do not lack a fully functional ER domain. The PKS often terminates with an ACP domain. No domain similar to the PT domain of the NR PKS or the core domain of the PR PKS is known.
PKS seems to exist, and there is no N-terminal SAT domain as found in the NR PKS. As with the NRs and PR PKSs, many HR PKS genes are known from the numerous fungal genome sequences, but as yet few gene sequences have been linked to the production of known compounds. However, of the few cases in which both gene and chemical product are known, some progress has been made in understanding function and programming.

The lovastatin polyketide synthases

Lovastatin (also known as mevinolin) is produced by A. terreus. The related compound compactin (mevastatin) is produced by Penicillium citrinum and is identical to lovastatin apart from the C-12 methyl group absent in compactin. Isotopic feeding experiments have shown that two polyketide chains are required: a nonaketide and a methylated diketide. The requirement for two polyketide synthases is evident in the gene clusters associated with biosynthesis ofLovastatin and Compactin where two PKS genes are found (4), lovB and lovF, which encode LNKS and LDKS in the case of lovastatin (Fig. 3B). LNKS formally should synthesize a fully elaborated nonaketide such as 47, which could undergo a biological Diels-Alder reaction to form dihydromonacolin L 48—which is the observed first PKS-free intermediate. Note that it is possible that the Diels-Alder reaction actually occurs at the more activated hexaketide stage. When lovB was expressed in the heterologous fungal host A. nidulans (4) however, the polyunsaturated compounds...
Alternaria solani produces a wide range of bioactive compounds derived from polyketides fused to amino acids. Examples include fusarin C, equisetin 54, and tenellin 55. Fusarin C 26 consists of a tetramethylated heptaketide fused to homoserine and is produced by strains of the plant pathogens Fusarium moniliforme and Fusarium venenatum. Genetic DNA libraries from these organisms were used to isolate a gene cluster centered around a 12-Kb ORF encoding a PKS fused to a nonribosomal peptide synthetase (NRPS) module 19. The PKS region is homogeneous to LNSK: KAS, AT, and DH domains are followed by CMeT, a defective ER, KR, and ACP domains. Like LNSK, SQTKS possesses a functional ER domain, but SQTKS carries out three modifications reactions occur only after the final extension (Fig. 1). HR PKS from Alternaria solani

Alternaria solani is a plant pathogen and the causative agent of early blight in solanum species. It produces numerous polyketides, such as solanopyrone A 56 and alternaric acid 57, and it is thus an ideal target species for speculative PKS gene-fishing expeditions. Fuji et al. (18) have conducted just such investigations, using PCR primers based on conserved PKS sequences as probes with genomic DNA libraries (18). An early investigation yielded two hits—one a HR PKS gene named alt5, and another, a NR PKS named psla. The alt5 gene encodes a typical HR PKS, which is known as PKS A5, with the usual array of catalytic domains. Inspection of the ER sequence suggested that it should be functional like those from LDKS and SQTKS. Expression of alt5 showed this to be correct—a single compound was synthesized in good yield (7–15mgg⁻¹), which proved to be the octamethylated deacetate pyrone 53, named alternaric acid. This compound is the most complex polyketide detected so far, and it is programmed to elongate the ACP chain length control, keto-reduction, methylation, and enoyl reduction. HR PKS-NRPS

Fungi produce a wide range of bioactive compounds derived from polyketides fused to amino acids. Examples include fusarin C, equisetin, and tenellin. Fusarin C 26 consists of a tetra- or pentamethylated heptaketide linked to homoserine and is produced by strains of the plant pathogens Fusarium moniliforme and Fusarium venenatum. Genetic DNA libraries from these organisms were used to isolate a gene cluster centered around a 12-Kb ORF encoding a PKS fused to a nonribosomal peptide synthetase (NRPS) module 19. The PKS region is homologous to LNSK: KAS, AT, and DH domains are followed by CMeT, a defective ER, KR, and ACP domains. Like LNSK, the ACP is upstream of an NRPS condensation (C) domain, but in this case the NRPS module is complete, which features downstream adenylation (A), thiolation (T), and C-terminal thiolester reduce (R) domains (Fig. 1). Directed knockout of the PKS-NRPS gene proved it to be involved in the biosynthesis of 26 and was thus named fusarin synthetase (FUSS). The functional ER domain and the fact that no lovC homolog seems to exist in the cluster, is consistent with the polyunsaturated nature of the polyketide moiety.

It is probable that FUSS assembles a tetramethylated heptaketide 50 attached to the ACP (Fig. 3c) — the structure of which is...
similar to the heptadiketide pyrone \textsuperscript{45} produced by LNKS in the absence of the LovC protein. In parallel, the C domain of the NRPS module seems to select, activate, and attach homoserine \textsuperscript{57} to the thiolation domain. The C domain then uses the amide of homoserine to form an amide with the ACP-bound polyketide, which forms a covalently bound intermediate peptide \textsuperscript{58}. The final reaction catalyzed by FUS may be the reductive release of the thiolester, which forms peptide aldehydes \textsuperscript{59}. Finally, Knoevenagel cyclization would give the putative preufusarin \textsuperscript{60}. Other genes in the FUS cluster are presumably responsible for the required additional transformation of \textsuperscript{60} to fusarin C, \textsuperscript{26} itself: epoxidation; oxidation of a pendant methyl to a carboxylate and esterification; and hydroxylation a to nitrogen.

A highly homologous PKS-NRPS gene has been shown to be involved in the biosynthesis of equisetin \textsuperscript{54} in Fusarium heterosporum \textsuperscript{(20)}. EFS possesses the same catalytic domains as FUS, but examination of the structure of \textsuperscript{54} indicates that the pyrollidinone carbon derived from the carboxylate of the amino acid (serine in this case) is not reduced, which indicates either a reoxidation mechanism, or the fact that the R domain does not produce an aldehyde intermediate in this case.

Conclusion

Recognition that the fungal PKS can be categorized into three subsets has allowed more detailed consideration of the programming elements. The NR PKS are arranged into loading, extension, and processing components, and to some extent this hypothesis has been verified by expression and study of individual catalytic domains and by the construction of hybrid NR PKS genes. However, the programming elements of the FR and HR PKS remain obscure. The first experiments to probe programming in HR PKS have involved domain swaps, but few conclusions have yet been drawn. Little information is known about the three-dimensional structure of fungal PKS—whereas sequence and domain organization similarity with mammalian FAS mean that broad descriptions of the architecture of the catalytic domains can be modeled, detailed hypotheses that involve individual domains or peptide motifs cannot yet be linked with programming.

Polyketides constitute a large class of microbial and plant-derived secondary metabolites that displays a vast array of structural diversity. These organic molecules vary in molecular weight, functional group modification, and include linear, polycyclic, and macrocyclic structural forms. Currently, polyketide natural products find clinical use as antibiotics, antiparasitic agents, antifungals, anticancer drugs, and immunosuppressants. Given these impressive and wide-ranging pharmacologic activities, an ever-increasing demand is placed on natural products research to uncover novel polyketide metabolites for the benefit of human and animal health. Modular polyketide synthases are nature’s platform for the expansion of chemical diversity. This review provides new perspectives on important biosynthetic mechanisms that contribute to this variety. This includes control of double-bond configuration and regiochemistry, introduction of β-branching during polyketide chain assembly, and other processes that contribute to introduction of unique chemical functionality into these fascinating systems.

Despite the promise of modern synthetic technologies to enhance pharmaceutical discovery significantly, natural products continue to be the greatest source of all new drug leads (1). Currently, many examples of natural product-derived pharmaceuticals are employed to benefit human health (2, 3); polyketides constitute a large class of microbial and plant-derived secondary metabolites that displays a vast array of structural diversity. These organic molecules vary in molecular weight and functional group modification; they include linear, polycyclic, and macrocyclic structural forms. Currently, polyketide natural products find clinical use as antibiotics, antiparasitic agents, antifungals, anticancer drugs, and immunosuppressants (Fig. 1a). Given these impressive and wide-ranging pharmacological activities, an ever-increasing demand is placed on natural products research to uncover novel polyketide metabolites for the benefit of human health.

Although the clinical use of polyketide-inspired pharmaceuticals has been appreciated for decades, polyketide-derived metabolites have been recognized recently for their role in bacterial virulence. For example, the pathogenesis of Mycobacterium ulcerans, the causative agent of the devastating skin disease known as Buruli ulcer, is the result of the secretion of polyketide-derived toxins known as the mycolactones (Fig. 1b) (4). These polyketide toxins are responsible largely for the necrotic lesions that are characteristic of this debilitating condition. As such, the disruption of mycolactone biosynthesis may lead to an effective chemotherapy for Buruli ulcer. Recent findings also suggest that the virulence of another mycobacterial species, Mycobacterium tuberculosis, could be partially dependent on polyketide biosynthesis. The cell surface sulfolipid-1 (SL-1) is among several virulence-associated molecules produced by M. tuberculosis. SL-1 consists of a sulfated disaccharide core (trehalose-2-sulfate) that displays four lipidic substituents; all but one substituent seems to be polyketide-derived (Fig. 1b) (5). Finally, the toxic agent in rice seedling blight, which is a highly destructive fungal disease that inflicts severe agricultural losses worldwide, has been identified recently as the polyketide metabolite, rhizoxin (Fig. 1b) (6). Interestingly, rhizoxin is not produced directly by the fungus (Rhizopus), but rather by the endosymbiotic bacteria Burkholderia that thrives within the fungus. Together, these three examples suggest that inhibition of polyketide biosynthesis may lead to effective chemotherapy for controlling certain human and plant bacterial diseases.
Polyketide Biosynthesis, Modular Polyketide Synthases

Prototypical Polyketide Biosynthesis

The biosynthesis of many important polyketide compounds occurs via a stepwise, assembly-line type mechanism that is catalyzed by type I modular polyketide synthases (PKSs). These modular PKSs are composed of several large, multifunctional enzymes that are responsible for catalyzing the initiation, elongation, and processing steps that ultimately give rise to the characteristic macrolactone scaffold (Fig. 2) (7-11). Structural studies have been critical in developing a sophisticated understanding of the overall architecture and mechanism of type I PKSs and their homologs in recent years (12-18). A review from the perspective of the 6-deoxyerythronolide B synthase (a well-studied type I PKS) was published recently by Khosla et al. (19).

It is well established that the sequential arrangement of modules within a PKS system serves effectively as a biosynthetic program, which is responsible for dictating the final size and structure of the polyketide core. Typically, initiation of polyketide biosynthesis begins by the acyltransferase (AT) catalyzed linkage of a coenzyme A (CoA) priming unit (e.g., methylmalonyl-CoA, malonyl-CoA, propionyl-CoA) to the acyl carrier protein (ACP) of the loading module. Once initiated, downstream elongation modules carry out repetitive extensions.
of the starter unit. In most PKS systems, each elongation mod-
ule contains at minimum an AT domain, an ACP domain, and a ketosynthase (KS) domain (Fig. 2a). The AT domain is re-
ponsible for loading the appropriate CoA extender unit onto the ACP domain (i.e., malonyl-CoA, methylmalonyl-CoA, etc.). The KS domain then catalyzes a decarboxylative condensa-
tion of the extender unit with the growing polyketide chain obtained from the preceding module to generate an ACP-bound β-ketoacyl product. In addition to the three core domains, each elongation module may contain up to three additional domains (ketoreductase [KR], dehydratase [DH], enoyl reductase [ER]) that are responsible for the reductive processing of the β-keto functionality prior to the next extension step (Fig. 2a). These reductive steps contribute greatly to the overall structural di-
versity that is observed among polyketide natural products. The presence of a KR domain alone generates a β-hydroxy function-
ality, the presence of both a KR and a DH domain generates an alkene, whereas the combination of KR, DH, and ER re-
results in complete reduction to the alkane. Finally, termination 
of polyketide biosynthesis is catalyzed by a thioesterase (TE) domain located at the carboxy terminus of the final elongation module. The activity of this domain results in the cleavage of
the acyl chain from the adjacent ACP; typically, intramolecular cyclization results in the formation and release of a macrocyclic ring. Tailoring enzymes, such as hydroxylases and glycosyl transferases, often serve to further modify the polyketide to yield the final bioactive compound.

The modular organization of type I PKSs has made them particularly attractive targets for rational bioengineering. Combinatorial biosynthetic efforts centered on prototypical modular PKSs have been the topic of many recent outstanding review articles (20–23). Currently, several strategies are being pursued that attempt to leverage PKS systems for the generation of structurally diverse polyketides. For example, it has been demonstrated that alterations of individual catalytic domains (i.e., inactivation, substitution, addition, deletion) within a PKS module can result in predicted structural alterations of the final PKS product. Likewise, the addition, deletion, or exchange of intact modules can also impart structural variety into polyketide metabolites. Using these and other approaches, hundreds of novel polyketide structures have been generated, which established the tremendous potential of these applications. However, these successes seem to be more the exception than the rule, as many efforts result in trace levels, or they fail to provide the desired metabolite. This finding suggests that much remains to be learned regarding the molecular intricacies of these complex biosynthetic machines. This review provides new perspectives on important mechanisms that contribute to structural diversity in modular PKSs. These mechanisms include control of double-bond configuration and regiochemistry, introduction of β-branching during polyketide chain assembly, and other processes that contribute to introduction of unique chemical functionality into these fascinating systems.

Polyketide Double Bonds

Trans double bonds

The presence of unsaturated carbon–carbon bonds within most polyketide compounds exemplifies the overall structural diversity that is a hallmark of this class of important natural products. Typically, the installation of double bonds into nascent polyketide chains relies on the two-step processing at the β-keto group by the successive activity of KR and DH domains that are embedded within a given PKS elongation module. After KS catalyzed chain elongation that extends the growing chain by two carbon atoms, the KR domain, when present, directs the NADPH-dependent reduction of the β-ketone to yield a 3-hydroxyacyl intermediate. Subsequently, an embedded DH domain within the elongation module catalyzes dehydration of the 3-hydroxyacyl intermediate, normally which results in the incorporation of an (E)-trans unsaturated bond into the growing polyketide chain (Fig. 3a). It should be noted that the KR catalyzed reduction of a β-ketoacyl intermediate has stereochemical consequences because a new chiral center is introduced into the growing oligoketide. A side from serving to enhance the structural diversity of the final polyketide product even more, the stereochemical outcome of this reaction can have profound effects on any subsequent processing or elongation reactions. As such, an understanding of how KR domains exert stereochemical control of their hydroxylated product is a critical aspect to deciphering the mechanism of DH-mediated double bond formation. Through bioinformatic and biochemical analyses, an appreciation of ketoreductase-influenced stereochemistry has emerged (24, 25). Thus, Caffrey (25) has proposed that KR domains can be divided into two classes, depending on the final configuration of the β-hydroxyl moiety. The so-called “A” class generates an L-3-hydroxy product, whereas the “B” class produces the D-3-hydroxy polyketide intermediate. A thorough little difference exists between these two putative classes at the amino acid sequence level, the presence of a conserved aspartate residue within an LDD motif correlates well with “B” class. This motif is absent in the defined “A” class of KR domains. An additional diagnostic feature of the “A” class of KR domains is the presence of a conserved tryptophan residue. Recently, Keatinge-Clay (18) has proposed a refinement of the KR class descriptions as originally suggested by Caffrey (25), effectively increasing the number of possible KR types from two to six (18). This new classification takes into consideration whether a given KR domain (either reductively competent or incompetent) is located in an epimerization competent module. Although this new classification offers a more complete description of PKS KR domains, for simplicity we will continue to use Caffrey’s KR nomenclature throughout our discussion of double-bond formation.

While examples of both D- and L-hydroxy group configurations can be found within polyketide natural products, recent evidence suggests that DH domains require a stereospecific 3-hydroxyacyl intermediate. Bioinformatic analyses performed on 71 KR domains for which the stereochemical outcome of the reduction is cryptic because of subsequent dehydration revealed that all belong to the “B” class of KR domains (25). As such, it appears that the generally preferred substrate for DH domains is a D-3-hydroxyacyl chain. However, direct experimental evidence has been difficult to obtain because the 3-hydroxyacyl intermediate is transient in modules that contain a DH domain. Recently, bioinformatic studies of the DH domain found in module 2 of the pikromycin PKS system (Fig. 2b) (26) have supported this hypothesis; inactivation of the DH domain resulted in the exclusive generation of the D-3-hydroxyacyl thioester intermediate from a diketide substrate (27). A side from this study, no other reports probe the substrate preference or catalytic mechanism of DH domains within PKS systems; therefore, much of what is known has been elucidated from studies of fatty acid biosynthesis (28). Previous studies on the dehydration step that is catalyzed by the yeast fatty acid synthase confirmed the syn elimination of water from a D-(3R)-hydroxyacylthioester substrate (29). This result is consistent with the stereospecificity of the PKS DH domain and may suggest that trans unsaturated bonds, typically found in polyketides, are likewise formed via syn water elimination.

cis double bonds

Although rare, several PKS biosynthetic systems can install cis double bonds into the final polyketide product (Fig. 4). Several possible mechanisms could account for the infrequent
Figure 3  (a) Traditional view of reductive processing at the β-ketone position in the growing polyketide chain. Presence of a ketoreductase domain leads to formation of an alcohol. An active dehydratase domain can further process the alcohol moiety to an alkene. Complete saturation to the alkane is accomplished by an enoyl reductase domain. (b) Proposed terminal double bond formation for curacin biosynthesis. (c) Proposed terminal double bond formation in tauromycin biosynthesis.

occurrence of this double bond configuration. One explanation is that an isomerization event occurs that converts a trans double bond into a cis double bond. This isomerization activity could be specified by the PKS elongation module, much like previously identified epimerization activities that are known to exist in some PKS and NRPS modules. Alternatively, the combined activity of KR-DH domains within certain modules could directly establish the cis double bond. Finally, it is possible that after reduction of the β-keto functionality, a trans acting DH could catalyze dehydration to form a (Z)-cis double bond.
bond. This trans activity might derive from a discrete enzyme encoded within the biosynthetic gene cluster or from an adjacent module within the PKS pathway. Additionally, examples exist in which some general rules may not hold true. Chivosazol, which is a potential antitumor agent, is one such example (30). The epothilones 6 (and Fig. 1a), which are produced by Sorangium cellulosum, are mixed NRPS-polyketide derived natural products that possess potent antitumor activity. Interestingly, some compounds feature a cis double bond between carbon atoms 12 and 13 that should be generated by PKS elongation module 4; however, sequence analysis of the epothilone biosynthetic gene cluster indicates that module 4 does not contain a DH domain requisite for the formation of the unsaturated bond (31). Thus, Tang et al. (31) hypothesized that the DH activity might occur from the subsequent module or by the
action of a post-PKS modifying enzyme. Biochemical experiments later demonstrated that the DH domain of module 5 catalyzed the cis double bond formation (32). To account for this atypical activity, it is proposed that the 3-hydroxythioester intermediate undergoes an ACP₄-To-ACP₅ transfer (32). A decarboxylation, the thioester intermediate would then be transferred to the KS₅ domain for subsequent elongation. Similarly, the an-
titumor phoslactomycin compounds (33) feature three cis double bonds, two of which seem to be installed by a KR-DH pair (see below); however, the elongation module (Pim₇) that should be responsible for generating the unsaturated bond between carbon atoms 2 and 3 does not appear to encode the required DH activ-
ity (33). Thus, it is likely that the source of this atypical activity comes from either a different module within the PKS system or a separate enzyme that could act either before or after TE medi-
ated termination of polyketide biosynthesis. A partial analysis is required to discriminate between these two possibilities.

Unlike the examples described above, most polyketide cis double bonds are installed through a successive KR-DH pair found embedded within the elongation module. In these cases, the stereochemistry of the 3-hydroxyacyl intermediate appears to be the discriminating factor between (Z)-cis or (E)-trans unsaturation. For example, the antitumor disorazolic compounds (34) display up to three cis double bonds per monomer (note: final compound is a condensed dimer). Sequence analyses of KR domains preceding DH domains that would be responsible for cis double bond formation suggest that they all belong to the "A" class (34). Thus, they are predicted to generate a L-3-hydroxyacyl intermediate. It is expected that the subsequent DH domain preferentially recognizes the L-3-hydroxyl group to facilitate the generation of the cis double bond. Interestingly, the module responsible for incorporating the cis unsaturated bond between carbon atoms 11 and 12 is split between two polypeptide chains (36). It cannot be ruled out that this modular dissection may play a role in formation of this particular double bond, as the cleavage point occurs between the DH and KR domain. Furthermore, it is intriguing that the major product, disorazole A₁, is composed of two nonidentical monomers that differ in saturation between carbon atoms 5 and 6. It has been suggested that the synthesis of the two different monomers is caused by poor activity of the DH domain (34); however, final proof requires additional experimental verification.

In addition to disorazole, several other known examples of polyketide natural products exist that have cis double bonds installed by an embedded KR-DH-DH domain pair. The potent antitumor compound curacin A (35) contains many interesting structural features. Among them is the presence of a cis double bond between carbon atoms 3 and 4. Sequence alignment of the KR domain encoded by curC (encoding the module responsible for generation of the cis double bond) suggests that it belongs to the "A" class of KR domains (35). Thus, this particular KR is predicted to generate a L-3-hydroxyacyl intermediate that is subsequently dehydrated to the cis double bond. Likewise, the KR domains that set up the cis double bonds found in the linear mixed NRPS-polyketide natural product bacillibrevin 1 are predicted to produce L-3-hydroxyacyl intermediates (36). Interestingly, two of the elongation modules that incorporate cis olefins are split between two polypeptides (36). As in disora-
zole biosynthesis, it is possible that these modular dissections contribute to the configuration of the unsaturated bond that is introduced by these modules.

Finally, we consider the conjugated cis olefins that span car-
bon atoms 12-13 of the phoslactomycin (33). An analysis of the K.R. sequences of elongation modules 1 and 2 could not clearly predict whether these reductive domains belonged to the "A" or "B" class. Therefore, Alhamadsheh et al. (37) genetically inactivated both the loading module and elongation module of Pim₁ and conducted feeding experiments with dithiolane analogs contain-
ing both cis and trans olefins. Results from this work indicated clearly that only the cis olefin containing dithiolane is accepted as a substrate for elongation module 2, suggesting that the product of module 1 must contain the cis double bond. Furthermore, this work demonstrated nicely that the phoslactomycin biosynthetic pathway cannot process trans dithiolane intermediates into ma-
ture products, which rules out the possibility of an isomerization domain in downstream modules.

Terminal double bonds

Termination of polyketide biosynthesis typically involves the TE mediated cleavage of the ACP₃-bound thioester, followed by cyclization to generate a macrocyclic lactone. Alternatively, the TE catalyzes the simple hydrolysis of the thioester to generate a linear free acid product. Here, we consider two of the relatively few known examples of polyketide natural products that are neither a macrocyclic nor a free acid, but instead terminate with a double bond.

Aside from containing a cis double bond noted above, the antitumor polyketide compound curacin A (3) also features a terminal olefin. Previously reported feeding studies suggested that the formation of the terminal double bond develops from successive decarboxylation and dehydration events (35). The biosynthetic gene cluster responsible for curacin A biosyn-
thesis has been identified and initially characterized, which enables the putative assignment of domains within the pre-
dicted elongation modules (35). Like most other known polyke-
tide biosynthetic pathways, the final elongation module of the curacin pathway, CurM, contains a terminal thioesterase do-
main that presumably plays a role in formation of the terminal olefin; however, biochemical evidence for such a role is lack-
ing. Interestingly, domain analysis of CurM also suggested the presence of a sulfotransferase (ST) domain immediately pre-
ceding the TE domain. Typically, ST domains are responsible for transferring a sulfuryl group from a donor molecule (such as 3'-phosphoadenosine-5'-phosphosulfate, PAPS) to a variety of acceptor carbohydrates, proteins and other low-molecular weight metabolites (38). Although STs have been characterized...
from both eubacterial and eukaryotic organisms, the presence of an ST domain within a PKS system is unprecedented.

Current efforts in our laboratory include elucidating the roles of the ST and TE domains in curacin A biosynthesis, and in particular, their potential functions in terminal olefin formation. One possible mechanism that is currently under consideration is shown in [Image 3b]. On reduction of the β-keto functionality of the ACP-bound thioester intermediate, the ST domain transfers a sulfuryl group from the donor molecule PAPS to the 3-hydroxyl group of the thioester chain. Consistent with this hypothesis, bioinformatic analysis suggests that the putative curacin ST domain contains the signature PAPS binding pocket (unpublished data); however, no experimental evidence suggests that this ST domain can catalyze the sulfuryl transfer or the formation of the terminal olefin product. Assuming our hypothesis is correct and that the ST domain functions as proposed, transfer of the sulfurylated intermediate to the TE domain would initiate hydrolytic termination of curacin A biosynthesis to produce the linear free acid. At this point, one of several chemical steps can be envisioned. Following hydrolysis, the TE may catalyze decarboxylation, after which the formation of the double bond would occur in a concerted process by displacement of the sulfate leaving group. Alternatively, a separately encoded enzyme might be responsible for decarboxylating the free acid generated by the TE domain. It is also conceivable that on TE catalyzed hydrolysis, the decarboxylation reaction occurs spontaneously due to the presence of the sulfate leaving group at carbon 3.

Similar to curacin, the polyketide metabolite tautomycetin 34 also possesses a terminal olefin. This polyketide metabolite has potential medicinal value because of its novel immunosuppressive activities (39). The tautomycetin biosynthetic gene cluster has been sequenced recently, which enables domain composition analysis of the terminal elongation module (40). Unlike the terminal module involved in curacin biosynthesis, the final tautomycetin elongation module does not contain the unusual ST domain. This finding may suggest that formation of the terminal olefin of tautomycetin 34 occurs by a different chemical mechanism. The final elongation module does contain a TE domain, which presumably terminates tautomycetin biosynthesis through generation of the free acid (Fig. 3c). As described for curacin, it is possible that this TE domain can also catalyze the subsequent decarboxylation event; however, in lieu of an activated leaving group at carbon 3, it is reasonable to expect that dehydration to remove the hydroxyl at carbon 3 would also be a catalyzed event. Alternatively, the terminal olefin could be installed during the post-PKS maturation of the polyketide to the final tautomycetin product. DNA sequence analysis of open reading frames that are downstream of the tautomycetin PKS gene cluster reveals two potential candidates, tncj and tncm, which may be involved in double bond formation (40). Bioinformatic analyses suggest that tncj might encode for a putative decarboxylase and that the gene product of tncm is a potential dehydratase.

**Atypical PKS Domains**

The wide distribution of PKSs in the microbial world and the extreme chemical diversity of their products do in fact result from a variety of the well-known catalytic domains described above for the canonical PKS systems. Taking a more theoretical view of polyketide diversity, González-Legier et al. (41) have suggested that even if the starter and extender units are fixed, over 100,000 linear heptaketide structures are possible using only the 5 common reductive outcomes at the β-carbon position (ketone, (R- or S-) alcohol, trans double bond, or alkane). Recently, it has become apparent that even this does not represent the upper limit for polyketide diversification. To create chemical functionalities beyond those mentioned above, nature has recruited some enzymes from sources other than fatty acid synthesis (the mevalonate pathway in primary metabolism is one example) not typically thought of as type I PKS domains. Next, we explore the ways PKS-containing systems have modified these domains for the catalysis of some unique chemistries observed in natural products.

**Methyl groups at the α- and β-carbons**

As described above for polyketide biosynthesis, the presence or absence of a methyl group on a carbon results from the growing polyketide chain is most often governed by the selection of the extender unit (malonyl-CoA versus methylmalonyl-CoA). However, in PKS systems that use trans acyltransferases (AT-less type I PKSs) (8, 42), the module by module control over extender unit selection is not possible. In most cases, malonyl-CoA is used as the extender unit, and a methyl group can be added to selected positions through the action of an embedded methyl transferase domain (MT) or downstream TE enzyme. For example, the C-6 methyl of leinamycin 8 is thought to be installed by the MT embedded in LnmJ (43), and the C-10 methyl of curacin A 3 is generated via the MT domain in CurJ (35), and the gem dimethyl groups on C-8 and C-18 of broycin 2 most likely are the consequence of the MT domains in BryD and BryC (44).

In contrast to the α-carbon methylations, the incorporation of methyl or methylene groups (or functional groups derived from such groups) at the β-position represents the assimilation of a full cassette of enzymes into the typical PKS machinery. Recently, a subset of type I modular PKSs (and hybrid NRPS/PKS megasynthases) have been identified that contain multiple enzymes acting in trans during the traditional linear assembly-line process to accomplish β-branching. Termed HMGS-CoA synthase (HMGS) cassettes, these enzyme systems provide a unique method of expanding the repertoire of the traditional reductive domains (KR, DH, ER). These enzymes work in conjunction with the PKS machinery to create unique functionalities observed at the branch points that include the pendant methyl groups of bacillaleus A 1 (36, 45, 46), mupirocin 9 (47), and viriginiamycin M 15 (48), which are the methoxymethyl and ethyl groups of myxavirucin A 30 (49, 50); the exo-methylene groups of difficidin B 4 (45), onamidic acid A 11 (51), and pedelin D 12 (51–53); the cyclopentyl ring of curacin A 3 (35, 54); the vinyl chloride of jasmineamide B 7 (55); the unique...

HMGS synthase cassettes

In primary metabolism, HMG-CoA synthase (HMGS) is responsible for the condensation of C-2 of acetyl-CoA onto the β-ketone of acetoacetyl-CoA to form 3-hydroxyl-3-methylglutaryl-CoA and free CoASH (Fig. 5a) (56). Several secondary metabolite pathways have been identified over the past five years that perform an analogous reaction, although they seem to use ACP-tethered acyl groups (Fig. 5b) as opposed to acyl-CoA substrates. After generation of the HMG-ACP analog on the growing polyketide chain, the product is usually dehydrated and decarboxylated to yield the branched intermediate. Found in 11 pathways to date (36, 45–55), included in the cassette are a discrete ACP, a decarboxylative KS (active site cysteine is replaced with a serine), an HMGS, and one or two enoyl CoA hydratase-like (ECH) domains. (Table 1, Figs. 5, 6).

HMGS cassette biochemistry

Three HMGS-containing cassettes (those in the curacin A, bacil laene, and myxovirescin pathways) have been validated biochemically in the past two years and will serve as the basis for our analysis of the individual components in this complex (46, 54, 57, 58). The mechanistic and structural details for HMG-CoA synthase in primary metabolism have been elucidated for both bacterial and eukaryotic HMGSs (59–63). Although polyketide HMGSs share only 20–30% sequence identity with their primary metabolism homologs (in both prokaryotes and eukaryotes), multiple sequence alignment reveals that the key catalytic residues (Glu/Cys/His) are conserved. As shown in Fig. 5b, the first step in the formation of the HMG-intermediate is the generation of acetyl-ACP. This step is accomplished through the loading via an AT of malonyl-CoA [or perhaps methylmalonyl-CoA in the case of TaE (58)]. Then, the decarboxylative KS converts the malonyl-ACP into acetyl-ACP, after which the tethered acyl group is condensed onto the β-ketone of the polyketide intermediate. Finally, formation of the HMG-analog is completed on addition of water.

Processing of the HMG-intermediate can vary considerably, but typically proceeds via dehydration and decarboxylation catalyzed by two enoyl-CoA hydratase-like domains (Fig. 5b). Based on sequence similarity, the members of the crotonase fold family observed in these HMGS cassettes can be subdivided into two groups, termed ECH1 and ECH2 (54). The successive dehydration and decarboxylation steps are catalyzed by the ECH1 and ECH2 enzymes/domains, respectively. Evidence for the specific function of the curacin ECH1 and ECH2 enzyme pair from the curacin pathway has been demonstrated using a coupled enzyme assay and ESI-FT-ICR MS (54). Using purified ECH1 (CurE) and ECH2 (the N-terminal domain of CurF) overexpressed in E. coli, (52) HMG-ACP was converted first to...
the above proteins, ACP, acetoacetyl-ACP, and malonyl-CoA in combination with PksL, PksF, PksG, PksH, and PksI. Using the model acceptor they assigned functional roles to AcpK, PksC, the tandem ACPs. Using radioactive biochemical assays together with mass spectrometry, reported the function of several discrete enzymes. Using radiative biochemical assays together with mass spectrometry, they assigned functional roles to AcpK, PksC, the tandem ACPs in PksL, PksF, PksG, PksH, and PksI. Using the model acceptor ACP, acetoacetyl-ACP, and malonyl-CoA in combination with the above proteins, a L2,3-isopropenyl-S-carrier protein was generated (46). Most recently, a similar in vivo investigation was conducted using the homologous enzymes from the myxovirescin pathway (58). The HMGS cassette reaction sequence proposed above held fast for the myxovirescin pathway, although the generation of the propionyl- or methylmalonyl-S-ACP could not be demonstrated. The authors have suggested that perhaps additional enzymes are yet to be identified to fill these roles to complete the $\beta$-ethylation at C16 in 3D. Two variations on the HMGS cassette theme already have been identified. In the biosynthesis of bryostatin 1 and leinamycin 8, one or both of the ECH-mediated steps is likely omitted based on the final natural product structures. The details of these deviations have not yet been established.

3-methylglutaryl-ACP then to 3-methylcrotonyl-ACP, which is the gained intermediate for subsequent formation of the cyclopropyl ring. Insights into the mechanism of the CurF ECH2 decarboxylation have been gained based on the recent crystal structure of the curacin ECH2 domain (64). Additional in vitro evidence for the function of these enzymes has been generated using proteins from the PksX pathway of Bacillus subtilis (46) and Myxococcus xanthus (58). Prior to the identification of bacillaene as the product of the PksX pathway, Cáderone et al. (46) and Dorrestein et al. (57) reported the function of several discrete enzymes. Using radioactive biochemical assays together with mass spectrometry, they assigned functional roles to AcpK, PksC, the tandem ACPs in PksL, PksF, PksG, PksH, and PksI. Using the model acceptor ACP, acetoacetyl-ACP, and malonyl-CoA in combination with the above proteins, a L2,3-isopropenyl-S-carrier protein was generated (46). Most recently, a similar in vivo investigation was conducted using the homologous enzymes from the myxovirescin pathway (58). The HMGS cassette reaction sequence proposed above held fast for the myxovirescin pathway, although the generation of the propionyl- or methylmalonyl-S-ACP could not be demonstrated. The authors have suggested that perhaps additional enzymes are yet to be identified to fill these roles to complete the $\beta$-ethylation at C16 in 3D. Two variations on the HMGS cassette theme already have been identified. In the biosynthesis of bryostatin 1 and leinamycin 8, one or both of the ECH-mediated steps is likely omitted based on the final natural product structures. The details of these deviations have not yet been established.

Recently, in vivo evidence for the function of these HMGS cassettes has come from the Müller lab (49, 50, 65). To date, all HMGS cassette proteins for myxovirescin A (Tab/TaC, TaE/TaF, TaK, TaX, TaY) has been individually deleted, and the impact on the products of the engineered *Myxococcus xanthus* strains has been analyzed. In addition, analysis of products from TaV (the trans-acting AT), TaG (a cytochrome P450) that is thought to hydroxylate the HMGS-installed $\beta$-methyl group at C12 of Myxovirescin A was abolished (or greatly reduced) in all above deletion strains. A appearance of novel myxovirescin analogs ($\beta$-methyl vs $\beta$-methyl transferase necessary for completing the transformation to the final methoxy-methyl functionality) strains have provided insights into this complex pathway. Production of myxovirescin A was abolished (or greatly reduced) in all above deletion strains. A appearance of novel myxovirescin analogs ($\beta$-methyl vs $\beta$-ethyl) at C16 in the TaE & TaF strains appears to be a result of TaB or TaC supplementation, which provides direct evidence for TaE/TaF in the formation of the ethyl branch point. However, independent biochemical verification of TaF function has been difficult to obtain (58).

**HMGS cassette architecture**

Analysis of the placement of the known HMGS cassettes identified to date into their biosynthetic clusters reveals a variety...
Figure 6: HMGS containing biosynthetic pathways. Portions of the PKS and PKS/NRPS pathways where the HMGS and related enzymes are located.

of possible architectures (Fig. 6). For example, the ECH₂ decarboxylase exists as a discrete enzyme downstream of the ECH₁ dehydratase (mupirocin and others), as an N-terminal domain of a large PKS (curacin and jamaicamide), and as an embedded domain (pederin and onnamide). Although most clusters published to date are mixed PKS/NRPS systems with tandem ATs and tandem ACPs at the site of HMGS modification, exceptions exist for each example (difficidin is PKS only, curacin and jamaicamide contain embedded ATs, and bryostatin and myxovirescin do not contain tandem ACPs at the site of HMGS modification).

As HMGS enzyme cassettes have been identified and functionally characterized only recently, many mechanistic details as well as the key protein-protein interactions needed to orchestrate communication among the polyolide components remain unclear. Details on how the individual proteins are brought to the correct place in the pathway to perform their functions are still unknown for most pathways. In the case of the PksX/bacillaene pathway, some intriguing microscopy performed on B. subtilis suggests that the bacillaene proteins are clustered into a huge mega-enzyme factory inside the bacterial cell (66). Whether this organization extends (or is limited) to the other members of HMGS cassette containing pathways remains to be observed. Additionally, in some pathways, key enzymes have yet to be identified. Two lingering questions include: 1) Which AT domain loads the discrete ACP in the embedded AT systems specified by the curacin and jamaicamide pathways? and 2) where are the missing domains located in the incomplete cassettes? Despite these remaining issues, the stage is now set for these unique suites of enzymes to be included and applied in the growing metabolic engineering/combinatorial biosynthesis toolbox.

The goal of this review has been to highlight a series of novel systems for creating chemical diversity in polyketide natural product biosynthesis. This review includes the mechanistic basis for introduction of diverse branching functionality involves the HMGS-containing enzymes that are being identified in a growing number of PKS and mixed NRPS-PKS pathways. The rapidly increasing knowledge and mechanistic understanding of these complex metabolic systems will provide growing opportunities to engineer chemical diversity using rational approaches.

Acknowledgments

Research on modular type I polyketide synthases in the Sherman laboratory is supported generously by grants from the National Institutes of Health (GM 076477, CA 108874, TW 007404), the Hans and Ella McCollum Vahlteich Research Fund at the University of Michigan College of Pharmacy, and the H.W. Vahlteich Professorship in Medicinal Chemistry, J.D.K., is supported by an NRSA postdoctoral fellowship (GM 075641) from the NIH.

This review covers the biosynthesis of terrestrial and marine polyethers and discusses their biologic properties and the molecular genetics and enzymology of the proteins responsible for their formation. The biosynthesis of monensin, nanchangmycin, nonactin, and the marine polyether ladders are discussed in detail. Novel enzymes found only in type I polyketide polyether gene clusters that are responsible for the epoxidation and cyclization of polyene biosynthetic intermediates are described. The macrotetrolide biosynthetic gene cluster, which is an ACP-less type II polyketide synthase that functions noniteratively is reviewed.

**Biological Background**

Interest in these compounds (Fig. 1) derives from their ability to transport ions across biologic membranes, and some terrestrial polyethers have been used widely in veterinary medicine. Marine polyethers are responsible for numerous cases of human food poisoning and toxic algal tides, which cause massive fish kills.

**Terrestrial polyethers**

At physiological pH, the ionophores are ionized with the fat-soluble part of the molecule residing in the lipid bilayer of the membrane and the ionized moiety in the aqueous milieu (4). Binding of the metal ion takes place at the membrane surface. As successive ether oxygen atoms from the ionophore bind to the metal, it loses its solvated water molecules, thereby forming a neutral zwitterionic metal-ionophore complex. Transport across the membrane can now take place, and at the opposite surface, the process is reversed to leave the metal cation and the anionic ionophore on the other side of the membrane. The ionophore must bind another cation (usually a proton) to return to its original starting point.

The anionic ionophores are highly selective for particular metal cations, and both kinetic and thermodynamic terms determine which cation is selected. Note that the thermodynamic stability of the metal-ionophore complex does not always determine the transport rate. For example, nigericin forms a much more stable complex with potassium but transports sodium much more quickly. In the presence of both sodium and potassium, however, the extra stability of the nigericin–potassium complex results in the preferential transport of potassium over sodium. Selectivities of ionophores are shown in Table 1 (5, 6). The carboxyl group may (e.g., nigericin) or may not (e.g., monensin) be involved in cation liganding via an ionic bond. Monensin has six liganding oxygen atoms but none for ionic bonds, and it is a weaker complexing agent than nigericin. Lasalocid can form a singly charged complex with doubly charged cations such as Ca$^{2+}$. The broad specificity of lasalocid results from the metal's sitting on top rather than within the oxygen system of the ionophore. For nonactin, the ester carbonyl oxygen atoms and the ether oxygen atoms are all liganding and form the apices of the ionophore.

Polyketide Biosynthesis, Polyethers

Commercial interest in the polyketide polyethers stems from their antibiotic activity. In many polyethers, the class is potent coccidiostats and can control coccidial infections in poultry when added at approximately 100 ppm to the feed (7). Coccidiosis is caused from an infection in the digestive tract by parasitic protozoa, most commonly in poultry from the genus _Eimeria_. Monensin was the first polyether antibiotic to be patented and was released onto the market in 1971. It is still widely used today and is marketed under the tradename of Coban® (Elanco, Toronto, Ontario, Canada). After monensin treatment, coccidia have been observed to literally explode at daily intake levels should be set in line with Australian limits of human consumption. Lasalocid residues have been detected in food for which 1.5% of these are fatal (11). These toxins are produced by marine microalgae, predominantly dinoflagellates, and are associated with red tides and lead to massive fish kills and molluscan contamination. Most dinoflagellate toxins are polyketides and include many polyethers with distinctive ring junctions resembling the rungs of a ladder. The dinoflagellate toxins are hazardous if ingested or ingested. They are odorless, tasteless, and not destroyed by cooking or autoclaving. These toxins are extremely toxic in minute quantities, and no acceptable exposure limits have been established. Okadaic acid 11 is a potent and specific inhibitor of protein phosphatases produced by the dinoflagellates _Prorocentrum lima_, _Dinophysis fortii_, and _Dinophysis acuminate_. It accumulates in bivalves and is one of the main toxins responsible for diarrhetic shellfish poisoning (DSP) (11). It has a highly unusual biosynthesis that has generated a lot of speculation because of the presence of "isolated" acetate chain methyl carbon atoms. Okadaic acid is a potent inhibitor of protein phosphatase A (11).

The brevetoxins (e.g., brevetoxin A 13 and brevetoxin B 12) are a family of lipid soluble neurotoxins produced by _Karenia brevis_ (formally known as _Gymnodinium breve_), which are struc-turally similar to yessotoxin. They are thought to exert their biological action through the depolarization of the sodium channels of the excitabile membranes (11). Binding of brevetoxin to the voltage-gated sodium channels changes its function by shifting the activation voltage for channel opening to a more negative value and inhibiting the inactivation of opened channels (resulting in persistent activation). If ingested, they cause neurotoxic shellfish poisoning. Brevetoxin derivatives have been patented as a treatment for cystic fibrosis, mucociliary dysfunction, and pulmonary diseases. Yessotoxins 14 are produced by dinoflagellates of the genera _Protoceratium_ and _Gonyaulax_. They cause selective disruption of the E-cadherin-catenin system in epithelial cells (11). In common with the other "ladder" shaped marine polyethers, yessotoxin interacts with transmembrane helix domains of the gambiaic acids 15, which are isolated from _Gambierdiscus toxicus_, are potent antifungal compounds that are particularly effective against filamentous fungi but inactive against yeasts. They are also cytotoxic, but they do not exhibit the neurotoxicity that is associated with other large marine polyethers such as yessotoxins, brevetoxins, and maitotoxins (11).

With a molecular weight of 3422 Da, maitotoxin 16 (see Fig. 4a later on in this article) is the largest nonproteinaceous natural product isolated (3). It is a marine polyether ladder produced by the dinoflagellate _G. toxicus_. Maitotoxin is a powerful activator of voltage-insensitive Ca²⁺ channels and exerts its biological effect through the increase of intracellular Ca²⁺ concentration (11). It can be used as a tool for studies on cellular events associated with Ca²⁺ flux. It stimulates synthesis and secretion of the nerve growth factor. The minimum lethal dose of the toxin in mice is 0.17 µg/kg (intraperitoneally).

The ciguatoxins (CTXs) are responsible for the symptoms of ciguatera fish poisoning caused by ingesting certain tropical and semitropical fish from the Indo-Pacific Oceans and Caribbean Sea. Ciguatoxin poisoning is the most frequent food-borne illness related to fish consumption although it is rarely fatal.
Symptoms include neurological, cardiovascular, and gastrointestinal disorders, and ciguatoxins can be detected in all body fluids (12). Most people recover slowly over time, which can take from weeks to years. P-CTX1 (17) is the most toxic of all ciguatoxins with an LD50 of 0.25 µg/kg intraperitoneally. The toxins derive from the Gambierdiscus spp., which produce less-potent compounds that are biotransformed in the livers of the fin-fish to the more toxic ciguatoxins. The compounds activate the voltage-gated sodium channels that result in an increase of intracellular sodium. In high doses, ciguatoxins block the voltage-gated potassium channels that lead to membrane depolarization and that contribute to a lowering of action potential threshold (12).
Chemistry

Classical feeding experiments with both stable and radioactive isotopic labels (7) enabled the biosynthetic origin of the polyethers to be elucidated and for a general stereochemical model to be proposed (1). More recent work on this class of compounds has focused on a genetic approach, and unusual and interesting genes specific to polyether biosynthesis have been isolated from these clusters.

Monensin

Monensins A and B are polyether ionophores produced by Streptomyces cinnamonensis that differ only in the sidechain at C16 (ethyl/methyl). Monensin acts as a specific ionophore to dissipate ionic gradients across cell membranes and is used widely in veterinary medicine and as a food additive in animal husbandry (7). Antimalarial activity has also been reported (8, 9). Monensin is the best studied of the polyether ionophore antibiotics, and it was the first to have its gene cluster sequenced (2).

Early feeding studies established that monensin A is biosynthesized from a classical polyketide pathway and is derived from five acetate, seven propionate, and one butyrate (for monensin B, an additional propionate unit replaces the butyrate) (7). Four of the nine oxygen atoms are derived from molecular oxygen, with the remaining five deriving from the corresponding carboxylic acid precursors (Fig. 2a). Based on these initial

\(^*\)"unnecessary" domain (sequence is indistinguishable from active Mon DH domains).

\(^{†}\)The AT of module 5 should incorporate an ethylmalonate extender unit, and it contains a signature sequence very close to the propionate sequence.

\(^{‡}\)Predicted to be inactive.

\(^{||}\)Originally assigned as double bond isomerase.

\(^{§}\)Originally assigned as epoxide cyclase.

Experiments, it was proposed that the monensin PKS produced a linear E,E,E-triene precursor \(^{24}\) that was oxidized and cyclized to give the final structure \(^{1}\). Alternative proposals using Z,Z,Z- and E,Z,Z-trienes have been made \(^{2}\).

Publication of the gene cluster for monensin \(^{2, 13-17}\) showed that the PKS comprised 12 modules in eight contiguous open reading frames consistent with the production of the linear triene premonensin \(^{25}\). The loading module contains an N-terminal KSQ domain that functions as a malonylCoA decarboxylase to generate starter units in situ. The monensin PKS does not contain an integrated C-terminal thioesterase domain at the end of module 12; instead an unusual 121 amino acid extension, rich in glycine, asparagines, and glutamine, was found \(^{13}\). **MonCII\(^{||}\)**, which was originally assigned as an epoxide cyclase, has been shown to hydrolyze monensinyl NAC thioester \(^{21}\) (Fig. 2c) as well as two other model substrates \(^{14}\). Deletion of **monCII** gave a mutant that produced none or only trace amounts of monensin, which is consistent with its role as a chain-terminating TE. Complementation of **monCII** on a plasmid restored monensin production. Moreover, cell-free extracts from the **monCII** mutant treated with KOH gave significant amounts of monensin that resulted from the hydrolysis of a monensinyl ester or thioester present in the cell-free extract. Two ORFs, **monAIX** and **monAX**, have been shown to function as Type II thioesterases. Deletion of **monAIX** and/or **monAX** resulted in a modest drop in the monensin titer, which is consistent with their editing Type II TE role \(^{14}\). Genes for late steps such as methylation (**monE**) and hydroxylation (**monD**) and several regulatory genes (**monR, R1, R1I**) were found in the cluster \(^{2, 13}\). **MonT** is proposed to be involved in monensin export and consequently ensures the
producing strain is self-resistant. The monC gene product is a flavin-dependent epoxidase. Deletion of monC results in complete loss of monensin production and the accumulation of the linear E, E, E-triene lactones \(\text{22, 23, Fig. 2d,}\) which differ from premonensins \(\text{25}\) only by the different cyclization pattern of the polyketide chain: \(\text{3,3-lactone} \text{22, 23, compared with a hemi-ketal} \text{25} (12).\) Strains in which the adjacent genes monB1 and/or monBII are deleted in addition to monC show the same results. No oxidized derivatives of \(\text{22 and 23}\) were found, which suggests that the epoxidase encoded by monC is necessary and sufficient for epoxidation of all three double bonds. These experiments are consistent with an E,E,E-configured triene as originally proposed by Cané et al. (1). Heterologous expression of \(\text{monC}\) in Streptomyces coelicolor gave a strain that could convert linaroil to linalool oxide with a 10-20-fold greater conversion activity than studies carried out previously with \(S.\) cinnamonensis (13).

MonB1 and monBII are highly homologous to each other and significantly similar to a \(\alpha,\alpha,\alpha\)-ketoesteroid isomerase of \(S.\) monomos testosteroni. Originally, it was proposed that monB1 and monBII interconverted \(\text{E, E, E-}\)double bonds to \(\text{Z}\) via an extended enolate ion during polyketide biosynthesis in two modules (resulting in an \(\text{E, Z, Z-}\)triene intermediate) (2). Their assignment has been revised in light of new experimental evidence that has shown that they are involved in the epoxide ring opening and concomitant polymer ring formation (16). Deletion of monB1 and/or monBII gave strains that produced no monensin. Instead, \(\text{C-3,0-demethylmonensins 18, C-9-epi-monomensins 19, and C-26-deoxy-epi-monomensins 20 (Fig. 2a),}\) were produced in addition to numerous minor components. The major products from these mutant strains were the \(\text{C-3,0-dimethyl}\) analogs. Hence, in the absence of the \(\text{C-3-methoxy group, nucleophilic attack by the C-5 hydroxy group from the si face of the C-9 carbonyl giving the natural epimer of the spiroketal takes place (Fig. 2a). In contrast, the presence of the methoxy group at C-3 leads to the C-5 hydroxy attacking the C-9 carbonyl from the re face leading to the unnatural spiroketal epimer 39. The C-26-deoxy-epi-monomensins result from them being poor substrates for MonA. Treatment with acid converted the epi-monomensins into the more thermodynamically stable corresponding monomers. Additional minor metabolites were detected in the cell culture but were produced in insufficient quantities to allow for structure determination. LC-MS analysis revealed that their molecular weights were identical to monensins A/B and C-3,0-demethylmonensins A/B, which suggests that they were intermediates with the correct oxidation state but cyclized incompletely. Treatment of these minor metabolites with acid led to their conversion to monensins A/B and C-3,0-demethylmonensins A/B. Taken together, these results show that the MonB enzymes are epoxide hydrolyase/cyclase enzymes that accelerate, but do not change, the stereochemical course of polyether ring formation (16). Since the pattern of products in MonB1 and MonBII mutants seem to be identical, it seems that their actions are somehow coordinated and could in principle exist as a heterodimer in \(S.\) cinnamonensis. Although the arrangement of the proteins is not known, it is clear that ring closure in monensin biosynthesis occurs step-wise in a precise order under enzymatic control from one or both MonB enzymes. The timing of the hydroxylation step at C-26 has also been shown to occur before either methylation or polyether ring formation (16). The biosynthetic pathway for monensin is shown in Fig. 2e.

**Nanchangmycin**

Streptomyces nanchangensis produces the polyether antibiotic nanchangmycin 29, the 16-membered macrolide meilingmycin, and at least two other antibiotics of unknown structure (18).

The nanchangmycin gene cluster comprises 30 ORFs in a region of \(\text{132 kb}\) of DNA (Table 3 (19, 20). The type I PKS, encoding 14 modules in 11 ORFs, is arranged in two distinct groups (\text{nanA1-A6, nanA7-A11}) with the sugar biosynthesis genes located in between. A KSQ domain is located in the loading domain in \(\text{NanA1}\) and the decarboxylation of malonate provides the acetate start unit. The type II ACP (\text{NanA10}), which lacks an ACP function. Either side of \text{nanA10} three unique polymer genes are located: \text{nanI}, \text{nanO}, and \text{nanE}, which are homologous to \text{monB1/bi, monC1, and monCII.}\) The epoxidase encoded by \text{nanO} oxidizes the triene precursor \(\text{30, which is then cyclized by NanE (Fig. 2b). Originally,}\) the chain-releasing (CR) domain located in module 14 was thought to carry out the release of the polyether chain from the nanchangmycin PKS (19). Recent work has shown that although the CR domain is required in vivo for the efficient production of nanchangmycin, it does not catalyze the release of the polyether chain from the PKS (20). \text{NanE,}\) in fact responsible for the release of the fully processed nanchangmycin. It is homologous to both \text{monC11} and \text{NigCII (which carries out an analogous role in nigericin biosynthesis). A gene encoding a cytochrome P450 (nanF) is located adjacent to the second PKS cluster and is thought to catalyze the oxidation of the C30 methyl group (19). It is proposed that the biosynthesis of nanchangmycin (Fig. 3b (19, 20)) begins with loading of malonyl CoA onto \text{NanAI.}\) Subsequent decarboxylation and 13 rounds of extension would result in a tetradecaketide intermediate 30 that is attached to the type II independent ACP \text{NanA10}. Two epoxidations of the triene intermediate by \text{NanO} and ring opening of the di-epoxide 31 by \text{NanI} take place while the PKS intermediate is still attached to the independent ACP \text{NanA10}. The polymer chain 32 is then transferred to the ACP of module 14 for the final round of chain extension. Release from the PKS (\text{NanE}) followed by hydrolase (at C-30 by the putative monooxygenase \text{NanP}) would give the completed aglycone polyether 33. Biosynthesis of the 4-0-methyl-L-rhodinose from D-glucose-1-phosphate (\text{NarG/1-G4, NanM}) and attachment to the aglycone by \text{NanG/5 provides the completed nanchangmycin.}\)

The novel nanchangmycin aglycone 29 (Fig. 3a containing a keto group at C-19 was produced from a mutant containing an in-frame deletion of the module \(\text{6 K R (19).}\)

**Nonactin**

The macrotetrolides 5-9 are a family of macrocyclic polyethers produced by \(S.\) griseus that exhibit a broad spectrum of biological activities (antibacterial, antitumor, antifungal, and immunosuppressive) (5, 21). They can act as ionophores and...
are effective against Gram-positive bacteria, mycobacteria, and fungi. The parent compound, nonactin 5, is an achiral molecule assembled from four molecules of enantiomeric non-actic acid \[ \text{\textit{34}} \] (Fig. 3c) in a (+)-(−)-(−)−ester linkage. The homologues \[ \text{\textit{6–9}} \] are derived from the substitution of ethyl groups for methyl groups on the macrocyclic backbone.

Classical biosynthetic studies with \(^{14}\text{C}\)-labeled compounds and later with stable isotopes established that nonactic acid is derived from two acetates (or malonates), succinate and propionate \([\text{\textit{Fig. 3d}}]\) (21). Feeding studies with \[^{36}\text{C}\] has shown that the first committed step of macrotetrolide biosynthesis is the coupling of the succinate unit with an acetate (or malonate) to give \(-\alpha\)-ketoadipate \[ \text{\textit{40}} \] (22). The late steps of non-actic acid biosynthesis \([\text{\textit{Fig. 3g}}]\) were shown to involve the cyclization of \textit{42a}\ into (−)-nonactate and \textit{42b}\ into (+)-nonactate, which demonstrates that a pair of enantiocomplementary pathways are operating in nonactate biosynthesis \(\text{\textit{32}}\). (+)-Non-actic acid is incorporated efficiently into nonactin. Both (+) and (−)-nonactic acids as well as their dimers have been isolated from cultures of \textit{S. griseus}.

Genetic characterization of the nonactin gene cluster has revealed that an ACP-less Type II PKS is used to assemble the macrotetrolides \(\text{\textit{22}}\). The non-PKS is highly unusual, catalyzing both C–C and C–O bond-forming reactions, functioning noniteratively and acting on acyl CoA substrates \(\text{\textit{32}}\). The late steps of nonactate biosynthesis \([\text{\textit{Fig. 3g}}]\) were shown to involve the cyclization of \textit{42a}\ into (−)-nonactate and \textit{42b}\ into (+)-nonactate, which

these 23 nongenes in S. lividans resulted in macrotetrolide production, thereby confirming that only these genes are required for macrotetrolide biosynthesis; sequestration of an ACP from elsewhere on the S. griseus genome does not occur.

The proposed biosynthetic pathway (Fig. 3g) requires three condensation and four reduction steps that would require at least three K5 and four KR genes. It has not been established whether the five K5 and four KR proteins function independently, but it has been demonstrated that all nine enzymes are required for macrotetrolide biosynthesis. Shen and Kwon (21) have suggested that the macrotetrolide PKS comprises noniteratively functioning subunits, which is unprecedented in all Type II PKSs known to date. NonJ and NonK have been assigned roles in dimerization (see below), which leaves NonPQU to carry out the three C–C bond-forming reactions. A mutant lacking the NonPQU genes was able to convert non-actinic acid into nonactin, whereas deletion of NonK resulted in no macrotetrolide formation. Hence, NonPQU represents a novel Type II minimal PKS that acts noniteratively, does not have an ACP, and uses acyl CoA substrates directly for polyketide biosynthesis.

NonJ has been shown to catalyze the first dimerization step to give (+)-nonactyl(+)-nonactyl CoA (44), and NonK is responsible for the stereospecific cyclodimerization to afford nonactin (21). All C–C bond forming KSs are characterized by a Cys–His–His (Asn) catalytic triad (including Non-PQU), whereas NonK is characterized by a mutated catalytic triad: Cys–Gly–Tyr–His. Replacement of the conserved cysteine residue in NonJ or NonK with glycine gave mutants that could not catalyze the transformation of (+)-non-actinic acid into nonactin. Taken together, NonK cannot function as a decarbonylase and instead the entire pathway to the C–C bond-forming steps in nonactin biosynthesis using the same active site cysteine that other KSs use for C–C bond formation. In common with NonPQU, NonJ and NonK act noniteratively on CoA substrates.

The product of the minimal PKS, 4L, is the branch point of the pathway that diverges into a pair of enantiomeric-specific pathways, each of which involves two KRs and affords (+)- or (-)-42. The nonactate synthase, NonS, catalyzes the intramolecular Michael addition of (+)-nonactinic acid 43a from (-)-42a. A NonS mutant supplemented with (+)-nonactinic acid could produce nonactin, monactin, and dinactin, but not trinactin and tetranactin, which require one (–)-homomonactate moiety, respectively. This process suggests that NonS can cyclize (-)-42a into (+)-nonactin 43b and (+)-homomonactate 35 only and that another nonactate synthase is required for the cyclization of (+)-42b to give (+)-nonactin 43b and (+)-homomonactate. Based on its high sequence homology to CoA ligases, NonL was identified as a CoA ligase catalyzing the transformation of (+)-nonactinic acid into (+)-nonactyl CoA. The sequence of reactions for the biosynthesis of nonactin and the other macrotetrolides in S. griseus is shown in Fig. 3g.

S. griseus is likely to be protected from nonactin by two mechanisms. The first mechanism seems to involve pumping excess antibiotic from the cell. Two genes, orf5 and orf6, which are clustered with the rest of the nonactin biosynthesis genes, show homology with A/B transporter genes. The second mechanism is the enzyme catalyzed hydrolysis of nonactin and homologues by NonR, which is homologous to serine protease and esterase enzymes and confers tetranactin resistance to S. lividans TK24. Overexpressed NonR has been shown to stereospecifically catalyze the hydrolysis of the macrotetrolide ring into homochiral nonactane-dimer 37 (Fig. 3f) in a two-step process (23). The macrotetrolides are converted initially into their secotetramer species and subsequently hydrolyzed to the dimer; in both cases, it is the bond between the alcohol of the (–)-nonactate and the carboxylate of (–)-nonactate that is cleaved. No trimer or monomers were detected.

**Marine polyether ladders**

All marine polyether ladders thus far characterized (e.g., maitotoxin 26 (Fig. 4a), the brevetoxins 12 and 13 and hemibrevetoxin B, the yessotoxins 34 (and the truncated atradiotoxin), the Pacific and Caribbean ciguatoxins, the gambieric acids 15 and gemberial (the gymnocins and brevena) can be grouped into 14 backbone structures (3).

Retrobiosynthetic analysis of these structures has led to the development of a model for the biosynthesis of these complex structures from the cyclization of a polyepoxide precursor (3). The model accounts for the conserved stereochemistry of the numerous ring junctions in these polyethers, which are syntrans (Fig. 4b). The required configuration of the rings can be derived from stereochimically identical all (R,R)- or (S,S)-trans epoxides, which are derived from the appropriate polyene (which may contain over 20 double bonds). Epoxidation of the polyene precursor takes place from the same face, and consequently, it is possible for a single monooxygenase with broad specificity to produce all trans epoxides. Ring closure requires an endo-selective opening of each epoxide.

Independently, Prasad and Shimizu (24) as well as Lee et al. (25) proposed that brevetoxin A is biosynthesized from the cyclization of a polyepoxide precursor in a series of 5,6 (R,R)-trans epoxide openings (Fig. 4c). Gallimore and Spencer (3) argue that the nine disulfated endo-tet closures required for this mechanism makes it mechanically unlikely and point out that an alternative cascade of 5S2 epoxide openings in the opposite direction from all (S,S)-trans epoxides yields the same structure.

Although it can be envisaged that a trans-polyene is converted by a monooxygenase to a polyepoxide intermediate, which is processed by an epoxide hydrolase (cf. NonR in monoenes biosynthesis) to the polyyclic ether, because of the reactivity of the polyepoxide intermediate (which may contain in excess of 20 reactive epoxide groups), this seems unlikely. An alternative mechanism is for the epoxidation and cyclization steps to be coupled in an iterative process whereby the production of an epoxide is followed by ring closure (Fig. 4d). Gallimore and Spencer (3) suggest that it may be possible for this process to be affected by the monooxygenase only: After epoxidation, the bound enzyme stabilizes the endo transition state relative to the exo as the hydroxyl nucleophile attacks. Once the ring has been closed, the enzyme would dissociate and move on to the next double bond. In this manner, a single enzyme could be responsible for the conversion of a polyene chain to a polyether ladder. In both cases, no restriction on...
Polyketide Biosynthesis, Polyethers

Figure 4  (a) Maitotoxin. (b) Common structure feature of marine polyether ring junctions (3). (c) Brevetoxin A biosynthesis as proposed by 1) Shimizu/Nakanishi (24, 25) and 2) Gallimore and Spencer from all (S,S)-trans epoxides (3). (d) Possible enzymatic routes to a fused polyether using 1) a mono-oxygenase and an epoxide hydrolase or 2) a mono-oxygenase only (3).

Of all the marine polyether ladder metabolites examined, only a single ring junction in the largest natural product, maitotoxin, could not be explained using the model (3). Three of the four ladders in maitotoxin conformed to the stereochemical model; however, ladder C requires an epoxide with the opposite stereochemistry to the other centers, which gives rise to the only
exceptional ring junction ("the K ring junction") in any of the known polyether ladders. To explain this anomaly, Gallimore and Spencer (3) refer back to the original stereochemical assignment by Satake et al., which is described as challenging, and they suggest that the assignment be reexamined.

Chemical Tools and Techniques

Early work on polyethers relied on the isolation and structure determination of the natural products followed by classical feeding experiments using both radioactive and stable isotopes to elucidate their biosynthesis (7). Today, advances in genetic techniques have allowed the gene sequences of the terrestrial polyethers to be studied although the number of published polyether clusters is small compared with macrolides and mixed NRPS/PKS systems. No marine polyether has had its gene cluster characterized, which reflects the difficulties with working with marine organisms and the lack of molecular tools available for these systems.

An interdisciplinary approach is required to study the polyethers involving chemists, biochemists, and molecular biologists. The first step is the isolation and structure determination of the polyether by natural product chemists. For the marine polyether ladders, this can be a huge undertaking in itself. Maitotoxin 16, for example, has four ladders, 32 rings, and a molecular weight of 3422 Da! Sophisticated NMR experiments have allowed the gene sequences of the terrestrial polyether clusters to be determined, which reflects the difficulties with working with marine organisms and the lack of molecular tools available for these systems.

Locating the polyether gene cluster can be done by using probes specific for polyketide genes to screen a cosmid library of total DNA. For both monensin 2 (2, 13) and nanchangmycin 28 (19), probes from the erythromycin PKS were used. Alternatively, the polyether’s resistance gene can be used to locate the gene cluster [e.g., monB (5)]. Sequencing and mapping of the cosmids in the library allows the gene cluster size and composition to be determined. More than one PKS sequence can be revealed, so care must be taken to ensure that the gene cluster of interest is being sequenced. For example, eight clusters were identified from the nanchangmycin producer S. nanchangensis, and the nanchangmycin gene cluster was identified through gene disruption (18). The organization and assignment of function of each ORF is carried out by sequence comparison. Cloning and overexpression of individual enzymes in the gene cluster is an important step in confirming the function and mechanism of a particular ORF. For example, sequence comparisons of both the monensin and the nanchangmycin clusters revealed no TE function required for the release of the polyketide from the PKS. However, cloning, overexpression, and characterization of M. Oilya and N. Esg (20) resulted in the reassignment from oxidative cyclization to Type I TE.

The preparation of mutants is an important tool to investigate the role of individual enzymes, and it is used to ascertain which genes in the cluster are essential for the biosynthesis of the polyether and whether modified/truncated products are formed. The effected gene can then be supplied on a plasmid to see whether activity can be restored. Chemists are required to analyze the fermentation mixtures for minor and truncated metabolites. In this manner, the triene lactones Z2 and Z3 were isolated from a 7L culture of a mutant strain of S. cinnamonensis lacking MonCI, and their structure was determined by NMR (15).

HPLC-MS is an essential technique for the separation and identification of these trace compounds, but unless sufficient quantities can be isolated for structure determination by NMR, chemists are also required to synthesize standards for comparison. Characterization of the gene cluster requires chemists to synthesize intermediates (often with stable isotopes at specific places) to be used as substrates for purified enzymes or to confirm the structure of products formed from modified genes.

Terpenoids constitute the largest class of secondary metabolites in the plant kingdom. Because of their immense structural diversity and the resulting diversity in physiochemical properties, these molecules are particularly important for plant communication with other organisms. In this article, we will describe the ecological significance of terpenoids for plants, how terpenoid formation is regulated, and the tools we have to improve our understanding of the role of terpenoids in plant ecology and to create crop plants with improved resistance.

As plants are sessile, they cannot run away to avoid confrontation. Instead, they have evolved many different defense strategies, which include morphological (e.g., thorns, spines, and thick cuticle) and chemical defenses (e.g., repellents, toxic proteins, and toxic metabolites). Here, we will focus on the chemical defense of plants mediated by chemical compounds and one class of metabolites in particular: the terpenoids. They are of great importance to plants because of their multitude of functions in signaling and defense. Virtually all plant species have been shown to contain terpenoids and/or to release them from leaves, flowers, fruits, and roots into the environment to defend themselves—directly or indirectly—against herbivores and pathogens or to provide a reproductive advantage by attracting pollinators or seed dispersing animals.

As plants are sessile, they cannot run away to avoid confrontation. Instead, they have evolved many different defense strategies, which include morphological (e.g., thorns, spines, and thick cuticle) and chemical defenses (e.g., repellents, toxic proteins, and toxic metabolites). Here, we will focus on the chemical defense of plants mediated by chemical compounds and one class of metabolites in particular: the terpenoids. They are of great importance to plants because of their multitude of functions in signaling and defense. Virtually all plant species have been shown to contain terpenoids and/or to release them from leaves, flowers, fruits, and roots into the environment to defend themselves—directly or indirectly—against herbivores and pathogens or to provide a reproductive advantage by attracting pollinators or seed dispersing animals.

Terpenoids, which are also known as isoprenoids, constitute the most abundant and structurally diverse group of plant secondary metabolites, consisting of more than 40,000 different chemical structures. The isoprenoid biosynthetic pathway generates both primary and secondary metabolites that are of great importance to plant growth and survival. Among the primary metabolites produced by this pathway are phytohormones, such as gibberellic acid (GA), abscisic acid (ABA), and cytokinins; the carotenoids, such as chlorophylls and plastoquinones involved in photosynthesis; the ubiquinones required for respiration; and the sterols that influence membrane structure (see also Steroid and Triterpene Biosynthesis) (Fig. 1). Monoterpene (C10), sesquiterpenes (C15), diterpenoids (C20), and triterpenoids (C30) are considered to be secondary metabolites (Fig. 1). Many secondary metabolite terpenoids are of commercial interest because of their flavor, fragrance, or medicinal properties. Here, we will discuss the role of terpenoids in plant signaling.

Biological Background

Induction of biosynthetic pathways, mechanisms, and functions

Terpenoids are derived from the cytosolic mevalonate pathway or from the plastidial 2-C-methyl-D-erythritol-4-phosphate (MEP) pathway (see also Terpenoid Biosynthesis). Both pathways lead to the formation of the C5 units isopentenyl diphosphate and its allylic isomer dimethylallyl diphosphate, which are the basic terpenoid biosynthesis building blocks (Fig. 1). Although increasing evidence suggests that exchange of intermediates occurs between these compartments, the cytoplasmic mevalonate pathway is generally considered to supply the precursors for the production of sesquiterpenes and triterpenes (including sterols) and to provide precursors for protein prenylation and for ubiquinone and heme-A production in mitochondria. In the plastids, the MEP pathway supplies the precursors for the production of isoprene, monoterpenes, diterpenes (e.g., GAs), and tetraterpenes (e.g., carotenoids).
After the formation of the acyclic precursors geranyl diphosphate, farnesyl diphosphate, and geranylgeranyl diphosphate, terpenoid scaffolds are generated through the action of terpene synthases (TPSs). Primary terpene skeletons formed by TPSs can be modified even more by the action of various other enzyme classes, such as the cytochrome P450 hydroxylases, dehydrogenases (alcohol and aldehyde oxidoreductases), reductases, glycosyl transferases, and methyl transferases (see also Chemistry of Cytochrome P450 Monooxygenases, Glycosyl Transferases and Methyl Transferases). localization of terpenoid biosynthesis

Terpenoids are implicated in several ecological and physiological functions and are often emitted from specific tissues at particular times related to their function. Many monoterpene and sesquiterpene synthase genes have been isolated and characterized from terpene-accumulating cells and tissues, such as leaf glandular trichomes, specific floral tissues, and fruits of agriculturally important plants. For plants that contain glandular trichomes, monoterpene production is considered to be localized exclusively in these organs. Resin ducts or oil glands can accumulate large amounts of terpenoids.

In floral tissues, volatile terpenes are often emitted at particular times to attract pollinators or to repel herbivores or microbial pathogens. Biosynthesis of the monoterpene β-ocimene and myrcene in snapdragon flowers, for example, is correlated with expression patterns of the corresponding genes in the flower petals that showed a (weak) diurnal oscillation under the control of a circadian clock (1). This finding indicates that these terpenes function as attractants for pollinating insects. In Arabidopsis, monoterpene and sesquiterpene synthases are not expressed in flower petals, but they are limited to the stigma, anthers, nectaries, and sepals (2), which suggest the importance of terpenoids for the defense of floral tissues against herbivores or microbial pathogens next to attraction of pollinators. Some terpene synthase genes exhibit expression in flowers as well as in fruits, whereas other genes are specifically expressed at particular stages of fruit development or ripening.

In contrast to the above-ground organs of plants, roots represent an unexplored area of terpene biosynthesis and function. To date, just a small number of terpene synthases have been identified in plant roots. In Arabidopsis, the terpene synthase genes that encode 1,8-cineole synthase and (Z)-γ-bisabolene synthase are expressed differentially in the stele of younger root growth zones and in the cortex and epidermis of older roots (reviewed...
in Reference 3). Little is known about the biological functions of volatile terpenes in roots at different developmental stages and in the interactions with root herbivores, microorganisms, and parasites. Terpene biosynthesis can be induced in roots under stress conditions, as shown in maize roots in response to attack by herbivores (4).

Terpenoids and Plant Signaling

Terpenoids are one of the major classes of compounds used by plants to communicate with their environment. This communication includes attraction of beneficial organisms (and unwanted attraction of herbivorous organisms) as well as defense against harmful organisms. With regard to the latter, plants employ direct as well as indirect defense mechanisms, against herbivores or fungal and bacterial pathogens. Direct defense includes physical structures, such as thorns and trichomes, and the accumulation of toxic metabolites or proteins to deter or even kill attackers. In many plant species, diterpenes and sesquiterpenes act as phytoalexins, which are low-molecular-weight compounds that are produced as part of the plant defense system against microorganisms. Compounds such as the bitter sesquiterpene cucurbitacin and the pungent sesquiterpenoid polygodial have been shown to be involved in direct defense against insects (Fig. 2).

Indirect defense implies that plants defend themselves against herbivores by enhancing the effectiveness of the natural enemies of these herbivores. These defense mechanisms can be constitutive like the formation of domatia, which serve as homes for ants and nites, or the production of foliar nectaries and nutritional structures that can be used by natural enemies of the herbivores. In addition, indirect defense mechanisms in plants can be induced. One of the most intriguing examples of this function is the emission of herbivore-induced plant volatiles, which attract the carnivorous natural enemies of herbivores. These herbivore-induced plant volatiles predominantly consist of terpenoids that mediate many interactions in a plant–insect community, both above and below ground (4, 5). The volatiles that plants produce in response to herbivore damage can affect various other interactions of the plant with community members (5, 6). Moreover, herbivore-induced plant volatiles can affect herbivore-plant and carnivore-herbivore interactions on neighboring plants through their effect on the neighbor’s phenotype (5, 7).

Terpenoids in direct defense

Direct-defense compounds can be either constitutively present in specific parts of the plant or be produced after induction by pathogens or herbivores. The latter compound will be less costly for the plant. For example, elicitor-induced accumulation of the antimicrobial sesquiterpenoid capsidiol correlated with the induction of 5-epi-aristolochene synthase, which is a branch-point sesquiterpene cyclase involved in the synthesis of sesquiterpene phytoalexins (8). In rice (Oryza sativa L.), 14 diterpenoid phytoalexins have been identified. All these compounds are accumulated in rice leaves after inoculation with the pathogenic blast fungus Magnaporthe grisea and exhibit antimicrobial properties (9). Another example is pyropolyp, which has generated considerable interest because of its potent insect antifeedant activity. In cotton (Gossypium spp.), gossypol and related sesquiterpene alkaloids, which are all derived from (-)-δ-cadinene, provide both constitutive and inducible protection against pests and diseases.

Figure 2. An overview of terpenoid-mediated interactions between plants with the surrounding environment. Floral scent to attract pollinators (1, e.g., β-myrcene); Protection of reproductive organs from fungal or bacterial infection (2, e.g., thujaplicin); Direct defense: repellency of herbivorous insects by volatile terpenoids (3, e.g., zingibene); Attraction of predators and parasitic wasps on insect or spider mite herbivory (4, e.g., 4,8-dimethyl-3(2H)-menthene); Priming or elucidation of defense in neighboring plants (5, e.g., α-cadinene). Defense compounds in beans against insect herbivores, fungi and bacteria (6, e.g., polygodial), fruit aroma to stimulate consumption and thereby seed dispersal (7, e.g., β-caryophyllene); Germination of parasitic plant seeds (8, e.g., strigol); Stimulation of growth and attachment of symbiotic mycorrhizal fungi (9, e.g., δ-desmosterol); Attraction of entomopathogenic nematodes after root feeding of beetle larvae (10, β-caryophyllene); Direct defense to protect against insect herbivores, fungal infection, or bacterial infection (11, rhamnol).

**Figure 1** Induction of terpenoids in cucumber and potato leaves after herbivory by spider mites (*Trionyxus unarius*) or thrips (*Frankinia occidentalis*) (Kappers R, Buskensmeier HJ, Dieder M, Unpublished results).

(Reviewed in Reference 12). Within a plant species, the quality of the volatile blend may be affected by the developmental stage of the herbivore, and the volatiles produced by plants upon insect egg deposition may differ from the one induced by feeding (11). Typical volatiles released from a multitude of species after herbivory are the so-called green leaf volatiles such as C6-alcohols, -aldehydes, and -esters, which are derivatives of the shikimate pathway such as methyl salicylate, and terpenoids such as (E)-4,8-dimethyl-1,3(*E*,*E*)-7-nonatriene, and 4,8,12-trimethyl-1,3(*E*,*E*)-11-tetradeca-tetraene. The terpenoids are by far the most important contributors to the induced volatile blend. To date, little information exists about how natural enemies respond to individual components found in induced odor blends, even though it is known whether they can distinguish between complex odor mixtures, A. Also, it is still unclear whether natural enemies use only a few compounds present in an odor blend for prey identification, or whether they use information from all odor compounds. For a multitude of tritrophic systems, it was shown that predatory mites and parasitoid wasps were attracted by terpenoid components from induced volatile blends, for instance (E)-4,8-dimethyl-1,3(*E*,*E*)-7-nonatriene and 4,8,12-trimethyl-1,3(*E*,*E*)-11-tetradeca-tetraene (4, 6, 12).

**Terpenoids in Aboveground Plant–Plant Communication**

Volatiles released from herbivore-infested plants mediate plant-plant interactions and may induce the expression of defense genes and emission of volatiles in healthy leaves on the same plant or of neighboring unattacked plants, thus increasing their attractiveness to natural enemies and decreasing their susceptibility to the damaging herbivores (Fig. 2) (reviewed in Reference 13). This phenomenon is called priming, and it prepares neighboring plants to respond more rapidly and intensively against subsequent attack by herbivorous insects (13), for example by increasing extra-floral nectar secretion to attract predatory arthropods (14).

Several reports showed that herbivore- and elicitor-induced plant volatiles, in particular green leaf volatiles and terpenoids, influence gene expression and result in priming of defense responses of neighboring conspecific and nonconspecific plants that were not attacked. Terpenoids emitted from herbivore-infested *Nicotiana attenuata* enhance the expression of numerous genes of neighboring conspecifics (15). One example is (E)-4,8-dimethyl-1,3(*E*,*E*)-7-nonatriene that can act as plant-plant signal by upregulating signaling pathways of *jasmonic acid* and ethylene in neighboring plants (16).

**Terpenoids in rhizosphere communication**

In the rhizosphere, plants use terpenoids for communication with other organisms. The fact that only a few such relationships have been demonstrated probably more reflects the difficulty of studying chemical signaling in the soil than the actual contribution of rhizosphere signaling to plant functioning. Surprisingly, among those rhizosphere-signaling relationships that have been uncovered, several constitute the attraction of pathogenic organisms by highly specific signaling molecules. Examples are the hatching of cyst nematodes, which is triggered by terpenoids (e.g., soybean cyst nematodes by glycoeclepin and potato cyst nematodes by solanoeclepin) (Figs. 1 and 2). From an evolutionary point of view, one must conclude that these molecules must have another, as yet unknown, positive function for plants or otherwise they would have been selected against. This function is illustrated by the example of strigolactones, which are apocarotenoid-signaling molecules that are secreted by the roots of many plant species. In the 1960s, these compounds were identified as the germination stimulants that trigger germination of the seeds of the root parasite Orobanchaceae (*Striga* spp. and *Orobanche* spp.) (17). These obligate parasites can only survive if they grow on the roots of a host plant from which they take water, assimilates, and nutrients. Several *Striga* and *Orobanche* species can be a nuisance in agriculture, where they can destroy complete harvests. To prevent the tiny seeds from germinating at too large distance from a host root, parasitic plants have evolved a requirement for so-called germination stimulants, collectively called the strigolactones, which are compounds that are produced by the roots of their hosts (Figs. 1 and 2).

The reason for the existence of the strigolactones remained unknown until 2005 when it was discovered that they are an important host-finding factor for arbuscular mycorrhizal (AM) fungi (18). In the arbuscular mycorrhizal symbiosis, plants obtain water and mineral nutrients from their fungal partners, which allow them to survive under various stressful conditions. AM fungi are obligate symbionts that have facilitated the adaptation of primitive plant species to life on land and colonize the roots of most land plant species. Apparently, mycorrhizal symbiosis required the production of strigolactones throughout the plant kingdom and then, indirectly, allowed for the later evolution of the host detection mechanism of parasitic plants using the same compounds (17).

Tritrophic interactions, for which so much evidence exists aboveground, are gradually being uncovered in the rhizosphere.
Regulation of Terpenoid Formation

Biotic and abiotic factors affecting terpenoid formation

The production of secondary metabolites by plants has been shown by many authors to be influenced by environmental conditions. Therefore, it can be expected that this finding holds for terpenoids involved in signaling. Knowledge of these effects may be important for improvement of biological control, resistance against attackers, or attraction of beneficial organisms (e.g., by applying the most optimal conditions for efficient signaling molecule production). The factors that have been shown to affect secondary metabolite production such as light, temperature, and water availability have also been investigated for their effect on herbivore-induced volatile biosynthesis. High light intensity and water stress are generally reported to increase induced volatile production and/or predator attraction for example in lime bean, kidney bean, maize, and cotton (reviewed in Reference 19). Fertilization had a strong positive effect on emission of induced volatiles in maize, even when results were corrected for plant biomass (19). Hence, climatic conditions and nutrient availability can be important factors in determining the intensity and variability in the release of induced plant volatiles.

In rhizosphere signaling, environmental conditions affect the production of signaling molecules. A particularly clear case is the production of strigolactones, which are the host-presence signaling molecules for AM fungi (see above). AM fungi help plants to absorb nitrogen and phosphate and hence improve plant growth in areas of the world where the concentration or availability of particularly phosphate in the soil is limited (17). Interestingly, root exudates of red clover, tomato, and rice grown under phosphate limitation produce much more strigolactones. It can be argued that in this way, plants improve the chance to attract AM fungi as quickly as possible. After colonization by AM fungi, plants seem to produce less strigolactones, which would be consistent with improved phosphate availability.

Genetic variation

Variability in induced plant volatiles complicates the reliance of natural enemies on these cues. One way of dealing with variability is through associative learning, which may allow parasitoids to learn which cues are most likely to lead them to suitable hosts at a particular time in a particular area. Moreover, recent studies suggest that plant volatile blends alone carry specific information on the herbivores by which they are attacked. For example, predatory mites can distinguish between the blends of apple trees infested by two herbivores species (20). Du et al. (21) showed that different aphid species elicit different volatile blends in bean plants and that the aphid parasitoid, Aphidius ervi, can use these differences to distinguish plants infested by its host, Aphis pisoni from those infested by a nonhost, Aphis fabae.

Little is known about the genetic variability in such herbivore-induced plant signals and about how the emissions in cultivated plants compare with those of their wild relatives. For conventional plant breeding for improved biological control through enhanced volatile production and hence predator attraction to be successful, genetic variation in the ability to produce herbivore-induce volatile-attracting volatiles is a prerequisite. The little information available on the extent of the variability comes mostly from studies on cultivated plants. Although rice plants infested with the brown planthopper, Nilaparvata lugens, were more attractive than uninfested plants, Rupas et al. (22) showed that constitutively produced rice volatiles in 6 out of 15 uninfested rice cultivars also attractive to the predator Corcythorinus lividipennis when compared with clean air. In gerbera, several cultivars differed in composition and amount of volatiles produced in response to spider mite feeding (23). Y-tube olfactometer experiments revealed differences between the gerbera cultivars in the odor preference of predatory mites. The composition of the volatile blend seemed to be more important for this difference than the total amount of volatiles produced, and particularly the terpenoids (E)-β-caryophyllene and limonene were mentioned by the authors as possibly important candidates in determining the difference in attractiveness between cultivars. Between maize cultivars and between different Zea species, large differences were found in the composition of the volatile blend induced by the application of the oral secretion of Spodoptera littoralis to mechanically damaged leaves (24).

Several problems have been associated with the comparison of genotypes for their production of induced volatiles when other differences between the genotypes can not be controlled (23). For example, differences may exist in direct defense between genotypes that cause differences in developmental rate of herbivores that may lead to differences in volatile formation. To circumvent this problem, in addition to spider mite infestation, we used jasmonic acid treatment in a comparison between seven cucumber genotypes. Earlier research had shown that jasmonic acid treatment mimics the effect of spider mite infestation in several plant species. Different cucumber genotypes.
produced different volatile blends on jasmonic acid treatment or spider mite infestation that are reflected in differences in the attractiveness of these genotypes to predatory mites (Kappers, Bouwmeester, Dicke, unpublished results).

Role of Terpenoids in Other Aspects

Terpenoids in plant reproduction

To attract pollinators and seed-dispersing animals and to ensure reproductive and evolutionary success, many flowering species release blends of volatile compounds from their flowers and fruits in addition to visual and tactile cues (Fig. 2). The bio-genetic pathways of fruit and flower volatiles can be derived from enzymatically controlled lipid, terpene, amino acid, carbohydrate, and phenylpropane metabolism. Floral scent bouquets may contain from 1 to 100 different volatiles, but most species emit between 20 and 60 different compounds (25). The total amount of emitted floral volatiles varies from the low picogram range to more than 30 µg/hour (25). Although flowers could be identical in their color or shape, no two floral scents are exactly the same because a large diversity of volatile compounds and their relative abundance and interactions within the scent bouquet. In addition to attracting insects to flowers and guiding them to food resources within the flower, floral volatiles are essential in allowing insects to discriminate among plant species and even among individual flowers of a single species (1).

To date, little information exists about how insects respond to individual components found in floral scents, even though it is known that they can distinguish between complex floral scent mixtures. It is still unclear whether insect pollinators use only a few compounds present in a scent for floral identification or whether they use information from all scent compounds. Recently, it was shown that honeybees can use all floral volatiles to discriminate subtle differences in the scent of four snapdragon cultivars that emit the same volatile compounds but at different levels (26). Floral volatiles could play many roles instead of or in addition to pollinator attraction. For example, many terpenes, including β-myrcene, (E)-β-ocimene, linalool, and (E)-β-caryophyllene, react readily with ozone and other reactive oxygen species (27). Thus, floral volatiles could function to protect the reproductive organs from oxidative damage. A variety of monoterpens and sesquiterpenes is reported to have antimicrobial activity (28). Hence, floral terpenes could help defend floral organs, like the moist stigma, from bacterial or fungal infection.

Practical Applications and Future Prospects

Practical applications

The great significance of terpenoids in mediating the interactions of plants with other organisms has prompted many researchers to explore the possibilities of using this knowledge to improve resistance of plants against attacking organisms. Now that many induced volatile blends have been identified, artificial mixtures could be composed that are effective in attracting natural enemies and could be used in crops. Alternatively, crops could be sprayed with jasmonic acid to induce volatile production that should lead to the increased presence of natural enemies. Occasionally, an example exists in which this approach has been unsuccessful (29), and several authors have expressed the feeling that this approach should fail in the long term, as the presence of the volatile cue and a prey are uncoupled.

If the volatile cue and the presence of a prey are not uncoupled (i.e., attractive volatiles are only or mainly produced on herbivory), then an adequate response of the crop to herbivory is most important. We have reviewed several studies in which the effect of environmental conditions on volatile production and herbivore attraction has been demonstrated, and researchers should take these results into account when designing their experiments. However, for a practical application such as the optimization of biological control, these factors may be important. It would be of interest to observe whether environmental conditions that stimulate induced volatile formation actually improve biological control in a field situation. A rather as yet completely ignored factor in the optimization of biological control is the selection for genotypes with improved (faster, stronger) response. Our results on cucumber and the results of other plant species demonstrate that genetic variation for this response is available. Additional research could demonstrate the effectiveness and the best and easiest way to exploit this variation in breeding.

Metabolic engineering

Several research groups have made significant progress with the metabolic engineering (see also Metabolic Engineering) of particularly monoterpene and sesquiterpene biosyntheses in a range of plant species (reviewed in Reference 30). These studies have shown that a high production rate of terpenes, including modified products, can be obtained using metabolic engineering. The importance of terpenoids in the interaction of plants with other organisms implies that their modification by plant metabolic engineering will have major effects on their response to the environment. Petunia plants that express the Clarkia breweri linalool synthase showed a delayed and less severe natural infection by mildew than the nontransformed plants under standard greenhouse conditions. Fruit of tomato plants transformed with the same gene were much more resistant to postharvest pathogens than the nontransgenic controls (30). Some effects of transgenic, volatile producing plants on insects have been reported. Transgenic tobacco plants transformed with three lemon monoterpene synthases were visited much less by herbivorous insects (e.g., whiteflies) but more by fruit flies than wild-type tobacco plants in the same greenhouse compartment (30).
choice assays, Arabidopsis plants transformed with the strawberry linalool/nerolidol synthase, which emit greater linalool levels than the control plants, significantly repelled the aphid Myzus persicae (reviewed in Reference 30). Recently, these observations were extended with even more convincing results: Transgenic chrysanthemum (Chrysanthemum x grandiflorum) producing linalool repelled western flower thrips (Frankliniella occidentalis) (reviewed in Reference 30). Increased levels of the diterpenoid cembratienols in trichome exudates of the transgenic tobacco plants resulted in greater resistance to aphids, which also occurred in field tests (reviewed in Reference 30). In studies on tritrophic interactions, transgenic plants become an important tool. A transgenic plants transformed with the strawberry linalool/nerolidol synthase with mitochondrial targeting signal emitted (35S)-E-nerolidol and (E)-DMNT and were attractive to carnivorous predatory mites (Phillasselus persimilis), which are the natural enemies of spider mites (reviewed in Reference 30). Transgenic Arabidopsis plants engineered for the production of sesquiterpenes, which is normally emitted by maize, attracted females of the parasitoid Cotesia marginiventris that located their lepidopteran hosts (the parasitoids were first exposed to the volatiles in association with their hosts) (reviewed in Reference 30). The sesquiterpene (E)-β-farnesene acts as alarm pheromone for many species of aphids, which causes dispersion in response to attack by predators or parasitoids. Overexpression of an (E)-β-farnesene synthase cloned from Melita s piperita, in Arabidopsis thaliana, yielded plants that had high emission of pure (E)-β-farnesene (31). These plants elicited potenti potential effects on behavior of the aphid Myzus persicae (alarm and repellent responses) and its parasitoid Diaeretiella rapae (an arrestant response).

It is conceivable that changes in the (induced) volatile production in commercial crops could lead to the development of biological control packages in which biological control agents trained specifically for the modified crop are included. It will be exciting to see whether these approaches can lead to plants with altered (improved) predator behavior and to crops with improved biological control.

Terpenoids are the largest class of all known natural products. Plants produce a variety of terpenoid compounds that number in the thousands. Some terpenoids are involved in plant growth and development directly (i.e., in primary metabolism), but most plant terpenoids are thought to function in interactions of plants with their biotic and abiotic environment and have traditionally been referred to as secondary metabolites. In addition to the isolation and identification of plant terpenoids, research has concentrated on the biosynthesis, the biological function, and the exploitation of plant terpenoids for human use as biomaterials and pharmaceuticals. Plant terpenoids are biosynthesized from C5 precursors by the action of prenyl transferases and terpenoid synthases. Often, terpenes are acted on by cytochromes P450 and other enzymes to increase their functionalization. Terpenoid biosynthesis in plants involves several subcellular compartments. The accumulation of terpenoids requires efficient transport systems and specialized anatomical structures. Using isoprene (a hemiterpene), menthol (a monoterpene), artemisinin (a sesquiterpene), and paclitaxel (better known under the registered trademark Taxol (Bristol Myers Squibb, New York)) and diterpene resin acids (diterpenes) as examples, we highlight some strategies, techniques, and results of plant terpenoid research with a strict focus on the low-molecular-weight (C5–C20) terpenoids of specialized plant metabolism.

Biological Background

Over 20,000 terpenoids have been identified (1), and more are being discovered continuously. Plant terpenoids are important in both primary and secondary (specialized) metabolism. Their importance in primary metabolism includes physiological, metabolic, and structural roles such as plant hormones, chloroplast pigments, roles in electron transport systems, and roles in the posttranslational modification of proteins. In secondary metabolism, the roles of plant terpenoids are incredibly diverse but are associated most often with defense and communication of sessile plants interacting with other organisms. Examples include terpenoid chemicals that form physical and chemical barriers, antibiotics, phytoalexins, repellents and antifeedants against insects and other herbivores, toxins, attractants for pollinators or fruit-dispersing animals, host/nonhost selection cues for herbivores, and mediators of plant-plant and mycorrhiza interactions (2, 3).

Some plants produce terpenoids in specialized cells or tissues such as the glandular trichomes on the surface of peppermint...
leaves, scent-releasing epidermal cells of certain flowers, or the epithelial cells that surround the resin ducts of conifers. These structures place high concentrations of terpenoids in areas most likely to be encountered by the interacting organism.

The biosynthetic pathways of plant terpenoids are highly regulated and highly spatially organized in subcellular compartments and sometimes in specialized cells. Terpenoid biosynthesis can be regulated by plant hormones, developmental programs, diurnal cycles, herbivory, or pathogen infection. Identifying what role specific terpenoids play in plants, how and where they are biosynthesized, and how their biosyntheses are regulated allows us to better understand their importance to the survival of the plant and thus make use of this knowledge in crop improvement or in the production of terpenoids for medical or industrial uses.

**Chemistry**

Much chemistry research in plant terpenoids has been to elucidate the structure, define the biosynthetic pathways, characterize the enzymes involved, and develop systems for the large-scale production of medicinal or industrially important terpenoids (4). Progress on the identification and the study of plant terpenoids is reviewed regularly in the journal *Natural Product Reports,* and the biosynthesis of terpenoids, including plant terpenoids, has been reviewed comprehensively (5). Plant terpenoids can be volatile or nonvolatile, lipophilic or hydrophilic, cyclic or acyclic, chiral or achiral, and they often have double-bond stereochemistry. The chemical diversity of terpenoid structures originates largely from the terpenoid synthases that stabilize different carbocation intermediates, allow rearrangements or water termination, and direct stereochemistry; the diversity also originates from the many different terpenoid-modifying enzymes.

Two major complementary approaches to studying plant terpenoids have been established. One approach involves the isolation and the structural identification of terpenoid chemicals of interest from plant tissues based on traditional natural product research followed by targeted search for the relevant enzymes and genes that control biosynthesis. The second approach explores the emerging plant genome sequences to discover complete sets of genes that encode terpenoid biosynthetic enzymes. The combination of these two approaches is the most powerful approach to a comprehensive understanding of plant terpenoid chemistry and its biosynthetic origins.

The diversity of plant terpenoids reflects the complexity and the diversity of the pathways that biosynthesize them. The recent sequencing of the genomes of four different plant species and large collections of expressed sequence tags (ESTs) from many other plants may indicate the diversity of pathways and chemicals we might expect in any one species. For example, the genes that encode putatively active terpenoid synthases (TPS) comprise at least 32 in the Arabidopsis (Arabidopsis thaliana) genome (6), at least 15 in the rice (Oryza sativa) genome (7), at least 47 in the poplar (Populus trichocarpa) genome (8), and at least 89 in the genome of a highly inbred grapevine (Vitis vinifera) Pinot Noir variety (9). The large gene family of TPS, which is important to generating structural diversity of terpenoid chemicals, apparently results from repeated gene duplication and subsequent neofunctionalization or subfunctionalization (10, 11). Most TPS produce more than one product from a single substrate, and these products are often modified by the action of additional enzymes such as cytochromes P450 and reductases. Thus, the number of distinct terpenoids found in any one plant species is predicted to be manifold higher than the number of TPS genes present in that species.

Genomics approaches, which can identify the candidate genes for terpenoid production, together with functional characterization of heterologously expressed enzymes and the identification of the resulting plant terpenoids, can enhance the discovery of the biochemical pathways substantially in plants as has been demonstrated in recent years with research in Arabidopsis (12), rice (13), and grapevine (14). Ideally, the functional genomics approach is combined with classical and modern approaches of isolation, identification, and metabolite profiling of terpenoids from plant tissue.

The combined genomics and chemical approaches to plant terpenoid research are not restricted to the few plant species for which more or less complete genome sequences are now available. The discovery of many of the genes and enzymes for the formation of terpenoids such as menthol and related monoterpenes in peppermint (Mentha x piperita) (15), artemisinin in Artemisia annua (16), taxol in the yew tree (Taxus) (17), and conifer diterpene resin acids in species of spruce (Picea) and pine (Pinus) (18) have been possible on the foundation of highly specialized efforts of EST and full-length cDNA sequencing combined with characterization of recombinant enzymes and analysis of the terpenoid metabolome of the target plant species.

**Common steps in plant terpenoid biosynthesis**

The universal precursors to terpenoids, the C5-compounds dimethylallyl pyrophosphate (DMAPP) and isopentenyl pyrophosphate (IPP), originate from two pathways in plants (Fig. 1). The mevalonate (MEV) pathway is well described in many eukaryotic organisms. This pathway is present in the cytosol/endoplasmic reticulum of plants. More recently, another pathway has been described, the 2C-methyl-D-erythritol-4-phosphate (MEP) pathway, which is found in the plastids of plants (19). The localization of the different pathways and the plastid-directing transit peptides found in hem-TPS, mono-TPS, and di-TPS, but not in sesqui-TPS, result in the production of terpenoids from at least two different precursors pools.

Hemiterpenoids are produced from the isoprenyl diphosphate (DMAPP). All other terpenoids are produced from DMAPP and IPP via longer-chain prenyl diphosphate intermediates formed by prenyl transferases. Prenyl transferases (20) catalyze the formation of geranyl diphosphate (GPP), farnesyl diphosphate (FPP), and geranylgeranyl diphosphate (GGPP) from one molecule of DMAPP and one, two, or three molecules of IPP, respectively (Fig. 2). Isoprenyl diphosphates are the substrates for all TPS, which lead to the hemiterpenoids, monoterpenoids, sesquiterpenoids, and diterpenoids, which will be highlighted with selected examples in the following sections.
Isoprene (C5, hemiterpene)

Isoprene (2-methyl 1,3-butadiene, Fig. 2) is the simplest terpenoid produced by many plants, and is produced abundantly by some tree species such as poplars. The mechanism of isoprene biosynthesis is a straightforward diphosphate ionization of the DMAPP precursor followed by deprotonation of the allylic cation (Fig. 2). Only a few isoprene synthases have been identified and characterized in plants, from Populus spp. (poplar) (21, 22) and Pueraria montana (kudzu vine) (23). These TPS contain a transit peptide that targets the plastids, and thus isoprene biosynthesis is derived from products of the MEP pathway.
isoprene is a major biogenic volatile organic compound (VOC; rivalling methane in global production) with emission from plants estimated in the order of more than 10^12 kg per year and therefore has been well studied for its role in atmospheric chemistry (24). Isoprene is also important in the context of global cycles of carbon fixation versus carbon emission from natural sources. Although isoprene is emitted in large amounts from poplars, which are actively being promoted as plantation species for biofuel (ethanol) production, its physiological function in plants is somewhat unclear. The protection from thermal and oxidative stress as well as release of excess carbon flux and photosynthetic energy are thought to be the main functions of isoprene in plants (21, 22).

Very recently, new molecular approaches have established a function of isoprene in thermotolerance through the use of under- and over-producing transgenic lines of poplar (25) or Arabidopsis (which normally produces no isoprene) using the poplar isoprene synthase (26). Other possible functions of isoprene remain to be tested using similar molecular approaches. The effect of down-regulation of isoprene emission in poplars remains to be tested in the field to explore whether it is viable to reduce emission of this biogenic VOC in plantation forests for biofuels production to maximize carbon fixation and minimize carbon emission. A closely related hemiterpene of plant origin isoprene remain to be tested using similar molecular approaches. The effect of down-regulation of isoprene emission in poplars is also under investigation in order to explore whether it is viable to reduce emission of this VOC in plantation forests for biofuels production to maximize carbon fixation and minimize carbon emission. A closely related hemiterpene of plant origin isoprene remain to be tested using similar molecular approaches. The effect of down-regulation of isoprene emission in poplars remains to be tested in the field to explore whether it is viable to reduce emission of this biogenic VOC in plantation forests for biofuels production to maximize carbon fixation and minimize carbon emission.

First, using geranyl diphosphate as substrate, (-)-limonene synthase generates (-)-limonene and minor amounts of myrcene, (-)-alpha-pinene, and (-)-beta-pinene. (-)-Limonene then undergoes a series of transformations ultimately to yield (-)-menthol. These modifications involve first the allylic hydroxylation to (-)-trans-isopiperitenol by the cytochrome P450 limonene-3-hydroxylase (CYP71D13). Allylic oxidation of this alcohol to (-)-isopiperitenone is then catalyzed by the NAD-dependent isopiperitenol dehydrogenase. Subsequently, NADPH-dependent (-)-isopiperitenone reductase catalyzes the formation of (+)-cis-isopulegone. (+)-cis-Isopulegone is enzymatically isomerized to the more stable alpha, beta-unsaturated ketone (+)-isomenthone—by (+)-cis-isopulegone isomerase. (-)-Menthone and (+)-isomenthone (in a 2:1 to 10:1 ratio) are then formed by the action of the NADPH-dependent (-)-isopulegone reductase. Finally, (-)-menthone reductase reduces (-)-menthone to (-)-menthol. All of these enzymes and their corresponding genes in Mentha have been isolated, functionally characterized, and their enzymology studied (15). For some enzymes, substrate specificities or product outcomes after directed mutations as well as enzyme localization have been investigated. The structure of (-)-limonene synthase has been determined recently (29). Based on the detailed knowledge of (-)-menthol and its biosynthetic pathway, it has become possible to improve the composition of the monoterpene-rich essential oil of Mentha through metabolic engineering (30, 31).

Artemisinin (C_{15}, sesquiterpenoid)

Artemisinin is used here as an example of a plant sesquiterpenoid with both traditional value as well as medicinal and social value in the twenty-first century. Research on artemisinin has also established new benchmarks for biochemical engineering and functional genomics of plant terpenoids. Artemisinin is a functionalized sesquiterpene with a unique peroxide linkage from the sweet wormwood (Artemisia annua). Chinese herbalists have used it since ancient times, and it is now used for its unique efficacy to treat multidrug-resistant strains of the malaria parasite Plasmodium falciparum. Its medicinal importance has prompted studies into its biosynthesis and its biochemical engineering so that cost-effective methods for producing it in large scale and in consistent quality may be realized.

Biosynthesis of artemisinin in planta begins with the formation of the sesquiterpene amorphophyll-4,11-diene in glandular trichomes of A. annua leaves (Fig. 4) by amorphophyll-4,11-diene synthase (32, 33). Amorphophyllene is oxidized to artemisinic acid in three steps by a multifunctional cytochrome P450 (CYP71AV1) (16). The remaining steps have not yet been established but are predicted to include nonsymmetrically catalyzed photooxidation reactions (34). The application of a semi-synthetic route from artemisinic acid to artemisinin, along with the availability of the characterized plant enzymes to produce artemisinic acid described above from A. annua, have permitted the complete synthesis of artemisinin via microbial host cells (16). Introducing these enzymes into Escherichia coli or Saccharomyces cerevisiae and engineering an unnatural, or fine-tuning the natural, mevalonate pathway in these microorganisms have resulted in significant production of artemisinic acid in fermentations (14, 35, 36).

Taxol (C20, diterpenoid)

Taxol is another example of a medicinally important functionalized plant terpene, in this case a diterpenoid, with large pharmaceutical and economic value (Fig. 5). Taxol is a potent anticancer drug that was isolated and identified from the bark of the Pacific yew (Taxus brevifolia) more than 35 years ago (37). The name Taxol is now a registered trademark, but the literature commonly uses this name rather than the generic name paclitaxel. The total synthesis of Taxol is possible (38), but it is not economically feasible currently because of the challenges of stereochemistry, low yield, and high cost. The study of Taxol by Croteau et al. (17) is an exceptional example of how a terpenoid biosynthetic pathway was rationalized, and the synthesis and testing of various hypothetical precursors with cell-free extracts have yielded the discovery of many enzymes and genes in this complex pathway. Because Taxol is only found at very low levels in slow growing trees, and is one of hundreds of Taxol-like compounds produced in a metabolic grid, the use of an inducible Taxus cell culture system has accelerated this research.

Taxol is biosynthesized in 19 steps from GGPP that originates from precursors of the MEP pathway (Fig. 5). The biosynthesis of Taxol begins with the formation of the tricyclic diterpene skeleton of taxa-4(5),11(12)-diene (17, 39). All genes for the enzymes in this early pathway have been identified in Taxus cuspidata and a taxa-4(5),11(12)-diene synthase has been identified in several Taxus species. The mechanism of this di-TPS has been explored in detail (39). Taxa-4(5),11(12)-diene is then hydroxylated by several cytochrome P450 taxoid oxygenases to yield a putative intermediate decorated with seven alcohol or ester groups. Many cytochrome P450 enzymes that catalyze these transformations have been identified and characterized, but two enzymes remain uncharacterized (17). The biosynthesis of the ester functionalities have been studied, and several acyl and aryl transferases have been identified and characterized. Finally, studies on the steps in the aromatic side chain assembly and attachment have yielded several enzymes that include a phenylalanine aminotransferase, a C13-phenylpropanoyl-CoA transferase, and an N-benzoyl transferase. Although the pathway of biosynthesis has not been resolved fully, what is known can be applied to improve Taxol production, which continues to rely on Taxus plants or cell cultures.

Diterpene resin acids (C20, diterpenoids)

Diterpene resin acids are abundantly produced in conifers of the pine family (Pinaceae) and in other plant species (Fig. 6). They are produced in the epithelial cells that surround the resin ducts that are found constitutively or in resin ducts induced in the xylem upon wounding and are important for the physical and chemical plant defenses against herbivores and pathogens (18, 40). Industrially, diterpene resin acids are important chemicals for the naval stores industry, in printing inks, as potential antimicrobials and pharmaceuticals, and are byproducts of wood pulping processes.

Two major steps exist in the biosynthesis of diterpene resin acids: the formation of the diterpene and the stepwise oxidation of the diterpene to the corresponding acid. Most conifer diterpenes are tricyclic; they are biosynthesized by bifunctional di-TPS that first cyclize geranylgeranyl diphosphate to (−)-copaeryl diphosphate and then cyclize this intermediate even...

bacatin III, R₁ = Ac 10-deacetyl-baccatin III, R₁ = H

Stereochemistry often is an integral component to both the chemical structure and the biological function of plant terpenoids. For volatile terpenoids, chiral GC stationary phases provide the enantiomeric separation for quantitative analysis, and, provided an authentic standard of known absolute stereochemistry is available, the availability of retention index information on at least two columns of different polarity increases the confidence in structural assignment. Such information is available for the more volatile terpenoids involved in flavors and fragrances (46), and insect semiochemicals (47). For nonvolatile terpenoids, LC-MS is often used, but there are no comparable databases of terpenoids for LC-MS as there are for GC-MS.

Structural determination

Hanson (43) has published an excellent review of the methods and the strategies for rigorous structural determination of terpenoids. Routine survey-style analyses of plant terpenoids often are not so rigorous in structural assignment. Databases of mass spectra [such as Wiley (New York) and NIST (Gaithersburg, MD) MS databases] or databases that combine mass spectra and retention indices (44, 45) facilitate assignment of some commonly encountered plant terpenoids. Of course, these databases are only helpful if they include the specific terpenoids that are being analyzed and the likely alternatives. Sometimes, in addition to having similar mass-spectral fragmentation patterns, two terpenoids may share very similar retention indices on the 5% phenyl methyl polysiloxane GC column used for these databases, which makes structural assignment without additional information impossible. The availability of retention index information on at least two columns of different polarity increases the confidence in structural assignment. Such information is available for the more volatile terpenoids involved in flavors and fragrances (46), and insect semiochemicals (47). For nonvolatile terpenoids, LC-MS is often used, but there are no comparable databases of terpenoids for LC-MS as there are for GC-MS.
Figure 6. Pathway of conifer diterpene resin acid biosynthesis. Bifunctional di-TPS convert geranylgeranyl diphosphate to various diterpenes, which are oxidized stepwise by multisubstrate and multifunctional cytochromes P450 to the corresponding diterpene acid. The oxidation of (-)-abietadiene to (-)-abietic acid is shown as an example.
configuration is available, elution comparison can establish absolute configuration of the unknown sample (49). Chiral phases for liquid chromatography can also be used to resolve enantiomers, both analytically and preparatively (50). Often, chiral synthesis is necessary to clearly establish the absolute configuration of an unknown terpenoid.

Molecular biology

The recent availability of plant genome sequences and the methods to clone homologous genes from different plant species using molecular biology approaches has provided the ability to identify the capacity of plants to produce additional terpenoids that may not have been detected in that specific plant species before. Rather than isolate, fractionate, and chemically identify a particular plant terpenoid profile, plant TPS or cytochromes P450 are cloned into a heterologous expression system, and the enzyme assay products of these recombinant enzymes with isoprenoid substrates are analyzed directly. This approach has proven useful in situations in which the terpenoids themselves may not be detectable in the plant under normal growing conditions, and the inducer or environmental conditions required for their production are not yet known (12).

Synthesis

Independent synthesis of the identified terpenoid is often required to confirm structural assignment (51) and to test the biological and/or pharmacological functions. In addition, biosynthetic studies often require the synthesis of putative precursors for functional characterization of enzymes. Terpenoid structures challenge chemists in many of the same ways that other natural products do. The stereochemistry, complex overall structure (polysaccharides, carboxylic skeletons, and often multiple functionalization) provides opportunities for synthetic organic chemists to develop new methodologies for synthesis. Recently, Maione and Baran (52) have reviewed some synthetic challenges in plants. Terpenoid synthase (AtTPS) gene family of Arabidopsis thaliana. M.G. Grelet. Genetics 2002 287:730-743.

Biochemical and metabolic engineering

Often, the original natural plant sources of medicinally or industrially important terpenoids cannot supply sufficient material for their demand. In some instances, such as Taxus for the production of Taxol (53), the original plant species is amenable to growth in plant cell culture for commercial production. For example, Taxol (53), the original plant species is amenable to growth in plant cell culture for commercial production. For example, Taxol is produced by site-directed mutagenesis of amino acids that are important in influencing product outcomes. These studies not only allow us to understand how the diversity of terpenoids evolved from gene duplication and neofunctionalization, but also allow us to modify multi-product TPS to favor one of the wild type products or to force the enzyme into producing unnatural products. Both techniques have use in the large-scale production of medicinally or industrially important terpenoids.

The Biology and Biochemistry of Steroid Hormones

S. Stoney Simons, Jr., Steroid Hormones Section, NIDDK/CEB, NIH, Bethesda, Maryland

doi: 10.1002/9780470048672.wecb563

Five categories of steroid hormones exist in humans, including androgens, estrogens, glucocorticoids, mineralocorticoids, and progestins. These hormones affect virtually every tissue and organ in the human body and play major roles in the development, differentiation, and homeostasis of normal individuals. Antisteroids usually possess nonsteroidal structures but still block the actions of the steroid hormones and are important tools in endocrine therapies of pathologic conditions. Therefore, how the body regulates where, when, and how much a response to steroids occurs is of major importance. Here we survey what is known about the genomic responses to steroid hormones, each of which is mediated by a unique intracellular receptor protein that interacts with the cellular DNA to modify the rates of gene transcription. These receptors are members of a much larger superfamily of steroid/nuclear receptors, most of which bind either nonsteroidal ligands or no known ligand. Nongenomic (i.e., pathways without initial involvement of genomic DNA) and secondary responses (i.e., changes that require protein synthesis to alter gene transcription) are additional important effects of steroid hormones but are not discussed here. The emphasis is on the biochemistry of the five classes of steroid hormones, the techniques used to study steroid hormone action, and the basic mechanistic steps by which steroids alter gene expression.

Steroid hormones can increase and decrease the level and/or activity of a large number of proteins in eukaryotes. Steroid hormones were first discovered in humans, where they play essential roles in development, differentiation, homeostasis, and endocrine therapies. However, current interest in steroid hormones is increasing because they constitute excellent model systems for examining the control of gene expression. Many human pathologies result from the inappropriate expression of protein(s). Thus, to treat disease states, it is critical to understand the normal processes governing how, when, and how much of the information encoded in the DNA of cells is transcribed to mRNA's and eventually into proteins, which perform most of the functions of cells. Steroid hormones provide excellent model systems with which to address these clinically relevant questions.

Biochemistry of Steroid Hormones

Five classes of steroid hormones are produced in humans: androgens, estrogens, glucocorticoids, mineralocorticoids, and progestins. The structures of several steroid hormones were elucidated in the 1930s. The common feature among each compound is the fused four-ring structure (Fig. 1a) or steroid ring structure that is the defining characteristic of all steroids. The first synthetic steroid, the estrogen equilenin, was prepared in 1939 (1). The numerous synthetic schemes for preparing steroid hormones will not be addressed here. The reader is directed to the article on the Chemistry of Steroid Hormones elsewhere in this reference for this material.
Steroid hormones bind to receptor proteins

The discovery that steroid hormones bind to unique proteins with high affinity and selectivity commenced with the demonstration by Jensen and Jacobson that [3H]estradiol bound tightly to species found only in the target tissues of estrogens (2). These binders were discovered to be intracellular proteins. In general, the protein that bound a given steroid with the highest affinity was called the cognate receptor for that steroid—i.e., androgen receptor (AR), estrogen receptor (ER), glucocorticoid receptor (GR), mineralocorticoid receptor (MR), and progesterone receptor (PR). More recently, these steroid receptors have been found to be members of a larger superfamily of about 150 members in over 30 subfamilies across a range of species (3). Humans contain 48 receptors. Each receptor protein shares a highly homologous domain of about 66 amino acids that contains two “zinc finger” motifs, each of which includes four cysteine residues (4). The homology between the rest of the receptor proteins is much less. Many members of this superfamily do not bind any known ligand and are thus called orphan receptors. Other members bind ligands that are not steroids, such as triiodothyronine (T3), retinoic acid, and vitamin D, which is not a steroid although its precursor is a steroid. The receptors for these later ligands are found almost exclusively in the nucleus of cells, in either the presence or the absence of ligand, and are therefore collectively called nuclear receptors. These receptors are discussed in the article entitled the Chemistry of Nuclear Receptors. This article will cover only the receptors of the five steroid hormones of Fig. 1b.

Structure of steroid hormones

Agonist steroids

The structures of the major steroid hormones in humans are shown in Fig. 1b. Each of these steroids elicits the maximal response from their cognate receptor and are called agonist steroids. The years after the structural elucidation of these steroids witnessed an explosion of synthetic activity aimed at making “better” steroids. These synthetic steroids (e.g., Fig. 1c) have largely supplanted the naturally occurring steroids both in clinical applications, which will not be covered here, and in research. The structures of the synthetic steroid hormones can be different from those of the natural steroids (e.g., DES...

Promegestone [R5020] (Progesterin)

Figure 1 (continued)

and DAC in Fig. 1c (5). These synthetic ligands are all active at lower concentrations than the natural steroids of Fig. 1b, and thus, they exhibit a greater sensitivity, or potency but have equal efficacy. More precisely, full agonists for a given receptor induce (or repress) gene expression to the same level. However, the concentration of these synthetic agonists required for half of the maximal response (=EC50) is lower than that of the natural steroids. The synthetic ligands are more stable to metabolic degradation, and thus, they are longer acting, and generally retain more activity when taken orally. They also possess greater specificity than the natural steroids so that there is less interaction with noncognate receptors (5).

Antisteroids

Not all compounds that bind to a given receptor give full agonist activity, and some give no activity. These agents also antagonize the actions of the above agonist steroids and are therefore called antagonists or antisteroids. The amount of residual agonist activity of an antisteroid, or the partial agonist activity, is expressed as percent of maximal activity of a full agonist steroid. Thus, a molecule with 15% partial agonist activity will be a more effective antisteroid than a different compound with 50% partial agonist activity. Some naturally occurring steroids are antisteroids for other receptors, such as progesterone, which is an antisteroid for glucocorticoid and mineralocorticoid receptors. Most antisteroids are synthetic and have very different structures (Fig. 1d). RU486 (RU38,486 or mifepristone) is of interest as it is an efficient antisteroid for PRs, GRs, and ARs (6) but not MRs (7) or ERs. Unfortunately, it is currently not possible to predict either what kind of activity a new steroid will have or even to which receptor it will bind. This issue will be discussed in greater detail below.

Current scope of steroid hormones chemistry

Initially, the study of steroid hormones involved relatively unmanipulatable biologic systems and was the purview of biologists. Over the years, new techniques in molecular biology such as cloning, protein identification, and protein purification have made it possible to alter selected macromolecules in cells and
The Biology and Biochemistry of Steroid Hormones

Antiestrogens

Figure 1 (continued)

Biologic Background of Steroid Hormones

In several instances, the steroid hormones were named for their most prevalent biologic activity. Thus, the steroids found to cause mobilization of glucose were called glucocorticoids. Mineralocorticoids were those steroids that regulated the balance of the mineral's sodium and potassium.

Source of steroids

All steroids are synthesized in humans from cholesterol. The adrenal gland can synthesize all endogenous steroid hormones and is the major source of glucocorticoids and mineralocorticoids. Most androgens are secreted from the testes, whereas most estrogens and progestins derive from the ovaries. In postmenopausal women and men, a variety of sources, such as adipose tissue, are the major source of estrogens, although in much lower amounts. The environment contributes many compounds, called xenobiotics and endocrine disrupters, that can compete with the actions of endogenous steroids with often incompletely documented effects, whereas plants are the source of phytoestrogens that are ingested both intentionally and unintentionally.

Transport of steroids

Almost all steroids reach the target organs through the circulatory system, which is the definition of an endocrine system. A target organ, or cell, for a steroid is one that contains the cognate receptors. Given the hydrophobic properties and relatively low solubility in water of most steroids, their concentration in the circulatory system is increased by their complexation with serum-binding proteins such as corticosteroid binding globulin (CBG). Although these proteins were initially thought to be passive carriers of steroid, evidence now exists that they play...
The Biology and Biochemistry of Steroid Hormones

a more active role in steroid hormone action (12). In general, steroids enter cells by passive diffusion, although multi-drug resistance transporters can facilitate the depletion of intracellular steroids (13).

Basic features of steroid hormone action

The general mechanism of receptor-mediated action of steroid hormones is very similar for each of the five classes. Briefly, the steroid enters the cell and binds to an intracellular protein. The resulting receptor-steroid complex is converted in a poorly understood step called activation to a form that binds to specific, biologically active DNA sequences (called hormone response elements, or HREs) of the nuclear chromatin. These HRE-bound receptor-steroid complexes recruit various cofactors and then interact with the transcription complex containing RNA polymerase II to modify the rates of transcription of a nearby DNA sequence coding for an expressed protein (Fig. 2). This alteration of transcription rate is typically fast (15–30 min) (14).

The mechanism of steroid receptor-mediated changes in transcription has occupied center stage over the last 40 years. Serious attention is only just beginning to be paid to the role of steroid receptors in other, often more rapid, processes that occur within minutes (15, 16), such as the estradiol-mediated activation of eNOS that proceeds in about 5 min (15). These types of responses are frequently called “nongenomic” to indicate that the steroid receptor does not interact with genomic DNA. Steroid receptors have been reported in mitochondria (17) and cell membranes, although it is not yet clear whether all of these receptors are the same as the intracellular steroid receptors (16, 18–22 vs. 23). Some of the membrane-bound receptors for steroids are G protein-coupled receptors (24–27). A recent report suggests that membrane-bound steroid receptors can interact with, and augment the transcriptional activity of, the intracellular receptors (24). Finally, steroids can bind to nonreceptor molecules such as enzymes and transport proteins (see above), which may have yet undiscovered consequences.

The “nongenomic” and “nonreceptor” responses to steroids will not be covered here. Instead, we will concentrate on the mechanisms by which the classic steroid hormones alter gene transcription via their intracellular cognate receptor protein. We will discuss only the primary effects of steroid hormones, which are those rapid (15–30 min) events that lead to changes in gene transcription without any requirement for protein synthesis. It should be remembered that at a sufficiently precise level, the mechanism of action of each class of steroid hormone is different from that of the others.

Methods for Study of Steroid Hormone Action

Most readers are probably familiar with the use of radioactive steroids, Scatchard plots, affinity labeling, sodium molybdate,

Figure 2: General steps in steroid hormone action and their assays. The basic model depicts steroid (S) binding to its receptor molecule (R) to form receptor-steroid complexes (RS), which attach to biologically active DNA binding sites (HRE) to eventually produce changes in the levels of specific proteins. Experimental techniques to follow R at various stages in this pathway are indicated at the first point that each method can detect a signal. Most methods can also be used to detect receptors at any step downstream of the one for which it is first used.
immunofluorescence, gel shift assays, and Western and Northern blots to study steroid receptors. Over the last approximately 10 years, molecular biology has introduced many new techniques that are directed toward detecting receptors at various stages in their mechanism of action (Fig. 2). Two hybrid assays were developed to detect interacting proteins (screening done in yeast) and then to characterize these interactions (usually performed in mammalian cells) (28, 29). Cell-free pulldown assays with one partially purified protein offer more definitive evidence for a direct interaction under cell-free conditions because many potential adapter proteins have been removed. This removal can be accomplished either by attaching an immunogenic or high affinity tag on one protein (30) or, in the case of steroid receptors, using the DNA binding properties of receptors to immobilize the receptor and associated proteins (31). Coimmunoprecipitation (co-P) assays demonstrate that two or more molecules from intact cells are present in the same complex. Mass spectral identification of copurified proteins (by binding or co-P) offer a more rapid method of identifying a large number of potential associated proteins, but time usually limits the number of subsequently examined proteins to those that seem to be particularly interesting (32). Fluorescent-tagged receptors are excellent for observing the real-time location of receptors, with FLIP and FRAP being methods of determining the rate of protein movement (33). Unfortunately, these methods are not yet sensitive enough to see receptors at a single copy of responsive genes. Chromatin immunoprecipitation (ChIP) assays reveal the presence and kinetics of molecules binding to small regions of responsive genes, like the HREs (34). The advantage of ChIP assays is their ability to interrogate endogenous genes, even if the resolution is low (∼500 bp). Chromatin conformation capture (CCC) assays detect two separated DNA sequences that are brought together because of the binding of one or more proteins (35). The use of transiently transfected siRNAs in tissue culture cells offers a much simpler method for blocking the expression of selected genes, or at least for reducing the level of translation from the corresponding mRNA, than for preparing gene knockouts in whole animals (36). Microarrays, in which the level of less of thousands of mRNAs can be determined, offer an unprecedented ability to determine the effects of steroid hormones on essentially the entire genome of a tissue (37). ChIP-on-chip assays use the microarray technology to determine to which regions of the genome receptors (and other proteins) are bound in ChIP assays (37). Systems biology approaches, and the associated model building, provide a powerful method of identifying testable mechanistic hypotheses for which no experimental evidence previously existed (38).

**Molecular Biology/Chemistry of Steroid Hormone Action**

**Structure of steroid receptors**

All members of the steroid/nuclear receptor superfamily have the same overall structural organization (Fig. 3) (39). The 66 amino acid DNA binding domain (DBD) is in the middle and is the criterion for superfamily membership because of the high amount of conserved sequence (4). The amino-terminal domain containing the activation function 1 (AF1) displays the greatest variability in length (∼200 to 600 amino acids) and possesses <15% homology between receptors. A small hinge-region separates the DBD from the multifunctional ligand binding domain (LBD) (40), which includes the second activation function (AF2) and is 245 residues long for GR (41). High amounts of homology exist between the LBDs of several steroid receptors, which accounts for the fact that ligand binding is rarely totally specific (5). Given the large number of biologic activities that are mediated by the LBD (see below and Reference 40), it is not surprising that most mutations are loss of function or neutral. Gain of function mutations that augment receptor properties are rare (42, 43), although many more mutations alter the binding properties of receptors (44–46).

**Receptor isoforms and variants**

Variations in the translational start site, and in mRNA splicing, are two common ways in which receptor isoforms can be formed. Isoforms with identical LBDs and different amino termini occur because of different transcriptional or translational start sites, such as the long and short forms of PR (PR-B and PR-A, respectively), a variety of ERs (47), and multiple forms of GR (48). These isoforms bind ligand with relatively unchanged affinity but usually display different biologic activities. Splicing isoforms can have dramatically altered properties, such as GRβ, which no longer binds steroid. GRβ is found in humans (49) but not in mice (50) and contains a different and smaller sequence for the C-terminal 50 amino acids than the full-length GRα. The sole steroid receptor encoded by two different genes is ER. The classic ER is ERα. The closely related ERβ was discovered only in 1996 (51) and often has very different biologic activities (52). The properties of these interesting additional forms of the steroid receptors, including post-translationally modified receptors, are beyond the scope of this article and will not be covered.

**Intracellular localization of receptors**
