CpG islands of tumor-suppressor genes are hypermethylated in cancer cells. Therefore, they recruit multiple repressors that lead to a characteristic histone modification pattern: the deacetylation of histones H3 and H4, the methylation of lysine 9 of histone H3, and the demethylation of lysine 4 of histone H3 (52). In addition, it has been shown that the polycomb protein EZH2 associates with DNMTs and that specific methylation of lysine 27 of histone H3 is required to establish DNA methylation in a subset of target genes (65).
DNA methylation in mammals is an epigenetic modification involved in a range of cellular functions and pathologies, including X chromosome inactivation, genomic imprinting, tissue-specific gene expression, cell differentiation, regulation of chromatin structure, carcinogenesis, and aging, and is indispensable for the survival of differentiated cells.

Chemical Tools and Techniques

Epigenetic modifications are key translators between genotypes and phenotypes. The goal of scientists is to understand the significance of each chromatin modification within a biologic process, genomic region, and given organism. The simplest scenario would be that every epigenetic mark corresponded to definable and predictable outcomes. However, many lines of investigation have shown that the function of these chromatin marks is more complex than previously thought and depends entirely on the biologic context.

We can study the function of epigenetic modifications from different points of view: this includes the investigation of the global epigenetic modifications of every cell type to generate its epigenome and the other components involved in epigenetic modifications, such as the histone-modifying enzymes, the proteins that read each modification, and the enzymatic activities or functional protein complexes that are recruited to this modification, as well as the downstream biologic effects. Below we will discuss the technology that may be used to analyze epigenetic modifications.

The epigenome is the map of epigenetic modifications of a given cell in terms of DNA methylation and histone modifications. Any techniques for studying epigenetic modifications at specific loci exist, and several of them have been adapted for large-scale analyses.

Histone modifications

The most powerful technique for studying histone modifications coupled with particular DNA sequences is chromatin immunoprecipitation, ChIP, with antibodies against specific modifications. The immunoprecipitated DNA is analyzed by PCR with specific primers to investigate the presence of a candidate DNA sequence. ChIP may be scaled up for global analyses with microarrays (ChIP-on-chip). Its use with genomic platforms has begun to yield extensive maps of histone modifications in model organisms such as Arabidopsis thaliana, yeast, Drosophila melanogaster, mice, and recently normal human cells, including stem cells (53). The ChIP-on-chip assay can be applied to any histone modification for which an effective antibody is available, although it has been used only with lysine acetylation and methylation. Some important histone patterns nevertheless have been established already. ChIP analyses are limited by their requirement for good-quality antibodies, and they need to be highly specific if they are to yield results that can be comparable across experiments. The majority of ChIP experiments still use polyclonal antibodies, but the generation and use of monoclonal antibodies, by which differences between antibody batches may be minimized, is an important goal.

Mass spectrometry is the most accurate technique for detecting global levels of histone modification. However, it requires great technical expertise and is difficult to apply across genomes. Acceptable data on global levels of histone modification currently can be obtained by combining other methods. For example, all histones (H3, H4, H2A, H2B, and H1) can be isolated by HPLC, and the corresponding eluted fractions can be analyzed by HPLC and liquid chromatography-electrospray mass spectrometry (LC-ES/MS). Specific modifications at each amino acid residue also can be characterized by using antibodies in western blots, immunostaining, and tandem mass spectrometry (MS/MS).

DNA methylation

The most accurate method for analyzing DNA methylation is the bisulfite treatment of DNA, which reproducibly changes unmethylated cytosines to uracil but leaves methylated cytosine unchanged. Any laboratory can study DNA methylation by using the bisulfite treatment combined with genomic sequencing or amplification by methylation-specific PCR. To detect minimal amounts of aberrant DNA methylation, quantitative PCR-based methods can be used, such as the bisulfite treatment in combination with MethylLight or pyrosequencing (54). Some other approaches are based on the uses of restriction enzymes that can distinguish between methylated and unmethylated recognition sites in genes of interest. This technology is less accurate because incomplete cutting of the restriction enzymes within the studied regions is a limitation. Both methods can be coupled with several genomic approaches for detecting DNA methylation patterns. Recently, a ChIP-on-chip-based method has been applied to DNA methylation, the methyl-DIP (54). The DNA that is immunoprecipitated with an antibody against 5-methylcytosine can be used as a probe for hybridization to genomic microarray platforms, which allows the rapid identification of multiple Cpg sites and simplifies the analysis of the DNA methylation.

Pre-mRNA splicing

John Karijolich and Yi-Tao Yu, University of Rochester Medical Center, Rochester, New York
doi: 10.1002/9780470048672.wecb520

Pre-mRNA splicing is an RNA processing reaction by which introns are removed from an mRNA precursor and exons are precisely joined together to form a functional mature mRNA. Splicing involves two successive trans-esterification reactions that occur in the spliceosome, which is a multicomponent complex composed of a large number of protein factors and five small nuclear RNAs (snRNAs), each functioning as an RNA–protein complex (ribonucleoprotein or snRNP). A significant body of evidence indicates that both spliceosome assembly and catalytic core formation are orchestrated by an intricate network of RNA–RNA interactions. Most eukaryotic introns invariably start with the dinucleotide GT (GU in RNA) and end with the dinucleotide AG. Splicing of these introns occurs in the major spliceosome containing five abundant snRNPs (U1, U2, U4, U5, and U6). In high eukaryotes, a rare class of introns also exists, beginning with the dinucleotide AT (AU in RNA) and ending with the dinucleotide AC. Removal of this class of introns requires the participation of a different set of snRNPs, namely U11, U12, U5, U4atac, and U6atac. Recent advances in pre-mRNA splicing have provided strong evidence for an RNA enzyme catalyzing the two trans-esterification reactions in the spliceosome.

Introduction

It was discovered in 1977 that several adenovirus genes (in the form of DNA) contained intervening sequences that were not present in their mature mRNAs (1, 2). Shortly thereafter, other eukaryotic genes were similarly found to contain intervening sequences that disrupt the real hereditary message. Thus, the intervening sequences were named introns and the protein coding sequences (including the 5’ and 3’ untranslated regions) were termed exons (3). Since the discovery of introns, the phenomenon of intron-containing genes (often referred to as “split genes”) has been found to be widespread in eukaryotes. In fact, almost all genes in high eukaryotes contain introns (the exceptions are those encoding histones and interferons). Even in budding yeast, more than 250 genes contain introns. Early work on RNA metabolism in eukaryotes identified a large number of short-lived heterogeneous nuclear RNAs (hnRNAs) that are much longer than mature mRNAs in the cytoplasm. The hnRNA sequence can form a perfect double-stranded RNA–DNA duplex when hybridized with its own gene (4). Taken together, these observations produced the realization that transcription of a gene initially produces a perfect copy of RNA known as mRNA precursor (pre-mRNA or hnRNA) containing not only exons but also introns. Introns must be removed from the precursor before the resulting mature mRNA is transported to the cytoplasm where it directs the translation of protein. The removal of introns from mRNA precursor is catalyzed by an RNA processing reaction known as pre-mRNA splicing. Pre-mRNA splicing occurs in the spliceosome, a massive protein–RNA complex consisting of a large number of proteins and five small nuclear RNAs (U1, U2, U4, U5, and U6 snRNAs), each of which functions as a small nuclear ribonucleoprotein (snRNP) (5–8). Over the years, the spliceosomal snRNAs (or snRNPs) have been extensively studied and their roles in pre-mRNA splicing have been well established. A fairly detailed picture has emerged in which intricate networks of interactions among the components of the spliceosome, in particular the RNA–RNA interactions, orchestrate the assembly of the spliceosome as well as the formation of the catalytic center for catalysis (chemical reaction of splicing) (6, 9–11). Here, we discuss spliceosome assembly and pre-mRNA splicing, with an emphasis on the U snRNAs as well as some important spliceosomal proteins (both snRNP proteins and non-snRNP proteins).
Pre-mRNAs Contain Conserved Sequence Elements at the Splice Sites

In the late 1970s and early 1980s, the sequences of many eukaryotic genes became available for study, thus making it possible to conduct a comparative analysis to identify important sequence elements in pre-mRNA. Careful inspection of higher eukaryotic genes revealed several consensus sequences in introns at or near the 5′ and 3′ splice sites (12, 13). The 5′ splice site consensus sequence is G/GURAGU (ü represents the 5′ exon-intron junction; R depicts a purine; the underlined dinucleotide GU is invariant). The 3′ splice site is YAG/G (here, ü represents the 3′ intron-exon junction; Y is a pyrimidine; the underlined dinucleotide AG is invariant), which is frequently preceded by a GU-rich region. In addition to the 5′ and 3′ splice sites, there is another consensus sequence, namely the branch site YNYURAGC (N can be any nucleotide and the underlined adenine is invariant) located 20–40 nucleotides upstream of the 3′ splice site (Fig. 1). In budding yeast, the three consensus sequences at the 5′ and 3′ splice sites (including the branch site) have also been identified; however, there is no or a less-conserved GU-rich region preceding the 3′ splice site. In contrast to the loosely defined consensus sequences in high eukaryotic pre-mRNAs, the sequence elements in yeast pre-mRNA are almost absolutely conserved: G/GUAGU at the 5′ splice site, CAG/G at the 3′ splice site, and UACUAAC at the branch site. Mutation of any invariant nucleotides within the consensus or conserved elements results in a total inhibition or a decreased

Figure 1 Major spliceosome assembly and action. First, U1 (red) assembles onto the pre-mRNA (in the 5′ complex) to form a commitment complex (CC). Then U2 (green) joins, converting complex CC to complex A. Subsequent joining of the U4–U5–U6 (blue–brown–purple, respectively) tri-snRNP forms the major spliceosome (complex B1). The newly assembled spliceosome then undergoes a dynamic rearrangement of RNA–RNA interactions resulting in the release of U1 and U4 and the formation of complex B2. Formation of complex B2 triggers the first catalytic step, the formation of the cut-off 5′ exon and the lariat structure, thus leading to the formation of a new complex (complex C1). After additional conformational changes, step 2—the joining of 5′ and 3′ exons—occurs and complex C2 forms. mRNA is then released, resulting in the formation of complex I. Finally, the lariat intron is released and the spliceosome disassembles. The 5′ splice site (5′-SS), the 3′ splice site (3′-SS) and the branch point adenosine (BP) are indicated. The consensus sequence elements at the 5′ and 3′ splice sites and the branch site are shown (R, purine; Y, pyrimidine; Yn, the polypyrimidine tract; N, any nucleotide). The thick lines represent snRNA strands (in colors) or the intron (black), and the boxes are exons. The short thin lines between RNA strands represent Watson–Crick base-pairing interactions. The lightning bulbs depict non-Watson–Crick base-pairing interactions. The bulged-out branch point adenosine is pictured after the joining of U1. The blue arrows indicate the chemical reactions, trans-esterifications, or nucleophilic substitution reactions. The yellow areas in complexes B2 and C1 represent the catalytic center for catalysis. U2–U6 duplexes [H helices 1 (or A and B), II and III] in the spliceosome are shown. The U6 intramolecular stem structure (intra-stem) is also pictured. The extended U6 intramolecular stem (before the first step of splicing, complex B2) or the U6 intramolecular stem plus U2–U6 H helix B (before the second step of splicing, complex C1), constitutes a structure that resembles domain V (active site) of group II introns (self-splicing introns). Note: Different nomenclatures are used to describe splicing complexes in mammals and yeast. Here, the nomenclatures are adopted from the mammalian system (66).
level of pre-mRNA splicing in both yeast and higher eukaryotes, further confirming their importance in the splicing process. The question that then develops is what role do these consensus sequences (and the invariant nucleotides) play during splicing? Are they recognized by other trans-acting cellular components, and if so, what are they?

### Early Recognition of the 5′ Splice Site and the Branch Site

Although identified and characterized in the 1960s (14, 15), U1 and U2 snRNAs had not been assigned functions until the discovery of split genes (or pre-mRNA splicing). In an attempt to link U1 to pre-mRNA splicing, researchers first analyzed the sequence complementarity between the snRNA and the conserved sequence elements in the pre-mRNA. Excitingly, the sequence analyses revealed a striking complementarity between the evolutionarily invariant 5′ end of U1 and the pre-mRNA consensus sequence at the 5′ and 3′ splice sites (16, 17). Although the original proposals for the involvement of U1 snRNA in splicing suggested that the 5′ end of U1 may base-pair with consensus sequences surrounding the 5′ and 3′ splice sites, in 1981 Mount and Steitz modified the model after observations that certain sequences in U1 predicted in binding the 3′ splice site were not conserved (18). Driven by this hypothesis, researchers carried out a series of experiments to confirm the involvement of U1 in pre-mRNA splicing. For instance, in 1983 the Steitz lab provided the first evidence that U1 snRNA’s primary role was the recognition of the 5′ splice site (19). Using an ultrathin transcribed RNA fragment of the major mouse β-globin gene, which contains an intron, they localized the U1 snRNP binding site by T1 ribonuclease treatment of the snRNA-RNA complex, immunoprecipitation of the resulting trimmed complex with anti-U1 antibodies, and T1 ribonuclease fingerprinting of the immunoprecipitate. Fingerprinting analyses revealed three oligonucleotideides present: CAG, UUG, and UAUCCAG. All three of these fragments can be found together in a single region that encompasses the 5′ splice site (GGGCGAGUGUUGUCCAG) (19). In a separate experiment, the 5′ and 3′ end region of U1 was destroyed by oligodeoxynucleotide-directed RNase H digestion, resulting in a loss of splicing activity (20). In addition, an elegant genetic suppression assay was used to verify the base-pairing interaction between U1 and pre-mRNA (21). In that work, a point mutation was first introduced into the 5′ splice site region of a pre-mRNA. As expected, splicing of the pre-mRNA was inhibited. However, when a compensatory point mutation was introduced into U1 snRNA at the site (within the 5′ end region) that was predicted to restore the base-pairing interaction, splicing activity was indeed rescued (21). Moreover, posttranslation cross-linking also detected base-pairing interaction between U1 and pre-mRNA (22). Along the same line, U1 was physically detected in the splicing complex (see below). Such an enormous amount of data has clearly demonstrated that, indeed, U1 recognizes pre-mRNA during splicing and that the recognition involves a direct base-pairing interaction between the U1 5′ end region and the pre-mRNA 5′ splice site (see Fig. 1). Binding of U1 as well as other splicing factors to the 5′ splice site of a pre-mRNA leads to the formation of an early complex, termed a commitment complex, that commits pre-mRNA to the splicing pathway (see below).

### Splicing Factors Recognize the 3′ Splice Site

U2AF (U2- auxiliary factor) is one of several splicing factors that have been implicated in 3′ splice site recognition (36, 39). U2AF has two subunits, namely U2AF65 (65 KD) and U2AF35 (35 KD). It has long been known that U2AF65 binds to the polypyrimidine track upstream of the 3′ splice site of pre-mRNA in high eukaryotes (36, 39, 41). However, the role of U2AF35 had remained elusive until 1999 when a connection between U2AF35 and the dinucleoside AG at the pre-mRNA 3′ splice site was finally established (42–44). Using a variety of experimental approaches, including U2AF depletion and reconstitution, cross-linking and immunoprecipitation, Soléx, nucleoside protection, and mutational analysis, three research groups independently demonstrated that U2AF35 is actively recognizing the dinucleoside AG at the 3′ splice site during splicing (42–44). Other splicing factors may also play important roles in 3′ splice site selection. For example, using the yeast genetic approach and the mammalian in vitro splicing system, researchers demonstrated that the splicing factor SiU7 is important for the selection of the canonical AG at the 3′ splice site during splicing (45, 46).
Splicing Occurs Via a Two-Step Trans-esterification Reaction Pathway

In the early 1980s, a mammalian in vitro splicing system (HeLa nuclear extracts) was developed, leading to the discovery of two splicing intermediates, the cut-off 5'-exon intermediate and the 2/3 lariat intermediate (intron-3' exon in a lariat form) (47, 48). Importantly, the lariat (or branched) structure was also identified in celluly derived RNAs (49, 50). Soon after, the yeast in vitro system also became available, and it, too, allowed the detection of the cut-off 5’ exon and the 2/3 lariat intermediates (51). A two-step trans-esterification reaction pathway was thus established (Fig. 2). In the first step, the 2’-OH of the branch point nucleotide adenosine attacks the phosphate at the 5’-exon–intron junction (5’ splice site), resulting in the cleavage of the phosphodiester bond between the 5’-exon and intron and the concurrent formation of a new 5’-2’ phosphodiester bond between the 5’ end of the intron and the branch point adenosine. Thus, a lariat-structured intermediate (the 2/3 lariat intermediate) and the cut-off 5’-exon intermediate are produced. In the second step, the 3’-OH group of the cut-off 5’-exon attacks the phosphate at the intron-3’-exon junction (3’ splice site), releasing the lariat intron product and generating the spliced mature mRNA product. According to this pathway, the branch point adenosine and the guanosines at the 5’ and 3’ ends of the intron are the key nucleotides as they directly participate in the chemical reactions. In fact, these three nucleotides are among the most conserved nucleotides in pre-mRNA (see above).

Spliceosome Assembly Pathway

It was anticipated that splicing occurs in a large RNA-protein complex (or the spliceosome), given that multiple snRNAs and proteins can be identified as functional components that participate in splicing. However, how big the spliceosome is and, perhaps more importantly, how it is assembled had remained largely unclear. The availability of the in vitro splicing systems in vitro during splicing (51). A two-step trans-esterification reaction pathway was thus established (Fig. 2) (66, 67). Finally, the lariat intron product is released at the branch point adenosine and its 2’-OH group are pictured. The lines represent the intron and boxes depict exons.

The assembly starts with a nonspecific H complex that forms as soon as the pre-mRNA is mixed with the splicing extracts (62, 66, 68, 69). This complex is then turned into a commitment complex (CC complex or the E complex) after binding with U1 snRNP and various protein factors, including SR proteins, U2AF (Mud2p in yeast), and SF1 (BBP/Msl5p in yeast) (23-28). The commitment complex is a complex that is committed to splicing out the intron on which it assembles. U2 snRNP then joins the commitment complex, converting it into a presplicing complex, namely complex A (27, 35, 58, 60-62, 66, 67, 69). After binding with the preformed functional U4/U6/U5 tri-snRNP (70-74), in which U4 and U6 are extensively base-paired with each other, complex A is then converted to complex B1 (61, 66, 67). Complex B1 undergoes a conformational change, and it becomes complex B2, which is now competent for the first step of splicing (62, 66, 67). After the first step of splicing and additional conformational changes, complex B2 is turned into complex C1 in which the second step of splicing occurs (63, 66, 67). Complex C1 then changes to complex C2, which contains spliced products (61, 66, 67). The mature mRNA is then released, changing complex C2 to complex I (62, 66, 67). Finally, the lariat intron product is released.
Dynamic Rearrangements of RNA–RNA Interactions within the Spliceosome

Although kinetic analysis of spliceosome formation led to the discovery of a stepwise assembly pathway, the detailed network of interactions among the components within the massive spliceosome had remained unclear until the early 1990s when a series of cross-linking and yeast genetic suppression experiments were carried out to tackle this problem. Several cross-linking techniques, including psoralen cross-linking to detect Watson-Crick base-pairing interactions, 4-thioU cross-linking to detect non-Watson–Crick contacts between two nucleotides, and direct short wavelength UV cross-linking to detect various interactions, were used effectively to capture the interactions between U snRNAs and pre-mRNA and among U snRNAs themselves (22, 75–79). Cross-linking was performed at various time points in parallel with splicing and spliceosome assembly assays, such that any detected cross-linking species could be assigned to a particular stage (splicing complex) during spliceosome assembly and splicing. In the meantime, sensitive yeast and mammalian genetic suppression assays also identified several novel RNA–RNA interactions (80–88). Recently, some of the RNA–RNA interactions within the spliceosome were further refined through the use of NMR spectroscopy (89). The large amount of data accumulated over the years provided a detailed picture revealing a network of RNA–RNA interactions within the spliceosome.

In addition to the early base-pairing interactions between U1 and the 5′ splice site and between U2 and the branch site, a number of new RNA–RNA interactions were detected at late times during spliceosome assembly, especially after the spliceosome is fully assembled (complex B1) (Fig. 3). Interestingly, the formation of some new interactions is accompanied by the dissociation of old interactions, indicating that dynamic rearrangements occur within the spliceosome. Specifically, entry of the U4/U6–U5 tri-snRNP to form complex B1 may be mediated at least in part through the base-pairing interaction between the 5′ end of U2 and the 3′ end of U6 (U2–U6 Helix II) (78, 82, 86). As soon as the U4/U6–U5 tri-snRNP enters the splicing complex, U5 snRNA interacts, in a non-Waston-Crick pairing manner, with the exon sequence at the 5′ splice site, and possibly with the exon sequence at the 3′ splice site as well (75–77, 83, 84, 87). In the meantime, a conserved sequence of U6 (ACA-GAGA) displaces U1 in interacting with the 5′ splice site (79, 88). Concurrently, or immediately after, U6 dissociates from U4. The freed U6 sequence then forms new duplexes with U2 (Helices I and III, see Fig. 3) (22, 81, 85, 89), which are believed to be at least part of the catalytic center (9, 30). This dynamic rearrangement results in the release of both U1 and U4 from the spliceosome and the formation of an active catalytic center for the first step of splicing (complex B2). After the first chemical reaction, the spliceosome undergoes additional conformational changes, resulting in the disruption of the base-pairing interaction between U6 and the 5′ splice site, the formation of U2–U6 Helix 1b, and the repositioning of the reaction substrates within the catalytic center (complex C1) (80, 89, 90). These conformational changes directly trigger the second step of splicing that generates the mature mRNA and a lariat intron products (complex C2). After the second step of splicing, further conformational changes occur, leading to the release of mature mRNA (complex I). Final conformation changes then take place, resulting in the release of the lariat intron and disassembly of the spliceosome (or complex I).

Protein Factors Facilitate and Modulate Spliceosomal Conformational Changes

It has long been proposed that the rearrangements of RNA–RNA interactions and/or conformational changes are orchestrated by spliceosomal protein factors (7). Indeed, multiple such protein factors have been identified, and many of them are members of the family of DEAD box ATPases, which can either directly promote the unwinding of RNA–RNA duplexes (also referred to as unwindases) or disrupt RNA–protein interactions (or even protein–protein interactions) (91). These spliceosomal ATPases function in a substrate-specific way, such that they each promote a specific conformational change (RNA–RNA interaction) at various stages along the pathway of spliceosome assembly and catalysis. For instance, Prp5 is an RNA-dependent ATPase that bridges U1 and U2 snRNPs at early times during spliceosome assembly, promoting stable interaction of U2 with the intron branch site (40, 92) and thus promoting complex A formation. As is, there is evidence that the incorporation of U2 snRNP into the spliceosome is facilitated by Sub6/UPF56 (U2AF-associated protein), another RNA-dependent spliceosomal ATPase that acts through disruption of an interaction between U2AF and the branch site (93). Brm, a U5 snRNP-associated protein and also an RNA-dependent ATPase, promotes the dissociation of U6 from U4 (94) in the spliceosome (presumably soon after complex B1 formation). In vivo analysis in S. cerevisiae suggests that the spliceosomal ATPase Psp28 may be actively disrupting the interaction between U1-C and the 5′ splice site so as to allow for the exchange of U1 for U6 (95, 96), which is part of the rearrangement occurring during the transition from complex B1 to complex B2. The spliceosomal ATPase Psp22, on the other hand, promotes the first step of splicing (97–101), presumably also through rearranging the RNA–RNA interactions required for catalysis. The spliceosomal ATPase Psp15 promotes the conformational changes required for the second step of splicing (transition from complex B2 to complex C1) (90, 102–105). Psp22, a spliceosomal ATPase as well, facilitates the conformational changes required for the release of mRNA (106, 107), promoting the transition from complex C1 to complex I. Finally, another spliceosomal ATPase Psp43 orchestrates

Pre-mRNA splicing

![Diagram of spliceosome](image-url)
the conformational changes required for the release of the lariat intron (108).

Besides DEK/DOG box ATPases, Snu114, a component of US snRNP and a GT-Pase, is also required for splicing, presumably through promoting the rearrangement between PpD and Snu114 itself, thus leading to the release of U1 and U4 before the first step of splicing (109). In addition to the ATPases/GT-Pases, several other spliceosomal proteins facilitate the rearrangements as well. Included in these proteins are the US snRNP-associated proteins p116 and p20 (Prp3p in yeast), which are thought to play a regulatory role in the unwinding of U4/U6 (110).

Yeast genetic analyses indicate that PpD also plays a role in modulating the function of the spliceosomal ATPases, Prp16 (90, 100) and Prp22 (113). Likewise, Isy1, a component of Prp NineTen Complex (NTC), plays a role in facilitating the function of Prp16 (112). Similar roles can be assigned to U1C and Cus2, which are implicated in modulating the functions of PpD and Prp5, respectively (96, 113). Importantly, the spliceosomal ATPases and their modulators are not only the key factors in orchestrating the conformational changes during spliceosome assembly and catalysis, but also play important roles in maintaining the fidelity of splicing. In this regard, it has been proposed that incorrect conformations (e.g., those caused by mutations in pre-mRNA and/or other spliceosomal factors) are discarded through these conformational changes catalyzed by the spliceosomal ATPases and their modulators (90, 108, 114–116).

**Prefabricated Spliceosome?**

In contrast to the stepwise spliceosome assembly model, recent observations have indicated that the spliceosome exists as a pre-formed complex that engages the pre-mRNA as such (117–121). The strongest evidence for this model comes from the S. cerevisiae system from which a 45S snRNP complex was isolated that contained all five snRNPs (121). This penta-snRNP complex contains nearly all known U1, U2, and U4/U6-US snRNP proteins as well as non-snRNP splicing factors. The complex has also been shown to function in yeast cell extracts depleted of endogenous RNAs by nuclease digestion. Importantly, while assembling onto the pre-mRNA, the snRNA constituents of the penta-snRNP do not exchange with endogenous snRNPs. Consistent with the idea of a preassembled spliceosome, it has also been reported that both U2 and the U4/U6-US snRNP function before the formation of complex A (122). Furthermore, recent analysis of splicing complex formation in HeLa nuclear extracts argues that a preassembled 200S RNP complex containing all snRNP components can assemble onto a short RNA containing a 5′ splice site (123). However, using chromatin immunoprecipitation/more (ChIP) analysis, the Neugebauer group (124, 125) and the Rambach laboratory (126, 127) have more recently suggested that the recruitment of spliceosomal snRNPs to nascent pre-mRNA (in vivo spliceosome assembly) in yeast occurs via a stepwise assembly pathway, which is similar to that observed in vitro (see above, Spliceosome Assembly Pathway). Thus, it remains controversial as to whether spliceosome assembly is a one-step process (the prefabricated penta-snRNP complex assembles onto pre-mRNA) or it proceeds in a stepwise fashion. Further study is necessary to clarify this important issue.

**Is Splicing an RNA-Catalyzed Reaction?**

It has long been suspected that the two trans-esterification reactions to remove the introns from a pre-mRNA are catalyzed by the RNA constituents in the spliceosome (128). This idea is bolstered by the fact that U snRNAs in the spliceosome do form functional structures (the extended U6 intramolecular stem in complex B2 and the U6 intramolecular stem plus U2–U6 Helix I b in complex C1; see Fig. 1) resembling domain V of group II introns, some of which are self-spliced via the two-step trans-esterification pathway identical to that of spliceosome-catalyzed pre-mRNA splicing (see above). Domain V of group II introns constitutes the catalytic center for catalysis during self-splicing (129–131).

Over the past decade, a growing body of evidence has suggested that pre-mRNA splicing in the spliceosome may indeed be catalyzed by its RNA constituents. For instance, Sontheimer et al. have shown that the first catalytic step of splicing occurs through a metal-ion-dependent pathway (132), an observation consistent with the two metal-ion model proposed for the spliceosome active site(s) (133). Later, using sulfur substitution followed by manganese suppression, Lin and colleagues have demonstrated that, through metal ion coordination, U6 plays a critical role in the catalysis reaction (134). Most recently, Valadkhan and Manley carried out an even more direct experiment to address this issue (135). In that experiment, they used only three short RNA oligonucleotides, corresponding to U2, U6 (designed according to U2–U6 Helices I, II, III, and the U6 intramolecular stem, see Figs. 1 and 3) and the branch site, respectively, and no proteins were included. Remarkably, the U2 and U6 oligonucleotides do form the functional structure for the first step of splicing (U2–U6 Helix I plus the extended intramolecular stem of U6), leading to the production of X-RNA, a product generated by a splicing-like reaction by which the branch point adenosine in the branch site oligonucleotide attaches a phosphate in the U6 oligonucleotide (Fig. 3). Taken together, the evidence accumulated thus far strongly supports the RNA-catalysis model for the spliceosome.

**A Parallel Spliceosome**

In high eukaryotes, there also exists a minor population of introns containing distinct consensus sequences at their 5′ and 3′ ends (136). The removal of these introns takes place in an analogous spliceosome containing a different set of U snRNPs (U11, U12, U5, U4atac, and U6atac) (137). Although initially dubbed AT-A C introns based on their termini, extensive genomic database surveys have revealed that the standard GT-A G terminal sequences are more prevalent (138, 139). Instead, what appears to distinguish this class of introns is longer and more
constrained consensus sequences at the 5′ end of the intron and the branch site, as well as the absence of a polypyrimidine tract upstream of the 3′ splice site (138, 139). The splicing machinery responsible for the removal of these introns is of much lower abundance (∼10^6 copies per cell) relative to components of the major spliceosome, which is compatible with the low frequency in which these introns appear in the genome (∼1/300 human introns) (140).

Remarkably, U11, U12, U4atac, and U6atac form structures that are almost identical to their counterparts in the major spliceosome, namely U1, U2, U4, and U6, respectively, despite the fact that the two sets of snRNAs are quite different in primary sequences (136, 137). Equally strikingly, the network of RNA–RNA interactions detected in the major spliceosome also exists in the U12-dependent spliceosome, further validating the importance of these dynamic interactions during spliceosome assembly and splicing (136, 137).

The main mechanistic differences between the two spliceosomes occur at the stage of intron recognition, rather than catalysis. Indeed, recognition of the 5′ splice site and the branch site occurs simultaneously by the U11-U12 di-snRNP (141). Furthermore, there is a requirement among U12-dependent introns for 5′ exon sequences to form U6atac-3′ splice site interactions (142). Lastly, more constrained consensus sequences, as well as the lack of a polypyrimidine tract, suggest that the assembly of this spliceosome is more dependent on snRNA-based interactions than assembly of the major spliceosome (140, 143).

doi: 10.1002/9780470048672.wecb517

RNA interference (RNAi) and microRNA (miRNA) pathways participate in posttranscriptional gene expression regulation. RNAi and miRNA biochemistry involve short (~22 nucleotide) regulatory RNAs: small interfering RNA (siRNA) and miRNA. Both siRNAs and miRNAs guide RNA–protein complexes to “target” complementary messenger RNAs (mRNAs) for cleavage or translational repression. Many proteins involved in these pathways have been elucidated. The biochemical mechanisms of miRNA/siRNA processing have been dissected in detail in plants and in animals using biochemical and genetic approaches. Here we review the current literature on RNAi and miRNA mechanisms with a special focus on the protein components.

Introduction

Much gene expression regulation occurs after mRNA transcription (1), and it is becoming increasingly clear that noncoding “regulatory” RNAs play central roles in posttranscriptional gene expression regulation. The breakthrough discovery of small regulatory RNAs and their multiple functions in gene regulation has heralded a fascinating new field in biology. Pioneering observations on the phenomenon of posttranscriptional gene silencing were reported in plants (2–5). However, the broader relevance of gene silencing mechanisms is confirmed in many other organisms, including the Nobel Prize winning discovery of RNA interference (RNAi) in worms (6). RNAi-related biological phenomena have now been elucidated in all known eukaryotic organisms. The similarities in RNAi mechanisms between plants and animals underscore the importance of this ancient gene regulatory mechanism. Moreover, in addition to mRNA “gene expression regulation,” RNAi-related mechanisms were shown to have diverse functions including transposon silencing (7), chromosome remodeling (8), and DNA methylation (9).

The molecular processes responsible for RNAi and its related pathways have been elucidated extensively over the last few years. Here we review the literature about the mechanisms of RNAi and miRNA pathways with a focus on the proteins involved.

Complementary Research Strands Come Together

In 1990, Jorgensen (10) attempted to enhance flower color by overexpressing an extra copy of chalcone synthase (chsA) gene in transgenic petunia plants (3). Unexpectedly, among many transgenic petunia plants both the endogene and the transgene of chalcone synthase were silenced. The transgenic flowers showed multiple colors or generated white segments. Loss of cytosolic chsA mRNA was not associated with a reduction of the gene transcription (11), which indicates that the phenotype resulted from a post-genetic transcriptional event. The phenomenon of silencing an endogenous plant gene, triggered by extra copies of a transgene with the same sequence, was termed “cosuppression” (10, 12).

Important advancements in the field that would eventually encompass RNAi and miRNAs came from the laboratory of Victor
A. Ambros et al. discovered that short noncoding RNAs (the product of the lin-4 gene) regulated the translation of another gene product (lin-14) via partially complementary sequences in the 3′UTR of lin-14 mRNA (13, 14). The significance of these data remained temporarily obscure—it was not until seven years later that a similar small regulatory RNA was discovered (15).

Thereafter, it was recognized that these molecules were representatives of a large, biologically important class of RNA (the designation “microRNAs” was first described in separate papers in 2001) (16-18). Although miRNAs work through pathways somewhat different from siRNAs (see below), the paradigm of antisense recognition by small regulatory RNAs, coupled with posttranscriptional regulation of mRNA, was thus established in animals.

In 1995, when worms were injected with antisense and sense RNAs to target a specific gene for down-regulation, Gao and Kemphues (19) found that both the control sense and the antisense RNAs induced similar gene silencing effects in worms. This phenomenon could not be explained fully at that time. In the seminal work of Fire et al. (6), dsRNA was finally demonstrated as a potent trigger in gene silencing by introducing tiny amounts of purified dsRNAs into C. elegans, and this phenomenon was termed “RNA interference”.

Although RNAi phenomena were described in different experimental contexts (labeled cosuppression in plants, RNAi in animals, and quelling in fungi), all these gene-silencing mechanisms have converged on a general paradigm. The common features of this paradigm share at least three characteristics: 1) Short (null) regulatory RNAs (siRNAs) of 21–23 nucleotides (nts) are the key players in mediating specific RNA degradation, 2) the degradation of target RNA depends on specific sequences, and 3) the machinery of the RNA-induced silencing complexes (RISCs) is similar in structure and function across most organisms.

The Mechanism of RNA Interference

Although RNAi and miRNAs were discovered in worms, major progress in revealing the RNAi pathway came from in vitro biochemical studies using a cell-free system from Drosophila syncytial blastoderm embryos, which was first carried out by Tuschi et al. (20). It was hypothesized that a population of 21–23 nt small RNAs could be generated in fly embryo lysates, which triggers the cleavage of radioactively labeled target mRNA at 21–23 nt intervals (21). Experimentally, these short RNA fragments were indeed detected in extracts of Drosophila Schneider 2 (S2) cells that were transfected with dsRNA (22). Moreover, RNA molecules of similar size were also found to accumulate in transgenic silenced plants (23). Based on these studies, Zamore et al. (21) proposed an early model of RNAi: Long dsRNAs are first cleaved into short dsRNA fragments of 21–23 nts. These short dsRNAs are then separated and integrated into a ribonucleoprotein complex, and the siRNA-ribonucleoprotein complex recognizes and binds the siRNA-specific complementary RNA that leads to destruction of the latter. This model laid a framework for the subsequent dissection of the RNAi pathway.

Generation of siRNAs and miRNAs

SiRNAs can be derived from several sources including long dsRNAs. dsRNAs can be produced many ways. They can be generated endogenously, for example, from transgene transcripts by RNA-directed RNA polymerase (RdRP) (24-27); by simultaneous transcription of sense and antisense DNA fragments from specific genomic loci (28); from viral replication intermediates (27, 29); or via introduction of genes that encode inverted repeats by genetic engineering (30, 31). Endogenously generated or exogenously introduced dsRNAs are then converted into 21-30 bp small RNAs by dicer (DCR), which is an RNase III family enzyme that initiates the RNAi (32).

miRNAs, which are derived from endogenous genes, are processed differently from siRNAs. A single-stranded RNA can form a “hairpin” or “stem-loop” structure where the RNA folds back and base pairs with itself. The “stem” of this structure thus serves as dsRNA for additional processing. Some “stem-loop” RNAs are processed to become miRNAs. MiRNA genes are transcribed by RNA polymerase II (pol II), mostly or in a few cases by pol III (33, 34), and the primary transcripts “pri-miRNAs” are processed by a microprocessor composed of a Drosha-like enzyme of RNase III family and a Pasha-like protein of dsRNA binding protein family (35-39). Or, in plants, pri-miRNAs are processed by the DCR family member DCL1 (40). Like all RNase III enzymes, Drosha leaves two nt 3′ overhangs and 5′ monophosphate groups. Processed pre-miRNAs are transported to the cytoplasm via the export-receptor Exportin-5 (41-43). MiRNAs not only are generated from miRNA genes located within intergenic regions, but also are derived from introns. A subset of intronic miRNA precursors from Drosophila can bypass the microprocessor and directly serve as DCR substrates (44, 45). These miRNAs are known as mirtrons. The spliced-intron lariats or mirtron precursors are debranched and refolded into stem-loop structures that have similar Drosha ends and are recognized by DCR1 in Drosophila (44, 45).

The final stages of miRNA maturation are deceptively complex. As indicated above, both dsRNA and stem-loop RNA structures such as miRNA precursors are recognized and processed by the cytoplasmic RNase III enzyme DCR (32). Humans and C. elegans encode only one DCR, which can process both dsRNA and mirtron precursors; Drosophila has two DCR genes, and the Arabidopsis genome encodes four DCR homologs with each responsible for distinct pathways (46). DCR binds and cleaves dsRNA endonucleolytically and generates a 21-25 bp long dsRNA (47-50). The short dsRNA fragments are separated, and one strand is incorporated into an effector complex, called RNA-induced silencing complex (RISC) (22), where it binds directly to a member of the Argonaute protein family. A Argonaute proteins— in plants as well as in animals—are at the heart of the function of RNAi and its related pathways.
The activity of Argonaute is affected dramatically by the sequence specificity of the loaded small regulatory RNA (i.e., the degree to which the small RNA is complementary to a "target" mRNA) (see below). In plants, miRNA-containing RISC guides predominantly target cleavage because plant miRNAs are usually extensively complementary to their target genes (51), although bona fide translational repression has been described in plants (52). In contrast, mammalian miRNAs are usually not fully complementary, and miRNA-guided posttranscriptional regulation leads primarily to the repression of gene expression via translational repression. To distinguish them from mRNA cleavage reactions mediated by RISC, effector complexes that contain mammalian miRNAs are often referred to as miRNA-RNP (53, 54).

The RISC Components and Function

The action of RNA interference is carried out by RISC. RISC is a ribonucleoprotein particle (RNP) with a "core" structure composed of a single-stranded siRNA or miRNA and an Argonaute protein (AGO). Depending on both the isoform of the AGO and the degree of complementarity between the siRNA/miRNA and the target sequence, interaction of RISC with mRNAs can result in multiple silencing events including endonucleolytic cleavage, translational repression, sequestration to P-body compartment, and mRNA degradation (Fig. 1).

Although AGO and small regulatory RNAs are the sine qua non, other proteins are also important to regulate the function of RISC. The complete protein repertoire of RISCs is not elucidated fully. The reported sizes of RISC vary from 160 kDa (minimal RISC) to 280 kDa (holo-RISC). The "holo" RISCs were found to be associated with many proteins in addition to the AGO protein and the small RNA. Both in vitro and in vivo studies showed that an AGO protein and a guide strand siRNA alone can form a functional "core" RISC to cleave the target mRNA. For example, either recombinant human AGO2, or biochemical-purified RISC from human or Drosophila cell lysate, are active complexes capable of substrate binding and cleavage (22, 55–61). Similarly, in Arabidopsis, the immunopurifiﬁcation of AGO1 proteins can interact with single-stranded siRNAs to form active RISCs (62). Both recombinant and endogenous RISC-directed target cleavages occur in a divalent cation (Mg$^{2+}$ or Mn$^{2+}$)-dependent manner. Other examples, however, indicate that activity of RISCs needs additional protein components or cofactors for its function. For example, in S. pombe, site-directed cleavage of the promoter region of the his3 gene requires the association of RITS complex with AGO1 protein (56–58).

Figure 1: Mechanisms of small RNA-protein complex mediated gene suppression. In cytoplasm, siRNAs and miRNAs are sorted and integrated into different types of RISC/RNP complexes. RISCs/RNPs that contain AGO proteins with or without RNase H activity (slicer) and the loaded siRNAs or miRNAs, execute gene suppression function via different mechanisms: 1) target mRNA cleavage by the slicer; 2) prevention of translation initiation by excluding the translation initiation factor eIF4E from binding to the mRNA-cap (m$^7$G) via an eIF4E-like domain (N2C) located on the AGO proteins; 3) ribosome drop-off from the target mRNA, which is induced by the RISC/RNP; 4) sequestration of target mRNAs to P-bodies for temporary storage or degradation. Under certain conditions (e.g., stresses), miRNPs help release the target mRNAs from P-bodies to resume the target mRNA translation. In the nucleus, siRNA-loaded RITS complex directs Chp1 to methylate of the ninth lysine of histone H3. RITS complex recruits the cellular proteins such as Chp1, Swi6, and TAS3, which lead to the chromatin remodeling and shutdown of gene expression in S. pombe. In humans, synthetic siRNAs that target promoter regions can interact with AGO2 protein and demethylate the H3K9, which leads to the activation of the target genes.
example, the RISC-directed multiple turnover target cleavage needs ATP, although a component that binds and hydrolyzes ATP has not yet been identified (58, 60, 61, 63). Several key components such as DCR, helicases, the GEMIN3 (a DEAD box helicase) (53) and its interacting protein GEMIN4, and dsRNA endonucleases have been identified in different organisms for their roles in RISC function.

### RLC and siRNA Loading onto RISC

After cleaving dsRNA to produce siRNAs, DCR may remain in association with siRNAs through interactions with its partner proteins, which change under different circumstance and different species (64, 65). These partner proteins include RDE-4 in C. elegans (66), the RPD-2 in flies (67), and the TRBP in humans (68). DCR interacts with these small RNA binding proteins and helps sorting small RNA duplex to form the RISC-loading complex (RLC). As its name suggests, RLC is responsible partly for loading the siRNA or miRNA into RISC. The transition from double-stranded to single-stranded RNAs during RISC assembly is achieved via RNA-protein and protein-protein interactions. The RLC is partially characterized in humans (69), Drosophila (see below) and C. elegans, but the exact composition is unknown.

siRNA-directed RISC assembly in Drosophila is one of the most experimentally dissected and understood systems in vitro. One of Drosophila’s two DCR homologs (DCR1s), DCR2, is involved in siRNA production and subsequently siRISC assembly, whereas DCR1 is involved in miRNA biogenesis (70), and its dsRNA binding partner is Loquacious (71, 72). Recent data indicate that the two pathways in Drosophila are interchangeable. A subset of miRNA duplexes can be sorted into the siRNA pathway after their biogenesis (64, 65). The sorting of miRNAs into RISC pathway requires the disassociation of miRNA duplex from DCR1 complex and a recruitment of the duplex to DCR2 complex. DCR2 is tightly associated with its partner, R2D2, to form a stable heterodimer (DCR2-R2D2), without which both are unstable in cells (67). The formation of RLC starts from the interaction between the siRNA duplex and the DCR2-R2D2 heterodimer (73, 74). DCR2 is a sensor protein that tends to form thermodynamically more stable siRNA duplex end and places the siRNA duplex onto DCR2-R2D2 in the appropriate orientation (73, 74). This directional positioning of the siRNAs on RLC during RISC assembly referred to as “asymmetric assembly of RISCs” or “asymmetric assembly of RLC” is a key function of RLC. The asymmetric complex assembly is defined mainly by R2D2 and the structures of the small RNA duplexes (73).

Whether siRNA/miRNA are loaded as double stranded, or are first unwound with only single-stranded guide siRNA being loaded into RISC, is still not fully understood. Initially, it was thought that a nonprocessive helicase that separated the two strands of the duplex was involved in RLC (74). In later studies, it has been suggested that siRNAs are loaded initially into RISC as duplexes, and AGO2 cleaves the passenger strand of the siRNA, which facilitates its displacement and leaves the siRNA guide strand bound stably to AGO2 (75–78). A recent report by Robb and Rana (79) demonstrated that human RNA helicase A (hRHA) is a siRNA-loading factor. hRHA interacts in human cells with siRNA, AGO2, TRBP, and DCR, and functions in the RNAi pathway. In RNAi-depleted cells, hRHA was reduced as a consequence of decreased intracellular concentration of active RISC assembled with the guide-strand RNA and AGO2. It is envisaged that other components of RISC are waiting to be identified.

### RISC-Mediated Target mRNA Interaction

The rules for the interactions between RISC and target mRNA are probably different between species and perhaps between tissues in a given species. Two recent papers from the Zamore laboratory (64, 65) provided their important findings about RISC-target interaction in Drosophila S2 cells or embryo lysate. Despite distinct pathways of siRNAs and miRNAs biogenesis, the authors showed that siRNAs and miRNAs are sorted by a common process that involves two types of functionally distinct Argonaute protein complexes: AGO1 and AGO2. The sorting of small RNAs between AGO1 and AGO2 is an active process that depends on the structure of the double-stranded siRNA and the double-stranded assembly intermediates. For example, DCR2-R2D2 acts as a gatekeeper for the assembly of AGO2-RISC, which promotes the incorporation of siRNAs and diverts the integration of miRNAs. An independent mechanism (yet to be identified) acts in parallel to favor assembly of miRNA duplexes into AGO1-RISC and to exclude siRNAs from incorporation into AGO1. Partitioned small RNAs may be loaded onto either AGO1 or AGO2, and this association then determines how the small RNA functions to repress gene expression either via transcript cleavage or via translation inhibition.

Both siRNA- and miRNA-guided RISCs can lead either to the destruction of the target mRNAs or to the suppression of the target mRNA translation. At least three conditions are essential for target mRNA to be cleaved site-specifically by RISC: 1) the sequence complementarity between the guide RNA and the mRNA target must be complete via the nucleotides numbered 2–11 complementary to the 5′ “seed” region of the siRNA, 2) RISC must comprise an AGO protein (e.g., AGO2 in humans) with RNase H-like endonuclease “slice” activity for forming a cleaving RISC, and 3) a scissile phosphodiester bond must exist on the mRNA target accessible to the endonuclease active motif located in the PIWI domain of the AGO protein. In general, target recognition, binding, and cleavage by RISC are determined mainly by the base pairing between the 5′ portion (~10 nt) of a siRNA or miRNA and their target mRNA. When recognizing complementary mRNA, activated RISC forms an effector complex with the target mRNA (80, 81). After cleavage, the target mRNA is degraded. Activated RISC, as a multturnover enzyme, is recycled to cleave additional mRNA targets (56). Only a few AGO proteins, such as AGO2 in humans (61, 82, 83); dAGO1 and dAGO2 in Drosophila (84); RDE1, PPD-1,
ALG1, and ALG2 in C. elegans (66); and Arabidopsis AGO1 and AGO4 (62, 85) have RNase H-like motifs at the PIWI domains that have been identified to have or potentially to have endonuclease (“slicer”) activity. The cleaving activity of the AGO “slicers” is divalent cation (e.g., Mg^{2+}) dependent (61, 86). It catalyzes the hydrolysis of the phosphodiester linkage of mRNA target at specific site and yields 3′ hydroxyl and 5′ phosphate termini on the cleavage products (59, 80). This specific cleavage site is predetermined on RISCs and is located precisely at the phosphodiester bond in the mRNA target between the nucleotides paired to base 10 and 11 of the guide RNA from the 5′ end (57, 61, 88, 87).

Crystal structure studies and biochemical analysis revealed that the phosphate group at the 5′ end of the guide RNA has an impact on the cleavage site fidelity by a RISC “slicer” active site (89–93). The guide RNA normally positions on the AGO protein in a RISC effector with the 5′-end anchored into the phosphate-binding basic pocket in M-id/Piwi-domain, the 3′-end bound with the PAZ-domain, and the middle sequence channelled with the “slicer” active site between the M-id/Piwi-domain and the PAZ-domain. To make the cleavage event occur, the scissile phosphodiester bond at the target must be positioned conducive by the conformational changes induced by the interaction among the AGO protein, the guide small RNA, and the target mRNA.

The structure of target mRNA also has a role in RNAi efficiency. Although the base pairing between a siRNA/miRNA and target site is important, in vitro approaches and bioinformatic prediction demonstrated that the sequence context that surrounds miRNA-binding sites influence the sensitivity to repression by a siRNA/miRNA (93–96). Sequence context could influence miRNA efficacy by mediating the binding of hypothetical cofactor proteins or by affecting the secondary structure of a target site and its accessibility to binding by the siRNA/miRNA. Multiple additional steps in the RNAi pathway including RISC assembly, siRNA strand selection, and target site accessibility might be affected by the target sequence composition. In a recent work by Ameres et al. (97), the authors demonstrate that RISC scans for its target sequences by transiently and nonspecifically binding single-stranded RNA, and it promotes siRNA-target RNA annealing when siRNA meets its target sequence. Their findings also show that cleavage competence of RISC is influenced by the secondary structure of the RNA target and that the 5′ portion of the siRNA determines the stable association of RISC with its target. This study provides insight into the cleavage event in RNAi and could improve the design of potent siRNAs.

RISC-Mediated Translation Inhibition

As stated, translation inhibition mediated by miRNPs/miRISC depends largely on the sequence complementarity of loaded miRNA to target mRNA and the type of AGO protein that is recruited in RISC. Partially complementary siRNAs/miRNAs loaded onto AGO protein that lacks “slicer” activity, is thought to produce translational inhibition. The following are at least four possible mechanisms to explain miRISC-mediated target mRNA translational inhibition: 1) RISC represses protein translation at the stage of translation initiation and postinitiation, 2) small RNA-guided RISC assists relocation and sequestration of the target mRNAs to cytoplasmic processing bodies (P-bodies, stress granules, etc.), 3) RISC guides mRNA decay triggered by rapid degradation of the mRNA, and 4) siRISC may cause immediate and/or fast protein degradation after translation (98).

Small RNA-guided RISC can inhibit translation at the initiation step of protein translation (99, 100) or at postinitiation stages (101–103). Pillai et al. (100) showed that in mammalian cells, let-7 miRNPs inhibits translation at the initiation step. The authors employed two independent approaches to investigate the inhibition process. One involved tethering the human AGO protein to the 3′-UTR of a reporter gene to mimic the mRNA-mediated translational repression in HeLa cells. The second approach was to assay the endogenous let-7 miRNPs for their inhibition of protein translation of a reporter mRNA that contains the let-7 targeting sites. The results demonstrated that the mRNA guided/associated miRNPs blocked the protein translation initiation in an m7G-cap-dependent manner, which suggests that miRNPs interfere with recognition of the cap.

The 5′ end of eukaryotic mRNAs is modified by the addition of a 7-methyl guanosine cap. Eukaryotic initiation factor 4E (eIF4E) binds the m7G cap directly, and this interaction is essential for the initiation of translation of most eukaryotic mRNAs. Regulation of translation initiation is the most common target of translational control, and preventing binding of eIF4E to the m7G cap is a commonly employed cellular strategy to inhibit translation (104). A recent study by Kirikidou et al. (105) indicates that the translation inhibition mediated by miRNP occurred at the initial translation stage. Kirikidou et al. (105) identified a cap-binding-like domain (MC) in the middle domain of AGO2. The MC domain demonstrates m7G-cap binding activity and is required for translational repression but not for assembly with miRNA or endonucleolytic activity. In addition to their finding, the authors propose that AGO represses the initiation of mRNA translation by binding to the m7G cap of mRNA targets, which is likely to preclude the recruitment of eIF4E, intrinsically. Thermann and Hentze (106) have shown evidence that DrosoPhila mir-2 function is mediated by inhibiting m7GppG cap-mediated translation initiation in association with the formation of large RNP complexes. miRISC may also mediate dropoff of translating ribosomes by causing ribosomes to exit prematurely from their associated mRNAs (103). Alternatively, protein translation might not be affected, but the nascent protein is degraded rapidly by the ability of miRNPs to recruit proteolytic enzymes that would degrade nascent polypeptides that emerge from the actively translating ribosomes. The hypothesis that miRISC/miRNPs repress protein translation posttranslationally is also supported by the fact that many mRNAs are associated with actively translating, endogenous mRNAs in polysomes (107). A recent study also found that in human and worm cells alike, depletion of the protein eff6 (an “anti-association” ribosome inhibitory protein known to
to prevent productive assembly of the 80 S ribosome abrogates miRNA-mediated regulation of target protein and mRNA levels (108).

The AGO proteins and the repressed mRNAs are enriched in the cytoplasmic processing bodies (P-bodies, also known as GW-bodies) (100, 109, 110). P-bodies represent discrete cytoplasmic foci, which are enriched in proteins involved in mRNA decay and translational repression. These proteins include deadenylases, decapping enzymes such as DCP1 and DCP2, and 5′-3′ exonucleases (111). On the other hand, P-bodies lack ribosomes and protein translation machinery. In P-bodies, mRNAs can undergo decapping and degradation (112), or they can be stored temporarily. As such, under certain conditions (e.g., stress) (113), the target mRNAs sequenced to and stored in P-bodies can be released and re-recruited by the ribosome to resume the translation.

Chu and Rana (114) showed that in some human cells, miRNA function requires RCK/p54, which is a DEAD-box helicase known to be essential for translational repression. RCK/p54 interacts with AGO1 and AGO2 in vitro and in vivo, facilitates formation of P-bodies, and is a general repressor of translation. Disrupting P-bodies did not affect RCK/p54 interactions with AGO proteins or its function in miRNA-mediated translation repression. Depletion of RCK/p54 disrupted P-bodies and dispersed AGO2 throughout the cytoplasm but did not affect RISC functions significantly. These studies also suggest that translation suppression by miRISC does not require P-body structural integrity and suggests that location of miRISC to P-bodies is the consequence of translation repression.

Downregulation of gene expression by miRNAs is also associated with a substantial degradation of some target mRNAs (115–118). Some mRNAs that are destined to undergo miRNA-mediated decay are first deadenylated (115, 119, 120). The CCR4:NOT1 was identified as deadenylase complex in Drosophila S2 cells (119). In addition, the GW182 protein was identified as a key factor required for miRNA deadenylation, miRNA degradation by miRNAs requires GW182, the CCR4:NOT deadenylase, and the DCPSLP decapping complexes. The following is a model proposed for this posttranscriptional gene suppression: AGO1-containing RISCs bind to mRNA targets by means of base-pairing interactions with miRNAs; AGO may then recruit GW182, which in turn marks the transcripts as targets for decay via a deadenylation and decapping mechanism (115, 119, 121).

Although miRNAs generally have been identified as negative regulators of expression of the target mRNAs in most cases, accumulating evidence now suggests that, in some circumstances, miRNAs are found to enhance protein translation from their target mRNAs. In some cases (e.g., under stress conditions), miRNA associated RISCs simply help the repressed target mRNAs be released from the P-body and recruited by the ribosome to resume protein translation as discussed above (113, 122). This derepression of the target miRNA translation by miRNA needs protein cofactors that are likely induced by stresses and can release translational repression by interacting with the 3′UTR of the target miRNA or by helping the target miRNA to reassociate with polyribosomes. The currently identified protein cofactors include AU-rich-element binding protein HuR (113 122) and apolipoprotein B mRNA-editing enzyme catalytic polypeptide-like 3G (APOBEC3G or A3G) (123). Moreover, synthetic siRNAs that target the promoter regions of the human genes E-cadherin, cyclin kinase inhibitor p21 (p21(CIP1)) (p21), and vascular endothelial growth factor induced the expression of these genes through chromatin remodeling related mechanism that requires the human AGO2 protein (124). These findings suggest more diverse role for miRNAs and siRNAs in the regulation of gene expression than previously appreciated. However, the degree to which these mechanisms are biologically widespread remains to be observed.

RITS Complex-Directed Chromatin Remodeling

Different from cytoplasmic RNA interference pathways is the RNA silencing pathway, which is named RNA induced transcriptional silencing (RITS) and occurs in the nucleus. RITS plays a general role in the construction of centromeres (125, 126). Extensive studies, most notably in the fission yeast Schizosaccharomyces pombe, have established RNA-dependent chromatin remodeling. H3K9 methylation is a central process for RNA-dependent formation of heterochromatin, by which genes are silenced in regions that contain repetitious DNA sequences (127–130).

Three “RNAi” genes are required for this process: RNA-dependent RNA polymerase (RDP1), DCR1, and AGO1. RDP1 is thought to amplify or to produce the initial dsRNA trigger for centromeric silencing in S. pombe. DCR1 is presumed to generate siRNAs from the trigger dsRNA. AGO1 is a component of the RITS complex, which is the effecter complex of siRNA-directed transcriptional silencing. In this pathway, siRNA homologous to the repeated sequences are generated by DCR and associate with an Argonaute via mechanisms not defined fully. These siRNAs/RISCs direct histone-modifying components, such as Ccr4, a H3K9-specific lysine methyltransferase (HKMT), to homologous loci. Ccr4 then methylated lysine 9 of histone H3 (H3K9). Methylated H3K9 recruits effectors like Swi6, Chp2, and other components (e.g., Ta53), which lead eventually to the formation of condensed heterochromatin structures (8, 129, 131–133). Interestingly, synthetic siRNAs that target the promoter regions of several human genes activated the gene expression that needs the human AGO2 and is associated with a loss of lysine-9 methylation on histone 3 at siRNA-target sites (124). It seems that methylation and demethylation of H3K9 to switch off and on genes are via related small RNA pathways in S. pombe and humans.

Summary and Conclusions

RNAi and miRNA pathways involve ancient evolutionary mechanisms for gene expression regulation. These pathways overlap in many aspects with regard to the processing of small regulatory RNAs and to the targeting of mRNAs for post-transcriptional gene expression regulation. Organisms have
evolved different ways of using these mechanisms, and researchers are only beginning to understand the biologic importance of these pathways. If the prior scientific literature is any indication, then many more surprises will develop as we seek to uncover the roles played by small regulatory RNAs and their protein partners.

The genome of an organism is deciphered by transcriptional processes to generate RNA and protein molecules that determine cellular fate and perform all cellular functions. The transcriptional machinery itself displays limited specificity and is involved in transcribing all genes in the genome. The exquisite specificity with which gene networks are expressed is mediated by regulatory proteins called transcription factors. Transcription factors bind to gene-specific regulatory sites in the genome and help assemble the complex multi-subunit machinery that transcribes the target gene(s). Spatio-temporal regulation of gene expression permits selective expression of a subset of genes within the genome and thus governs the diversity of cell types and cellular function in response to physiologic signals. The central role of transcription factors in regulation of specific genes and networks is underscored by the fact that their malfunction is linked to the onset of a wide array of diseases, including developmental disorders, cancer, and diabetes. Thus, a major goal at the interface of chemistry, biology, and molecular medicine is the ability to generate synthetic molecules that function as transcription factors. Here we discuss the common properties of transcription factors, summarize the alluring value of targeting gene expression with small molecules, and summarize the current advances toward regulating the expression of desired genes and gene networks with artificial transcription factors.

Introduction

Multicellular organisms consist of a diverse array of cell types, yet this diversity belies the fact that they all contain an identical genomic complement. Specific gene regulatory programs are set into motion during cellular differentiation to confer a unique cellular identity (1, 2). Selective gene expression is directed by gene-specific transcription factors (TFs) that decipher various signals to regulate the expression of relevant target genes and gene regulatory networks. TFs target unique sites in the genome and nucleate the assembly of the transcriptional machinery (Fig. 1). TFs achieve this action by interacting with several protein complexes, including nucleosome-remodeling and -modifying enzymes, the proteasome, coactivators, corepressors, general transcription factors (GTFs), and RNA polymerase II (3-14). Generally, the process of gene transcription by RNA polymerase II can be described by three stages: 1) initiation, which involves the assembly of the transcriptional machinery at the gene promoters, 2) elongation of the nascent transcript, and finally, 3) termination, with release of the full-length transcript that is processed to yield mature mRNA (15, 16). Initially, TFs were thought to act only at the first stage of transcription, but recently they have been implicated in other steps of this intricately choreographed process (1) (Fig. 1a). In addition to TFs that control common cellular functions, different cell types have a unique cell type-specific complement of TFs that regulates the expression of genes and transcriptional networks that are unique to a given cell type.

Most TFs are composed minimally of two key functional protein domains: the regulatory domain (RD), which is used to activate or repress transcription, and the DNA binding domain (DBD), which targets the TFs to specific sites within the genome (1). Different TFs may contain additional domains that confer unique properties. For example, in the case of ligand-sensitive TFs, such as the nuclear receptor family, TFs also contain a ligand binding domain (LBD), which allows the TF to alter its functional state based on the presence or absence of small molecule signals (17-20) (Fig. 1b). The individual protein domains often are functionally self-contained, and these functional
Figure 1: Function of transcription factors. (a) TF binding. Highly compact chromatin, which correlates with hypoacetylation and reduced transcription, limits TF binding. To overcome this inhibition many TFs recruit chromatin-remodeling and -modifying enzymes to promoters. TFs typically recruit the transcriptional machinery to a promoter through protein–protein interactions with the mediator complex. (b) TF transport. Many nuclear receptors are kept in the cytoplasm until they bind their ligand. Ligand binding induces transport into the nucleus. (c) TF modification. Posttranslational modification of TFs before, during, or after transcription initiation frequently regulates TF activity or even DNA binding.

modules have been shown to be interchangeable between TFs (1). This realization led to the development of the widely used two-hybrid assay where DBD and RD are noncovalently assembled by the dimerization of attached proteins or small molecule ligands (21–25). In an additional application of modular design, ligand binding domains of nuclear receptors have been used to confer small molecule control on other transcription factors (19, 26, 27). More recently, engineered DBDs have been assembled in a modular fashion with RD and LBD to generate a class of artificial transcription factors (ATFs) (28–30). Modular assembly that uses synthetic counterparts of DBDs and RDs have also yielded synthetic ATFs that are not limited to peptidic RD and DBD, which allows the use of a wide variety of synthetic compounds as functional modules (29, 31–34). The assembly of ATFs with synthetic modules that harness the cooperative DNA binding properties of eukaryotic TFs has led to a class of molecules that function as protein–DNA dimerizers (34–36).

A significant amount of research has been dedicated to identifying the numerous factors involved in specific gene transcription. However, a greater focus has been on identifying the gene targets of TFs. Understanding the patterns of gene expression that are produced by TFs, individually and subsequently in complex combinatorial assemblies, will provide an increased understanding of how the genome is deciphered to give rise to a functional organism (37, 38). Nearly 6% of the human genome is thought to encode TFs (39, 40). Only a handful of these ~2000 TFs have been characterized to the point that we can comprehensively define their gene targets (41–48). As careful analysis of TFs from other organisms is performed, it is becoming increasingly clear that complex transcriptional circuits regulate a network of genes, which leads to the final cellular response to a given stimulus (49–51). The gene regulatory networks also have led to the realization that key nodes may regulate a defined cascade of gene transcription (2, 52–55). To aid in understanding this major problem of the postgenomic era, it will be essential to have an arsenal of engineered modulators of transcription, including ATFs, to help elucidate these mechanisms fully (29, 33, 34). These factors also will be useful for targeting transcription to alter the gene expression profiles of individual cells or even entire organisms to suit a required need. A striking example of this use has been seen in the emerging field of synthetic biology that unites several scientific disciplines toward the goal of manipulating genetic networks (56) and generating molecular precursors for industrial use (57). The ability to use ATFs to modulate transcription selectively, without the need for direct manipulation of endogenous factors, holds promise to expand their application into several emerging technologies such as metabolic engineering (58).
These finely tuned transcriptional networks can go awry with devastating consequence (59). Although cells possess active systems to prevent and repair transcriptional errors, the disruption of transcription through mutations in TFs has been implicated in a wide variety of diseases (Table and references therein). As such, this situation makes transcriptional regulators a logical target for drug therapies. The vast majority of TF protein assemblies are driven by cooperative interactions that involve several protein–protein interfaces, yet enzymes involved in transcription are a more common target for drug design. Because of the inherent difficulty in disrupting such interfaces, TF–protein–protein interactions are often an underexplored target (1, 60).

Below we discuss examples where chemical approaches have been used to alter transcriptional function by using small molecule inhibitors or activators. We also address strategies to overcome the limitation of targeting protein–protein interfaces. It is clear that the ability to manipulate transcription will be a powerful tool not only to elucidate gene networks or to generate molecule inhibitors or activators. We also address strategies to overcome the limitation of targeting protein–protein interfaces. A glimpse into the incredible potential of targeting TFs with small molecules is provided by the success achieved through regulating nuclear receptors and histone deacetylases. Below we touch on the insights gleaned from studying the nuclear receptor class of TFs and on the impact of targeting histone-modifying enzymes. We then discuss exciting new developments in the creation of ATFs and the importance of additionally targeting transcriptional processes for chemical intervention.

**Ligand-Dependent Transcription Factors: Nuclear Receptors**

Nuclear hormone receptors are ligand-inducible TFs that modulate transcriptional rates in response to their cognate ligands (18). Based on homology, the receptors contain a variable amino terminal region that harbors a ligand-independent activation activity, a highly conserved zinc finger DNA binding domain, and a carboxy-terminal ligand-dependent activation domain (LBD) (Fig. 2a) (61, 62) (19). Ligands for nuclear receptors include a diverse array of lipophilic compounds such as steroid hormones, fatty acids, eicosanoids, bile acids, and oxysterols (18). However, some receptors identified by sequence homology have no known ligands and therefore are referred to as orphan receptors; a subset of these receptors may have no natural ligand. When ligand binding occurs, the LBD undergoes a conformational change in which the carboxy-terminal helix 12 is positioned to form a hydrophobic groove that is necessary for coactivator binding (Fig. 2a) (63). Whereas some receptors are bound to heat shock proteins in the absence of a ligand, the structure of helix 12 in other unliganded and antagonist-bound receptors favors the binding of corepressors (proteins that maintain the surrounding chromatin in a transcriptionally inactive state) to a region of the receptor that overlaps the coactivator binding site. The change in helix 12 position and the resulting switch from co-repressor to coactivator interaction when agonist binding occurs translates into a transcriptional response (17).

**Synthetic ligands to modulate nuclear receptor activity**

The biologic systems that are modulated by nuclear receptors include many metabolic responses, which makes them attractive targets for drug discovery. In fact, currently marketed drugs exist for many receptors including the vitamin D receptor (VDR), glucocorticoid receptor (GR), estrogen receptor (ER), and peroxisome proliferator activated receptors (PPARs) (64–67). Transcriptional activation by nuclear receptors is accomplished through ligand binding to the receptor; therefore, the most common mode of repressing the activity of this TF class is through the use of antagonist ligands that function by binding to the ligand pocket of the receptor and retaining the inactive, corepressor-bound state (17). Some of these ligands can act as agonists or antagonists depending on the target tissue (68). One of the most well-studied examples of non-natural ligands used in the clinical setting is the selective estrogen receptor modulators (SERMs) in the treatment of breast cancer (69). Two examples of SERMs, Tamoxifen and Raloxifene, bind to and act as antagonists of the estrogen receptor in breast tissue (Fig. 2c). Both drugs also have been shown to protect against osteoporosis. However, Tamoxifen treatment has shown an increased risk of uterine cancer because it acts as an agonist in the uterus, whereas Raloxifene does not (68, 70). The tissue-selective function of SERMs seems to be determined by the coregulatory proteins that are expressed in the target tissues. SERMs induce a conformational change in the receptor such that it selectively interacts with a subset of coregulators and correspondingly activates or represses the transcription of the target genes (70).

Similarly, synthetic thyromimetics such as CGS 23245 that target the thyroid hormone receptor beta are designed to lower plasma concentrations of cholesterol in patients with hypothyroidism without incurring the negative cardiac side effects that administering the natural hormone would induce (Fig. 2a) (71). Recently, a new thyromimetic compound, CO23, has been designed specifically to target the TR alpha form in vitro and in vivo and could be used to study the effects of the thyroid hormone receptor modulated transcription in the heart (72). SERMs and thyromimetics are only a small selection of the plethora of synthetic agonists and antagonist ligands that exist for nuclear receptors. Many of these synthetic ligands can target specific isotypes/isofoms of their target receptors and target these receptors in a tissue-specific manner. This class of small molecule regulators of transcription contains the largest and most diverse compilation of molecules that regulate transcription and has yielded numerous therapeutic agents.

As an alternative to using synthetic analogs for disease treatment, the natural ligand for the retinoic acid receptor, all-trans-retinoic acid (ATRA), is used effectively in the treatment of acute promyelocytic leukemia (APL) (73). Chromosomal translocations in APL patients are responsible for the cellular transformation in this disease. The transformation results in a fusion of the retinoic acid receptor alpha (RARA) with another protein (73). Treatment of APL patients with pharmacologic doses of ATRA induces complete remission by restoring normal granulocytic differentiation (74, 75).

Progress in chemically targeting the nuclear receptor class of TFs continues unabated. The development of assays that use time-resolved fluorescence energy transfer and fluorescence polarization techniques has enabled high-throughput screening (HTS) to detect equilibrium binding, nucleic acid hybridization, and enzymatic activity with such targets as kinases, phosphatases, proteases, G-protein coupled receptors, and nuclear receptors (70, 76, 77). These HTS assays also are being used to screen large libraries of natural or synthetic ligands in search of both endogenous ligands of orphan receptors and synthetic ligands for receptors of potential therapeutic use. As SERMs show unanticipated side effects, new criteria for small molecule regulators of nuclear receptors are being formulated. An ideal drug lead would be a ligand that retained the beneficial effects of the activated receptor in the target tissues without incurring negative side effects. With information from ERα and TRβ and the power of HTS assays, synthetic NR ligands can be pursued to maximize potential therapeutic efficacy.

Small Molecule Regulation of the TF Environment: HDAC Inhibitors

Another approach to regulating the activity of transcription factors is to modify the chromatin state and therefore the accessibility of the promoter and TF binding sites (78, 79). Chromatin states are modulated partially by posttranslational modifications of the histones in nucleosomes, which have significant effects on transcription levels (14, 80). These modifications include phosphorylation, methylation, acetylation, and ubiquitination (80, 81). An early indication of the importance of these covalent modifications on transcription emerged from the observation...
that many transcriptional coactivators contain histone acetylase activity, whereas corepressors contain deacetylase activity (Fig. 12) (82). Several clinically important transcription factors, such as ERα, recruit chromatin-modifying enzymes that constitute a critical step in the function of the TF (14, 83). In the active or agonist bound state, ERα interacts with histone acetyl transferases (HATs), and in the inactive or antagonist bound state the TF instead recruits histone deacetylases (HDACs) (84).

When a transcriptional repressor recruits a HDAC to a gene promoter, the HDAC deacetylates proximal histones, a process which is thought to enhance chromosomal condensation and thereby reduce the ability of transcriptional activators to bind the promoter (14). The observation that chromatin condensation correlates with histone deacetylation was possible only by using small molecule HDAC inhibitors (85). The HDAC inhibitor activity of the short chain fatty acid sodium butyrate was identified and led to the suggestion that histone acetylation increases DNA accessibility for TFs and the transcriptional machinery (85). The hydroxamic acid containing natural product Trichostatin A (TSA) was a known and fungal agent for 14 years before it was determined to be a potent inhibitor of HDACs (86). Like many HDAC inhibitors, TSA acts by using a bulky hydrophobic group to block the HDAC pocket and a polar region to interact with the HDAC active site zinc atom (Fig. 3) (87).

HDAC inhibitors that were purified from natural sources and/or synthesized chemically have shown exciting biologic properties such as the induction of cellular differentiation, growth arrest, and apoptosis in several different cancer cell types in culture (88). Additionally, currently three classes of synthetic HDAC inhibitors are undergoing clinical trials (Fig. 3c) (89). These inhibitors include hydroxamic acid containing molecules such as suberoylanilide hydroxamic acid (SAHA), PXD-101, and MS-275 (90-92). The drug MS-275 is a class of benzamide containing HDAC inhibitors that show efficacy in treating some tumors and lymphoma (93). Both the hydroxamic acid and benzamide-containing inhibitors are general HDAC inhibitors thought to affect most of the more than nine different classes of HDACs. In contrast, a sulfonamide anilide-containing inhibitor currently being tested in clinical trials, MGCD-0103, is thought to be isotype specific, which could reduce negative side effects (94). In contrast to all of these synthetically prepared inhibitors, depsipeptide is a natural product purified from Chromobacterium violaceum that functions as an HDAC inhibitor and is proving to be highly effective in clinical trials (95). The search for highly specific HDAC inhibitors with extremely low toxicity and other negative side effects continues.

ERα serves as an example of a TF that is dependent on an HDAC for its activity (84). The reduction in expression of this nuclear receptor is a key step in the carcinogenesis of breast cancer and correlates with poor prognosis. ERα has been shown to bind HDAC1 directly in vitro and in vivo, and the overexpression of HDAC1 in MCF-7 cells leads to a reduction in both ERα protein levels and ERα transcriptional activity. Overexpression of HDAC1 also causes increased cell proliferation of MCF-7 cells (96). Thus, it has been suggested that HDAC1 plays a critical role in breast cancer progression. Consistent with this hypothesis, HDAC inhibitors including TSA, SAHA, and others have been shown to induce a re-expression of ERα and a corresponding increase in the expression of ER target genes in breast cancer cells that lack ERα activity. Moreover, cells treated with HDAC inhibitors have reduced proliferation and, separately, because of the increase in ERα levels, these cells have an increased sensitivity to anticancer drugs (97). These studies have led to clinical trials that use HDAC inhibitors in the treatment of breast cancer and several other cancers (84).

HDAC inhibitors have revealed the complex relationship between chromatin and transcription. One limitation of using HDAC inhibitors as therapeutics is the effects on the deacetylation of other nonhistone cellular targets. HDAC inhibitors are known to have effects beyond chromatin remodeling, including microtubule and aggresome regulation (98). Despite these limitations, applying a chemical strategy has unveiled the importance of chromatin dynamics in the mechanism of transcriptional regulation. Next generation HDAC inhibitors that specifically inhibit targeted HDACs or HDAC-substrate interactions in desired cell types and at specific promoters would increase the use of HDAC inhibitors (99). However, engineering such specificity is nontrivial, and targeting protein–protein interactions presents a significant challenge for a small molecule. Some successes in addressing this challenge are described below and offer lessons in the design of molecules that use coupled equilibria to target protein interfaces.

**TF Interfaces: Targeting Molecular Interactions**

The rewards of targeting NRs and HDACs strongly imply that transcriptional regulation (TFs in particular) is an exciting yet underexplored target for chemical intervention. Despite their seemingly simple architecture, TFs have been fairly recalcitrant to chemical perturbation—this situation may well be because of the weak molecular interfaces between TFs, their myriad and perhaps redundant interactions with components of the transcriptional machinery, or the lack of our understanding of the functional properties of the targeted TF or its closely related isoforms that also may exist in the same cell (60). Even so, examples exist of TF inhibitors that block TFs and prevent their association with cellular partners. These examples include small molecules that bind DNA to prevent TF–DNA interaction and include several TF–protein binding inhibitors. Moreover, new approaches have been developed to block (or enhance) competitively the function of TFs.

**TF–DNA interactions**

Several current cancer therapeutic agents, such as cisplatin, can inhibit cancer by conjugating to DNA and thereby preventing transcription, replication, and repair in actively reproducing cancer cells (100). Other successful therapeutic agents trap topoisomerase II in a covalent complex with genomic DNA, and these nucleoprotein complexes are very physical barriers to RNA and DNA polymerases (101). Unfortunately, such approaches can lead to a wide range of side effects in several
Figure 3  Histone deacetylase inhibitors. (a) The mechanism by which many HDAC inhibitors function. A hydrophobic moiety blocks the active site of the HDAC. A flexible linker extends into the cleft, and a polar group interacts with the active zinc atom. (b) Crystal structure of TSA (left) and SAHA (right) in the active site of a HDAC-like protein HDLP (87). (c) Examples from four major classes of HDAC inhibitors.
normal cell types that exhibit rapid growth. To overcome this significant limitation, new strategies are being developed to inhibit sequence-specific interactions between TFs and their binding sites. In a recent study, the Hypoxia-inducible factor-1α (HIF-1α) was targeted because this TF has been implicated in tumor evolution and metastasis (102). An ELISA-based screen led to small molecules capable of blocking DNA binding by HIF-1α. One screened molecule, echinomycin (a quinoxaline antibiotic, Fig. 4a (103), could disrupt HIF-1α DNA binding by specifically targeting the hypoxia-responsive element (HRE) in vitro and in U251 cells (102).

Polyamides, a class of sequence-specific, minor-groove DNA binders, also have been used to target HIF-1α and many other TF DNA interactions successfully (104–109). This targeting is achieved by steric occlusion, as when a polyamide occupies the site of a minor-groove binding TF (or a TF that has minor groove contacts), by steric interference of a major-groove binding TF with a tripeptide-conjugated polyamide (104), or by allosterically modifying the DNA groove width that inhibits binding in cases in which a TF alters DNA structure when binding (106). In addition, a polyamide conjugated to acridine, a DNA intercalator, was used to prevent DNA binding by a bZIP TF (107). Conjugating the acridine to a sequence-specific polyamide conferred site specificity to the acridine moiety that intercalated between the base steps of the bZIP binding site and prevented TF binding to DNA (107). Such strategies offer a rational approach to disrupting TF-DNA interactions at targeted sites.

A novel approach to disrupting DNA binding by nuclear receptors relies on displacing the zinc atom from its zinc finger DBD. The cysteine thiols of zinc fingers are particularly labile, and recently disulfide benzamide (DIBA), an electrophile, was found to block both ligand-dependent and ligand-independent ERα-mediated cell growth. DIBA disrupts the ERα zinc finger, which releases the chelated Zn(II), and thereby inhibits ERα dimerization and DNA binding, which leads to the loss of both ERα-mediated transcription and estrogen-mediated breast cancer growth (Fig. 4a (110, 111)). The attractive feature of this alternative method for modulating nuclear receptor activity lies in the fact that it targets a completely different region of the TF. Breast cancer patients taking anti-estrogens or prostate cancer patients taking androgen receptor antagonists often develop resistance to the treatment after acquiring a mutation in the LBD (112). A small molecule inhibitor of the DNA binding domain would be a useful treatment to overcome such drug resistance.

DNA-binding small molecules have been isolated to enhance the DNA binding of a mutated C2H2 zinc finger protein (30). A structural variant of zif268, C7, was mutated at two critical residues involved in Zn(II) coordination and subsequently used in a screen to identify small molecules that would complement the mutation. A potent compound (2-(4’quinoline)benzimidazole) was identified that significantly restored the DNA binding and transcriptional capability of the mutated protein (Fig. 4a). This method for developing a small molecule-dependent zinc finger TF may be a valuable tool in the study of this class of TFs.
The transcription factor p53 is a tumor suppressor protein important in regulating genes that control the cell cycle and especially programmed cell death, or apoptosis. The transcription factor p53 is a tumor suppressor protein important in regulating genes that control the cell cycle and especially programmed cell death, or apoptosis. (113, 114). Therefore, it is not surprising that p53 protein mutations are involved in the genesis of several cancers (115-117). Other than the direct protein mutations in p53, several other routes to p53 inactivation in cancer exist that involve MDM2 or hDM2 in humans. In normal functioning cells, MDM2 binds to p53 and maintains the p53 in an inactive state until cellular stress or DNA damage activate cell signals to induce p53 phosphorylation (118). These signal cascades lead to the phosphorylation of p53 at several key residues important for the p53-MDM2 interaction, which disrupts the interface with MDM2 and releases p53 to perform its regulatory function. In several cancers, the expression of MDM2 is highly upregulated and prevents p53 dissociation despite cellular signals that should trigger the p53 release (115). The p53-MDM2 interface is a well-defined deep hydrophobic pocket and has become an important target for small molecule inhibitors of the p53-MDM2 complex (116, 121-124). These compounds fall into distinct categories. The first category consists of the compounds that mimic the naturally occurring interface by using peptidomimetic drugs. Several examples of this exist including those based on β-peptides, such as p53-1 and p53-3, which were identified as inhibitors of the p53-MDM2 interface (122). p53-1 not only disrupted the p53-MDM2 interaction but also, more importantly, did not disrupt other protein interactions tested, which implies strong specificity for the p53-MDM2 complex. Another class of compounds based on a terphenyl backbone was used to mimic the secondary structure of the p53 N-terminal peptide (121, 124). Here, several terphenyl compounds were identified that disrupted the p53-MDM2 interaction and, importantly, also were shown to be membrane-permeable and able to activate p53 when tested in vivo.

The second category comprises small molecule inhibitors, including chaotropes (123), sulfonamides (125), and a promising new class of inhibitors that were identified from a chemical screen, the cis-imidazoline analogs called nutlins (Fig. 4c) (116, 120). The nutlin compounds not only increased p53 activity in vivo but also showed a 90% inhibition of tumor growth when added to a cancer cell line. Other successful examples of using small molecules to disrupt the interactions between TFs and protein targets, such as the CBP/CREB and Myc/Max interfaces, are discussed in recent reviews (126-128). In many cases, small molecules are found for a TF of interest through assays developed with known protein partners. Structures of the interacting protein domains also have been invaluable for drug discovery. For several important TFs, however, the specific cellular partners with which they interact are unknown. In this case, using small molecule screens on solid supports is an extremely useful tool for drug discovery. In one such screen, diversity-oriented synthesis (DOS (129)) was used to identify a small molecule binder of Hap3p, a yeast protein of the Hap2/3/4/5p complex that is involved with aerobic respiration (130). For this assay, 12,396 DOS compounds were attached covalently to a solid surface and subsequently probed with Hap3p to yield a specific small molecule (Fig. 4c). HTS approaches have been limited by the fact that chemical libraries often are designed to interact in deep hydrophobic binding pockets. Future studies need to target the relatively shallow protein–protein interactions that are found at TF interfaces.

Transcription Factor Mimics: ATFs

Although in some cases small molecules can be effective at influencing protein–protein or protein–DNA associations, not all interactions can be so targeted, nor do these molecules allow for gain-of-function effects. To surmount these difficulties, researchers are working to create artificial molecules with functional properties akin to those of natural transcription factors.

Modular design

The construction of ATFs has been aided by the modular nature of natural transcription factors (Fig. 5a, 29). TFs tend to have their DNA recognition and regulatory functions located on separable domains, as discussed earlier (19, 131). ATFs have been constructed mimicking this modularity. Early work on ATFs focused on combining the DNA binding module from one protein with the regulatory domain of another, which results in a TF with the DNA recognition of the first and the regulatory activity of the second (29). In addition to R and DBD, the modularity of nuclear receptors also has been exploited in such a fashion for nearly 2 decades with fusion of the ligand binding domains of an NR conferring ligand dependence on the chimeric protein (26, 132-134).

DNA binding domains

Zinc fingers commonly are used as DBDs in the construction of ATFs (Fig. 5a). The number of sequences that can be recognized by zinc finger proteins has been extended through structure-based engineering, phage-display, and other selection techniques (135, 136). Engineered zinc finger proteins have been expressed as fusions with several regulatory domains, which yield engineered regulators with diverse DNA recognition properties (137-139). Although zinc finger-based ATFs have been invaluable in the creation of the engineered TFs, the use of proteins as exogenously applied ATFs is limited somewhat by the requirement for cell entry, nuclear localization, and potential immune response (140, 141). Although cell uptake peptides and nuclear localization signals can be attached to proteins (142), these proteins usually are introduced into cells with gene therapy techniques. Thus, synthetic “drug-like” molecules may be more useful for therapeutics and in vivo studies.

Most effort thus far on artificial transcription factors has focused on the DNA binding domain (Fig. 5c). Several synthetic DNA binding molecules have been used. One approach is to recognize the double-stranded DNA, either with triplex forming oligonucleotides (143, 144) or with peptide nucleic acids.
Artificial transcription factors. (a) Protein-based ATFs can consist of a DNA binding domain (DBD) that recognizes DNA and an activation domain (AD) that interacts with and recruits the transcriptional machinery. (b) Protein–DNA dimerizers do not interact directly with the transcriptional machinery but can bind and recruit other DNA binding molecules, which in turn interact with the transcriptional machinery. (c) Examples of molecules that act as functional domains used in ATFs. A DNA binding domain is connected, via a linker domain, to either an activation domain or a repression domain.

Although triplex-forming polymers can display activation domains and increase expression (142), they are limited to targeting purine-rich DNA strands. A more versatile DNA binding molecule is the pyrrole-imidazole polyamide. Polyamides attached to natural activation peptides can promote transcription over 30-fold (143–152).

Regulatory domains

Efforts in ATF design have used naturally occurring regulatory modules, which typically include multikilodalton protein domains. Many regulatory modules can be reduced to short peptides that contain most of the regulatory activity (Fig. 5c) (29, 32). In addition to these naturally occurring peptides, genetic screens have found new activating peptides, many that have similarities with natural activator peptides (33, 153). Peptoids with regulatory properties that can function in intact cells also have been identified (154) (Fig. 5c).

Comparatively few nonpeptidic activation domains exist. Some of the first were found in genetic screens, which identify RNA molecules that can promote transcription in yeast (155–157). This finding provided the first evidence that activation modules did not necessarily have to be peptides. More recently, grafting functional groups (similar to those in natural peptidic activation domains) onto an isoxazolidine skeleton resulted in a class of small molecules that are capable of activating...
transcription to the same extent as a much larger peptide (158). Library screening and structure-based design studies have identified larger synthetic compounds that can function as activators (32). For example, screening for inhibitors of the endothelial specific transcription factor (ESK) /Sur2 interaction revealed compounds that bound to Sur2, part of the mediator complex in general transcription (159). More structure-based engineering to improve Sur2 binding produced shrenochor, which, when conjugated to a polypeptide DNA binding molecule, produced a synthetic ATF that activated transcription 3.5-fold in vitro (160, 162). Unfortunately, this synthetic artificial transcription factor is not cell permeable (160).

In comparison with activation, much less has been done with transcriptional repression. The work done thus far has relied exclusively on naturally occurring repression domains and a few synthetic peptides with modest activity (29, 31, 162). The strategy employed to reduce gene expression with small molecules has focused on the inhibition of TF-DNA binding with a competing DNA binding molecule rather than on the active repression of transcription (29). One possible application toward direct repression effects is targeting histone-modifying complexes to gene promoters (29, 163). A clive repression has great potential, as demonstrated by recent reports of the reduction of HIV virus production by zinc finger-repression domain fusions (164, 165).

**Protein–DNA dimers**

Although direct interaction with the transcriptional machinery is a common property of TFs, certain TFs do not interact with the machinery directly but instead interact with other TFs, which leads to the assembly of regulatory complexes (36). Synthetic molecules based on this principle were successful in nucleating the cooperative assembly of an ATF-TF complex on a target DNA binding site. The first generation of such “protein-DNA dimers” uses polyamides to display dipeptides that can interact with a specific TF. This class of bifunctional molecules is sufficient to change the distribution of a TF on DNA (35, 36, 166). This interaction also has been shown to be modulated by the linker that is used to connect the two domains (36). Protein-DNA dimers represent another advance in mimicking the characteristics of natural TFs.

**Ligand-responsive artificial transcription factors**

Although in the past few years much success with creating artificial molecules with functions similar to TFs has been achieved, these synthetic molecules still do not exhibit the versatility of TFs. Most notably, ATFs lag in their ability to be regulated by external signals. The activity of TFs is controlled finely by signals from the external environment and by internal cellular conditions. Some success has been found in the use of nuclear receptor LBDs in conferring small molecule control of zinc-finger-based ATFs (28, 59, 167, 168) and found with small molecule binding RNA aptamers (169). Other techniques have used chemical inducers of dimerization (170) or small molecule-dependent DNA binding elements, such as engineered zinc fingers and the Tet regulatory system (30, 171, 172), for ligand-responsive gene control. In the Tet regulatory system, doxycycline is used to regulate transcription through repression (Tet-OFF) or activation (Tet-On). In the Tet-OFF system, tetracycline transactivator (tTA) binds to the tet promoter (Ptet) and activates a gene of interest. The addition of doxycycline (Dox, a tetracycline derivative) prevents tTA binding to Ptet and effectively inhibits gene expression. For the Tet-On system, a reverse tetracycline transactivator protein (rTA) requires Dox for binding to Ptet therefore, dosing with Dox will activate the transcription of a gene of interest (173). A few reports of ligand-responsive small molecule-based ATFs used for gene control have been made.

**Targeting TF-Modifying Enzymes: Indirect Regulators**

A parallel approach to modulating gene expression is to target enzymes that modify and thereby control the function of TFs (Fig. 3c). Targeting the active sites of enzymes or “druggable” pockets that permit the interaction between enzymes and their substrates has been highly successful in yielding several important chemical tools and even therapeutic agents (59, 96, 174, 175). As more cell signaling pathways are investigated, it is becoming increasingly clear that the signal transduction culminates in the posttranslational modification of a specific set of TFs (176, 177). These modifications define the function of the TF. In some cases, the modification leads to the ability of the TF to translocate to the nucleus and to regulate target genes; in other cases, modifications can lead to proteolysis and degradation of the TF. A wide array of posttranslational modifications of TFs have been reported, including phosphorylation, glycosylation, acetylation, methylation, ubiquitination, sumoylation, and ribosylation (178–184). This wide array provides numerous opportunities to target enzymes that act on TFs and thus indirectly regulate the expression of desired genes and networks. Although promising examples of this approach already exist, the rational targeting of TFs by chemically perturbing the modifying enzyme is not practiced widely yet. An interesting recent example is that of the Myc/yeast enzyme factor 2 (MEF2) that is specifically deacetylated by HDAC3 (185). Like many other HDACs, HDAC3 has biologic targets beyond histones and MEF2 is one of its known substrates (186). In cells, hyperacetylated MEF2 is a potent activator and deacetylation by HDAC3 greatly attenuates MEF2 activation potency. Chemical inhibition of HDAC3 prolongs the acetylated state of MEF2, which leads to increased expression of its target genes (185). As a key regulator of the gene networks that trigger cells to differentiate into skeletal muscle cells, prolonged MEF2 function because of HDAC3 inhibition increases myogenesesis of C2H10 T1/2 cells (185). MEF2 activity also is regulated by other modifications, for example a phosphorylation-dependent switch between an acetylation and a sumoylation on lysine 403 that changes MEF2 from a potent transcriptional activator to a transcriptional repressor (187). The complex interplay of posttranslational modifications on the transcription factor MEF2 shows the rich promise of exogenously regulating transcription by targeting indirect regulators.
Several other examples of indirect targeting of TF activity have been reported, and a prominent example is Nuclear Factor kappa B (NF-κB), a TF that plays a central role in rapid cellular response to stress signals (188). NF-κB regulates the immune response to infection and is involved, therefore, in several inflammation pathways that contribute to diverse ailments such as arthritis, asthma, and cancer (189-191). The activity of NF-κB is modulated by Inhibitor of kappa B (IκB), which binds and inhibits the function of NF-κB (192). The inhibitory protein is in turn regulated by the IκB Kinases (IκK). When cellular signaling occurs, the IκK enzyme is activated and it phosphorylates IκB. This modification marks IκB for degradation and frees NF-κB to translocate to the nucleus and to activate transcription of its target genes (193). The aberrant overactivity of NF-κB in several diseases has prompted a concerted effort to identify antagonists of IκK activity (112). Many IκK inhibitors have been identified and exploited to modulate the activity of NF-κB and ameliorate disease symptoms (111). As we develop a better understanding of the relationship between cellular signals and the enzymes that regulate downstream TF function, we can anticipate the use of indirect targeting approaches to decouple signaling from the undesirable expression of genes and transcriptional circuits.

**Future Directions**

The genomic revolution is dramatically changing our perspective on gene regulatory networks that govern cell fate and function. The rapid pace of discovery at this scientific frontier will provide unprecedented insight into the networks that define cellular differentiation, the response to various internal and external signals, and a broad array of devastating diseases. In addition, the potential for regulating gene networks in non-natural ways for metabolic engineering offers an unimaginable boon to the biotechnology industry (194). Similarly, the ability to regulate their functional role in cellular physiology. TFs provide the promise of positive regulation of any desired gene or gene regulatory network (33). As such, they serve as a complementary tool to negative regulation by RNAi. A recent series of reports suggests that in addition to ATFs, duplex RNA molecules in some contexts may stimulate the expression of target genes (196).

As Niels Bohr famously noted, “It is very difficult to make an accurate prediction, especially about the future.” Although we cannot anticipate the new and creative approaches that will be developed to regulate desired genes and networks, no doubt exists that transcriptional regulatory methods will be developed to explore how information encoded in genomes is deciphered in the genomes of organisms. Once that understanding is at hand, these same molecules, be they RNAi, ATFs, or tools that remain to be invented, will be used to correct the malfunctioning TFs that participate in the onset of disease or to program the cells to perform new metabolic tasks. This exciting challenge faces the chemical biologists, synthetic biologists, genomics, and future practitioners of personalized molecular medicine.

Transcription Factors

Transcription Factors

Aminoacyl-tRNA synthetases (aaRSs) are critical components of the translation machinery for protein synthesis in every living cell. Each aaRS enzyme in this family links a single amino acid covalently to one or more tRNA isoacceptors to form charged tRNAs. Identity elements within the tRNAs serve as molecular determinants or antideterminants that aid in selection by cognate aaRSs. Some aaRSs also have an amino acid editing mechanism to clear their mistakes. The canonical aaRSs and aaRS-like proteins have functionally diverged to perform many other important roles in the cell. Their versatility and adaptability have provided unique opportunities to develop biotechnology tools and to advance medical research.

**Ubiquity of aaRS Structure and Function**

The aaRSs are an ancient family of enzymes that have a lengthy and diverse evolutionary history. For their central role in protein synthesis, the aaRSs generate aminoacylated tRNAs, which are transferred to an elongation factor such as EF-Tu in bacteria for delivery to the ribosome. Some aaRSs have diverged functionally to perform other secondary roles that impact critical cellular activities. In addition, paralogs that bear sequence homology to aaRS domains participate in a wide array of activities in the cell.

**Aminoacylation of tRNAs**

The aaRSs catalyze the covalent attachment of an amino acid to the universal 3′-adenosine at the terminus of tRNA. Aminoacylation consists of a two-step reaction mechanism. First, an amino acid is activated via ATP to form an aminoacyl adenylate intermediate. Second, the amino acid is transferred to the 3′-end of tRNA, releasing AMP (Fig. 1a). Generally, amino acid activation can occur in the absence of tRNAs. However, glutamyl- (GluRS), glutaminyl- (GlnRS), arginyl- (ArgRS), and lysyl- (LysRS-I) tRNA synthetases require tRNA as a cofactor for the activation step.

Representative X-ray crystal structures have been solved for each of the 20 canonical aaRSs (Table 1). This wealth of molecular information has provided a starting point to begin to unravel diverse paradigms that govern substrate recognition, the mechanism of aminoacylation, and alternative functions. In many cases, multiple cocrystal complexes with various substrates, analogs, and inhibitors are available. Fifteen aaRS X-ray crystal structures have been solved in complexes with their cognate tRNAs. Crystalization of individual aaRS domains has also provided insights into structure-function relationships of this diverse family of enzymes.
Figure 1 Aminoacylation reaction. (a) The overall aminoacylation reaction is performed in two steps by the aaRSs. Two modes of amino acid editing can hydrolyze the mischarged tRNA product (posttransfer editing) or misactivated aminoacyl adenylate intermediate (pretransfer editing). (b) The first step of the ATP-dependent aminoacylation reaction activates amino acid to generate an aminoacyl adenylate intermediate. (c) In the second step, the activated amino acid is transferred to the tRNA molecule and AMP is released.

The aaRSs can be divided evenly into two classes based on the architectures of their catalytic domains: the presence of specific consensus sequences and their chemical properties (6). The catalytic core of Class I aaRSs is composed of a Rossmann dinucleotide binding fold that is marked by two signature consensus sequences: KMSKS and HIGH (Fig. 2). Class II aaRSs are typically dimers or tetramers and possess a more unique catalytic core that is made up of seven antiparallel α-helices flanked by β-strands. These enzymes have three consensus motifs [Fig. 2. Motif 1 1GΦX3XΦXΦΦΦ is at the dimer interface, whereas motif 2 [FRXE-H(RXXX)FXXX(D/E)] and motif 3 [GΦGΦGΦ(D/E)(RΦΦΦΦ)] are part of the active site that represents a hydrophobic amino acid]. Each of the two distinct classes of aaRSs aminoacylates a set of amino acids with diverse chemical properties that would be important for protein function. Interestingly, LysRS is represented in both classes (7).

Recently, two new aaRSs that activate O-phosphoserine and pyrrolysine have also been added to the Class II group (8, 9). Both classes of enzymes catalyze the common aminoacylation reaction but via different mechanisms (1). Class I and Class II aaRSs bind ATP in an extended and bent conformation, respectively (Fig. 2). In addition, class I enzymes bind the tRNA acceptor stem from the minor groove side, which orients the 2′-hydroxyl group of the A76 ribose for attachment of the amino acid (Fig. 3). In contrast, Class II aaRSs aminoacylate the 3′-hydroxyl of the terminal adenosine, because the enzyme binds to tRNA via its major groove. Class II phenylalanyl-tRNA synthetase (PheRS), which charges amino acids onto the 2'-hydroxyl group of A76 of tRNAφM, is the only known exception to this rule.

The aaRSs possess diverse polypeptide domains and insertions, in addition to their catalytic core. Likely, these domains evolved to enhance specificity and fidelity and, in some cases, confer other functions (4, 5). One such domain is the C-terminal anticodon-binding domain that is widely varied (1). For example, GluRS and GinRS have highly conserved active sites within their canonical aminoacylation cores but have appended N-terminal anticodon-binding domains that are composed primarily of either α-helices or β-strands, respectively. In addition, common RNA-binding protein domains such as the OB-fold have been incorporated into aaRSs such as LysRS-II. In at least half of the aaRSs, an internal or appended domain confers amino acid editing activity (3).

Alternative chemical activities

By virtue of their long evolutionary history, as well as of their capacity to bind RNA, ATP, and other small molecules such as amino acids, the aaRSs have been recruited to carry out many diverse alternative functions in cells (4) (Fig. 4a). One such function includes capitalizing on its aminoacylation function to proofread RNA processing and maturation in the nucleus that occurs before tRNA export to the cytoplasm for protein synthesis. In addition, aminoacylation of tRNA-like structures, such as the 3′-end of viral genomes in plants and tmRNA in Escherichia coli, is important for viral replication and for ribosome recycling, respectively.

The RNA binding properties of aaRSs, such as leucyl- (LeuRS) and tyrosyl- (TyrRS) tRNA synthetases, have also been exploited to enable excision of self-splicing group I introns in some mitochondria. Others, including threonyl- (ThrRS) and alanyl- (AlaRS) tRNA synthetases from E. coli, are involved in transcriptional and translational regulation through interactions with their mRNA and DNA, respectively. PheRS also binds specifically to DNA, but the function of this property remains unclear. Some of the most diverse roles for aaRSs include cytokine and anti-angiogenic activities for TyrRS and tryptophanyl-tRNA synthetase (TrpRS), respectively.

*These aaRSs have a hydrolitic editing pathway to clear misactivated and mischarged amino acids.

### aAR5-like proteins

Proteins with sequence homology to aAR5s perform diverse cellular functions (5) (Fig. 4b). Some of these proteins resulted from aAR5 gene duplications and are called paralogs. Other paralogs are composed of just one domain of an aAR5 that has multiple domains.

Paralog examples include E. coli YadB, which resembles GluRS. YadB attaches glutamate to a queuosine base yielding an essential tRNAAsp anticodon modification. In addition, two methionyl-tRNA synthetase (MetRS)-like proteins called Arc1p and Trib11 bind to tRNA. Although the role of Trib11 is not understood, Arc1p aids in delivery of tRNAs to their cognate aAR5s subsequent to nuclear export.

Several aAR5s possess amino acid editing domains, which hydrolytically clear mistakes in cis (3) (Table 1). Interestingly however, some archaeal and bacterial synthetases rely on paralogs of editing domains that hydrolyze mischarged products in trans (10, 11). These products include the YbaK and ProX (or PrdX), which edit Ala-tRNAPro, and AlaX that hydrolyzes mischarged Ser-tRNAAla and Gly-tRNAAla.

### Chemistry of Aminoacylation

#### Recognition of tRNAs by aAR5s

One of the most significant features of the aminoacylation reaction is the specific recognition of a set of tRNA isoacceptors by their corresponding aAR5 (2). A correct tRNA-aAR5 pairing relies on molecular “identity elements” that are composed of individual nucleotides, modifications, base pairs, or structural motifs. Positive identity elements (or determinants) enhance the selection of a tRNA by its cognate aAR5, whereas negative identity elements (or antideterminants) prevent the formation of incorrect tRNA-aAR5 pairs. These identity elements can be classified as either major or minor elements based on the level of their impact on recognition.

Most identity elements are present at the two distal ends of the molecule: the acceptor stem and the triplet anticodon (Fig. 5). In the acceptor stem, the unpaired discriminator base N73 is a crucial recognition factor for most aAR5s. Also, the first few acceptor stem base pairs are unique to many tRNA-aAR5 pairs. These identity elements can be classified as either major or minor elements based on the level of their impact on recognition. Binding of uncharged tRNA to a HisRS-like domain of the GCN2 kinase protein in Saccharomyces cerevisiae under starvation and stress conditions elicits a cascade of molecular events to upregulate genes for amino acid and nucleotide biosynthesis. The accessory subunit Polγ of mtDNA polymerase γ, which shares structural homology to both the catalytic and the anticodon binding domains of glycyl-tRNA synthetase (GlyRS), increases the processivity of the catalytic subunit of DNA-Pol and was proposed to serve as a primer recognition factor.

#### Recognition of tRNAs by aAR5s

One of the most significant features of the aminoacylation reaction is the specific recognition of a set of tRNA isoacceptors by their corresponding aAR5 (2). A correct tRNA-aAR5 pairing relies on molecular “identity elements” that are composed of individual nucleotides, modifications, base pairs, or structural motifs. Positive identity elements (or determinants) enhance the selection of a tRNA by its cognate aAR5, whereas negative identity elements (or antideterminants) prevent the formation of incorrect tRNA-aAR5 pairs. These identity elements can be classified as either major or minor elements based on the level of their impact on recognition.

Most identity elements are present at the two distal ends of the molecule: the acceptor stem and the triplet anticodon (Fig. 5). In the acceptor stem, the unpaired discriminator base N73 is a crucial recognition factor for most aAR5s. Also, the first few acceptor stem base pairs often serve as determinants for many tRNAs. The structural domains of aAR5s play specific roles in the recognition of tRNAs (12). In general, the more conserved catalytic domain binds the acceptor stem during aminoacylation. A is indicated, diverged domains in most aAR5s interact directly
Chemistry of Aminoacyl-tRNA Synthetases

Figure 2: Mode of ATP binding to aaRSs. (a) Active site of GluRS enzyme bound to ATP (PDB 1N75). The consensus sequences KISKR (KMSKS) and HVGT (HIGH) are highlighted on the protein. (b) Active site of GlyRS enzyme bound to ATP (PDB 1B76). The consensus motifs 1, 2, and 3 are highlighted on the protein. Class I and Class II aaRSs bind ATP in an extended and bent conformation, respectively. ATP is shown as dark spheres.

with the tRNA anticodons to enable discrimination. The only exceptions are LeuRS, SerRS, and AlaRS, which do not require anticodon interactions for aminoacylation. SerRS and LeuRS interact, respectively, with up to four and six tRNA isoacceptors that have highly varied anticodons. In some aaRSs, accessory domains enhance recognition.

Unique architectural features of tRNAs also can serve as identity elements (2). For example, the long variable loop of tRNA<sub>Ser</sub> interacts specifically with SerRS. SerRS and LeuRS interact, respectively, with up to four and six tRNA isoacceptors that have highly varied anticodons. In some aaRSs, accessory domains enhance recognition.

Antideterminants are defined as nucleotides that block mis-aminoacylation of the tRNA by a noncognate aaRS (2). A few examples of unmodified nucleotides or base pairs that act as antideterminants include A73 in human tRNA<sub>Leu</sub> that hinders aminoacylation by SerRS, U34 in yeast tRNA<sub>Glu</sub> that interferes with MetRS binding, and a G3:U70 base pair in yeast tRNA<sub>Ala</sub> that blocks ThrRS. In addition, lysidine 34 and m1G37 are located in the anticodon structures of E. coli tRNA<sub>Ile</sub> and yeast tRNA<sub>Asp</sub> and serve as antideterminants against MetRS and ArgRS enzymes, respectively. Interestingly, tRNAs that are charged by Class I aaRSs possess antideterminants against Class II aaRSs and vice versa (2).

Reaction mechanism

The overall two-step aminoacylation reaction relies on mechanistically distinct features of the Class I and Class II enzymes (1). In the Rossmann fold of Class I aaRSs, ATP binding is stabilized by interactions with the conserved KMSKS and HIGH consensus sequences. The β- and γ-phosphates interact with Mg<sup>2+</sup>. The α-NH<sub>3</sub> group of the bound amino acid

Figure 4  Cellular roles of aaRSs and aaRS-like proteins. (a) Alternative functions of aaRSs. The canonical aaRSs perform diverse functions in the cell that are distinct from their primary role of aminoacylation in protein synthesis. (b) AaRS-like proteins. Proteins that either resemble aaRSs or are paralogs of aaRSs are widespread in nature and carry out a variety of activities.

is stabilized via hydrogen bonds with a conserved aspartate. Amino acid activation occurs by in-line nucleophilic displacement, where the ω-carboxylate oxygen of the amino acid attacks the ω-phosphorous atom of ATP (Fig. 1b). The flexible KMSKS peptide loop forms hydrogen bonds between the conserved lysine and serine and the pyrophosphate moiety of ATP during the transition state. Cleavage of the phosphoanhydride linkage between the ω- and β-phosphates of ATP releases PPi. In the second step, the 2’ ribose hydroxyl of the tRNA A76 attacks nucleophilically the carbonyl carbon of the aminoacyl adenylate intermediate to cleave the mixed anhydride. When amino acid is transferred to the tRNA molecule, AMP is released.

In Class II aaRSs, the bound ATP molecule interacts with motifs 2 and 3 (Fig. 2). The ω- and γ-phosphates bend toward the adenine ring and are stabilized by three Mg2+ ions. The ribose of the ATP molecule adopts a 3’-endo conformation, as opposed to the 2’-endo conformation in Class I aaRSs. The amino acid side chain tends to bind by a lock-and-key mechanism, whereas its backbone interacts via an induced fit. Similar to Class I aaRSs, activation proceeds by an in-line nucleophilic displacement mechanism. The transition state is stabilized by interactions between the ω- and γ-phosphates and arginine residues in motifs 2 and 3, respectively. The 3’-hydroxyl of the A76 ribose nucleophilically attacks the carbonyl carbon of the aminoacyl adenylate intermediate, forming aminoacyl-tRNA and AMP.

Amino acid editing

Nine aaRSs that include representatives of both classes possess a hydrolytic editing mechanism to clear misactivated amino acids (3) (Table 1). Hydrolysis of misactivated amino acids can occur either before or after transfer to tRNA (Fig. 3a). Pretransfer editing hydrolyzes adenylate intermediates but can be RNA-dependent. Posttransfer editing cleaves mischarged tRNA. In general, aaRSs that edit seem to employ both pathways, although one may predominate.
Figure 5  Protein–RNA interactions of aaRSs. The cloverleaf secondary structure of tRNA$^{\text{Leu}}$ folds into an L-shaped tertiary molecule. The tRNA can bind in an aminoaacylation complex, where the 3'-end is located in the canonical Class I or Class II core as shown in the upper right for the *P. horikoshii* LeuRS-tRNALeu aminoacylation complex. In aaRSs that edit, a second complex can be formed, where the 3'-end interacts with a separate domain such as the connective polypeptide insertion (CP1) that contains a hydrolytic active site as shown in the lower right for the *T. thermophilus* LeuRS-tRNALeu editing complex. (Table 1; PDB files 1WZ2 and 2BYT).
O-phosphoseryl-tRNA synthetase (SepRS) acylates tRNA synthetase (CysRS). Interestingly, a Class II enzyme called SepSecS (9) or Sec synthase (SecS) (13), converts O-phosphoseryl-tRNACys, which is then converted to Sec-tRNACys by Sec synthase (SelA). A pyridoxal phosphate-dependent enzyme called Sep-tRNA:Sec-tRNA synthetase (SepSecS) (9) or Sec synthase (SecS) (13), converts Sep-tRNACys to Sec-tRNACys. Finally, a pyridoxal phosphate-dependent enzyme called Sep-tRNACys synthetase (SepSecS) (9) or Sec synthase (SecS) (13), converts Sep-tRNACys to Sec-tRNACys.

In vivo, SepSecS has been achieved using E. coli strains that are auxotrophic for certain amino acids. Initially, cells are grown in the presence of a formyl group is added to the charged methionine via its amino moiety by the methionyl-tRNA formyltransferase enzyme, which uses N10-formyl tetrahydrofolate as the formyl donor. This formylated tRNA will then be expected to be modified to Pyr-tRNA by a mechanism that remains undefined (1). Formylation of methionylated tRNA allows differentiation of the AUG start codon from internal AUG codons (14). MetRS is a Class II enzyme that recognizes specific sec-tRNA sequences called selenocysteine insertion elements (SECISs), which are located 3' to a UGA codon on a stalled ribosome-bound mRNA. It is also responsible for delivering Sec-tRNA to the A site of the ribosome (9).

In archaea and eukaryotes, incorporation of Sec into polypeptide synthesis occurs by several mechanisms. In E. coli, SecRS produces the mischarged Ser-tRNA, which is then converted to Sec-tRNA by Sec synthase (SelA). A pyridoxal phosphate-dependent enzyme called Sep-tRNACys synthetase (SepSecS) (9) or Sec synthase (SecS) (13), converts Sep-tRNACys to Sec-tRNACys.

The appropriate aaRS can also be overexpressed to boost charged tRNA production of analogs that are poorly activated. Editing-defective aaRSs can also be capitalized on for global incorporation of amino acid analogs into proteins. Nonstandard amino acids can be either incorporated globally at multiple sites within a protein or inserted at specific locations (1, 12). Global misincorporation of nonstandard amino acids can produce protein analogs with altered physical properties that confer, for example, varied tensile strengths and elasticities (16). These unique biomaterials can be used in many medical applications, such as altering properties associated with cell adhesion. In other applications, routine replacement of methionine by selenomethionine aids in X-ray crystal structure determination. Global incorporation of amino acid analogs into proteins has been achieved in vivo using E. coli strains that are auxotrophic for certain amino acids. Initially, cells are grown in the presence of the analog to reach sufficient biomass. The standard amino acid is then replaced by an analog in the media, followed by induction of a target protein for expression. The appropriate aaRS can also be overexpressed to boost charged tRNA production of analogs that are poorly activated.

*An alternative direct pathway wherein pyrrolysine is charged to tRNAPyl by pyrrolysyl-tRNA synthetase (PylRS) has also been described (9).
proteins, can be cross-linked readily to introduce diverse chemical properties to the protein. Other novel amino acids that have been incorporated successfully into proteins via editing defective aaRSs include α-aminoarbutic acid by ValRS, norfloxacin and norvaline by IleRS and LeuRS, and unsaturated amino acids such as allylglycine, homoallylglycine, homopropargylglycine, and 2-butylnorvaline by LeuRS.

Site-specific incorporation of novel amino acids in proteins (orthogonal aaRSs)

Site-specific insertion of novel amino acids in proteins originally was accomplished in vitro by generating mischarged suppressor tRNAs, which have anticodons that pair with amber “stop” codons. The tRNAs were aminoacylated chemically with natural and novel amino acids and were then incorporated at specific stop codons using in vitro translation systems.

Orthogonal aaRS:tRNA pairs were developed to incorporate nonstandard amino acids at specific protein sites in vivo (15). Within an organism, the orthogonal aaRS cannot recognize any endogenous tRNA molecules. Likewise, the orthogonal tRNA cannot be aminoacylated by any genome-encoded aaRSs.

Two general strategies have been employed to engineer successfully orthogonal pairs. First, aaRS and tRNA pairs from distant organisms; for example, S. cerevisiae were used in an E. coli system. Second, these aaRSs and tRNA molecules were altered via rational and/or random mutagenesis, typically using in vivo selection systems, until they evolved to orthogonality.

Orthogonal pairs have been selected that can incorporate genetically more than 30 unnatural amino acids in E. coli, yeast, or mammalian cells. These amino acids include photosensitized amino acids, glycosylated amino acids, and amino acids with chemically reactive groups that are used to modify selectively native proteins. This group also includes amino acids with novel properties that could be used as probes in protein structure-function analysis in several techniques, such as FRET, X-ray crystallography, NMR, and IR spectroscopies. Perhaps the best characterized is a Methanococcus janaschii TyrRS:tRNATyrCUA orthogonal pair that is expressed in E. coli and incorporates the synthetic amino acid D-methyl-L-tyrosine. Other examples include the yeast AaspRS:tRNAλmerC, and yeast TyrRS/E. coli RNA84C orthogonal pair that function in E. coli, the LeuRS:tRNATyrCUA pair that functions in yeast, E. coli TyrRS:tRNATyrCUA and GlnRS:tRNAfMetCUA pairs, the Bacillus subtilis TrpRS:tRNATrpCUA, and the E. coli TyrRS/Bacillus steaetheromophilus RNA5pCUA pairs, all of which function in eukaryotic cells.

AARSs and Medicinal Therapeutics

Each member of the aaRS family is central to the viability of every living cell. Not only are they essential to protein synthesis, but also they are critical to many other important and diverse cellular activities (4). Species-specific inhibition of a single aaRS has been a proven drug target for antimicrobial development. Human aaRSs have long been associated with autoimmunity. More recent reports have linked aaRS defects to neurologic problems. Finally, the discovery of an impressive and growing list of aaRS alternative activities, which include roles in apoptosis, angiogenesis, and immunity provide new pathways to novel medicinal therapeutics.

aaRSs as antibiotic targets

Enzymes in the aaRS family are a promising target for the development of novel antibiotics (17). Selective inhibition of just one essential aaRS would be lethal to the pathogen. The best example is mupirocin, a commercially marketed IleRS inhibitor. Mupirocin, also known as pseudomonic acid, originally was isolated from Pseudomonas fluorescens and is used as a topical antibiotic against gram-positive bacteria, particularly Staphylococcus aureus. It binds directly to the first lysine of the conserved KMSKS sequence in the aminoacylation active site (18).

aaRS-linked autoimmune diseases

Antisynthetase syndrome is a condition that involves the production of antibodies that bind to and inhibit aaRSs (1). Several human aaRS antibodies have been identified as markers for this autoimmune disease. These antibodies are generally found in one third of all patients with polymyositis and dermatomyositis, which encompasses chronic inflammatory muscle and skin disorders. These patients exhibit muscle inflammation, interstitial lung disease and arthritis, and mortality related to cardiopulmonary complications. To date, six human cytoplasmic aaRSs, including HisRS, ThrRS, AlaRS, IleRS, GlyRS, and AaspRS, have been identified as autoantigens and have been paired, respectively, with Jo-1, PL-7, PL-12, OJ, EJ, and KS autoantibodies. In any given condition, the patient’s serum has only one of the above autoantibodies. Although the origin of antisynthetase antibodies is not known, it is clear that elucidating their functions in autoimmune diseases may provide avenues to new therapeutics (1).

aaRS genetically linked neurologic diseases

Mutations in aaRS genes have been linked to progressive neurodegeneration and neuropathies. In one example, a single amino acid substitution (A734E) in the amino acid editing domain of mouse AlaRS enzyme results in the accumulation of misfolded proteins in Purkinje cells within the adult cerebellum (19). This modest editing defect triggers the unfolded protein response and cell death in terminally differentiated neurons. Charcot-Marie-Tooth neuropathies can be caused by single mutations in genes encoding either TyrRS (20) or GlyRS (21, 22). The TyrRS-based mutation primarily affects aminoacylation and has been proposed to impair protein synthesis. In contrast, the molecular basis of pathogenesis remains unclear for GlyRS mutants, because they seem to retain aminoacylation activity (22).
aaRS-linked immunity and apoptosis

Under apoptotic conditions in human cells, TyrRS is secreted and then cleaved by the extracellular enzyme leukocyte elastase into two fragments. The two fragments have distinct cytotoxic activities (22). The C-terminal fragment is homologous to the endothelial monocyte-activating polypeptide-II cytochrome. It stimulates the production of myeloperoxidase, TNF-α, a tissue factor, and migration of polymorphonuclear and human umbilical vein endothelial cells. It also has leukocyte and monocyte chemotactic activities, which are dependent on a heptad loop located in the first β-strand of the β-barrel structure.

The N-terminal fragment (mini-TyrRS) is a proangiogenic factor. An ELR tripeptide found in CXC-chemokines with proangiogenic activity is located in the Rossmann fold of mini-TyrRS and is responsible for its angiogenic function. mini-TyrRS also has interleukin-8-like activity, which includes stimulation of polymorphonuclear cell migration and binding to the IL-8 receptor.

aaRS anti-angiogenesis activity

Human TrpRS is involved in the inhibition of angiogenesis; the formation of capillaries from blood vessels (23). It is activated either by alternative splicing or by proteolysis. An alternative splicing results in six different mRNA species, one of which codes for a protein called mini-TrpRS. Mini-TrpRS is regulated by INF-γ and blocks endothelial growth factor (EGF)-induced angiogenesis by inhibiting apoptosis of endothelial cells. The proangiogenic activity of mini-TyrRS and the antiangiogenic activity of mini-TrpRS suggest that the two aaRSs might play cooperative, but opposing, roles in the regulation of angiogenesis.

Proteolysis by leukocyte elastase generates two N-terminally truncated fragments called T1-TrpRS and T2-TrpRS. The larger T1-TrpRS is similar in size to mini-TrpRS and has comparable angiostatic activity. T2-TrpRS, the smaller fragment, is an inhibitor of retinal and vascular EGF-induced angiogenesis and thus has tremendous potential as a novel anticancer agent. T2-TrpRS is homologous to the IL-8 receptor.

The limitation of a triplet code with only four bases from which to choose and the size limitation of viral genomes has placed evolutionary pressure on translational coding. Organisms and viruses have developed a variety of methods of translational recoding, including codon reassignment and frameshifting, temporarily altering the canonical reading of mRNA to meet their needs. A translational recoding event can be caused by alterations in the mRNA and/or the tRNA and may even necessitate specific ribosomal elongation factors. Scientists also desire to alter the genetic code by manipulation of natural recoding events and by exploitation of artificial genetic code expansion.

Introduction

With the availability of 64 three-letter combinations of the genetic code, 61 of which code for the 20 canonical amino acids and 3 of which are stop codons, both nature and humans have used a variety of mechanisms to expand the genetic code to incorporate additional amino acids. The genetic code is not entirely universal. A small subset of the genetic code has been reassigned in certain organelles and a limited number of species. In certain cases, the genetic code is expanded only when pertaining to a specific mRNA. These recoding events often compete with standard decoding. Thus, recoding events can play a role in regulation or increase of genetic diversity (1). Programmed frameshifting, translational bypassing, and codon redefinition are three types of translational recoding. Both frameshifting and bypassing occur by slippage of the mRNA in the ribosome during translation. Bypassing involves skipping a block of nucleotides during decoding and is frame independent, for example, it may or may not cause a change of frame. Codon redefinition temporarily assigns a new meaning for a codon. Natural mechanisms of codon redefinition to incorporate additional amino acids include N-formylmethionine, selenocysteine, and pyrrolysine (Table 1 and Fig. 1a). Scientists have incorporated a vast array of noncanonical amino acids through the means of artificial genetic code expansion.

Frameshifting and Bypassing

Several mRNAs have been shown to cause the ribosome to shift frames, either +1 (3') or -1 (5'), with frequencies of shift ranging from a few percent up to 50% in cases of programmed frameshifting (2). Although frameshifting occurs in a wide variety of prokaryotes and eukaryotes (1), many frameshifting events have been found in viruses, transposons, and insertional elements (3, 4). This may occur because recoding provides a means for viruses and mobile genetic elements to condense protein coding and/or regulatory information in their compact genomes (5).

Several factors enhance ribosome slippage. Slippery sequences, such as the heptameric sequence A–AAA–AAU, favor RNA movement or misalignment and thus increase the probability of frameshifting (6). The presence of rare sense codons, codons under aminoacyl–tRNA limitation (amino acid starvation), or stop codons can increase frameshifting, which suggests that ribosomal pausing contributes to initiation of peptidyl–tRNA slippage (7). The combined stimulatory signals encoded in mRNAs that undergo programmed ribosomal frameshifting can greatly increase the probability of tRNA slippage at a specific shift site, with up to 50% of the ribosomes changing frame in some cases. Programmed ribosomal frameshifting sites include a slippery sequence in the mRNA and an mRNA feature to enhance the slippage. In addition to pauses caused by a low-abundance tRNA or a stop codon, secondary structures, including stem-loops and pseudoknots, may also enhance programmed frameshifting events (4, 8).

Crystallographic, molecular, biochemical, and genetic studies have provided insight into the mechanics of the highly efficient levels of -1 ribosomal frameshifting caused by mRNAs pseudoknots (4). During the RNA accommodation step on the ribosome, the anticodon loop of the aminocyl–tRNA moves 9 Å and normally pulls the downstream mRNA a similar distance. A downstream mRNA pseudoknot wedged into the entrance of the ribosomal mRNA tunnel resists this translocation. The tension in the mRNA between the A-site codon and the mRNA pseudoknot can be relieved by unwinding the pseudoknot, which allows the downstream mRNA to move forward and be read in frame, or by slippage of the mRNA backward by one base, which causes +1 frameshift.
Frameshift into the residues at the 3' end of T7 gene particularly shift-prone codon (12). A short Shine–Delgarno-like programmed frameshifting site. The presence of a C 3' of the low RF2 concentration increases frameshifting efficiency and (10). High concentration of RF2 favors termination, whereas and production of full-length RF2 is an autoregulatory process concentration of RF2 in the cell, the frameshifting efficiency of termination at the UGA stop codon directly depends on the base is the first base of the stop codon. Only one leucine is in the 3' direction toward the overlapping UUU where the last sequence located three nucleotides 5' of the shift site, and which can pair with the 16S rRNA of the translating ribosome, may realign by creating tension in the mRNA.

Several features of the RF2 mRNA aid in creating this programmed frameshifting site. The presence of a C 3' of the UGA makes a poor termination context (11), and CUU is a particularly shift-prone codon (12). A short Shine-Delgarno-like sequence located three nucleotides 5' of the shift site, and which can pair with the 16S rRNA of the translating ribosome, may create a pause to allow more time for slippage, or may promote reorientation by creating tension in the mRNA.

Some mRNA sequences have been found that cause low-to-moderate frameshifts without the aid of nearby stimulator sequences. These sequences include the four consecutive U residues at the 3' end of T7 gene 10, which permit a -10% frameshift into the -1 frame to yield protein 10B (14) and the sequence CCC UGA, which permits a -3% +1 frameshift (15). Strings of four or more G or U residues that precede a stop codon have been shown to facilitate a low level of frameshifts (13). The UUU phenylalanine codon followed by a pyrimidine also causes low-to-moderate +1 frameshifts (16, 17). Sequences prone to frameshifting have been identified from phage-display isolates that were expressed, although they lacked an identifiable open reading frame (18). More studies of these mRNA sequences revealed that the sequence CCC CGA is a weak (1–2% efficiency) translational frameshift site in E. coli (19). Because the arginine-coding CGA is one of the rarest in E. coli (20), it likely creates a prolonged vacancy in the ribosomal A site. This vacancy would allow the peptidyl–tRNA* in the P site to slide rightward one base and still pair with a CCC triplet; thus, it would cause shifting to the reporter frame.

Frameshift-suppressing RNAs with an extra nucleotide in the anticodon loop were originally thought to cause a +1 frameshift by recognizing a four-base codon (21). Experimental contradictions to the four-base translocation model, including RNA suppressors with normal anticodon loop size but altered bodies (22), led to the development of a peptidyl–tRNA slippage model for several frameshift RNA suppressors of the CCCN (proline) and GGGN (glycine) suppression sites (23). In this model, slippage of the mRNA occurs when the suppressing RNA has moved to the ribosomal P site, and this slippage is in competition with the decoding of the next codon, where the presence of a stop codon or a low-abundance codon can increase slippage.

The presence of rare sense codons or codons under aminocacyl–tRNA limitation (amino acid starvation) contributes to translational bypassing or hopping (24, 25). In bypassing, ribosomes suspend translation at a certain site and then resume translation downstream without decoding a block of intermediate nucleotides, and thus a single protein is synthesized from two separated coding sequences. Depending on the number of nucleotides skipped, bypassing may cause a change of frame.

An extreme example of translational bypassing occurs in the translation of the bacteriophage T4 gene 60 (13). The ribosome reads the first 46 codons of the mRNA, pauses at a UAG stop codon, hops over 47 nucleotides (a 50-nucleotide coding gap), and resumes translation. This bypass requires matched codons. The peptidyl–tRNA pairs first with one codon, slips, and then pairs with the matching codon, which results in only one
amino acid being inserted for the two matched codons and any intervening nucleotides. The stop codon after codon 46 pauses the ribosome and allows time for slippage. The sequence context of the UAG codon creates a very poor termination site (11). In addition to the stop codon, a stem-loop structure that contains the stop codon and take-off site GGA within its stem and a cis-acting signal in the nascent peptide that consists of a stretch of charged and hydrophobic amino acids specified by codons preceding the gap enhance bypass efficiency (13).

**Codon Redefinition**

*N*-formylmethionine

All organisms initiate protein synthesis with either methionine or its derivative *N*-formylmethionine (fMet). In all organisms, two classes of methionine-tRNAs are present with one class used only for initiation and the other for peptide elongation (26). Archaeal and cytoplasmic eukaryal protein synthesis initiates with methionine. Bacteria and eukaryotic organelles (mitochondria and chloroplasts) require *N*-formylmethionyl–tRNAfmet as a translation initiator. Typically, the formyl group and the methionine are removed from the protein even while the protein is still being synthesized on the ribosome (26).

Synthesis of fMet occurs on its tRNA. The tRNAfmet is charged by MetRS with methionine, which then is formylated by methionyl–tRNA formyltransferase (MTF) in the presence of the formyl donor N10-formyltetrahydrofolate (27). Initiation factor IF2 sequesters the fMet–tRNAfMet and excludes it from the ribosomal A site. Instead, IF2-bound fMet–tRNAfMet is transported to the ribosomal P site. EF-Tu--GTP can bind methionyl–tRNAfmet, although at a lower affinity than

Unique structural properties, including the absence of a Watson–Crick base pair between nucleotides 1 and 72 at the end of the acceptor stem and the presence of three consecutive base pairs at the bottom of the anticodon stem, distinguish initiator tRNAs from elongator tRNAs (30). Observations from the E. coli crystal structure suggest the high specificity recognition between Met–tRNAMet and MTF mainly involves recognition of the acceptor arm (32). The lack of a Watson–Crick base pair at position 1-72 is important not only for the formation of this tRNA by methionyl–tRNA transformylase (32) but also for the prevention of the initiator tRNA from acting as an elongator tRNA. The three consecutive G–C base pairs on the acceptor stem of initiator tRNAs are required for targeting the tRNA to the ribosomal P site (33).

Selenocysteine

The trace element selenium plays an essential role in the activity of some bacterial and eukaryotic antioxidant enzymes (34). Selenium is incorporated into proteins in the form of the so-called twenty-first amino acid, selenocysteine, which is encoded by a UGA stop codon. Although the chemical structure of selenocysteine differs from cysteine only by the replacement of the sulfur atom with selenium, the lower pKa of selenocysteine results from the coaxial Watson–Crick base pair between nucleotides 1 and 72 at the end of the acceptor arm (31). The lack of a Watson–Crick base pair at position 1-72 is important not only for the formylation of this tRNA by methionyl–tRNA transylase but also for the prevention of the initiator tRNA from acting as an elongator tRNA. The three consecutive G–C base pairs on the acceptor stem of initiator tRNAs are required for targeting the tRNA to the ribosomal P site (33).

Selenocysteine synthesis occurs on tRNA^Sec (Fig. 1B). The secondary structure of tRNA^Sec differs from that of canonical tRNAs. Selenocysteine tRNAs are considerably larger than other tRNAs (36). Although tRNAs normally undergo processing of a 5' leader sequence, tRNA^Sec does not have a 5' triphosphate on its terminal guanosine (37). In eubacteria, archaea, and eukarya, a conservation of extensions of the acceptor stem and the D stem in tRNA^Sec exists. An extended 6 bp D stem, in eukarya, a conservation of extensions of the acceptor stem and phosphate on its terminal guanosine (37). In eubacteria, archaea, and eukarya (9), position between bacteria (8) and eukarya (37), a 13-bp A–T arm is necessary instead of the canonical 3–4 bp, was shown to be a major identity determinant for serine phosphorylation in eukarya (38). A 13-bp A–T arm is necessary for binding to SelB in bacteria and for serine to selenocysteine conversion in eukarya (41, 42). Investigation of posttranscriptional modification of the vertebrate tRNA^Sec revealed only four modified bases, which is fewer than canonical tRNAs (43).

In bacteria, seryl–tRNA synthetase initiates selenocysteine biosynthesis by charging tRNA^Sec with serine. The aminoacylation efficiency of this reaction is only 1-10% that of aminoacylation of tRNA^Met (44). In E. coli, selenocysteine synthase, encoded by selD, catalyzes the conversion to seryl–tRNA^Sec to selenocysteinyll–tRNA^Sec (45). Seryl–tRNA^Sec covalently binds to the pyridoxal phosphate (PLP) of selenocysteine synthase. From in vitro studies, after the elimination of a water molecule from the seryl moiety, formal addition of hydrogen selenide to the double bond of the aminocarboxylic intermediate occurs (46). Selenophosphate, which is synthesized by selenophosphate synthetase encoded by selD, acts as a selenium donor in vivo (47). In archaea (42) and eukarya (48), selenocysteine also starts with the serylation of tRNA^Sec by seryl–tRNA synthetase. In the presence of Mg^2+ and ATP, phosphoseryl–tRNA^Sec kinase specifically phosphorylates the seryl moiety of Ser–tRNA^Sec to produce O-phosphoseryl–tRNA^Sec (49). The conversion of O-phosphoserine (Sep) to selenocysteine proceeds by the action of the PLP-dependent enzyme Sep–tRNA:Sec–tRNA synthase (SepSecS) using selenophosphate as a selenium donor to produce Sec–tRNA^Sec (50). As the phosphate of Sep provides a better leaving group than the water of serine, Sep to Sec conversion is more chemically favorable than Ser to Sec conversion. This favorableness and the greater stability of the Sep–tRNA^Sec as compared with Ser–tRNA^Sec (49) would enhance the production of Sec–tRNA^Sec in archaea and eukarya, which have more extended selenoproteomes than bacteria (50).

To ensure that the opal codon codes selenocysteine only when needed, a cis-acting stem-loop structure designated as the Sec Insertion Sequence (SECIS) element must be present in the mRNA (34). In E. coli, a 38-nt SECIS is positioned immediately downstream from the opal codon, whereas the archaea and eukaryotic SECIS can be located several hundred nucleotides downstream in the 3' untranslated region of the gene. The presence of the SECIS in the 3' untranslated region yields greater sequence flexibility of proteins in the expanded selenoproteomes of archaea and eukarya. The ability of higher eukaryotes to translate selenoproteins with SECIS elements in the coding region suggests that the location of the SECIS element in the 3' UTR is not a requirement in higher eukaryotes but rather an evolutionary adaptation (51).

For delivery to the ribosome, special elongation factors are necessary. In E. coli, EF-Tu does not bind tRNA^Sec. Instead, a selenocysteine-specific elongation factor SelB, with an N-terminal domain that has sequence similarity to EF-Tu, recognizes the aminocarboxylic moiety and exclusively binds selenocysteinyll–tRNA^Sec (52). Like EF-Tu, SelB binds GTP. The C-terminal extension of SelB consists of four winged-helix domains arranged in tandem that bind the SECIS element and undergo a structural change during SECIS binding that is proposed to allow for communication between the tRNA and mRNA binding sites (53). A SelB conformational change during SECIS binding would be another mechanism to ensure that selenocysteine is not inserted at random codons (53). Thus, a quaternary complex of SelB, selenocysteyll–tRNA^Sec, GTP, and the SECIS element is necessary for selenocysteine insertion in E. coli. When in excess, this quaternary complex interacts with a SECIS-like element in the 5' nontranslated region of the selAB operon that encodes SelA and SelB to repress synthesis (54).

In archaea and eukaryotes, additional SECIS-binding proteins bridge a SelB-like protein and the SECIS element (55). M use EF–Sec and archaeal M. jannaschii Mseg (SelB) contain N-terminal domains functionally homologous to elongation factor EF–Tu (56, 57). The C-terminal extension does not interact with the SECIS. Instead, it interacts with bridging proteins. In eukarya, SECIS binding protein 2 contains both ribosomal and SECIS binding activity.
RNA binding domains, which are important for Sec incorporation (58). Ribosomal protein L30 found in eukaryal and archaeal kingdoms also has the ability to bind SECIS RNA (59). The exact roles and players in eukaryal and archaeal secenocysteine insertion remain unknown.

The location of the SECIS element in the 3′ untranslated region in arachaea and eukarya allows complete flexibility in the amino acid sequence surrounding the secenocysteine residue and allows for multiple secenocysteines in one protein (60). Expressing secenocysteines from archaea and eukarya or selective secenocysteine insertion in E. coli can be difficult because the E. coli SECIS element immediately follows the opal stop codon. In a case where the secenocysteine occurred at the N-terminus of an essential phage coat protein (M13 pII) to couple phage production effectively to nonsense suppression (66, 68, 69). The cloned sequences also suggested that the lower stem of the SECIS can be fully randomized and unpaired, and conservation of the loop and upper stem bulged U was observed. Additional phage library studies suggested much more flexibility in the sequence of the upper SECIS stem than previously thought, with one functional clone having five substitutions. This sequence flexibility would make it easier to express eukaryotic proteins in bacteria.

Secenocysteine displayed on the surface of the phage provides a uniquely reactive functional group, which permits the use of small electrophilic compounds for regiospecific covalent phage modification (68). This method has been used in setting up a system for enzyme evolution (76). Secenocysteine tags have also been used for protein purification and labeling using 4-phenylarsine oxide-Sepharose (PAO–sepharose) columns, which have also been used for protein purification and labeling using 4-phenylarsine oxide-Sepharose (PAO–sepharose) columns. The standard elongation factor EF-Tu directly recognizes RNA in vitro, which suggests that a specialized elongation factor may not be necessary for pyrrolysine incorporation (84). Studies of the activation of tRNAPyl by the PylRS from Desulfotomaculum hafniense showed that the discrimination between the acceptor and D stems is shorter by one nucleotide than the typical two-nucleotide junction. Mass spec analysis of the tRNAPyl revealed a relative mass of the RNA in vitro, which revealed a relatively low mass of nucleoside modifications, especially in the anticodon stem-loop (83). The standard elongation factor EF-Tu directly recognizes RNA in vitro, which suggests that a specialized elongation factor may not be necessary for pyrrolysine incorporation (84). Studies of the activation of tRNAPyl by the PylRS from Desulfotomaculum hafniense showed that the discrimination between the acceptor and D stems is shorter by one nucleotide than the typical two-nucleotide junction. Mass spec analysis of the tRNAPyl revealed a relative low mass of nucleoside modifications, especially in the anticodon stem-loop (83). The standard elongation factor EF-Tu directly recognizes RNA in vitro, which suggests that a specialized elongation factor may not be necessary for pyrrolysine incorporation (84). Studies of the activation of tRNAPyl by the PylRS from Desulfotomaculum hafniense showed that the discrimination between the acceptor and D stems is shorter by one nucleotide than the typical two-nucleotide junction. Mass spec analysis of the tRNAPyl revealed a relative low mass of nucleoside modifications, especially in the anticodon stem-loop (83). The standard elongation factor EF-Tu directly recognizes RNA in vitro, which suggests that a specialized elongation factor may not be necessary for pyrrolysine incorporation (84).

In contrast to Sec–tRNA Sec and fMet–tRNA fMet formation, Pyrrolysine (Pyl), the twenty-second amino acid, has been discovered incorporated in methyamine methyltransferases from Methanosarcinae, a branch of methanogenic archaea that has the ability to reduce a wide variety of compounds to methane including carbon dioxide, acetate, methanol, methylated thiol, and methylated amines (72). Methanogenesis from methyamines as (mono-, di-, or trimethylamine) uses non-homologous, substrate-specific methyltransferases: monomethylamine methyltransferase (mtMB), dimethyamine methyltransferase (mtMB), and trimethylamine methyltransferase (mtMB) (72). Sequencing of the Methanosarcinaceae (73) and Methanococcoides genomes shows all methanogen methylamine methyltransferase genes contain in-frame amber codons that must be suppressed to produce full-length protein (72, 74). The crystal structure of Methanosarcina bacteri MtmB revealed a lysine with its Nε in an amidic linkage with (4R,5S)-4-substituted-pyrrolidine-2-carboxylate at the coding position corresponding to the stop codon (75). The C-4 substituent of pyrrolysine was identified as a methyl group from tandem mass spectrometry of Methanosarcina bacteri MtmB, MtMB, and MtMB (76). In Mtb B, Pyl is located at the enzyme active site and likely serves as a strong electrophile (77). Each methylamine transferase specifically methylates its cognate corrinoid protein (MtMC, MtMB, MtMC, or MtMB) using its specific methylamine (74). Methylcobamide:coenzyme M methyltransferase (MtMB) demethylates the corrinoid using zinc to form the nucleophilic coenzyme M thiolate (78). Reduction of methyl-coenzyme M to methane is the major energy-conserving step of methanogenesis (79).

Near the mtnB1 gene in Methanosarcinae are the pytTSBCD genes, which represents a "genetic code expansion cassette" that allows for the production and insertion of pyrrolysine when transferred to E. coli (77, 80). PylS is an archael class II pyrrolysyl–tRNA synthetase (81). PylB, PylC, and PylD may play a role in pyrrolysine biosynthesis (82). The pyt gene encodes RNA (83), which has a CUA anticodon (82). Structural differences exist between RNA and other RNA molecules (82). In RNA, the anticodon stem can form an additional base pair creating a six-base pair stem and three-base variable loop. With only a five-base pair anticodon stem, the link between the D stem and anticodon stem is two nucleotides instead of the typical one nucleotide. The junction between the acceptor and D stems is shorter by one nucleotide than the typical two-nucleotide junction. Mass spec analysis of the RNA revealed a relatively low mass of nucleoside modifications, especially in the anticodon stem-loop (83). The standard elongation factor EF-Tu directly recognizes RNA in vitro, which suggests that a specialized elongation factor may not be necessary for pyrrolysine incorporation (84). Studies of the activation of RNA by the PylRS from Desulfutobacterium hafniense showed that the discrimina-
from gene \textit{mtmB1}, which contains an internal UAG stop codon (86, 87). These studies suggest that \textit{M} \textit{ethanarciacnaecae} may use both direct and indirect charging of tRNA\textsubscript{Pyl} to ensure efficient readthrough of the UAG stop codon (83).

Much debate surrounded the existence and necessity of a pyrrolysine insertion element (PYLIS) analogous to the SE\textsubscript{CIS} element until the examination of in vivo contextual requirements for pyrrolysine in \textit{M} \textit{ethanarciacnaecae} revealed that although either termination of translation or pyrrolysine insertion elements are present in \textit{M}. \textit{barkeri} with or without a PYLIS structure present, the presence of a PYLIS element increases the efficiency of pyrrolysine insertion (88). This study concluded that the need for high concentrations of \textit{m} \textit{ethylamine methyltransferases when grown on \textit{m} \textit{ethylamine would make read-through enhancement provided by the PYLIS at least greatly advantageous if not essential. The presence of pyrrolysine seems to be isolated to a small subset of prokaryotes. Searches of completely and incompletely sequenced prokaryotes genomes thus far have revealed only seven organisms that could use Pyl, including four members of archaea \textit{M} \textit{ethanarciacnaecae} genera, the archaea \textit{M} \textit{ethanarciacnaecae} \textit{burtonii}, the Gram-positive bacteria \textit{Deinococcus} \textit{thermoacidophilus} \textit{halnense}, and the symbiotic \textit{delatproebacterium} of the gutless worm \textit{O} \textit{livus} \textit{alagavensii} (82, 89). Analysis of Pyl-containing archaea revealed that less than 5% are predicted to terminate at UAG, and thus in these organisms, as complex a system as controls se-lenocysteine insertion may not be needed to regulate the read- ing of UAG as pyrrolysine (90).

Artificial Genetic Code Expansion by Directed Translational Recoding

The complement of known cotranslationally incorporated amino acids is currently limited to the “standard” twenty, plus selenocysteine, pyrrolysine, and N-formylmethionine. The ability of the ribosome and elongation factors to accept a variety of tRNA structures and appended amino acids has allowed the development of several methods that recruit the translational machinery for incorporation of noncanonical (“unnatural”) amino acids at defined positions in expressed proteins. Such expansion of the genetic code has allowed specific incorporation of amino acid-like structures with unique chemical, steric and biological properties into any protein of interest (91, 92). All of these methods rely on the following components: 1) a tRNA that will insert the desired residue efficiently at defined positions in a single expressed protein, while not being recognized by any of the endogenous aminoacyl-tRNA synthetases in the expression system being used, and 2) a method for coupling the desired amino acid to the acceptor stem of the tRNA.

Choice of tRNA

The first criterion for a candidate tRNA to be used as a delivery vehicle for noncanonical amino acids is the ability to insert its appended amino acid site specifically into a target protein. An obvious route is redefining existing codons to encode the noncanonical residue. Rather than using a cis sequence element to recode an existing coding triplet (analogous to the selenocysteine insertion pathway), a more straightforward approach is nonsense suppression. Because amber (UAG) suppressors are ubiquitous in nature and genomes have evolved to use the UGA and UAA as the predominant termination codons, most methods for noncanonical amino acid insertion rely on amber suppressor tRNAs. Frameshift suppressors have also been used (93). A third- tionally, synthetic orthogonal base pairs, in which one or more unnatural nucleotides in the tRNA anticodon, have also been used (94), although this method requires the use of in vitro protein expression systems.

The second criterion is that the tRNA not be recognized by the endogenous aminoacyl-tRNA synthetases in the host organism. This requirement is crucial, as the endogenous synthetases not only aminoacylate the tRNA with a canonical amino acid after it gives up its noncanonical residue on the ribosome but also may remove a noncanonical residue from the tRNA via natural proofreading mechanisms. Early work (95) in which translation was carried out in an \textit{E}. \textit{coli}-based in vitro system used an amber suppressor based on tRNA\textsubscript{TM} from Saccharomyces cerevisiae, which had been demonstrated to be unrecognized by the endogenous aminoacyl-tRNA synthetases in \textit{E}. \textit{coli}. Later work in vivo in expression systems employed, for example, archaeal tRNAs (\textit{i.e.}, \textit{M} \textit{ethanarciacnaecae} \textit{annachii} tRNA\textsubscript{TM} in an \textit{E}. \textit{coli} system (96), \textit{E}. \textit{coli} tRNAs in a yeast expression system (97), and bacillus tRNAs in a mammalian expression system (98), although the natural tRNAs are often measurably aminoacylated in these heterologous expression systems. With appropriate genetic selection systems (vide infra), a fully orthogonal mutant tRNA could be generated that is not recognized by the entire synthetase complement in the chosen expression system.

Methods of aminoacylation

The second half of the problem is how to get the amino acid onto the tRNA before translation. Early work by Peter Schultz and coworkers (95) employed a variation of a chemical misacylation strategy originally developed by Sidney Hecht (99). This method avoids the intractable problem of regiochemically coupling an amino acid onto a 76-nucleotide forest of competing functional groups by focusing the derivatization on the 3’ acceptor stem of the tRNA only. The chimeric DNA-tRNA \textit{dimer pDCpA} is synthesized and specifically aminoacylated on its 3’ end using the cyanomethyl ester of the desired amino acid. The use of deoxycytidine greatly simplifies the synthesis of the \textit{dimer} (100), and the use of the cyanomethyl ester obviates the need for internal protection of the \textit{dimer} before aminoacylation (101). \textit{T4 RNA ligase} then is used to ligate the resulting aminoacyl-\textit{pDCpA} onto an amber suppressor tRNA lacking its 3’ terminal CA generated by in vitro transcription (102), which generates the full-length aminoacyl-tRNA. Despite the presence of a deoxynucleotide at position 75 and a lack of any of the ubiquitous tRNA modifications, the tRNA can participate in translation and give up its loaded amino acid in response to the corresponding amber codon. The use of chemically misacylated tRNA requires the use of an in vitro protein expression system, but the strength of this approach is its flexibility. In theory, any
amino acid-like structure can be coupled to tRNA using identical chemistry, which gives the user the ability to incorporate many amino acid variants into a protein in a relatively short amount of time.

The principal drawback of the chemical aminoacylation approach is low yield of expressed protein. This low yield is a result not only of the inherent low yields of in vitro protein synthesis systems, but also of the tRNA not being recycled after giving up its amino acid on the ribosome. An obvious solution is to employ an aminoacyl-tRNA synthetase to aminoacylate the tRNA, which permits both in vivo expression and recycling of the tRNA. It has long been known that under auxotrophic conditions a naturally occurring synthetase can be tricked into incorporating a media-supplemented noncanonical amino acid that is structurally related to its cognate substrate, for example, incorporation of selenomethionine in place of methionine for X-ray crystallography (103). As this strategy uses the existing in vivo pool of tRNAs, incorporation is global rather than site specific. Nevertheless, this approach has become a powerful tool for generating novel biomaterials (104).

Homogenous, site-specific incorporation of a noncanonical residue in vivo requires a fully orthogonal synthetase-tRNA pair, in which the synthetase recognizes no other tRNA or amino acid, and the tRNA is not recognized by any other host synthetases. Such a pair can be generated by rational mutagenesis (105), but a more general approach uses a “double-sieve” genetic selection system (106). Briefly, amber suppressor tRNAs that are not recognized by host synthetases are selected from a library of tRNA variants coexpressed with a lethal gene (bar), which results in in-frame amber stop codons. Surviving tRNA variants are then coexpressed with the desired cognate synthetase in the presence of an amber suppressor tRNA with an in-frame amber codon, which results in selection of tRNAs that are recognized only by the desired synthetase. Synthetases that can aminoacylate only the now-fully-orthogonal suppressor tRNA with the desired amino acid, but not the canonical amino acids present in vivo, could be obtained via an analogous two step genetic selection (96): Coexpression of the synthetase library with the RNA and an amber gene with an in-frame amber codon in the presence of the desired amino acid results in selection of synthetases capable of aminoacylating the RNA with the desired amino acid or any of the canonical amino acids. Coexpression of these selected synthetases with a lethal gene with in-frame amber codons in the absence of the desired amino acid then yields the desired fully orthogonal synthetase-tRNA pair that will direct insertion of only the desired noncanonical amino acid in vivo. Similar strategies have been used to create orthogonal synthetase-tRNA pairs in yeast (97) and mammalian cells (98). In all cases, the noncanonical amino acid must be supplied exogenously in the media, which theoretically limits residues to those that are compatible with the cellular transport machinery and that are not substrates for intracellular metabolic pathways. These issues could be addressed by engineering a biosynthetic pathway for the noncanonical amino acid directly in the organism, which results in a fully self-contained organism with an expanded genetic code (107).

Applications

A detailed discussion of the hundreds of noncanonical amino acids incorporated via these methods is outside the scope of this article. Most applications fall into four main areas: protein labeling, protein modification, investigation of protein structure–function relationships, and engineering activity “switches” into enzymes (reviewed in References 91 and 92). Labeled residues can be incorporated directly via this method, such as isotopically enriched residues for NMR, spin labels, and fluorescent tags. Additionally, many residues have been incorporated that carry orthogonally reactive side chains (e.g., keto groups, acids, alkenes, and thiocysteates) that permit specific modification of a single residue with a variety of appended labels under conditions in which the rest of the proteome is unreactive. Other protein modifications (glycosylation, PEGylation, metal-binding sites, cross-linking agents, and redox-active groups) can be incorporated either directly or by posttranslational modification. A variety of backbone and side-chain modifications have been used to study protein folding and hydrophobic packing, and altered nucleophiles and hydrogen-bond donors/acceptors have been used to explore enzymatic catalysis. Finally, photochemical switches that allow precise control of proteases, transcription factors, and protein splicing have been incorporated.

Implications

A variety of amino acid-like structures has been incorporated via directed artificial translational recoding, including α-hydroxy acids, N-substituted amino acids, and severely constrained amino acids (e.g., 1-amino-1-carboxycyclopropane), along with myriads side chains that far exceed the length and shape parameters of the canonical 20 residues. The ability to accommodate such a broad range of structures suggests that the translation machinery may have evolved to accept many other amino acids beyond the canonical 20 and that other naturally occurring co-translational amino acids remain to be discovered, as evidenced by the recent discovery of the “twenty-second amino acid" pyrrolysine.

The screening of chemical libraries is one of the major sources for new leads in drug discovery. The large size of chemistry space compared with the library sizes that are feasible to screen requires careful selection of the compounds for the screening library to maximize screening success. Besides issues around technology compatibility and chemical tractability of the compounds, the main objective is to increase the probability of obtaining hits for the screened targets. Diversity selection approaches have often shown only limited success. In the absence of any knowledge, it is proposed to screen smaller “lead-like” ligands with preference. When knowledge about the target is available, it can be used for target-focused compound selection or for library design. In the screening process, physical high-throughput screening (HTS) can be combined with virtual screening either to avoid the high-throughput primary screen of the whole library or to limit false negatives by combining primary HTS and virtual screening results. Screening an initial subset then using the results obtained to predict likely hits for subsequent screening rounds in sequential screening can lessen the number of compounds to be screened, but it causes a greater logistics effort and has the risk of missing compounds that are not well represented structurally by the initial set. Data analysis and visualization of the screening results are a necessary final step of a screening campaign to ensure that the prioritization of compounds followed up is based on all available relevant information.

When in vitro biologic assays replaced in vivo animal models as the first tool to assess biologic activity of molecules in drug discovery, the possibility existed to test many more compounds than was possible before. This triggered the hope that the slow process of lead discovery, which relies to a large extent on medical chemists’ intuition and serendipity, could be accelerated by a systematic brute-force screening of large collections of chemical compounds, for which the term “chemical libraries” has been introduced. Consequently, the pharmaceutical industry has built up high-throughput screening (HTS) facilities (see the article “High Throughput Screening (HTS) Techniques: Overview of Applications in Chemical Biology”), in which in vitro assays could be performed in a highly parallel, miniaturized, and automated way. With HTS available, it became not only possible to screen the historically accumulated compound collections of pharmaceutical companies, but also a much greater number of compounds exist. This finding triggered the demand for a highly parallelized and automated synthesis of compounds to feed the HTS machinery (see the articles “Combinatorial Libraries: Overview of Applications in Chemical Biology” and “Small Molecule Combinatorial Libraries”). Although large pharmaceutical companies screen compound libraries in the magnitude of 10⁶ molecules, this approach is far away from a systematic brute-force approach because the chemistry space is estimated to contain 10¹³–10⁶⁰ small molecules (1). The conservative estimate of 10¹³ molecules is based on well-established chemical reactions and commercially available reagents (2). Extrapolation from a systematic enumeration of all theoretically viable organic molecules up to 11 non-H atoms toward 25 non-H atoms (the average size of drug-like molecules) suggests the existence of 10²⁷ unique structures (3). Because only a small subset of the chemistry space can be screened, the compounds must be chosen appropriately to maximize the success of the screen. Three groups of criteria for this exist.
The enzyme in biochemical assays in an unspecified way can lead to the detection of false-positive hits. The exact cause for the aggregate formation and the mechanism and conditions of the enzyme sequestration are not understood completely; however, experimental procedures have been suggested to detect false positives caused by aggregation (7).

The second property of importance for bioavailability is the polar surface area (PSA) that is associated with intestinal absorption and cell membrane penetration by passive transport. Compounds with a high polar surface are less likely to penetrate the lipophilic environment of the cell membranes by passive transport. Like the logP, PSA can be computed by summing up fragment contributions (8) with H-bonding fragments as the main contributor.

The role of the physical chemical properties discussed so far is the rationale behind two popular rules of the thumb to estimate “drug-likeness”: Lipinski’s rule-of-five (9), in which counts of hydrogen bond donors and acceptors take the place of the PSA, and the “Egan Egg” (10) (see Table 1).

**Chemical purity and stability**

To rationalize the results of a screen and to derive structure activity relationships (SAR) guiding the additional optimization of the compounds, it is prerequisite that the activity of a compound sample results from the structure being attributed to it. This can only be ensured if the compounds included in the screening collection are reasonably pure. Typical purity requirements are in the range of 85% to 95%. Impurities that interfere with the assay technology especially must be avoided.

To remain in that state of purity, the compounds must be chemically stable under the conditions of storage, and because the fresh production of screening solutions from powder sample is not feasible for each individual HTS, the compound must be stable in DMSO solution over a period of time if the stock solution is intended to be used.

A chemically unstable compound is also not well suited to be marketed as a drug: therefore, insufficient chemical stability is also an issue for optimizability. If the compound contains chemical groups that are reactive toward DNA, the compound can become mutagenic, which constitutes another liability for optimization.

Practically, the stability issue is addressed mostly by the application of substructural filters to remove compounds with known labile and reactive functionality. Several sets of substructure filter sets published share a large degree of overlap (13, 14).

**Other reasons for technology incompatibility**

In addition to the general criteria discussed above, each assay technology can also suffer from technology-specific interference of chemical compounds. A sub-fluorescent compounds can interfere with any fluorescence-based readout. In assays that use the biotin-streptavidin interaction, biotin analogs are potential false positives.

First, the compounds must be compatible with the compound handling and screening technology used and should not cause assay artifacts. Second, the library must contain molecules with the desired activity. Last, once a hit is identified, the molecule must be optimizable into a drug candidate with suitable efficacy, bioavailability, therapeutic window, and, in the case of industrial drug discovery, patentability (see the article “Lead Optimization in Drug Discovery”).

**Technology Compatibility and Optimizability**

These two objectives are discussed together because many of the selection criteria for screening compounds are important to fulfill both objectives, namely physical chemical properties and chemical purity and stability. Especially with respect to optimizability, a violation of the selection criteria discussed here is not a definite reason for exclusion, but it is a liability of the compound, which needs to be addressed during the optimization of the compound that follows the discovery of the hit. The more such liabilities a compound exhibits, the more difficult the optimization of a lead compound will be. Also, not every violation of a technology compatibility criterion is a hard reason for exclusion, but rather it increases the potential of a compound to cause artifacts under a certain assay technology; appropriate experimental procedures are required to detect these artifacts.

**Physical-chemical properties**

Generally, biologic assays are performed in aqueous solution, typically in a concentration of up to 50–100 \( \mu \)mol. These solutions are produced by diluting a stock solution of the compound in dimethylsulfoxide (DMSO) in the millimolar concentration range with buffer. Therefore the compounds must be soluble in water and in DMSO under the respective conditions, or a potential activity of the compound remains undetected or is underestimated largely. Water solubility is equally important for bioavailability of the drug, in which sufficiently high blood plasma levels must be achieved for efficacy. Unfortunately, neither the experimental determination of water solubility nor its prediction by computational methods is straightforward, because both depend not only on the hydrophilicity of compound, but also on the lattice energy of the crystal (4). Thus, based on Yalkowski’s equation (5) as a guideline to estimate water solubility, the logarithm of the octanol–water partition coefficient (logP) has been used frequently. It can be predicted by summing up fragment contributions that have been fitted on experimental data (6) as the ratio between hydrophobic and hydrophilic fragments. From a high lipophilicity as indicated by a high computed logP (ClogP), it can be concluded that the water solubility of the neutral compound is low; however, a low ClogP does not guarantee high water solubility. Protonation of basic groups or deprotonation of acidic groups lead to ionic species that frequently have higher solubility than neutral compounds.

In this context, it is noteworthy that lipophilicity is not only related to low aqueous solubility, but also to the tendency of compounds to form aggregates. Such aggregates can sequester the enzyme in biochemical assays in an unspecified way and can lead to the detection of false-positive hits. The exact cause for the aggregate formation and the mechanism and conditions of the enzyme sequestration are not understood completely; however, experimental procedures have been suggested to detect false positives caused by aggregation (7).

The second property of importance for bioavailability is the polar surface area (PSA) that is associated with intestinal absorption and cell membrane penetration by passive transport. Compounds with a high polar surface are less likely to penetrate the lipophilic environment of the cell membranes by passive transport. Like the logP, PSA can be computed by summing up fragment contributions (8) with H-bonding fragments as the main contributor.

The role of the physical chemical properties discussed so far is the rationale behind two popular rules of the thumb to estimate “drug-likeness”: Lipinski’s rule-of-five (9), in which counts of hydrogen bond donors and acceptors take the place of the PSA, and the “Egan Egg” (10) (see Table 1).
Selection of Compounds with Desired Biologic Activity

In this section, it will be discussed how likely the screening library is to contain compounds that are active on the targets of interest. In the absence of any knowledge about the structure of the target or its ligands, only diversity-based sampling methods can be used. Knowledge about the target or its target family can be used for the design of target (family)-focused library.

Diversity-based strategies

The central hypothesis for all diversity-based strategies of compound selection is the similarity property principle, which states that molecules with similar structures can be expected to have similar properties and to bind to the same target proteins (15). Following this principle, it is only necessary to screen one representative molecule out of a group of molecules with similar structures because the other molecules of the group should have the same behavior as the representative. Consequently, many algorithms exist to select diverse subsets of molecules from a database that represent the groups of unselected molecules. These algorithms have been reviewed elsewhere (16, 17) and only a short overview is provided here. Most methods encode the molecular structures as a descriptor vector, from which similarity coefficients for pairs of molecules can be calculated without aligning the molecules. Then, these similarity coefficients are used in diversity selection or clustering algorithms (18). From a clustering solution, a diversity selection is obtained by choosing one or more representative molecules from each cluster. Each molecule in a diverse subset is expected to represent the nonselected molecules, and it can be interpreted as the center of a cluster formed by its similar neighbors. For the sake of a more descriptive discussion, the clustering viewpoint is assumed in the following paragraphs; however, the arguments made can generalize to other diversity-selecting procedures. A literature to clustering, rule-based methods, typically based on the molecular scaffold, can be used to create partitions of molecules from which the representatives are selected (19–21).

Despite initially high expectations, diversity-based strategies for compound selection have shown only limited success. Diversity selection from the MDL Drug Data Report (MDDR), a database that contains only molecules with documented pharmacological properties, led to an enrichment of covered activity classes (22). However, diversity selections from a compilation of screening data that includes inactive molecules did not lead to an enrichment of targets covered by selected compounds (23). In a clustering experiment, the intraclass similarity of the IC50 vectors of the compounds measured in a uniform panel of assays was not much greater than the intra-group IC50 similarities of compounds grouped randomly (24).

How can these results be understood? At first, the similarity property principle is only valid on rather short similarity ranges. According to a popular rule of thumb, molecules that have a Tanimoto similarity coefficient of 0.85 calculated over the Daylight fingerprints are supposed to be very similar; however, often they differ significantly in their protein binding properties (25). Also, the inversion of the similarity property principle that dissimilar molecules should also have dissimilar protein binding properties is not generally true (26).

Second, the theory that the screening of only one representative per structural cluster is sufficient to determine the activity of the cluster assumes that the screening procedure is error free.

</table>
Any error in the screening for the representative molecule is extrapolated to the whole cluster and leads to its misclassification. To compensate screening errors and to determine its activity correctly, it is necessary to screen several representative molecules from a cluster of molecules with assumed common biologic activity. A statistical model to determine the number of representatives that need to be screened per cluster based on empirically estimated false positive and negative rates has been published by Harper et al. (27). They described that the probability that a compound is active is determined by the product of the probability $\pi_i$ of the cluster that contains the active compound (variable from cluster to cluster) and a probability $\alpha$ that describes the probability of an individual active compound, provided the cluster is active. In this model, $\alpha$ accounts for the average error of the screening process that leads to an erroneous determination of an individual compound’s activity and errors of the clustering procedures that lead to the erroneous grouping of a compound to a cluster with different activity. The activity related to the common “chemotype” or pharmacophore of the cluster $i$ is described by $\pi_i$, and even an active cluster with a high $\pi_i$ is likely to be missed if $\alpha$ is low. If $n_i$ compounds per series are screened, the probability to find at least one hit if the cluster is active equals $(1-1-\alpha)^{n_i}$.

The third reason for the limited success of diversity-based strategies is the low baseline probability for bioactivity, with hit rates of 0.1% as the typical order of magnitude. In the case where a clustering was highly predictive of biologic activity, with active clusters that show a 100-fold enrichment of active compounds, this would still indicate that, on average, only 10% of compounds in any given active cluster are active. If the cluster was sampled with only one compound, the probability that the cluster is identified correctly as active would only be 10%. This theory is illustrated qualitatively in Fig. 1.

**How large should a screening library be?**

Because of the inefficiency of an untargeted, diversity-oriented sampling, it is not possible to determine a meaningful library size as sufficient to sample the chemistry space. However, one can only get value out of a screening library that is matched by adequate resources for screening, compound logistics, and data handling. The costs for this and for the compounds practically limit the library size. The statistical model by Harper et al. (27) predicts the growth of the expected rate of successful screens. Successful means here that at least one hits series is found. According to this model the average number of hits series identified per assay increases linearly with the number of compounds in the library, assuming the average number of compounds per series is kept unchanged. However, the probability of success does not grow linearly with the size of the library. Each incremental addition of compounds leads to a smaller increase of the probability of success than the previous addition of the same number of compounds.

**How large should the molecules in the library be?**

The probability of a molecule to match the binding site of its target is assumed to be dependent on the size of the molecule. This relationship is described by the qualitative model of Hann et al. (28). After an initial increase, the probability that a ligand matches the binding site in exactly one orientation decreases with the ligand size. In addition, the number of potential molecules increases exponentially with the number of atoms; therefore, with increasing cutoff for the molecular size, it becomes more and more difficult to sample the chemistry space (3, 11). On the other hand, the larger the molecule, the more binding contacts it makes if it fits the binding site perfectly, which leads to a higher binding affinity (29). The binding affinity that is required minimally for detection depends on the sensitivity of the assay. An increase of assay sensitivity leads to a decrease of the required minimal size for ligands that have the potential to bind with a detectable affinity. For the reasons stated above, it makes sense to screen molecules in the size range that is large enough to allow for a detectable affinity, but not larger. Lead-likeness criteria have been formulated based on this finding (see Table 1). In fragment-based screening (FBS), highly sensitive biophysical assay technologies are used to detect the binding events of small molecular fragments to proteins (12). In the molecular size range used in FBS, the hit rate is, in accordance with the Hann model, much higher than in conventional biologic assays. The observed affinity is much lower (30), which requires the fragments to be amenable to chemical transformation to evolve them to molecules for which activity can be validated and be optimized using biochemical assays.
series, the ligand efficiency for the best compound after each optimization step is in most cases constant, what indicates that an increase of affinity coincides with an increase of molecular weight (MW). To achieve a final drug candidate with a potency of less than or equal to 10 nM and a MW less than or equal to 500 Da to comply with Lipinski’s rule, a LE of 0.016 pK_{DA}^{-1}

is the minimum requirement. Conventional HTS are typically sensitive enough to detect compounds K_{i} in the range of 1 μM.

Assuming that the ligand efficiency is indeed constant for a chemical series, and only ligands with LE greater than or equal to 0.016 pK_{DA}^{-1} have the potential to optimized into a suitable drug candidate, then it would be sufficient to screen compounds with a maximum MW of 375 Da. Likewise, for a biophysical fragment screen that can detect K_{i} in the range of 1 mmol/L, a maximum MW of 188 Da would be sufficient if the binding constant translates into an inhibition constant of the same order of magnitude. However, the criterion of LE greater than or equal to 0.016 pK_{DA}^{-1} may not be achievable for every target. In Reference 32, chemical series exist with lower LE values that nevertheless went into preclinical development. It must also be taken into account that a screening with a low LE can still be a suitable tool compound and may serve as a starting point to design a scaffold with a higher LE, which has not been present in the screening library. The definition of optimization of a chemical series used by Hajak is very narrow, and it allows an initial hit fragment to grow but not to have parts of it removed. In the exploration of HTS hits, pruning operations are frequent, although an ideal library also would have contained the compound that resulted from the pruning in the first place. Therefore, such LE-derived cut-off criteria for screening hits rarely can be applied stringently.

**Target family-focused screening libraries**

The limitations of the brute-force sampling of the chemistry space lead to attempts to identify structures that would have a greater chance of success. Virtual screening methods are now well-established technologies (33) (see the article “Computational Approaches in Drug Discovery and Development”). Moreover, these methods work on individual targets, of which some knowledge is needed either about protein structure or about ligands. When assembling a screening library for lead discovery, the main objective is to design a broadly usable collection that also contains ligands for targets about which very little is known. Fortunately, drug targets are not isolated in the pharmacology space, and many pairs of targets share some common ligands, especially if they belong to the same protein family (34). Within a protein family, ligands are often similar enough that searching for chemical similarity with the ligands of one representative member also identifies ligands of the other members without reported activity on the reference protein (35). According to the SAR homology concept (36), targets of one family often share similar ligands, and similar SAR behavior. This allows the library design to focus on a target family rather than an individual target and to leverage the whole set of knowledge for a target class (see the article “Target Family-Biased Compound Library: Optimization, Target Selection, and Validation”). Typically, chemical similarity searching is based on the comparison of molecular descriptor vectors with similarity coefficients (37). Although similarity searching with the individual ligands and combination of the results by data fusion can be highly successful (38), the numerical or binary nature of the descriptor vectors allows a whole range of machine learning techniques to be applied from other areas of multivariate statistics. Examples of these techniques are binary kernel discriminators (38), support vector machines (39), emerging patterns (40), naive Bayesian classifiers (41), and self-organizing maps (42). Self-organizing maps have become especially popular because of the intuitive visualization of their results (43, 44). Often, the results depend strongly on the target class chosen and the available data. For this reason, one key success factor is to compile as comprehensive and accurate a reference set as possible, which requires bioactivity databases that are well integrated into both bioinformatics databases that describe protein family membership and chemical databases that characterize the ligands. Although considerable room for improvement still exists in this sector, a wide range of databases has become available, and they were reviewed recently (45) (see the article “Small Molecules, Drug-Target Databases”).

Structure-based virtual screening technologies use the complementarity between the structural features of ligand and its target protein-binding site. Docking, which tries to predict explicitly the orientation of a ligand within the binding site (pose) and to estimate its binding energy (score), is the most frequently used method and has now become well established (46). However, a new method uses the target-ligand complementarity for the generation of predictive models without generating binding poses (47).

To make docking suitable to identify the ligands of a whole target family, it is necessary to address the issue of how to deal with family members without an available protein structure and how to overcome the inaccuracy of the scoring functions for the analysis of the docking results. A substantial improvement of the results can be obtained by using not only the docking score as a decision criterion to retain or reject a pose, but also the key interactions between ligand and protein. Based on binding affinity of known ligand, the scoring weights of different interactions can be adjusted to reflect the SAR of the ligands (48). Ligand-protein interactions can be described by discrete bit vectors comparable with chemical fingerprint descriptors, which allow the efficient and fast filtering of poses as described for the design of a kinase-focused library (49). Recently, a method has been described to train the weights of interactions in the scoring functions automatically based on a set of known ligands. This method allowed the authors to predict not only the activity for the kinase to which the ligand has actually docked into, but also, by using a training set of activity data for a second kinase that is different from the one used for docking, the activity for this second kinase. This method allows predicting activity for kinases without a known structure (50). It is an example of a method in which classical docking is combined with statistical learning. To apply these methods, both protein structures and activity information over large set of ligands is required. Even further generalizations of the binding sites are schematic descriptions of kinase binding sites summarizing the features of several kinase inhibitor complexes and the variations in their binding pockets between different kinases.
Such qualitative models have been used successfully to design kinase-focused libraries. In the case of G-protein coupled receptors (GPCRs), the structural information is rather sparse; bovine rhodopsin is the only GPCR for which a crystal structure is currently available. However, this structure could be used to determine which residues are positioned within the binding cavity. A qualitative model has been derived to visualize the molecular recognition of ligands in different GPCRs that depend on the amino acids side chains exposed in the binding site (52). Although many methods described above can be used to screen individual structures or enumerated libraries for potential biologic activity, they offer, with exception of the generalized binding site models, no guidance for the de novo design of new scaffolds that have an increased potential for biologic activity on a range of targets. One of the earliest concepts to offer such guidance is based on the observation, that common core scaffolds exist, which can be differentiated by modification of its side chains into ligands that are individually selective for different target proteins. Evans et al. (53), who made this observation in the case of the benzodiazepine core contained in selective ligands, proposed that the limited number of protein folds in the pro- teome also leads to a limited number of ligand-sensing cores. A ligand-sensing core is defined as the folding pattern of the protein in a sphere with a diameter of 20–30 Å around the binding site without taking the individual protein side chains into account (57). Different side chains in the ligand-sensing core can lead to a variety of diversely functionalized binding cavities, which may fulfill different functions and may occur in more than one target family. A privileged structure might be a suitable scaffold that orients its side chains in different regions of the binding pocket that is defined by the ligand-sensing core. Depending on the amino acid side chain, which is exposed in the binding pocket by the individual protein, different functional groups are required to be present on the privileged scaffold. The concept of biologically-oriented synthesis (BIOS (58)) suggests that in absence of detailed knowledge of an individual target protein’s structure, it is required to screen a diversely-functionalized library around a privileged or biologi- cally pre-validated scaffold for the ligand sensing core in order to identify the correct substitution pattern for the individual target.

Natural products

Natural products are a traditional source of biologically active compounds, which are used either as drugs themselves or have inspired the discovery of synthetic drugs (59) (see the articles “Natural Products: An Overview” and “Natural Products to Probe Biosynthetic Pathways”). They cover a wide range of chemical classes (59), and they are expected to be fine-tuned by evolution to fulfill a purpose that is often still unknown, but likely to involve the interaction with biomolecules. The capability of an organism to produce many variations of a metabolite at a low effort is considered a beneficial evolutionary trait of a species, which allows it to adapt its range of produced metabolites quickly to a changing environment. For this reason, the metabolic pathways involved in the synthesis of natural products are often branched in phyto and lead to high chemical diversity in collections of natural products (60). The synthetic complexity of natural products makes them often difficult to optimize. It has been shown, however, that not only natural products themselves, but also synthetic libraries of simplified analogs that retain only the key features of the original natural product can be applied successfully in screens for biologically active compounds. It has been demonstrated that from such a simplified natural product, core selective ligands for different targets can be derived and may be regarded as privileged structures (58).

Screening Processes and Strategies

The next question is how to make the best use of a library assembled according to these design principles. The goal of screening is to identify as many actives as in the screening library possible and to characterize them by measuring dose re- sponse curves, confirming both the chemical identity and the purity of the sample. Part of a thorough characterization of the hits is also running the the counter assays necessary to confirm that the observed activity results from the interaction of the ligand with the target and is not the result of an artifact caused by a technology incompatibility of the compound. These tasks must be executed with the lowest possible experimental effort, reagent costs, protein, and compound consumption. Al- though in basic research it may be sufficient to identity a limited number of tool compounds, in pharmaceutical industry it is of interest to identify as many of the active chemical series present in the screening library as possible and to establish intellectual property, because the attrition in the next steps of drug discovery is high.

HTS processes

Typically, the screening process (see the article “High Through- put Screening (HTS) Techniques: Overview of Applications in Chemical Biology”) begins with the production of stock solutions by dissolving powder samples and reformating the solution samples into a uniform deck of stock solution plates. These samples are then stored under controlled conditions, and from these samples the screening plates are produced by plate replication systems. Perhaps the most direct approach to screening is first to measure the dose response curves with the prefabricated assay plates that contain the compounds in the different concentrations ([Fig. 2a]). This technique has been shown to be feasible with a high level of automation for libraries up to the size of 100,000 samples. Because the same number of data points is measured
for active and inactive compounds, absence and presence of activity are determined with the same degree of reliability. This reliability is an advantage for building SAR models. In addition, the analysis of the dose response curve shapes allows some conclusion as to whether the interaction between ligand and protein is specific (61). However, in the pharmaceutical industry, larger libraries of a million or more compounds are often screened, and it is desirable to have a lower consumption of protein and compounds.
Virtual screening is a process that uses computational methods to predict the activity of compounds. The process requires the availability of a relatively small number of hits in experimental screening. Between the primary screening and validation, a confirmation screen can be performed in which, for the primary hits, the single concentration experiment is repeated, and only hits with confirmed activity are validated (Fig. 2b). In any case, it is necessary to confirm chemical identity and purity of the samples found active to avoid false positives and false negatives. For the same reasons, counter screens or secondary assays that use different read-out methods are performed to exclude an unspecific interaction of the compound with the assay system.

This process requires the capability to access large subsets of the screening library. Typically, this process step, called cherry picking, individual samples must be taken from the mother plates with stock solution and dispensed into plates for the confirmation or validation screen. In addition, dilution series for dose-response curve measurement must be produced of the cherry-picked samples for validation. Technically, cherry picking is a nontrivial task, and if all compounds with significant primary activity are to be confirmed, which can be several thousand compounds, and not only the screening capacity for confirmation screening needs to be available, but also the cherry-picking capacity for these samples must be available.

For large screening libraries, these processes can only be run with a high degree of automation in sample storage, cherry picking, screening, and chemical analytics. These automation steps must be driven by an informatics platform that tracks the contents of plates, collects the results of the different readers used for screening, and performs normalization, curve fitting, and detection of errors that may result from spillage and carry-over of compounds in the pipetting process or edge effects (62, 63). The results of these automated preprocessing steps must be presented to the screen in an appropriate visualization after each screening step for quality control and final decision making, pivotal for the primary screening and its results justify the follow-up of more compounds than can be processed, then chemoinformatics techniques such as clustering can be used to ensure appropriate representation of all chemical classes in the validation set. Also in this step, compounds can be removed that interfere with the assay technology and are unlikely to interact specifically with the target (64). The decisions taken at these steps must be handed over to the cherry-picking system for automated process. The software tools used for these different tasks must be well integrated to achieve a process that runs smoothly (65). Integration of in silico screening

Because of the large investments in the hardware and software infrastructure required for HTS, to replace the primary screening in HTS by virtual screening, followed by the validation of a relatively small number of hits in experimental screening is seen as a valuable alternative (Fig. 2c). However, this task is only feasible if either information about protein structure or reference ligands is available (33). In addition to the physically available in-house collection, virtual screening can include compounds from vendor catalogs and even enumerated virtual libraries from which the hit compounds are then purchased or synthesized. Compilations of screening compound catalogs exist both publicly, such as ZINC (compiled by the Shoichet laboratory at UCSF, San Francisco, http://zinc.docking.org), which contains docking ready 3D structures (66), or in the commercial sector such as ChemNavigator (Chemnavigator, San Diego, http://www.chemnavigator.com), which is linked to a sample procurement service. Several cases have been reported in which active ligands have been discovered successfully using such processes (67). However, if automated high-throughput experimentation is abandoned, then only small numbers of compounds can be validated (typically below 1000), whereas typical HTS setups allow the validation of a couple of more than 1000 compounds. Similar to physical HTS, but to a higher extent, virtual screening is affected by false positives and false negatives. In typical virtual screening, accumulation of more than 10% of the false positives in the top 10% ranking compounds is an excellent result that is almost never reached in practice (68, 69). Assuming an industrial HTS library of a million compounds, to validate a virtual screening hitlist that consists of only 1% of this library despite the inevitably high false-negative rate this will cause, requires HT experimentation. Data fusion of HT experimentation and virtual screening can be expected to compensate errors of each of the methods and to allow the validation of a significant number of hits. Virtual screening in this setup no longer has the purpose to save investment in HT experimentation, but to maximize the positively validated compounds over the whole process to identify as many true positive hits in the collection as possible to feed in the drug discovery process (Fig. 2d).

Sequential screening

Instead of screening the whole library in one batch, it has been proposed to screen an initial subset and use the screening results from this subset to train a statistical model to predict and to prioritize the remaining library. The remaining library is then screened, and the cycle of model building, prediction, and screening can be executed several times, which is referred to as sequential or iterative screening (70). Although this seems to be very attractive because it reduces the number of compounds that require screening, the multiple selection cycles lead to a longer overall screening time increasing the assay logistics effort. Together with the multiple cherry-picking and data processing cycles this may cause more effort than the savings from screening less compounds. In sequential screening it is necessary to choose an initial set. In the absence of reasonable knowledge for the selection of a focused subset, the initial set must be selected by diversity selection, whose limitations have been discussed above. In a compound collection that has been designed to avoid unnecessary redundancy by applying reasonable diversity selection, little can be gained by additional diversity selection. Any active compound class not represented reasonably by the initial screening set is unlikely to be recovered in the additional screening cycles, because the statistical models built on the screening results cannot make valid predictions for it. However, one can expect to identify
addition of actives in the series covered by the initial set. Recently, it has been demonstrated that screening 25% of a one million compound library selected as a diversity set based on full plates followed by one prediction and screening cycle offers a reasonable compromise between logistical efforts, numbers of compounds screened and hit series covered (Fig 2e (71)). When the screening cost per compound is high and dominates the logistics effort sequential screening can be expected to be beneficial, provided it is acceptable to identify only a limited number of tool compounds instead of as many hit series out of the library as possible.

Analysis, Reporting, and Visualization

Often, the number of validated hits in an HTS is so high that the results cannot be analyzed without computational assistance. The primary objective of HTS analysis is to identify chemical series, which are characterized by a common structural core that allows the exploration of the series in a joint chemical synthesis effort and aligns the structures of a series to derive SAR. Therefore, in HTS analysis, compounds are grouped by structure, which can be achieved either with clustering procedures, especially those based on maximal common substructures (72, 73) or with rule-based classifications (18, 39, 74). An advantage to the clustering methods is that they adapt themselves to the data set, whereas an advantage for the rule-based method is that they can be more resilient to changes in the composition of the screening library. In the beginning of HTS, hits were often prioritized by potency alone; however, nowadays it is recognized that a wide range of properties has an impact on the additional success of a chemical series. Therefore, each series must be annotated with all information relevant for their additional prioritization, such as potency and ligand efficiency on the screening target, activity on other targets, and calculated or measured physical chemical properties. It is also of interest to identify inactive compounds that contain the substructure of an active series. The data set generated in this way is very information-rich, which requires special visualization techniques that are able to display several properties simultaneously and interactively (75, 76). Because the data visualized results from different experiments or computational procedures, its aggregation is a nontrivial task, which requires highly modular and interactive (77). Because the data visualized results from different experiments or computational procedures, its aggregation is a nontrivial task, which requires highly modular and interactive computational chemistry. Rev. Comput. Chem. 2002;18:1–40. Bartlett PA, Entzeroth M, eds. 2006. RSC Publishing, Cambridge. pp. 137–159.

Cyclooxygenases (COXs) are key enzymes of bioactive lipid metabolism that catalyze the committed step in prostaglandin biosynthesis. Inhibition of COX catalysis is a principal mode of action of nonsteroidal antiinflammatory drugs (NSAIDs). The combination of structural and functional analysis of COX-inhibitor interactions has provided important insights into the molecular determinants of inhibition. Although COX protein structure does not change significantly on inhibitor binding, a surprising variety of binding modes and molecular interactions are observed with different NSAIDs. This article focuses on recent advances in our understanding of these interactions with emphasis on arylcarboxylic acid-based inhibitors and their derivatives.

Cyclooxygenases (COX-1 and COX-2) are bifunctional enzymes that carry out two sequential reactions in spatially distinct but mechanistically coupled active sites—the double dioxygenation of arachidonic acid to prostaglandin G_2 (PGG_2) and the reduction of PGG_2 to PGH_2 (Eq. 1) (1). A richidonic acid oxygenation occurs in the cyclooxygenase (COX) active site, and PGH_2 reduction occurs in the peroxidase (POX) active site. The CDXs are homodimers of 70 kDa subunits, and dimerization is required for structural integrity and catalytic activity (2). The first crystal structure solved for a COX enzyme (ovine COX-1 with the bound inhibitor flurbiprofen) revealed an asymmetric unit containing two identical monomers that exhibit extensive contacts in a large subunit interface; each subunit contains the inhibitor bound only in the COX active site (3). Although it has been assumed that both subunits are active simultaneously, recent work suggests that substrate or inhibitor binding in the COX active site at one subunit precludes the binding of another molecule at the other subunit (4). This cooperativity between subunits is consistent with the observation that CDX-2 dimers only bind a single molecule of flurbiprofen tightly, and this is sufficient to inhibit all COX activity (4). The molecular details of the communication between subunits are not yet understood, but their elucidation will have a significant impact on defining COX-inhibitor interactions.

Ligand Binding to COX Enzymes
Each monomer of COX consists of three structural domains: a short N-terminal epidermal growth factor domain, a membrane-binding domain, and a large, globular C-terminal catalytic domain (Fig. 3a) (3). The COX and POX active sites are located on opposite sides of the catalytic domain with the heme prosthetic group positioned at the base of the peroxidase.
site. The epidermal growth factor domain and catalytic domain create the dimer interface and place the two membrane-binding domains on the same face of the homodimer about 25 Å apart (5, 6). The membrane-binding domain of cyclooxygenase is composed of four amphipathic α-helices, with hydrophobic and aromatic residues that project from the helices to create a surface that interacts with one face of the lipid bilayer (3). Three of the four helices lie in the same plane, whereas the last helix (helix D) projects up into the catalytic domain (5). The catalytic domain constitutes the majority of the COX monomer and is the site of substrate binding and NSAID action.

Substrate and inhibitor gain access to the COX active site (Fig. 1b) at the base of the membrane-binding domain, which leads into a long hydrophobic channel that extends deep into the catalytic domain interior (3). This hydrophobic channel narrows at the interface between the membrane-binding domain and the catalytic domain to form a constriction composed of three residues (Arg-120, Tyr-355, and Glu-524) that separate the "lobby" from the active site. The active sites of COX-1 and COX-2 are nearly identical in the amino acid residues that constitute the primary shell of the active site but differ in the presence of a side pocket in COX-2 bordered by Val-523 and Trp-387. A small, hydrophobic pocket formed by Val-349, Ala-527, Ser-530, and Leu-531 surrounds the 2-aryl ring of COX-2 selective inhibitors (e.g., celecoxib and rofecoxib). In addition, the last helix of the membrane-binding domain (helix D) is positioned differently in COX-2 and shifts the location of Arg-120 at the constriction site, which allows for a larger solvent-accessible surface at the interface between the membrane-binding domain and the COX active site in COX-2.

**Time-Dependent Inhibition of COX by Indomethacin and its Ethanolamines**

Kinetic studies of COX inhibition reveal that many NSAIDs interact with COX through a multistep mechanism in which a rapid, reversible step is followed by one or more slow steps that may be poorly reversible (Eq. 2) (9, 10):

\[
E + I \overset{k_1}{\rightarrow} EI \overset{k_2}{\rightarrow} EI^* \overset{k_d}{\rightarrow} E + I^* \quad (2)
\]

Although dissociation of the E–I* complex is often too small to be measured, none of the NSAIDs other than aspirin cause covalent modification of COX enzymes. Rather, the final step of binding for many NSAIDs corresponds to the formation of a tightly bound and functionally irreversible protein–inhibitor complex, E–I*. Indomethacin (INDO) is a highly potent, time-dependent inhibitor of COX (10). Although its time-dependent kinetics were first reported over 30 years ago, the mechanism of its tight binding was not understood. A crystal structure of the complex of INDO with murine COX-2 provides a detailed view of the binding orientation and critical protein–ligand interactions (8). The carboxylic acid of INDO binds at the constriction site of COX, forming an ionic bond with Arg-120. The heterocyclic scaffold occupies the oxygene-nase channel, with the methoxy group projecting toward Val-523 and the para-chlorobenzoyl moiety projecting toward Tyr-385 and Trp-387. A small, hydrophobic pocket formed by Val-349, Ala-527, Ser-530, and Leu-531 surrounds the 2'-methyl group on the indole ring (Fig. 2b). The importance of the interaction with the 2'-methyl group was revealed by a combination of protein mutagenesis and inhibitor modification (11). Site-directed mutants of COX-2 were generated, which altered the size of the hydrophobic pocket via
Structures and inhibitory activities of indomethacin, sulindac sulfide, and their derivatives demonstrate the importance of the 2′-methyl group for inhibition of COX by indomethacin and sulindac sulfide. (a) Indomethacin bound in the active site of COX-2. The 2′-methyl group of indomethacin, shown with its Van der Waals surface, sits in a hydrophobic pocket that consists of Val-349, Ala-527, Ser-530, and Leu-531. Hydrogens are included on the residues of the pocket (V349A) did not significantly alter the potency of INDO. Although INDO exhibited diminished potency toward V349I, the binding kinetics for V349I were similar for wild-type COX-2 and all Val-349 mutants. Dissociation of this complex, as judged by k−2, is not measurable for wild-type COX-2, V349A, or V349I. However, a measurable and, in fact, rapid k−2 was observed with V349L. As a result, most of the inhibitor was competed off within a few minutes after the addition of arachidonic acid. This finding suggests that the reversibility of the second step in the time-dependent mechanism is the primary determinant of the potency of COX inhibition by INDO and that this is largely defined by interactions between the 2′-methyl group and the hydrophobic pocket.

A derivative of INDO that lacks the 2′-methyl group was synthesized, and its interactions with COX-1 and COX-2 were studied (Fig. 2b) (12). This compound, des-methyl INDO (DM-INDO), is a poor inhibitor of wild-type COX-1 and COX-2 and all Val-349 COX-2 mutants. Again, potency is dependent on the reversibility of the second step of the binding mechanism. Curiously, DM-INDO displays COX-2 selectivity, despite complete sequence conservation within the hydrophobic pocket in COX-1 and COX-2. Although selectivity may be related to the magnitude of k−2, which is an order of magnitude faster for COX-1 than for COX-2, the structural basis of selectivity of DM-INDO inhibition has not been elucidated.

Sulindac sulfide, the bioactive metabolite of sulindac, is structurally very similar to INDO and is a slow, tight-binding inhibitor of COX. As with INDO, removal of the methyl group from sulindac sulfide results in loss of COX-2 and COX-2 inhibition (14). However, it should be noted that the benzylidine double bond of des-methyl sulindac sulfide (DM-SS) exists in the E-conformation, whereas sulindac sulfide exists in the Z-conformer. Many clinically relevant NSAIDs exert off-target effects unrelated to their ability to inhibit COX enzymes. For example, INDO and SS induce apoptosis of tumor cells and modulate γ-secretase activity (15, 16). INDO also activates the nuclear transcription factor PPARγ (17). The complexity of in vivo pharmacologic effects makes it a challenge to separate the contribution of COX inhibition from other effects in a given pharmacologic response. Thus, the removal of COX inhibitory activity by a minor modification, such as the removal of a methyl group, provides an opportunity to dissect COX-dependent and COX-independent effects of certain NSAIDs. In fact, DM-INDO and DM-SS activate PPARγ in HCA-7 cells with dose responses similar to those of the parent drugs (14). Likewise, the des-methyl compounds exhibit potency similar to the parent compounds in their ability to induce apoptosis in RKO cells, a human colon cancer cell line, and to activate PPARγ in cellular reporter assays.

Gastrointestinal toxicity is a classic side effect of INDO and other potent, nonselective COX inhibitors. It is widely accepted that this toxicity arises from inhibition of PGE2 production in the gastric mucosa; however, other mechanisms have been proposed (15, 18). C57BL/6 mice were administered INDO or DM-INDO at 5 mg/kg, a dose above the LD50 of INDO. Whereas the gastric mucosa of INDO-treated animals exhibited significant tissue necrosis, the gastric tissue from DM-INDO-treated animals was identical to that of healthy control animals (14). Furthermore, the LD50 of DM-INDO in...
Cyclooxygenase Inhibition: Recent Advances in the Mechanisms of

C57BL6 mice was 20-fold higher than that of INDO, which suggests that toxicity of INDO is closely associated with inhibition of COX.

Understanding how a drug works on the molecular level is critical to elucidating its pharmacologic effects. INDO provides a striking case study of how subtle interactions, revealed by protein structure-function analysis, can be exploited to dissect the off-target effects of drugs. DM-INDO and DM-SS may provide scaffolds for probing or fine-tuning the beneficial side activities of the parent drugs, while reducing dose-limiting toxicity.

For many NSAIDs, including flurbiprofen and INDO, the ionic bond between Arg-120 and the carboxylic acid of the inhibitor is absolutely required for time-dependent inhibition of COX-1 (10, 19); the methyl esters of INDO and other NSAIDs were shown to be very poor inhibitors of COX-1 (10). However, this interaction is not a universal requirement for inhibition of COX-2 (20). Conversion of the INDO carboxylate group to neutral esters and amides provides a general and facile method for generating COX-2-selective inhibitors (21).

A notable exception is a series of α-substituted ethanolamides of INDO, which exist as R/S-enantiomeric pairs (22). Across a range of α-substitutions, the R-enantiomers are consistently COX-2-selective. However, the S-enantiomers efficiently inhibit both COX-1 and COX-2.

Crystal structures of the pair of α-ethyl-substituted enantiomers bound to COX-1 provide a surprising structural basis for the enantioselectivity of inhibition (23). The R-enantiomer (8) binds in a conformation similar to that of INDO bound to COX-1 or COX-2 (Fig. 3). The para-chlorobenzoyl group is oriented toward Tyr-385 and Trp-387, and the methoxy projects toward the side pocket, and the ethanolamide is positioned at the constriction site. The hydroxyl group of the ethanolamide forms a hydrogen bond to the guanidinium of Arg-120. To accommodate the hydroxyethyl substituent, Arg-120 must rotate away from Tyr-355 and toward Glu-524. The ethyl group extends through the constriction.

The S-enantiomer (9) adopts a very different conformation (Fig. 3). In this case, the methoxy group projects toward the apex of the channel, with the para-chlorobenzoyl wedged into a groove below Leu-531 and the 2′-methyl group positioned above Tyr-355. The ethanolamide moiety inserts into the side pocket, which consists of His-90, Gin-192, Leu-517, Phe-518, and Ile-523. The substituted ethanolamide of 9 makes several hydrophobic interactions with Phe-518 and Ile-523. The hydroxyl group can hydrogen bond to His-90 and Gln-192. In COX-2, the sulfone or sulfonamide moiety of the diarylhetarocycles use this side pocket, which is enlarged by conservative amino acid substitutions in the primary and secondary shells, and provide the basis for COX-2-selectivity of this class of inhibitors (7, 8). Notably, attempts to model 8 in a conformation similar to the noncanonical conformation of 9 indicate that the R-enantiomer cannot take advantage of the same network of interactions and could not avoid steric clashes with protein side chains.

The kinetics of 8 and 9 binding and inhibition with COX-1 reveal an interesting profile. Pre-steady state kinetic measurements indicate that binding of 8 and 9 proceeds by a multistep mechanism like that of INDO (Eq. 2). Although $K_i$, the ratio of $k_1$ to $k_2$, is similar for 8, 9, and INDO, formation of E–I* proceeds at a much faster rate (10-fold) for 8 and 9 than for INDO.
Cyclooxygenase-Inhibition, Recent Advances in the Mechanisms of

Inhibition by Aspirin and Salicylate

The development of aspirin in the late 1890s is a landmark in the evolution of the pharmaceutical industry (24). Many decades later, aspirin was shown to inhibit prostaglandin biosynthesis by covalently modifying COX (25, 26). Inactivation results from acetylation of Ser-530, which is located above Arg-120 and across from Tyr-385 in the COX active site (27). Mutagenesis of Tyr-385 to Phe in COX-2 reduces acetylation of Ser-530 by greater than 90%, which suggests the importance of hydrogen-bond formation in acetylation (28). Indeed, a crystal structure of COX-1 acetylated by bromoacetyl salicylic acid reveals a hydrogen bond between Tyr-385 and the carbonyl oxygen of the bromoacetyl group (29). It has been proposed that hydrogen bonding by Tyr-385 stabilizes the incipient anion state of the heme that oxidizes Tyr-385 to a tyrosyl radical in the active enzyme. This reduction seems to be caused by the peroxide oxidation of the heme prosthetic group (and presumably the oxidation of Tyr-385) because substitution of Mn3+ protoporphyrin IX for heme eliminates hydroperoxide antagonism of salicylate and acetaminophen inhibition (31, 32). Hydroperoxide-antagonism of COX inhibition may be related to the purported differential sensitivity of COX-1 and COX-2 to certain NSAIDs because COX-1 requires approximately a 10-fold higher concentration of peroxide than COX-2 to achieve full activation (33, 34).

Acetylation of COX-1 completely abolishes cyclooxygenase activity presumably by blocking the binding of arachidonic acid in the COX active site. However, acetylated COX-2 can oxidize arachidonic acid to a 15(R)-hydroperoxy derivative (35). This ability is because of the greater size of the COX-2 active site. Mutagenesis of the side pocket residues, Val-523, Arg-513, and Val-434, to the COX-1 variants (Ile-523, His-513, and Ile-434) eliminates the ability of acetylated COX-2 to oxidize arachidonic acid (36). This finding indicates that acetylated COX-2 can accommodate arachidonic acid in its active site in a binding mode that allows oxygenation at carbon-15 to 15-hydroperoxyeicosatetraenoic acid. This finding may be pharmacologically important because 15-hydroperoxyeicosatetraenoic acid is a substrate for oxygenation by lipoxygenases to lipoxin A4 (37). Lipoxin A4 and related compounds have potent antiinflammatory activity, and the contribution to its formation by acetylated COX-2 may account for some of the antiinflammatory activity exhibited by aspirin.

Diclofenac and Lumiracoxib: Novel Mechanisms for Inhibition and COX-2 Selectivity

The importance of Tyr-385 in aspirin acetylation of Ser-530 suggests that it may play a broader role in interacting with electron-rich centers. In fact, the crystal structure of a catalytically inactive mutant of COX-2 with bound arachidonic acid reveals the arachidonate bound in an inverted, noncanonical orientation in which its carboxylate group is hydrogen-bonded to both Tyr-385 and Ser-530 (38). This conformation is not a productive conformation for arachidonate oxygenation, but
or leucine alter the size of the pocket and lead to changes in lumiracoxib and diclofenac exhibit large differences in the selectivity of COX-2 inhibitors (e.g., celecoxib and rofecoxib) and does not contain structure of the diarylheterocycle class of COX-2 selective inhibitors. Lumiracoxib lacks the tricyclic short plasma half-life (41, 42). Lumiracoxib displaces a 500-fold greater selectivity for COX-2 than COX-1 with its carboxylic acid moiety coordinated to Ser-530 and Tyr-385 at the top of the active site and not ion-paired nor hydrogen-bonded to Arg-120 and Tyr-355 (39). This binding mode seems to be the binding mode responsible for inhibition because mutation of Ser-530 to Ala abolishes diclofenac inhibition whereas mutation of Arg-120 to Gin is without effect (39). Interestingly, diclofenac also seems to make use of the small hydrophobic binding pocket composed of Ala-527, Val-349, Ser-530, and Leu-531 that INDO uses to insert its 2′-methyl group. Mutations of Val-349 in this pocket to alanine or leucine alter the size of the pocket and lead to changes in the potency of indomethacin and diclofenac (11, 40).

A close structural analog of the non-selective COX inhibitor diclofenac, lumiracoxib displays a 500-fold greater selectivity for COX-2 than COX-1 in vivo and exhibits a unique pharmacologic profile that includes rapid absorbance and a relatively short plasma half-life (41, 42). Lumiracoxib lacks the tricyclic structure of the diaryheterocycle class of COX-2 selective inhibitors (e.g., celecoxib and rofecoxib) and does not contain a sulfonamide or sulfone group. Although structurally related, lumiracoxib and diclofenac exhibit large differences in the selectivity of COX-2 inhibition, and the molecular basis for this difference in the selectivity of COX inhibition only recently was elucidated.

As expected from its structural resemblance to diclofenac, lumiracoxib binds to COX-2 in an inverted orientation similar to that of diclofenac with hydrogen-bonding interactions between the carboxylate of the inhibitor and Ser-530/Tyr-385 at the top of the active site (43). A comparison of this crystal structure with a model of lumiracoxib bound to COX-1 leads to the conclusion that the COX-2 selectivity of lumiracoxib arises from the insertion of the methyl group on the phenylacetic acid ring of the inhibitor into a small groove provided by the movement of a primary shell leucine residue (Leu-384) in the COX-2 active site. The movement of Leu-384 is thought to be restricted in the active site of COX-1 because of the presence of bulky secondary shell residues lying behind it (Ile-525 and Phe-531) that prevent the movement of Leu-384 with inhibitor bound.

Prior structure-activity studies with diclofenac analogs indicated that methyl or chlorine substituents on the lower aniline ring of the inhibitor in the ortho position are required for potent inhibition of COX (44). Analogs with halogen substitutions (fluorine or chlorine) at the 5′-position of the phenylacetic acid ring demonstrate an even higher potency for COX inhibition (44).

Although the selectivity of lumiracoxib for COX-2 has long been demonstrated in vivo, the chemical and structural basis for the balance that exists between potency and COX-2 selectivity was determined only recently for this inhibitor (40). An extensive structure-activity analysis with a library of lumiracoxib analogs indicates that the 5′-methyl group on the phenylacetic acid ring of the inhibitor is the major determinant for COX-2 selectivity, and that the chemical nature of the substituents in the ortho positions on the lower aniline ring exert the major influence on the potency of COX inhibition (2,6-dichloro, 2,6-dimethyl, or 2-chloro-6-methyl substitutions are preferred). Interestingly, the structure-activity study also suggests a contributory role for the chlorine atom of lumiracoxib in COX-2 selectivity, a key finding not divulged by the crystal structure determination. Site-directed mutagenesis of the small hydrophobic binding pocket valine residue (Val-349 to Ala, Ile, or Leu) in COX-2 also supports a role for lumiracoxib binding interactions in this region of the active site (40).

The resultant structure-activity analysis of lumiracoxib analogs with the V349 mutants indicates a preference for a chlorine substituent on the lower aniline ring for potent inhibition of COX-2, with F, Cl, CI-CI, or CI-CH3 substitutions allowed at the 2,6 position to maintain potency. These data suggest that the chlorine atom on lumiracoxib (similar to diclofenac) binds in the small hydrophobic pocket that consists of V349, S530, A527, and L531 and that this interaction may contribute to the potent inhibition of COX.

The structure-activity studies with diclofenac and lumiracoxib reveal that the COX-2 inhibitor activity of lumiracoxib results from a fine balance between potency and selectivity. The principal determinant of potency is the dihaloarylamine ring, whereas the meta-methylphenylacetic acid ring primarily controls selectivity. An F → Cl substitution in the dihaloarylamine ring of lumiracoxib increases the tightness of binding (potency of

2. Xiao G, Chen W, Kilmac R. Effect of substrate, especially at elevated concentrations of arachidonic acid, on aspirin-induced COX-2 selectivity but reduces potency. In kinetic analyses, understated differences exist in side-chain conformations, displacement of main-chain protein atoms, and kinetics of inhibitor binding. Different inhibitors use different sets of interactions to optimize their binding in the COX active site, which can afford the selectivity and potency of inhibition in vivo. The interactions of a variety of selective and nonselective inhibitors with COX-1 and COX-2 have been probed by a combination of crystallography, mutagenesis, and chemical modification. Although the macromolecular protein structure is essentially the same in all COX-inhibitor complexes, seemingly different interactions exist in side-chain conformations, displacement of main-chain protein atoms, and kinetics of inhibitor binding. Different inhibitors use different sets of interactions to optimize their binding in the COX active site, which can afford significant perturbations of selectivity and potency (4S). This situation gives rise to a striking variety of bound orientations that illustrate the impact of subtle interactions on ligand-protein association. Problems remain to be solved with this fascinating class of enzymes that should provide additional insights into the potency and selectivity of different classes of inhibitors. The challenge will be to use this information to create novel classes of inhibitors or to address the pharmacological deficiencies of extant inhibitors (e.g., gastrointestinal toxicity, cardiovascular toxicity, and renal toxicity).

Cyclooxygenase Inhibition: Recent Advances in the Mechanisms of

Forward Chemical Genetics

Young-Tae Chang, National University of Singapore and Singapore Bioimaging Consortium, A*STAR, Singapore
doi: 10.1002/9780470048672.wecb178

With the successful results of the Human Genome Project, we are now faced with the problem of handling numerous gene targets whose functions remain to be studied; this challenge is being undertaken by the field known as functional genomics. Chemical genetics is an emerging new paradigm to attack this challenging problem, of which there are two approaches: forward and reverse. Although reverse chemical genetics uses a "cause-to-effect" approach, forward chemical genetics uses an "effect-to-cause" approach. As opposed to conventional genetics where gene knock-outs or overexpression, forward chemical genetics uses a small-molecule library to produce a novel phenotype that eventually is employed in the elucidation of gene function. Compared with conventional genetics, chemical genetics holds several unique advantages. A successful forward genetic study provides not only knowledge about a novel gene's function, but also it provides a small molecule on/off switch that can regulate biologic processes. These small molecules will be extremely useful biologic probes as well as potential new drug candidates. Three main components make up forward chemical genetics: 1) chemical toolbox generation, 2) phenotypic screening, and 3) target identification. Although all three components require additional refinement, target identification poses the greatest challenge. Herein, the general concepts of chemical genetics, with a focus on the forward approach, and the technical overviews for each component are described.

Chemical genetics, in the simplest of terms, can be defined as a "genetics" study using "chemical" tools (1). Elucidating the function of every gene from the sequence data of tens of thousands of genes (so-called functional genomics) is the next major step for the human genome project. Geneticists conventionally have investigated the function of unknown genes by comparing the normal phenotype with that of knockouts, or through the overexpression of target genes. A novel approach using chemical library screening to find interesting phenotypic changes through the targeting of a specific gene product, a protein, has emerged as an alternative tactic—so-called chemical genetics. In chemical genetics, one chemical compound may specifically inhibit or activate one (or multiple) target proteins. Therefore, the compound is equivalent in conventional genetics to a gene knockout or to the overexpression of a gene. As in classic genetics, chemical genetics is divided into two approaches: forward and reverse.

Genetics and Chemical Genetics
Forward and reverse approach

Forward genetics (FG) operates "from effect to cause" or "phenotype (physically apparent characteristic) to genotype (genetic sequence)" and requires no specific gene target at the onset. It studies changes in phenotype(s) such as morphology, growth, or behavior resulting from random genomic DNA mutations or deletions induced from radioactive or chemical mutagenesis, and then it identifies the gene responsible through mutation mapping. Forward chemical genetics (FCG) mimics FG by substituting random mutagenesis with a collection of a library of typically unbiased (not targeted) compounds as protein function regulators in place of mutagens (2). The first step in both FG and FCG is to screen for changes induced by either the inhibition or the stimulation of a protein’s function, and both go on to identify the genetic cause but in different ways. FG goes after genetic mutation, which is a permanently retained marker, but FCG needs to identify the protein partner for the small molecule. This target identification is one of the greatest challenges in chemical genetics (3).

With the help of molecular biology techniques, reverse genetics (RG) was a later development in genetics and operates "from cause to effect" (genotype to phenotype) (4). Reverse genetics begins with selecting a gene of interest, manipulating it to produce an organism harboring the mutated gene, and characterizing the phenotypic differences between the mutant and the
lethality, thus providing a partial knockout phenotype (13). Allows the use of sublethal doses of the ligand and avoids full gene because the deletion may be lethal (12). Chemical genetics others intact (11). Additionally, if a gene is essential for survival and dissect particular functions of that protein while leaving multiple functions, and chemical genetics can potentially isolate the protein (10). It is always possible that one protein may have from those that develop from merely a particular function of protein entirely from the organism (9). Therefore, it is difficult to determine the effects that develop from the deletion separate from those that develop from merely a particular function of the protein (10). It is always possible that one protein may have multiple functions, and chemical genetics can potentially isolate and dissect particular functions of that protein while leaving others intact (11). Additionally, if a gene is essential for survival or development, a total knockout such as in classic genetics, may abolish the chance to study the later stage function of that gene because the deletion may be lethal (12). Chemical genetics allows the use of sublethal doses of the ligand and avoids full lethality, thus providing a partial knockout phenotype (13).

Advantages of forward chemical genetics

In FCG, the starting point is a selection of the protein of interest using previous information. The chemical libraries are mainly tested for only one selected protein target. This article is a more focused study of the known (most likely well-validated) target protein usually focused on improving on the chemical probes, which in a sense narrows down the scope of the work. In contrast, FCG studies whole cells or organisms, and thus, the compounds are screened against multiple potential targets simultaneously. A successful FCG will identify a novel gene product (target protein) and its on/off switch, the small-molecule complement. Therefore, FCG promises an efficient “two-birds-with-one-stone” approach. However, the unpredictable pharmacologically usable results have kept pharmaceutical companies from making a full commitment to FCG, leaving the field to be developed by the academic community thus far.

Compared with classic genetics, FCG offers several advantages and provides access to previously unstudied biologic space. Use of chemical tools offers greater ease and flexibility than does classic genetic modification. Classic genetic techniques are relatively difficult to employ especially in mammals because of their diploid genome, physical size, and slow reproduction rate. On the other hand, FCG studies may be conducted on any complex cellular or animal models without the need for any time-consuming genetic modifications that may prove lethal or in which the cell (animal) can mask the phenotype through related gene functional compensation for the mutation. Especially important is FCG’s promise in operating in the relevant context of human cells at physiologic conditions that has strained traditional genetics techniques. Therefore, FCG fills a major gap in genetic studies where no, or suboptimal, model systems exist. Additionally, chemical genetics also allows for the possibility of “multiple knockouts” by adding multiple specific ligands, which is a situation often described as a “nightmare” for the geneticist (8).

Second, classic genetic knockouts, in principle, delete the protein entirely from the organism (9). Therefore, it is difficult to determine the effects that develop from the deletion separate from those that develop from merely a particular function of the protein (10). It is always possible that one protein may have multiple functions, and chemical genetics can potentially isolate and dissect particular functions of that protein while leaving others intact (11). Additionally, if a gene is essential for survival or development, a total knockout such as in classic genetics, may abolish the chance to study the later stage function of that gene because the deletion may be lethal (12). Chemical genetics allows the use of sublethal doses of the ligand and avoids full lethality, thus providing a partial knockout phenotype (13).

Another advantage of chemical genetics is real-time control. Chemical genetics allows for this control by the ability to introduce rapidly a cell-permeable ligand at any stage that may yield the desired phenotype as quickly as diffusion-limited kinetics will allow. The chemical genetics inducer-protein effect is a “switch” that can turn the event under study ON or OFF in real-time and allows for kinetic in vivo analysis, which is something not usually possible in classic genetics. A temporal control is available in classic genetic studies through conditional alleles, such as temperature-sensitive mutations, they often have unwanted broad side-effects that may interfere with the desired result (4). The antisense oligonucleotide and RNA interference (RNAi) are other popular alternatives for conditional knockouts (10) that work by inhibiting the synthesis of the target protein from mRNA. However, as their effects are delayed until all existing proteins are degraded, they are particularly ill-suited to time-sensitive studies, such as signal transduction, that occur on the milliseconds-to-hours time scale.

Chemical genetics and classic genetics are techniques that compliment each other well (14). One of the greatest advantages of classic genetics is the incredible specificity of a gene knockout. Although some chemical ligands can be specific switches with specificity approaching that of a gene knockout’s, the low specificity of many ligands often give “off-target” effects in which the probe may interact with proteins other than the protein(s) targeted. This low specificity makes defining specific protein functions very difficult because these off-target effects may lead to toxicity or false or unwanted positive/negative biologic results. In addition to this lack of specificity, chemical genetics cannot yet match the generality of genetics. Geneticists can, in theory, “knockout” any gene as long as the genomic sequencing is completed in the desired species, which is an ability that at this point exists as nothing more than a dream for the chemical geneticist (8). These situations are the perfect place for the integration of chemical and classic genetics (15).

Importantly, unlike drug development where specificity is tantamount, in chemical genetics, ligands need not be completely specific, so long as they give an identifiable phenotype that allows for the deciphering of the target protein’s function and that its side effect are relatively small. Whereas one may desire compounds with affinity in the subnanomolar range capable of producing the desired effect, in reality, compounds of low micromolar affinities are often accepted as good-to-reasonable candidates in chemical genetics (3). Despite this issue, and with an understanding of the necessary medicinal chemistry follow-up modifications and studies required, chemical genetics still has the advantage of immediately offering a potential drug lead, rather than simply a target gene or protein, as in classic genetics. Interestingly, a lead compound developed in drug discovery that may not possess pharmacokinetic properties suitable for therapeutic purposes may still be used as a probe in chemical genetics studies (16). In fact, the lower pharmacokinetic property requirements for chemical genetics probes compared with drugs allows for the use of a greater variety of functional groups and for a maximization of the chemical space in library constituents (15).
Components of Forward Chemical Genetics

With the advent of combinatorial library techniques that facilitate the synthesis of a large number of molecules (Fig. 1a, in combination with the success of HTS [high-throughput screening]), a large number of compounds can be easily and rapidly screened to discover a novel small molecule (hit compound). Once the hit compound is selected in a cellular or organism system (Fig. 1b), the next step is to identify the target protein and the biochemical pathways involved. An on-bead affinity matrix or tagged molecule (photoaffinity, chemical affinity, biotin, or fluorescence), which is obtained through the modification of the lead compound (Fig. 1c), is commonly used in the identification of the target protein. The protein is identified by “fishing out” the target through the exploitation of the binding affinity of the proteins toward the immobilized molecule (Fig. 1d), followed by gel separation (Fig. 1e) and mass-spectrometry. Some small molecules and their target proteins identified FCG thus far are summarized in Table 1 (16–46). In summary, the forward chemical genetics procedure is composed of 1) preparation of chemical toolboxes, 2) phenotypic screening, and 3) target identification and validation.

Chemical toolboxes

Collections of compounds, so-called libraries, are the absolute starting point for any chemical genetics study. These library compounds can be either natural products or synthetic compounds with various designs.

Natural products

Natural products have evolved alongside the various life forms on earth. Each surviving natural product may have its own reason for existence in the context of biologic function, so-called, biologically validated. That is why many natural products have been used for medicinal purposes for so long. For example, colchicine has been used as a drug for over 2000 years. Therefore, it is generally accepted that collections of natural products have a higher probability of delivering pharmacologically useful compounds than a typical synthetic combinatorial library, (9, 47). Natural products are obtained from sources such as plants, soils, and marine sponges. The most difficult in natural product discovery is isolating any active components out of the whole mixture extract. The typical and time-consuming isolation route is known as bioassay-guided purification. The purification procedure involves iterative processes in which compounds undergo multiple rounds of extraction/chromatography guided by the screening results of the successive crude extracts. These studies are hampered by overlooking potentially highly active low-abundance compounds, the cytotoxicity of one component masking the desired effect of another component, and bioactivity resulting from complicated synergistic effects (2, 48). In addition, determining the structure of the compound is another laborious and challenging task. Over the past decade and a half, these drawbacks led to a retreat from natural products by most pharmaceutical companies. However, the disappointment in the number of drugs originating from combinatorial chemistry and the continued benefits of natural products are luring many companies back to them. Currently, major pharmaceutical companies are re-embracing natural products and natural product-like libraries. Natural products need not have their use restricted to therapeutics, but they can be of great value to chemical genetics studies. Extremely exciting is the integration of traditional natural products and their scaffolds with modern combinatorial and HTS tools. Perhaps success will lie in a balance of the old and the new.

Natural product-like compounds

Natural product-like libraries offer a highly desirable middle ground between those who seek powerfully bioactive compounds from natural libraries and those who seek the ease of synthesis found in libraries composed of small organic molecules. Natural products are typically chiral, are extremely complex, and contain many stereogenic centers. These structures are often highly potent and serve as attractive leads for drug development (49). Natural products can be considered privileged structures in a biologic context and an excellent starting point for library design with a high probability for biologic activity. These compounds often contain sets of related and homologous pharmacophoric groups throughout families of natural compounds (50). Natural product-like libraries are those collections of compounds whose structures are based on or share high structural homology with natural products. These libraries may be designed to generate derivatives of a natural product scaffold. In addition, some have sought to generate natural product-like libraries not to improve on known activity but to expand a molecule’s functionality into a previously unknown area of biologic space (51). The synthesis of natural product-like libraries,

Diversity-oriented synthesis

After the combinatorial boom of the 1990s, a well-documented disappointment in the number of quality leads has set in (52). The compounds coming out of early combinatorial libraries simply did not perform up to the designer’s expectations. Guidelines such as Lipinski’s rules are helpful for generating more drug-like small molecules, but it has been argued that compounds from solid-phase organic synthesis may not be chemically diverse enough to generate the desired selectivity and potency (53).

Diversity-oriented synthesis (DOS) is a new term for a method of library construction in chemical genetics. Advocates of the DOS approach point to the archetypical case of a flat aromatic or heterocyclic core dotted with various diverse appendages that have largely failed to deliver the promised drugs. The discrepancy between the success of natural products and the traditional combinatorial libraries’ as yet disappointing rate of lead generation has forced the question of whether natural products occupy regions of chemical space evolutionarily fine-tuned to be the most potent and active compounds (54). Thus, one of the stated goals of DOS is to create extremely diverse libraries populating the maximum amount of chemical space in order to explore the greatest amount of biologic space.

DOS draws its name from its contrast to the traditionally used approach of target-oriented synthesis (TOS). Beginning with a known target (often natural product), TOS uses retrosynthetic analysis to work backward from a complicated product to simple and available starting materials. The goal of TOS is to get to a precise region of chemical space—a single target or a few closely related derivatives. Retrosynthetic analysis is not applicable to DOS because no target structure is available, and thus, the library cannot be targeted. Therefore, new thinking and planning strategies are required, and the idea of forward synthetic analysis has been proposed, which moves in the direction of simple to complex, or reactants to products, in contrast to TOS. DOS strategies focus on maximizing diversity by using branched and divergent pathways where the products of one reaction are common substrates for the next and where any follow-up chemistry must be efficient and systematic (55, 56). Molecules that occupy a greater degree of 3-D space, or those that are more globular/spherical, are a popular goal of DOS, as opposed to the relatively flat or circular molecules traditionally used in combinatorial chemistry (54).

Tagged libraries

Tagged libraries represent unique opportunities in library design (57). In this approach, libraries may be synthesized by any means and designed around any type of scaffold, but they must contain some functional tags integrated into the library. These tags are incorporated into the library compounds from the beginning, and they bestow some additional function into the molecules. The most common example of a tag is a fluorophore, but many more variations exist that allow the compounds to have functions extending beyond their biologic activity that may aid in areas such as target identification or ligand assembly. Peptide nucleic acids (PNAs) are oligonucleotide-like molecules that have their DNA backbone removed and reattached with an achiral polyamide backbone that can hybridize with DNA through strand displacement (58). PNA tags have been used in the development of tagged libraries that allow for the spatially addressable localization and identification of probes on a DNA microarray.

Click chemistry offers unique tags that can be used to generate library members through strategies such as target-guided ligand assembly. Sharpless developed click chemistry as a rapid reaction that proceeds in a short amount of time through “spring-loaded” highly exothermic, irreversible reactions to form carbon–hetero bonds (59). One of the most common bonds is a (2 + 3) Huisgen 1,3-dipolar cycloaddition between an azide and an alkyn moiety, which is described as an energetically “near-perfect” reaction. Click chemistry’s main advantage is the swift and clean nature of these reactions that can greatly assist library synthesis and lead discovery. Click chemistry–based tags have also been incorporated into studies of activity-based protein profiling (ABPP) (60). ABPP is a chemical genetic method that uses probes to monitor and visualize changes in protein functions/levels in the cell, especially changes that occur on a posttranslational level. In a traditional ABPP study, the probe carries a tag/reporter, such as biotin or fluorescence, whose size and physical properties may adversely affect probe-target interaction, cellular uptake, and probe distribution. In the click chemistry–based approach, the probe is functionalized with a tag bearing a simple azide moiety, which prevents much less of a disturbance in the system. After screening and binding to the protein target, an acetylene bearing reporter is added, and this facilitates the conversion of a hit compound to affinity matrix without the need for a time-consuming structure-activity relationships (SAR) study (44). The tagged strategy is applicable to any type of library scaffold and allows for rapid transfer from biologic screening to target identification.

Instead of tags being external to the active portion of the molecule, internally tagged fluorescent compound libraries were also demonstrated in a chemical genetic study. In many cases, the addition of an exogenous reporter or tag can alter the effect or cellular distribution of the original molecule. Tagging the molecule intrinsically avoids this problem. In this strategy, the probes being studied are all intrinsically fluorescent through their known fluorescent scaffold, and no additional tagging is required to visualize cellular localization (61) or to visualize a bound protein (62).

Dynamic combinatorial libraries

Traditional combinatorial libraries are synthesized primarily by parallel or split-pool techniques as static pools of discrete
molecules. Although using compound mixtures fell out of favor in combinatorial chemistry, they found renewed use in supramolecular chemistry in the form of dynamic combinatorial chemistry (DCL). The dynamism of DCLs results from the reversible interchangeability possible with their components. In these systems, every member of the library and the targets themselves affect all other members of the library, particularly in terms of library composition (63). Any stabilization of one member will result in an equilibrium shift and thermodynamic redistribution, by LeChatelier’s principle, of the library mixture favoring the best binder. Advantageously, library construction and screening can be combined in one step, because amplification of the best binder can be analytically detected. Therefore, the use of DCLs is as much an application of HTS as is library development. Whereas traditional combinatorial libraries rely on their sheer numbers, DCLs offer an alternative approach through self-replication and amplification.

The use of dynamic combinatorial libraries requires three steps: 1) the collection/design of a library capable of undergoing reversible constituent interchange, 2) conditions whereby the library may undergo interconversion, and 3) a step that selects the “fittest” binder and possibly involves its amplification. When a template or ligand is used to amplify the concentration of a member of the library, called “survival of the fittest,” the Darwinian implications of this often lead to it being referred to as “molecular evolution.” In a molecular evolution system, the fittest binder is amplified with each successive round of screening, whereas the poor binders’ concentration will either be unaffected or decrease. Although widely applied for many other purposes, DCLs have also been used to identify protein ligands, which make them a promising tool in chemical genetics library development.

Annotated chemical libraries

Generally, an assay is required to design followed by extensive screening. Truly daunting is the follow-up work to identify a hit compound’s mechanistic mode of action or target protein. An alternative approach to designing and building large collections of compounds of which no known biologic activity information exists is the use of an annotated chemical library (ACL). An ACL is a collection of compounds of diverse structure from various sources possessing experimentally bona fide biologic activities and mechanisms. An ACL contains compounds with diverse sets of biologic activity, whereas a typical library would even in a best-case scenario be composed of just a fraction of a percent of active compounds. One need not synthesize even a single compound to generate an ACL; one merely needs to identify, collect, and annotate. ACLs operate by assigning previously reported biologic activity to each compound without any required regard for the pathway or phenotype under study.

Phenotypic screening

Once libraries of compounds are assembled, the next step in chemical genetics is evaluating them for their biologic activity (i.e., assay or screening). Although virtually any kind of organisms can be used for phenotypic screenings in FCG, the most popular model systems have been Saccharomyces cerevisiae (budding yeast), Arabidopsis (plant), zebrafish embryo, drosophila (fruit fly), Caenorhabditis elegans (worm), and various mammalian cell cultures.

A stays must be designed with maximum sensitivity, selectivity, reproducibility, and cost-effectiveness in mind (64). Given the size of today’s libraries, the option of doing anything other than HTS is something less than desirable. Screening technologies have progressed in miniaturized steps from high-throughput (384 well plates) to ultra-high-throughput (3456 well plates) screening (u-HTS), and their limits have not yet been reached. However, although screening methods have matched the enormity of many libraries, the screens must be reliable and reproducible, and the data must also be manageable. Not only have the number of assays increased, but assays have increased in the dimensionality of the data produced, so-called “high-content screening.” Therefore, a significant challenge in HTS, and especially in u-HTS, is the development of tools that allow for data management and analysis in chemical genetics.

Yeast

Budding yeast (S. cerevisiae) is a robust and powerful tool in chemical genetics. Three significant advantages of yeast as a model organism in understanding cellular responses to chemical perturbation include its ease of growth, high genetic conservation with humans, and the size of the collection, up to 6000 genes, which makes their use a very high-throughput screen.

Plants

Plants offer an attractive platform for phenotypic screening in chemical genetics: 1) All known plant growth regulators are small molecules, the experimental protocols for analyzing plant growth regulators are well defined and can be easily adapted to unbiased chemical genetic screens; 2) the genomes of the most common systems are already sequenced and annotated, and the activities and mechanisms. An ACL contains compounds with diverse sets of biologic activity, whereas a typical library would even in a best-case scenario be composed of just a fraction of a percent of active compounds. One need not synthesize even a single compound to generate an ACL; one merely needs to identify, collect, and annotate. ACLs operate by assigning previously reported biologic activity to each compound without any required regard for the pathway or phenotype under study.

Zebrafish

Zebrafish (Danio rerio) have become a promising whole-organism screening method in chemical genetics for many of the same reasons they are popularly used in developmental biology and genetics. Whole-organism screening is preferred in some cases over target-based screening because it allows for a more unbiased discovery in a relevant physiologic context. However, although mammals provide an excellent relevant screening context, their use is expensive, requires a great deal of space, large quantities of compounds, strict regulations, is laborious, and often raises ethical questions. Because of these limitations in mammals, systems such as zebrafish have been popularized as a result of the many advantages they present. First, zebrafish, unlike other systems such as yeast or round worms, are vertebrates with discrete organs such as the brain, sensory organs, heart, muscles, and bones. These organ systems are very close to their human counterparts, in terms of their high level of structure, and this aids in their suitability for chemical genetics and drug discovery. Additionally, zebrafish are small enough in their
early embryonic stages to live in a well of a microtiter plate. They are also prolific reproducers, which allows for the screening of large libraries. Lastly, zebrafish embryos are a desirable model because of their complete transparency that allows for the multiple observations of dynamic processes in every organ and structure without the need for dissection or for sacrificing the animal.

**Drosophila**

Drosophila has been used by geneticists in many studies. Their short life cycle and low cost make them a desirable animal model. Although they bear less genes than humans, cases exist of one Drosophila gene representing several human genes, and this kind of feature makes it a popular model system for studying human disease pathways. Additionally, Drosophila is an excellent compliment to *C. elegans* RNAi studies in which some knockouts are unavailable, such as genes expressed in the nervous system.

**C. elegans**

*C. elegans* has had little use by researchers in chemical genetics thus far, but it is of growing use in drug discovery and is poised to make a large contribution. It is merely a matter of time until it becomes a widespread tool in chemical genetics. *C. elegans* was the first multicellular organism to have its genome completely sequenced. The knowledge and the experience that comes with it will prove invaluable in future *C. elegans* applications in chemical genetics. The worm is small and transparent, which allows for full visualization of its developmental processes and contains complex structures such as a digestive tract, nervous system, and muscles. Additionally, it has a short life cycle and produces many progeny, which makes it more compatible with high-throughput screening. An advantage, RNAi screens were first used and developed in *C. elegans* and the large amount of experience in this field will greatly aid multipronged chemical genetic approaches, particularly target identification.

**Target identification and validation**

Target identification is an integral part of chemical genetics studies and is its most rate-limiting and challenging step (57). Much of the difficulty originates from the weakly binding compounds often identified in FCG screening. The possibility of success in target identification greatly increases with increasing binding affinity. Whereas nM or pM binding constants will make target identification much easier, mid-µM results are much more common. Some simple approaches exist such as "the guess and test" where one hypothesizes a target and performs in vitro tests to validate it, or "guilt by association" identification where targets are implied or hinted at through studies such as mRNA transcription profiling (12). However, as in most FCG, without a clue toward the identity of the target protein, an ab initio target identification technique is required.

**Affinity matrix**

The most commonly used tool in target identification is the pull-down experiment, which is also known as the classic "fishing experiment" using an affinity matrix. This procedure typically involves the attachment of the "hit" molecule to a solid-phase resin such as agarose beads. The solid-linked material is then exposed to a cell extract. This process is commonly performed by passing the extract over a column of the immobilized material.

Although commonly used, affinity experiments are beset with drawbacks. First, the compounds need to be derivatized to include a handle for attachment to the resin, unless they intrinsically bear some functional tag that allows for it. The so-called tether effect can alter the activity of the compound, and tedious structure-activity relationships (SAR) studies are required to optimize the attachment point. As a solution, this SAR work could be avoided by introducing the intrinsic linker tag strategy (57). Two other requirements are needed for any hope of success in affinity matrix experiments: 1) high-affinity ligands and 2) high abundance of target. The end result of the affinity matrix relies on the multiplication of affinity and on the abundance. Also, during the cell extract preparation, a serious dilution occurs, at least 100 times. It is totally possible that the target protein exists in a complex with other protein(s) in intact cells, but it may be segregated into a monomer in the cell extract, and thus, it no longer binds to the small molecule. Therefore, a new technique, which can be performed in vivo without breaking the cellular integrity, is highly desirable.

**Photoaffinity**

Another interesting alternative is photoaffinity labeling, which involves attaching a photoaffinity moiety and a reporter tag. Although this method does require significant SAR knowledge, it does not require immobilization of the compound on solid support (3). Photoaffinity simply uses a photo-activated cross-linking group that forms a covalent bond during irradiation and a reporter, such as a radioactive isotope or biotin, that allows for isolation or ease of identification. Libraries have been designed bearing photoaffinity groups to exploit this approach.

**Tag for mass spectrometry**

Labeling proteins with "heavy" and "light" tags and screening the "hit" compound versus an inactive control, followed by mass spectrometric comparison of the two samples, is another approach that avoids many of the common pitfalls in affinity methods (3). Techniques such as stable isotope labeling with amino acids in cell culture and isotope-coded affinity tagging (ICAT) exemplify these techniques.

**Yeast three-hybrid system**

Genetic approaches also exist to tackle this problem. A promising approach is the yeast three-hybrid system (37). This work evolved from yeast two-hybrid screens and has grown in use (65). Three components are required for these studies: 1) a protein containing a DNA binding domain fused to a small molecule with a ligand binding domain, 2) a protein with a transcriptional activation domain fused to another ligand binding domain, and 3) a bivalent small molecule. The bivalent small molecule is composed of a known ligand with an affinity for the protein containing the DNA binding domain, a probe portion of the molecule that is being tested for novel protein binding, and a
linker connecting the two faces of the bivalent small molecule. Should the probe portion of the small molecule bind to the protein bearing the transcriptional activation domain, that protein is brought into a proximal relationship with the DNA and allows for the activation of the downstream reporter gene, which thus indicates successful target identification (66). The advantages of the Y3H system are that the identification of ligand binding proteins is linked to the selection of the cDNAs that encode the proteins, that phenotype and genotype are closely linked, and that these systems are explored in vivo. However, one drawback of this approach is that it is limited to simple, unicellular organisms, but work is underway to overcome this hurdle (3).

Drug western
In this approach, tagged small molecules are used to probe electrophoretically resolved cell extracts or cDNA expression libraries. Drug westerns involve bacteriophages infecting bacteria grown in a Petri dish with a cDNA library. Lysis caused by a viral infection leads to a clearing, called a plaque, containing a single member of the library. The proteins in the plaque are transferred to nitrocellulose where they are screened with tagged small molecules. Any hit plaques are isolated, a single protein–(GFP)–fused protein library was expressed in mammalian cells. When mixed together, the target proteins bind to the nanoparticle. An exogenously applied magnetic field assembles the GFP fused proteins whereby the signal can be visualized in vivo using a magnetic field assemblage (67).

Protein microarray
Protein microarrays are derived from and are complimentary to DNA microarrays. Here, collections of proteins are immobilized on a microarray surface and are probed for specific binding with tagged small molecules or by comparing the profiles of healthy versus diseased tissues (68). Although a very direct approach, protein microarrays suffer from the lack of large numbers of purified and stable proteins available for immobilization on the microarray surface. Although they have found great utility in proteinomics, their development has been slow because of several technical challenges.

Magnetism-based interaction capture (MAGIC)
A unique in vivo target identification method in mammalian cells has been reported recently. The Hit compound was attached covalently to magnetic nanoparticles and a green fluorescent protein–(GFP)–fused protein library was expressed in mammalian cells. When mixed together, the target proteins bind to the nanoparticle. An exogenously applied magnetic field assembles the GFP fused proteins whereby the signal can be visualized (69). Although a chemical modification of the Hit compounds is still required, this is the only technique reported so far to visualize a small-molecule–target-protein interaction in mammalian cells.

Display cloning
A phage display-based direct cloning of cellular protein has been demonstrated as a possible technique for target identification (70). The surface protein library was constructed using human brain cDNA, and a biotinylated FK506 probe molecule was used as a chemical bait. During the affinity selection, the FK.BP12 (FK506-binding protein) gene emerged as the dominant library member and was the only sequence identified after the second round of selection. Although the approach has been demonstrated successfully by isolating a full-length gene clone of FK.BP12, its broad application potential to novel target identification remains to be explored.

Metallointercalators as Probes of DNA Recognition and Reactions

Katherine E. Augustyn, Valerie C. Pierre and Jacqueline K. Barton, California Institute of Technology, Pasadena, California
doi: 10.1002/9780470048672.wecb328

Here we describe studies of metallointercalators bound to DNA. These octahedral transition metal complexes primarily bind noncovalently by stacking within the DNA helix. Given the rich photophysics and photochemistry of the ruthenium and rhodium complexes we employ, we have used a variety of biophysical studies to characterize their interactions with DNA. X-ray crystallography has also provided atomic resolution detail as to their binding to the duplex. Complexes have been designed that target DNA with high specificity. We have, for example, designed metal complexes that bind specifically to mismatched sites in the DNA duplex, and these have found application in the detection of single nucleotide polymorphisms and studies of mismatch repair deficiency. The photophysical properties of the metal complexes along with their intercalative stacking have been useful in particular as tools to characterize long-range charge transport in DNA. Using metallointercalators tethered to the duplex, oxidative damage to DNA from a distance has been demonstrated. The metallointercalators may serve as models for DNA-binding proteins, not only in binding DNA sites with high specificity, but also in carrying out electron transfer chemistry mediated by the DNA base-pair stack. Certainly these metallointercalators have proven to be powerful probes of this chemistry.

Our laboratory has focused on studies of metallointercalators that bind to duplex DNA through an ensemble of noncovalent interactions. Here we describe some of our studies with these complexes, including experimental design and applications. We focus attention in particular on the utility of these complexes in probing DNA-mediated charge transport chemistry. Our review here is not intended to be exhaustive but instead is focused on some examples of work from our laboratory to illustrate the effectiveness of these complexes in probing recognition and reactions with DNA (see Reference 1 for additional references). Indeed these complexes in several respects can be regarded as small mimics of DNA-binding proteins, but ones where their photophysics and photochemistry, as well as their inherent stability, allow us to sensitively probe their chemistry with DNA.

Investigations of the interactions of metallointercalators with DNA must start with a range of photophysical, nuclear magnetic resonance (NMR), and crystallographic studies. The complexes that we use are all substitutionally inert so that no direct coordination with the DNA bases occurs. The primary interaction involves intercalation of one ligand into the DNA base stack from the major groove. There is a concomitant doubling of the base-pair rise, from 3.4 Å to 6.8 Å, and the base pairs separate to accept the intercalating ligand. In the stack, the intercalator seems like a new base pair (2). A bulky metallointercalator that is not so easily accommodated in this stacked structure binds through an alternative means, where the sterically demanding ligand inserts instead from the minor groove side at a thermodynamically destabilized mismatch site, with ejection of mispaired bases. In this case, the stacked ligand replaces a base pair. Both with intercalation at B-DNA sites and insertion at mismatched DNA sites, chiral discrimination in binding of the octahedral complexes is evident; that is, there is a necessity sterically to match the chirality of the metal complex to that of the double helix (Fig. 1). Indeed, the $\Delta$ enantiomer favors interaction with right-handed B-DNA, whereas the $\Lambda$ enantiomer preferentially binds left-handed Z-DNA. These enantiomeric preferences...

Figure 1 Examples of chiral metallointercalators that bind DNA with little site selectivity (above) and with high specificity for the targeted sites shown (below). In the center is shown schematically the basis for enantiomeric discrimination in stacking in the right-handed DNA helix. For the $\Delta$-isomer, the ancillary ligands have a right-handed orientation in the DNA groove, whereas for the left-handed $\Lambda$-isomer, steric clashes between the ancillary ligands and phosphate backbone can develop.

control further the reactions of complexes on the DNA helix. DNA-mediated charge transport involving $\Delta$-isomers similarly is more efficient than with left-handed complexes that are not as well coupled electronically into the right-handed double helix.

Metallointercalator/DNA Interactions and Site-Specific Targeting

Early photophysical and photochemical studies

Major groove intercalators bind DNA with high affinity ($K_a > 10^6 \text{ M}^{-1}$) and, in some cases, high sequence specificity. Indeed, an extended aromatic system on the ligand outward from the metal center, as in the case of the phi (9,10-phenanthroquinone dimer) or dppz (dipyridyl[3,2-a:2',3'-c]phenazine) ligands, favors its intercalative stacking between the base pairs of the double helix. The intercalating ligand of these complexes thus behaves as a stable anchor in the major groove, oriented parallel to the base pairs, and directing the orientation of functionalized ancillary ligands with respect to the DNA duplex. Photophysical studies first provided support for intercalation (4). Extensive NMR studies and a crystal structure detailed the nature of the intercalation for the metal complexes via the major groove of the DNA (2). Interestingly, although not all of these complexes are sequence specific, they still demonstrate chiral discrimination: The $\Delta$ enantiomer interacts preferentially with right-handed B-DNA through stacking within the DNA duplex.
Importantly, these complexes possess rich photochemical and photophysical characteristics that have been exploited advanta-
giously both to probe interactions with DNA and to understand
further aspects of DNA chemistry. A well-studied example is
[Ru(bpy)(dppz)]²⁺, which has found many uses as a molecular
light switch (5). The Ru complex shows solvatochromic lumini-
scence in organic solutions. In aqueous solution, however, it
does not luminesce because of the ability of water to deactivate
the excited state through hydrogen bonding with the phenazine
nitrogen atoms of the intercalating ligands. Upon intercalation
in DNA in aqueous solution, it is brightly luminescent, reflect-
ing the shielding of the intercalating ligand from bulk solvent.
This is akin to introducing the complex into a local organic sol-
vent that shields the ring nitrogens on the intercalating ligand
from protonation.

If ruthenium complexes have shown uses as molecular light
switches, rhodium analogs have been proven to be efficient
agents for photoactivated DNA strand cleavage (6). This re-
activity enables us to mark directly the site where the metal
complex intercalates in the double helix and thus character-
izes the recognition properties of the complex. The observed
reactivity upon excitation at short wavelengths (313-325 nm)
leads to radical formation on the intercalating ligand with sub-
sequent hydrogen atom abstraction from the adjacent deoxyri-
bosine ring. Degradation of the sugar radical then leads to direct
DNA strand cleavage. In the absence of oxygen, photolysis of
[Rh(DPB)(phi)]³⁺ bound to DNA results in the formation of 3′
phosphate and 5′ phosphate termini, as well as free bases. In the presence of oxygen, different products re-
sult: Direct strand cleavage is observed, but products include,
together with the 5′ phosphate termini, base propanoic acid,
and a 3′ phosphoglycaldehyde end. These results are consistent with
the previously described radical chemistry at the C3
position. However, because both the crystal and the NMR structure of the
major groove intercalator revealed that the C2′H of the sugar
is closer to the intercalating ligand than the C3′H, we propose
that initial reaction of the photo-exicted intercalator occurs with
the C2′H abstraction followed by H-migration to form the C3′
radical and subsequent degradation of the sugar ring (2).

Although rhodium intercalators efficiently cleave DNA upon
photoactivation, DNA cleaving agents that do not require pho-
toactivation have the advantage of being more convenient to
use in many research laboratories. Bisfunctional agents have
thus been developed in which metal coordinating peptides were
covaletly tethered to a metallointercalator (7). In these bi-
functional conjugates, [Rh(phi)bpy]³⁺ behaves as a targeting
vector that delivers the metal ions to the sugar phosphate back-
bone. The Zn(II) and Cu(II) centers of the metallopeptide, once
delivered, promote DNA strand cleavage.

In a similar approach, luminescent DNA cross-linking probes
were designed by conjugating short peptides to ruthenium in-
tercalators (8). In this case, [Ru(phen)(bpy)(dppz)]²⁺ delivers
the peptide to the oligonucleotide and oxidizes it upon irradi-
ation in the presence of an oxidative quencher. This then enables
the nearby tethered peptide to cross-link with the oxidized sites
of the DNA. A delivery of the peptide by the metal-
lointercalator is not essential for cross-linking, this technique
advantageously yields cross-linking adducts that are lumines-
cent and are thus easily detectable. Furthermore, these cross-links
may resemble those found in vivo under conditions of oxidative
stress.

**DNA recognition based on shape and functionalities**

One of the earlier and important findings with the metalloin-
tercalators is the importance of matching the chirality of the
metal complex with that of the double helix. The discrimi-
nation basically depends on the size of the ancillary ligands
relative to that of the DNA groove. Although some selectivity
is observed for intercalation into B-DNA with metal complexes
containing phenanthroline or bipyridine as ancillary ligands,
the most striking stereospecificity is observed with metal complexes
with bulky ancillary ligands such as [Rh(DPB)(phi)]³⁺ (9). The
enantiotopic rigidity of the rhodium complex selects one peri-
cleaves the sequence 5′-CTCTAGAG-3′ upon photoactivation.
However, no intercalation and cleavage is observed with the \(\lambda\)
enantiomer even with 1000-fold excess of metal complex.

The remarkable specificity of \(\Delta-\text{[Rh(DPB)(phi)]³⁺}\) enables
the efficient inhibition of the restriction endonuclease XbaI.
Notably, no comparable inhibition of XbaI is achieved with other metallointercalators and \(\Delta-\text{[Rh(DPB)(phi)]³⁺}\) also does not
inhibit restriction enzymes that bind to alternative se-
quences. Thus, this coordination complex effectively mimics
a DNA-binding protein.

Sequence-selective metallointercalators were also designed
de novo by matching the functionality of the ancillary lig-
ads positioned in the major groove with that of the targeted
base pairs. Targeting of 5′-CG-3′, for instance, is achieved
with the complexes [Rh(NH₃)₄(phi)]³⁺, [Rh[(R,R)-Me₂trien](phi)]³⁺, and
\(\Delta-\text{[Rh(en)(phi)]³⁺}\) through hydrogen bonding between the ax-
ial amines of the metallointercalators and O6 of guanine (11).
The predictive design of sequence-specific metallointercalators
was expanded with \(\Delta-\alpha-\text{[Rh}(\text{R, R})-\text{Me}_{2}\text{trien})(phi)]³⁺\), which is a complex that directly reads out the sequence 5′-TGCA-3′
(Fig. 2). The targeting of this site was based on predicted
hydrogen bonding contacts between the axial amine and the
O6 of guanine, as well as of the methyl groups on the metal complex and the methyl
groups on the flanking thymines. A high-resolution NMR so-
lution structure followed by the first high-resolution crystal
structure of a metallointercalator bound to DNA later revealed
atomic resolution detail of the interaction 3. As predicted, this
DNA unwinds to enable complete and deep intercalation of the
phi ligand of the metal complex, which intercalates through the
major groove, thereby causing a doubling of the rise in the in-
tercalation site. The metallointercalator thus behaves as a newly
inserted base pair, which the DNA accommodates with minimal
structural perturbation.

Metal-intercalators have also been designed to target specific
sequences based on their shape and on their functionalities.
A derivative of [Rh(phen)(phi)]³⁺, called 1-[Rh(MGP)(phi)]³⁺,
contains pendant guanidinium groups on the ancillary phan-
ethroline ligands, and it was designed to bind a subset of

WILEY ENCYCLOPEDIA OF CHEMICAL BIOLOGY © 2008, John Wiley & Sons, Inc.
sequences recognized by the former. As predicted, the \( \Delta \) enantiomer recognizes the sequence 5'CATATG-3' specifically. Surprisingly, however, the \( \Delta \) enantiomer does bind DNA and recognizes the sequence 5'-CATATG-3' despite the large steric size of the ancillary ligands (11). Plasmid unwinding assays and NMR studies established that the \( \Delta \) enantiomer of the metallointercalator binds DNA by unwinding it up to 70\( ^\circ \). It is in this conformation that the complex can span the entire six base-pair binding site and contact the N7 position of the flanking guanines with the pendant guanidinium groups. Replacing these flanking guanines with deazaguanine demonstrated that the absence of the N7 nitrogen removed selectivity for the site. It is therefore the guanidinium functionalities of the ancillary ligands that are responsible for the recognition of the guanine, whereas it is the shape of the metallointercalator that enables the recognition of the "twistable" central 5'-ATATG-3' sequence.

This peculiar binding of a bulky \( \Delta \) enantiomer and unwinding of the DNA has found biological application in inhibiting transcription factor binding to DNA. 5'-\( [\text{Rh}[(R,R)\text{Me}_2\text{trien}]\phi]_3 \)-1 has been used to site specifically inhibit a transcription factor from binding to a modified activator recognition region (12). In competition experiments with yeast Activator Protein 1 (yAP-1), the metal complex was able to compete with the protein at concentrations as low as 120 nM. This work illustrates the potential applicability of the complexes as therapeutic agents, in inhibiting transcription factors sequence-specifically.

Detection of mismatched DNA sites

In contrast to the sequence specificity of major groove metallointercalators that is achieved through interactions of the ancillary ligands, the site-specificity for mismatched DNA is conferred by the intercalating ligand. DNA mismatch detection requires an extended or bulky intercalating ligand too wide to intercalate readily in well-matched B-DNA. The chrysene quinone diimine (chrysi) ligand of [\( \text{Rh}[(\text{bpy})_2\text{chrysi}]_3 \)]\( ^{1+} \) is 0.2\( \AA \) wider than the span of matched DNA and 2.1\( \AA \) wider than the intercalating phi ligand (Fig. 3). The resulting rhodium complex recognizes and cleaves upon photoactivation over 80% of mismatch sites in all possible single base-pair sequence contexts around the mispaired bases (15). The extremely high selectivity of [\( \text{Rh}[(\text{bpy})_2\text{chrysi}]_3 \)]\( ^{1+} \) for thermodynamically destabilized sites was demonstrated through the ability of the metallointercalator to recognize and photocleave a single mismatch within a 2725 base-pair plasmid (16).

The bulky rhodium complex binds single base mismatches with binding affinities of 0.3-20 \( \times \) 10\(^{5}\) M\(^{-1}\) as determined by quantitative photocleavage titrations. Importantly, the mismatch-specific binding affinities directly correlate with independent measurements of thermodynamic destabilization of the single base mismatch, thereby supporting the hypothesis that helix destabilization is a crucial factor in determining the binding affinity of the metal complex for the mismatched site (15). This hypothesis was recently confirmed by NMR studies and the crystal structure of the bulky metallointercalator bound to its target single base mismatch (14). Significantly, in contrast to phi complexes, \( \Delta [\text{Rh}[(\text{bpy})_2\text{chrysi}]_3 \)]\( ^{1+} \) inserts into the DNA stack via the minor groove and ejects both mismatched bases out of the double helix; the bulky chrysi ligand thus replaces a destabilized base pair. Nonetheless, the metallointercalator only minimally distorts the DNA, which accommodates insertion of the extended intercalating ligand simply by opening its phosphate backbone. Furthermore, as opposed to major groove intercalation, where DNA strand cleavage involves abstraction of the C2'H of the deoxyribose ring, \( \Delta [\text{Rh}[(\text{bpy})_2\text{chrysi}]_3 \)]\( ^{1+} \) preferentially abstracts the closer C1'H of the sugar adjacent to the mismatched site, resulting in different cleavage products (17).

Similar selectivity for thermodynamically destabilized sites in DNA is achieved with the use of other extended intercalating ligands. An analog of the chrysi complex, [\( \text{Rh}[(\text{bpy})_2\phi]_3 \)]\( ^{1+} \), also targets with high selectivity single base mismatches and promotes direct DNA strand scission upon photoactivation (18). The phi complex binds its target with higher affinity than...
Metallointercalators as Probes of DNA Recognition and Reactions

Figure 3 Monofunctional (top) and bifunctional (bottom) bulky metallointercalators that target single base mismatches in DNA. In the center is shown a view of the crystal structure of the complex inserted into the DNA from the minor groove at the mismatched DNA site, with ejection of the mismatched bases (14).

does the chrysi analog; site-specific photocleavage is evident even at nanomolar concentrations. This increase in affinity is attributed to greater stability in the stacking of the heterocyclic intercalating ligand with the flanking base pairs upon insertion. Notably, the increased affinity is not detrimental to the high selectivity of the metal complex, which binds mispaired versus well-paired sites in the same ratio as [Rh(bpy)2chrysi]3+. Metallointercalators that selectively and efficiently target single base mismatches have found several applications both as biologic probes and as potential chemotherapeutic agents. For instance, [Rh(bpy)2phzi]3+ was used to probe the relative frequency of mismatched sites in cell lines deficient versus proficient in their mismatch repair machinery (18). The relative cleavage observed with the phzi complex in healthy cell lines was low compared with that in cancer cell lines that carried mutations in essential repair proteins. These results support previous studies on the association of mismatch repair deficiency and cancer.

We have also investigated the design of fluorescent probes for mismatched DNA. The luminescent ruthenium complex, [Ru(bpy)2(tactp)]2+, containing a bulky intercalating ligand that is analogous to the dppz ligand of the popular molecular light switch was prepared and showed luminescence enhancement with mismatched DNA (19). A more efficient fluorescent probe for mismatched DNA was later accomplished by tethering a charged fluorophore to the bulky metallointercalator (20). In the Rhodium–Oregon Green conjugate, ion pairing between the cationic rhodium and the anionic fluorophore moieties dramatically quenches the fluorescence of the conjugate in aqueous solution and in the presence of matched DNA. However, with mismatched DNA, the bulky rhodium complex binds the DNA polyanion, and the resulting electrostatic repulsion with the anionic Oregon Green fluorophore drives the latter away from the rhodium center so as to reduce intramolecular quenching. The fluorescence of the conjugate is thus increased over 300% upon binding to a mismatch site.

Mismatch targeting metallointercalators have also been applied to the discovery of single nucleotide polymorphisms (SNPs). SNPs are the largest source of genetic variation in humans; yet their detection remains difficult as current methods have poor signal-to-noise ratio and yield many false positives. In this regard, mismatch selective metallointercalators have proven to be valuable new tools (21). When pooled genomic samples containing low-frequency SNPs are amplified, denatured, and annealed, mismatches are statistically generated at the polymorphic DNA sites. With photoactivation, these DNA mismatches are cleaved selectively by [Rh(bpy)2chrysi]3+ or [Rh(bpy)2phzi]3+. Fluorescent labeling of the cleaved products...
and separation by capillary electrophoresis thus permits rapid identification with single-base resolution of the SNP site. This method is remarkably sensitive, and minor allele frequencies as low as 5% can be readily detected.

Can these mismatch recognition agents be targeted inside cells? Intracellular delivery was first achieved by tethering a cell-penetrating peptide such as D-octaarginine to the rhodium complex (22). The resulting conjugate binds and with photocatalysis it selectively cleaves DNA neighboring single-base mismatches, although the presence of the oligoarginines is found to increase non-specific binding of the conjugates for both matched and mismatched DNA. Noticeably, the peptide does not affect the selectivity of the rhodium-induced photocleavage of the mismatch site. Similarly, the rhodium complex does not interfere with the delivery properties of the cell-penetrating peptide and the conjugates rapidly localize in the nucleus of HeLa cells.

A different strategy for the cellular uptake of metallointercalators consists of increasing the “greasiness” of the ancillary ligands (23). In agreement with studies on cis-platin analogs, increasing the lipophilicity of dopp complexes of ruthenium favors their passive uptake by HeLa cells. Importantly, the metal complexes are stable to the intracellular environment. Indeed no degradation in luminescence is evident, as would be expected based on changes in complex coordination.

A mentioned, deficiencies in the mismatch repair machinery (MMR) of cells are associated with an increased susceptibility to cancerous transformation. We have developed bifunctional metallointercalators as potential chemotherapeutic agents in which the rhodium complex serves as a targeting vector toward mismatches. For instance, the bulky metallointercalator was tethered to an aniline mustard known to form covalent adducts to 5′-GNC-3′ sites (24). The bifunctional agent demonstrates preferential alkylation of mismatched over fully matched DNA at concentrations where unmodified organic mustards show little reaction. Notably, the tethered alkylation does not inhibit binding of the intercalator at the mismatch site, and similarly, the metallointercalator does not hinder alkylation of the DNA. The site-selective alkylation at mismatched DNA thus renders these conjugates useful tools not only for the covalent tagging of DNA base-pair mismatches but also as new chemotherapeutic agents.

Similarly, a potential chemotherapeutic drug was designed via a bimetallic conjugate that combines a metallointercalator specific for DNA mismatches tethered to a reactive cis-platinum analog that coordinates DNA and inhibits transcription and replication (25). The recognition of a DNA mismatch by the bulky rhodium intercalator directs the reactivity of the platinum unit to a site close to the mismatch that may or may not be the preferred site for platinum coordination. Indeed, in the latter case, the rhodium targeting dominates over the platinum reactivity. This ability to tune the reactivity of the cis-platinum analog could lead to therapeutic agents for MMR-deficient cell lines.

Interestingly, the parent monofunctional metallointercalators have also shown promise as potential chemotherapeutic agents targeted to MMR-deficient tumor cell lines. Indeed, both [Rh(bpy)2chrysi]3+ and [Rh(bpy)2phzi]3+ inhibit cellular proliferation differentially in MMR-deficient cells compared with cells that are MMR-proficient (18). Significantly, the inhibition of cellular proliferation depends strictly on the mismatch repair deficiency of the cell and thus correlates with the ability of the bulky metallointercalators to target DNA mismatches. For instance, it is the α enantiomer of [Rh(bpy)2chrysi]3+ that is active both in targeting the mismatches and in inhibiting DNA synthesis; neither mismatch binding nor inhibition of cellular proliferation is observed with the β enantiomer. A additionally, the cellular response is enhanced with photocatalysis, which is an effect that correlates with the ability of the rhodium intercalators to promote strand cleavage at the mismatch site upon photocatalysis. Targeting DNA mismatches may thus provide a cell-selective strategy for chemotherapeutic design.

Metallointercalators as Probes of DNA-Mediated Charge Transport

Early photophysical studies

Rhodium and ruthenium intercalators have served as powerful probes of DNA-mediated charge transport. Since DNA-mediated charge transport depends so sensitively on π-stacking, it is reasonable that a probe that intercalates into DNA, with optimum π-stacking, might also serve as a powerful probe of this chemistry. Our earliest studies of DNA-mediated charge transport employed a ruthenium complex containing dopp as the photooxidant and a rhodium complex containing phi as the electron acceptor. Assemblies containing 5′-labeled [Rh(phen)2(dcpp)]2+ (phen′ = 5-amido-glutarate-1,10-phenanthroline) with and without 5′-labeled [Rh(phen)2(phen)]2+ were designed where fluorescence quenching of the photooxidant was observed only in the presence of the electron acceptor (26) (Fig. 4). Given a 0.75-eV driving force, little spectral overlap between the excited state of ruthenium and the ground state of rhodium, and the fact that the tethered complexes are well separated on a 15-mer duplex, the observed results were consistent with DNA-mediated charge transfer. This work set the stage for many varied experiments using metallointercalators to characterize this interesting chemistry.

A additional experiments spectrally identifying the ruthenium (I) intermediate confirmed that the quenching mechanism was caused by charge transfer (27). When bound to DNA, [Ru(DMP)(dppz)]2+ decays with two lifetimes corresponding to the two orientations of the intercalating dopp ligand. After excitation at 480nm of intercalating [Ru(DMP)(dppz)]2+ (DMP = 4,7-dimethylphenanthroline) in the presence of [Rh(phen)2(bpy)]2+ a negative transient was observed on the microsecond timescale at 440nm after the initial bleach corresponding to the decay of the ruthenium excited state. As the rhodium concentration was increased, the observed decrease in luminescence intensity but not in lifetime of the ruthenium excited state indicated that the quenching and hence the rate of charge transport was fast relative to the measurement. The same transient was also observed when [Ru(NH3)6]2+ was used as the quencher, albeit with a slower rate of formation. As expected, the decay kinetics of the transient was similar for both quenchers. Differences in quenching kinetics...
between \([\text{Rh}(\phi_2)_{2}(\text{bpy})]^{3+}\) and \([\text{Ru}(\text{NH}_3)_6]^{3+}\) are attributed to intercalation. The intercalative \([\text{Rh}(\phi_2)_{2}(\text{bpy})]^{3+}\) exhibits static quenching, whereas the diffusional \([\text{Ru}(\text{NH}_3)_6]^{3+}\) shows dynamic quenching.

**Long-range oxidative damage from a distance**

Oxidative conditions within the cell can lead to damage of the DNA bases. Guanine, which has been experimentally determined to have the lowest oxidation potential of the naturally occurring bases, is the most easily damaged (28). Upon oxidation, the neutral guanine radical can react with water or oxygen to form permanently damaged products such as 8-oxo-G, oxazolone, or imidazalone (29). Many organic photooxidants such as anthraquinone, riboflavin, and napthalimide have been shown to specifically damage the 5′-guanine of a guanine doublet (30).

The rhodium intercalator, which is tethered to the terminus of an oligonucleotide, was first employed to demonstrate oxidative damage to DNA from a distance through DNA charge transport (30, 31) (Fig. 5). With an excited state potential greater than 2.0 eV versus NHE, the rhodium intercalator serves as a potent photooxidant. Irradiation at 365 nm of 5′-radioactively labeled DNA duplexes containing the tethered rhodium intercalator results in oxidative damage through long-range hole transport that can be revealed by gel electrophoresis after treatment in hot piperidine; piperidine promotes strand breaks neighboring the base lesion 29. If these same duplexes are irradiated at shorter wavelength (313 nm), hydrogen abstraction leads to direct scission of the DNA backbone, indicating the exact position of intercalation. Comparison of the irradiation products of 15-mer oligonucleotides containing two sets of guanine doublets with a 5′-tethered rhodium intercalator versus one where the photooxidant is intercalated noncovalently reveals that the damage patterns show little distinction in oxidation of the proximal and distal guanine doublets 31. However, the 5′ guanine in both doublets was more susceptible to damage than the 3′ guanine. This finding is consistent with ab initio molecular orbital calculations that have indicated that the HOMO is localized on the 5′ guanine of a guanine doublet 32. This preferential reaction at the 5-G of guanine doublets has become a signature for one-electron DNA oxidation 30. Irradiation at 313 nm reveals that the covalently tethered rhodium intercalates three bases from the tethered end, whereas the noncovalent complex intercalates throughout the duplex. As the covalently bound rhodium intercalates far away from the observed damaged guanines, oxidation must therefore occur through long-range DNA-mediated charge transport. A detailed analysis of the damaged products by high performance liquid chromatography (HPLC) after enzymatic digestion showed that the primary damage product was 8-oxo-G.

Oxidative DNA damage has also been studied using the ruthenium intercalator, \([\text{Ru} \text{phen} \text{dppz} \text{bpy}]^{3+}\). When excited by visible light and quenched by non-intercalating quenchers such as \([\text{Ru}(\text{NH}_3)_6]^{3+}\), \([\text{Co}(\text{NH}_3)_5\text{Cl}]^{2+}\), or methyl viologen, a powerful ground state oxidant, \(\text{Ru(III)}\), is generated. With a 1.5 V potential versus NHE, \(\text{Ru(III)}\) can oxidize DNA bases in a similar manner to photoexcited \([\text{Rh}(\phi_2)_{2}(\text{bpy})]^{3+}\) (30). This flash quench technique, originally developed by Gray and coworkers to study electron transfer reactions in proteins, can also be applied to study DNA charge transport (33). DNA duplexes containing 5′ tethered \([\text{Ru} \text{phen} \text{dppz} \text{bpy}]^{3+}\) were
Metallointercalators as Probes of DNA Recognition and Reactions

Figure 5  Schematic representation of a metallated duplex designed to probe long-range oxidative damage in DNA. Oxidative damage is found at the 5’-G of the guanine doublet.

irradiated at 442 nm in the presence of either methyl violo-
gen or [Ru(NH3)6]3+, and preferential damage was observed at the 5’-guanine of a guanine doublet, which is consistent with one-electron oxidation chemistry. HPLC analysis showed 8-oxo guanine also as a primary oxidation product. To rule out guanine damage caused by singlet oxygen sensitization, duplexes containing tethered ruthenium were irradiated in the absence of quencher. Damage was only observed at guanines near the ruthenium intercalation site, and was not 5’-specific. Furthermore, this damage without quencher increased when the experiments were performed in D2O, a characteristic of singlet oxygen chemistry.

Spectroscopy of charge transfer intermediates

Spectroscopic studies provide a means to characterize DNA-mediated charge transport in more detail and to provide a link to biochemical observations. The flash quench technique was first used in experiments involving the synthetic oligonucleotide poly(G-G-C) (30). In the presence of poly(dG-dC), the negative absorbance at 440 nm, caused by excited state quenching of intercalated [Ru(phen)(dppz)2+] by non-intercalating [Ru(NH3)6]3+, disappeared concomitantly with a rise in a positive signal at 390 nm, which is consistent with the formation of the guanine radical. A difference spectrum of this species was obtained with strong positive features at 390 and 550 nm, indicative of the deprotonated neutral guanine radical. Importantly, this signal was not observed in the presence of the synthetic oligomer poly(dA-dT) nor in the absence of quencher in poly(dG-dC). Formation of the radical occurs in less than 10−7 s or within the time scale of quenching of the ruthenium excited state.

Spectroscopic studies of long-range DNA charge transport were then carried out on assemblies containing tethered [Ru(phen)(dppz)2(Lpy)2]2+ as the oxidant and the artificial base 4-methylindole as a guanine analog (34). The oxidation potential of 4-methylindole is lower than that of guanine, and the higher extinction coefficient of its radical at 600 nm renders it particularly amenable to spectroscopic studies of DNA-mediated charge transport. Excitation of ruthenium with oxidative quenching induces charge injection into the duplex. Hole migration to the methylindole base gives rise to a positive absorbance at 600 nm. However, if a mismatch is introduced into the intervening π stack of the duplex, DNA-mediated charge transport is disrupted, which leads to a complete attenuation of methylindole radical formation.

The effect of sequence on charge transfer rate was assessed with assemblies containing a tethered ruthenium photoxidant separated from the methylindole hole trap by a series of A-T base pairs of increasing length. Over distances of 17-37 Å, methyl-indole radical formation is found to occur concomitantly with quenching of the Ru(II) excited state. Thus the rate of radical formation over this distance through AT tracts is greater than 107 s−1, and over these distances, charge transport through the DNA is not rate-limiting. Furthermore, guanine radical formation can compete with that of the methylindole radical as charge equilibrates across the duplex (35).

Distance dependence of charge transport

Our earliest results had indicated that DNA charge transport might be significant over long molecular distances and certainly over longer distances than had been demonstrated in studies of protein electron transfer. The tethered rhodium intercalator was employed in the design of assemblies to examine relative oxidative damage at two guanine doublets within a 28-mer duplex.
Metallointercalators as Probes of DNA Recognition and Reactions

...the distal double guanine sites then served as an indicator of the proximity of the rhodium intercalator, whereas the distal doublet was placed in two base-pair increments at increasing distances from the photooxidant. The damage ratio between the proximal and distal double guanine sites then served as an indicator of charge transport efficiency. Remarkably the damage ratio did not show significant diminution as a function of distance over 75 Å. DNA charge transport thus shows a very shallow distance dependence that is not a result of helical phasing.

Similar studies were also carried out using the ruthenium intercalator, [Ru(phen)(dppz)(bpy')]2+. A comparison of oxidative damage with the rhodium and ruthenium photooxidants was carried out in a 63 base-pair duplex containing six sets of guanine doublets arranged at 19 base-pair increments. Both complexes were able to oxidize all six sets of double guanines, indicating that DNA charge transport chemistry could be observed at distances up to 197 Å away from the intercalation site. Oxidative damage to DNA in fact can develop over biologically significant distances.

Cyclopropyl amine-substituted bases have provided very fast traps for DNA charge transport using an irreversible ring opening reaction associated with oxidation (37). Guanine is in fact a poor oxidative trap, because the guanine radical reacts only on the microsecond-to-millisecond timescale with water and oxygen to form irreversible products; model studies suggest that irreversible ring opening of the N2-cyclopropylguanine radical occurs on the picosecond time scale. Recently our laboratory has designed a series of rhodium-tethered duplexes, in which the oxidative trap is N2-cyclopropylguanine (38). With intervening adenine tracts as the bridge between the intercalator and the trap, a shallow distance dependence is observed, now with prominent periodic features. Interestingly, if the same experiments are repeated monitoring guanine damage, the periodicities are not apparent. These periodicities were also absent in assemblies containing AT base-pair bridges, and they were less pronounced when the intervening bridge consisted of AI, ATC, or ATC (I = inosine) repeats.

An analogous hole trap, cyclobutylycycloisine, has also been used to monitor charge transport through the higher energy pyrimidine bases (39). Rhodium-tethered duplexes containing a distally placed cyclobutylycycloisine were irradiated and ring opening was observed. This striking result indicated that rhodium-induced charge transport can oxidize not only guanine bases but also cytosines. These findings indicate that charge transport through DNA must involve all the DNA bases, not only the low energy guanines we observed using gel electrophoresis.

Taken together, our results from gel electrophoresis and cyclobutylycycloisine ring opening can be rationalized by considering a novel mechanism for DNA-mediated charge transport: conformationally gated domain hopping. Two general mechanistic extremes are used to describe DNA-mediated charge transport, including superexchange, in which the donor and acceptor are lower in energy than the orbitals of the intervening DNA base-pair bridge, and hopping, in which the donor and acceptor have similar energies to the DNA base-pair bridge. In the superexchange mechanism, the charge tunnels from the donor to the acceptor without actually occupying the DNA bridge.

In the hopping mechanism, the charge hops from the donor to the acceptor, transiently occupying discrete sites on the bridge. A superexchange mechanism would exhibit an exponential distance dependence as a function of donor acceptor separation, but a hopping mechanism would result in a more shallow distance dependence so long as the hopping rate exceeds the rate of radical trapping. Although our results cannot be explained by either of these mechanistic extremes alone, we propose a mechanism in which the charge migrates through the DNA by hopping between transiently generated delocalized domains, defined by base sequence and dynamics. We describe a domain as a series of four to five bases acting in concert, over which a charge can delocalize. As the gel electrophoresis experiments measure guanine radical trapping on the millisecond timescale, contributions from base dynamics are not easily revealed. However, when the faster assay of oxidation-induced ring opening is used, additional effects from base dynamics can be discerned. Base motions, occurring on picosecond time scales, contribute to conformational gating of the charge transfer events, both limiting and facilitating the migration of charge between domains (40).

Sensitivity of charge transport to DNA conformation and dynamics

The importance of DNA conformation to DNA-mediated charge transport was evident also in many of our early photophysical studies. In fluorescence quenching experiments using assemblies containing the organic intercalator, ethidium, tethered to one end of the duplex, and the rhodium intercalator tethered to the other end, quenching by photoinduced electron transfer was found with a well-matched duplex, but no significant quenching was observed with an intervening CA mismatch (41). A well \( \pi \)-stacked array of heterocyclic aromatic bases is essential to the efficient transport of charge over a duplex. Perturbations in the intervening \( \pi \)-stack inhibit long-range oxidative damage. Assemblies containing a series of single base mismatches located between proximal and distal guanine doublet sites relative to a tethered ruthenium photooxidant were designed to explore the effect of stacking disruption on charge transport yield (42). These studies showed the dependence of charge transport efficiency on the dynamics of a mismatch; those mismatches that are relatively well stacked, as in purine-purine mismatches, cause only small attenuations in charge transport yield, whereas disruptive mismatches cause significant attenuations. In addition to mismatches, bulges can also disrupt the integrity of charge transport (43). Duplexes containing a tethered rhodium photooxidant and an AT bulge positioned in between a proximal and a distal double guanine site showed a drastic decrease in damage at the distal guanine doublet site, again underscoring the necessity of a well-stacked duplex. Indeed, the sensitivity in charge transport yield to intervening perturbations in base stacking is two important consequences: 1) the path of charge transport must be through the bases rather than through the sugar-phosphate backbone, and 2) the reaction can report sensitively upon the integrity of the DNA duplex.

An interesting study using the base flipping enzyme Methyltransferase Hhal (M.Hhal) showed that disruption of the \( \pi \)-stack by protein binding with insertion of a nonaromatic amino acid...
side chain can also significantly attenuate charge transport. M.HhaI performs its alkylating reaction on DNA after flipping out the central cytosine in the 5′-GGCG-3′ sequence and inserting a guanine residue in its place. An assembly containing a covalently tethered rhodium photooxidant and proximal and distal 5′-GG-3′ doublets separated by the M.HhaI target site was used to investigate charge transport yield in the presence versus absence of the enzyme. Site-specific binding of the enzyme to its target sequence was effective in eliminating oxidation at the distal doublet guanine site. Moreover, when a mutant enzyme containing tryptophan in place of guanine in the wild type was used instead, insertion of the aromatic amino acid served to restore the base-pair stack, leading to extensive damage at the distal site. From these studies it seems that the binding of DNA-binding proteins can both inhibit and activate long-range DNA charge transport.

Biological opportunities for DNA charge transport

We have extensively studied the effect of sequence, structure, and distance dependence of DNA-mediated charge transport. However, the ultimate question remains: is DNA-mediated charge transport an issue, indeed perhaps even a useful reaction, within the cell? We already knew that charge transport chemistry could occur over long enough distances to be biologically relevant, and that DNA-binding proteins could modulate the chemistry, but we needed also to determine whether this chemistry could occur within the tightly packed nucleosome structures found in cells. Within these structures, the DNA is highly bent, wrapped around a positively charged histone octamer, containing a S′-tethered rhodium was therefore constructed (45, 46) (Fig. 6); upon phototransactivation of the tethered rhodium, oxidative damage at a distance to guanines within the core particle was observed. In fact, the efficiency of damage was similar to that observed on the same DNA in the absence of bound histones. We have also shown that rhodium can induce DNA damage in the nucleus of HeLa cells 47. Moreover, in these studies, if we compare sites of rhodium binding with those of strong oxidative damage, we determine that oxidative damage can occur at a distance within the cell nucleus. Long-range charge transport through DNA does develop within the cell.

A additional evidence indicating that DNA charge transport may be biologically relevant comes from studies with DNA repair proteins such as MutY and EndoIII that contain [4Fe-4S] clusters (48). Bound to DNA, the redox potential of the [4Fe-4S] cluster in these proteins is found to be shifted so that the protein is more easily oxidized. By comparing potentials both bound to DNA and free, we estimate that the binding affinity of the oxidized form is at least three orders of magnitude higher than that of the reduced form. Based on these studies, we have proposed a model in which base excision repair enzymes can locate damaged DNA using DNA-mediated charge transport. A repair protein in its reduced state can bind to DNA, becoming more easily oxidized so as to transfer an electron to another DNA repair protein bound at a distal site, reducing the distally bound protein, and promoting its dissociation. But this DNA-mediated reaction can only occur if the intervening DNA base stack is intact and well stacked; if not, the protein remains associated with the DNA and on a slower time scale can progressively migrate to the damaged site. DNA-mediated charge transport thus serves to redistribute the repair proteins in regions of the genome near damage. The redistribution of repair proteins to a damage site using DNA-mediated charge transport essentially provides a way for the proteins to scan large regions of DNA without physically binding to each base. Recognizing that damage is particularly important under conditions of oxidative stress, when guanine radicals are generated. We also used the flash quench method with ruthenium intercalators to show that guanine radicals can provide the first signal for repair, promoting the oxidation also of the DNA repair proteins in a DNA-mediated reaction (49).

Implications and Conclusions

These experiments hopefully serve to illustrate the use of metallointercalators in probing recognition and reactions on the DNA helix. Starting with relatively simple coordination complexes that contain a wealth of photochemical and photophysical properties, functionalizing second and third generation derivatives, we have designed metallointercalators of high affinity, high specificity, and high usage in targeting and reacting with DNA. These complexes can serve as mimics of DNA binding proteins, competing effectively with them for DNA sites and perhaps even carrying out comparable electron transfer chemistry. These experiments, however, provide only a sampling of what might be considered in the future. Can these metal complexes, for example, serve as the basis for new chemotherapeutic designs targeted selectively to cancer cells? Perhaps the experiments we have described will inspire a new generation of complexes to follow with even more powerful applications to biology and medicine.

Figure 6. A nucleosome core particle is shown containing a 146 base-pair DNA duplex wrapped around a histone octamer with a rhodium intercalating photooxidant tethered to the DNA terminus. This particle was constructed to probe DNA charge transport through a nucleosome (45). Seven sets of guanine doublets are located at the red positions along the duplex. Oxidative damage initiated by rhodium photoactivation is observed at the guanine doublets, demonstrating long-range oxidation within the nucleosome.

Phosphate Mimics, Cyclic Compounds as

Amanda C. Nottbohm and Paul J. Hergenrother, Department of Chemistry, Roger Adams Laboratory, University of Illinois, Urbana, Illinois

doi: 10.1002/9780470048672.wecb641

Compounds that contain phosphate and diphosphate moieties are not ideal biologic probes. Not only does their ionic character inhibit cell membrane permeability, but also, once inside a cell, the ester and the anhydride functionalities are likely targets for enzymatic cleavage. Thus, replacements for the phosphate motif are important as enzyme inhibitors, DNA or RNA analogs, phospholipid mimics, and phosphorylated metabolite analogs. To date, several classes of phosphate mimics have been developed that have been grouped into four categories: phosphorus-containing, sulfur-containing, dicarboxylates, and the novel cyclic mimics, which will be the focus of this review.

From nucleic acid phosphodiester linkages to reversible post-translational modifications, the phosphate motif is one of life’s most versatile functional groups. Cellular energy is stored in phosphorylated compounds such as ATP, and coenzymes often contain the pyrophosphate moiety. Protein interactions, stability, and activity are often mediated by the controlled introduction or removal of phosphate groups; indeed, it has been estimated that over 30% of human cellular proteins contain covalently bound phosphate groups (1). This modification has been implicated in the regulation of cell cycle progression, transcription control, protein synthesis, glycogen metabolism, and intracellular transport (2, 3). A host of disease states including cancer, inflammation, diabetes, atherosclerosis, immunodeficiency, and the bubonic plague (4–7) have been associated with the disruption of the phosphorylation machinery within the cell.

Although the ionized state of the phosphate moiety at physiologic pH likely allows for more efficient retention of phosphorylated intermediates within the cell wall and organelles (8, 9) and slows hydrolysis greatly (10), this charged state also prevents compounds that contain phosphate and diphosphate moieties from being useful biologic probes. Not only does their ionic character hinder cell membrane permeability, but also, once inside a cell, both the phosphate-ester and -anhydride functionalities are likely targets for enzymatic degradation. Thus, much effort has been directed toward the development of novel replacements for the phosphate motif, as such compounds might become new enzyme inhibitors, DNA or RNA analogs, phospholipid mimics, and isosteres of phosphorylated metabolites.

Therefore, the challenge is to design functional groups that mimic both the electronic properties and the spatial arrangement of the phosphate group while retaining cell permeability and stability. This task is extremely difficult considering the unique ability of the tetrahedral phosphate moiety to connect two modular subunits while possessing a negative charge. Additionally, this anion usually plays a major role in enzymatic binding and recognition events (11), as it often forms ionic contacts with both metal ions and lysine/arginine residues. Thus, phosphate replacements that lack ionization run the risk of not binding to their protein target. The ionization states and $pK_a$ values for free phosphate in solution are shown in Fig. 1 (12, 13). Interestingly, it has been demonstrated that the $pK_a$ of the phosphate group can change drastically on binding; in the binding of SH2 domains to phosphotyrosine-containing peptides, the phosphate in phosphotyrosine undergoes a large downward shift in $pK_a$ (from a free $pK_a$ of 6.1 to a bound $pK_a$ of 4.5) on binding, and additional studies indicated that 25% of the free energy of binding is caused by the second negative charge on the phospho monoester (14).

Current classes of phosphate isosteres have been developed to interact with target proteins in the same fashion as the phosphate moiety, but with increased bioavailability and stability in a physiologic environment. These phosphate motif replacements can be grouped broadly into four categories: three “traditional” replacement motifs (phosphorus-containing, sulfur-containing, and carboxylate linkages) that have been reviewed previously (3, 15), and the more unique cyclic mimics, which will be the major focus of this review (See Fig. 2 for general structures of mimics discussed in this review).

Common Phosphate Isosteres: Phosphonates, Sulfones, and Carboxylates

Phosphonates

Phosphonates, sulfones, and dicarboxylates are the most prevalent phosphate mimics in medicinal chemistry. Although the phosphate moiety makes the smallest perturbation, these compounds often do not solve the problem of cell membrane permeability (16-21), and can be limited in their biologic activity. Because of the high ionization constant of phosphonates compared with phosphates (%207), phosphonates are not di-ionic under physiologic conditions, and the oxygen-to-methylene substitution removes a potential hydrogen bonding moiety, which often leads to greatly reduced binding affinities (3). Nonetheless, development of phosphate inhibitors of glycosyltransferases (23-25), fucosyltransferases (26), and squalene synthetase (27) has led to the introduction of phosphonate-containing inhibitors with IC50 values of 100 nM, whereas the phosphonate-containing inhibitor with the same nonfluorinated analogs of UDP-galactose inhibited galactosyltransferase activity competitively with Kᵢ's of 62 to 969 μM (31). As indicated by the relatively weak activities of phosphonates, often these compounds are not adequate mimics of the phosphate group because of their increased pKa relative to the parent phosphate (Table 3). Through the introduction of one or two fluorine atoms, one can decrease the phosphonate pKa slightly to match a standard phosphate more closely; increasingly potent inhibitors have been developed through the application of this concept. For example, when incorporated into a hexameric peptide sequence, phosphonodifluoromethyl phosphenylalanine inhibitors of protein tyrosine phosphatase 1B have been developed with IC50 values of 100 nM, whereas the nonfluorinated analogs inhibit at 200 μM (28) (Fig. 3). In general, the biologic activity of (α-monofluoro)alkylphosphates remains less explored, which is surprising given the fact that their pKa is almost identical to that of the phosphate group (Table 3). Few studies have compared the activities of phosphonate-containing inhibitors with both their nonfluorinated and difluorinated equivalents, yet it has been reported that the introduction of a new stereochemical center with monofluorinated phosphonate analogs of glucose 6-phosphate is 11 times less potent than the 7(R)-monofluorophosphonate analog of glucose 6-phosphate isomer in studies of glucose 6-phosphate dehydrogenate substrates (32). Of course, because of the increased hydrophobicity...

Phosphate Mimics, Cyclic Compounds as pTyr Pmp

IC50 200 μM

F2Pmp
IC50 0.1 μM

Figure 3 Phosphonomethyl phenylalanine (Pmp) and phosphonodifluoromethyl phenylalanine (F2Pmp) are nonhydrolyzable phosphotyrosyl (pTyr) mimetics. Hexameric peptide sequences that incorporate either Pmp or F2Pmp inhibit protein tyrosine phosphatase 1B. The difluoro analogs are most potent, presumably because of their reduced pKa relative to the phosphonate.

Forms of sulfur can provide isosteric replacements for a phosphate, but they will lack the full negative charge. Although a direct comparison with the phosphate moiety is difficult to make, studies have indicated that the oxygen of DMSO carries an effective charge of ~0.63 (31), whereas the Mulliken atomic charge on a diaryl sulfone is ~0.616 (32). On the other hand, computational examination of the ESP charges on the oxygens of phosphotyrosine molecules have found that they carry charges of ~0.73 or ~1.06 for the monoanionic and dianionic forms, respectively (33). It must be noted that these cannot be considered direct comparisons because Mulliken charges are calculated based on the linear combination of atomic orbitals method, and ESP charges represent the electrostatic potential around an atom.

Multiple efforts have been made to replace phosphorous-containing linkages with sulfur-containing isosteres in the context of enzyme inhibition. In a search for nonionic transition state analog inhibitors of restriction enzymes, Blätter et al. (34) found that nucleic acid duplexes that incorporate a dimethyl sulfone in place of a phosphodiester have distorted backbones similar to those in restriction enzyme bound DNA. Chimeric DNAs that incorporate sulfone linkages were synthesized, and depending on the location of the dimethylene sulfone linker, either between the first AT unit or the second AT unit in the EcoRV recognition site, Ki values were 20 nM and 120 nM.

Figure 4 (a) Analogs of DNA that contain a dimethyl sulfone group have a distorted backbone compared with the natural biopolymer, which makes them useful as inhibitors of restriction enzymes. (b) A sulfonylbenzoyl nitrostyrene inhibitor of tyrosine protein kinase was designed based on a transition state model of the reaction of ATP with tyrosine residues and exhibits good activity. (c) Based on salicyl-AMP, a sulfamoyl-containing compound exhibits remarkable activity in the inhibition of siderophore biosynthesis.

Cyclic Phosphate Mimics

In an effort to improve cell permeability/bioavailability, recently developed phosphate isosteres often have decreased overall charge. In the past, it has been proposed that reduced p-tency is often a trade-off with increased cellular permeability of phosphate replacements (3), but these trends are beginning to change. A recent review of enzymatic phosphate recognition (11) pointed out that the phosphate-binding mode depends greatly on orientation within the protein. A thorough burial binding pockets often are filled with neutral amino acid residues, cationic residues play a larger role in phosphate recognition and binding closer to the surface. Additionally, over one third of phosphate binding sites do not contain a metal or other cationic phosphate binder (11); thus, the chances of using a neutral, more drug-like compound are increased in these cases. Next, cyclic phosphate mimics including tetronic acid, squaric acid, thiazolidinone, rhodanine, perfluorooxy- and sulfhydantoin-based derivatives (see Fig. 2) will be discussed.

Cyclic phosphate mimics: tetronic acid derivatives

Using a 3-acyltetronic acid as a phosphate-mimicking core (Fig. 6a), potent inhibitors of cdc25B (a dual specificity phosphatase [DSP]) and vaccinia VHR-related phosphatase (VHR) were identified recently (43). Drawing on general natural product inhibitors of protein tyrosine phosphatases (PTPs), Sodeoka et al. (43) searched for a novel core structure that could interact specifically with the active site loop of DSPs. Although previous attempts to find PTP inhibitors focused on phosphonates and carboxylates as phosphate core isosteres (44), the acidic 3-acyltetronic acid group of the known VHR inhibitor RK-682 (Fig. 6b) looked promising as a general replacement for the phosphate moiety. A library of 36 tetronic acid derivatives was synthesized, and some selective inhibitors of both cdc25B and VHR were identified. In particular, a tetronic acid derivative with a diazomalonyl group was found to be extremely potent against cdc25B (Fig. 6b), with a 30-fold selectivity for cdc25B over VHR. In general, the library showed good selectivity for VHR and cdc25B over general tyrosine phosphatases. Most crucially, modeling studies indicated that the dissociated 3-acyltetronic acid anion can act as a hydrogen-bonding phosphate mimic, whereas the R and R2 groups provide two positions for additional derivatization, which allows for increased specificity.

Cyclic phosphate mimics: squaric acid-based motifs

Over the years, squaric acid and its derivatives have found several uses in medicinal chemistry: Squaric acid inhibits glyoxy-

sulfone-3-cyclobutenedione) is an inhibitor of pyruvate dehydrogenase and transketolase (46); and other derivatives serve as antagonists of the N-methyl-D-

(a) Chaetomellic acid A is a novel dicarboxylate-containing natural product that is thought to mimic farnesyl pyrophosphate and thus to inhibit the enzyme FTPase. This compound can exist in either the dicarboxylate or anhydride form. (b) As peptides that contain aromatic oxamic acids are good inhibitors of tyrosine kinase p56Lck SH2 domains, it is believed that the oxamic acid moiety may mimic the phosphate group. (c) A symmetric 3,5-disubstituted benzoate analog of S3P (substrate) and EPSP (product) inhibits EPSPS.

Searching for an isostere with similar charge distribution to that of the phosphate group for the creation of oligodeoxynucleotide analogs, Sato et al. (48, 49) also examined squaric acid derivatives. Squaric acid contains two acidic hydroxyl groups (pK_a values of 0.54 and 3.48, respectively) as well as two highly polarized carbonyl groups (50). Ab initio calculations of electrostatic charge distributions indicate that although a dissociated dimethyl phosphate has –0.84 charges on each of the oxygen atoms, N-isopropyl-N'-methylsquaryldiamide has similar polarizing patterns, with –0.47 and –0.51 charges on the oxygen atoms of the carbonyl groups (49). Furthermore, similar to phosphate functionality, the squaric acid motif contains carbonyls that can function as hydrogen-bonding partners and binding sites for divalent metal ions (Fig. 7a) (51, 52).

On the basis of these calculations, a modified 3′-5′ thymidine dimer derivative (Fig. 7b, TsqT) was synthesized (49). Based on both UV and CD spectra of TsqT and the corresponding phosphate derivative (TpT), the dimer that contains the squaryldiamide linkage is similar structurally to the natural TpT. Thus, the TsqT dimer structural motif was incorporated into oligodeoxynucleotides using standard phosphoramidite chemistry, producing 5′-CGCATsqTAGCC-3′ and 5′-GACGCA sqTAGCCGAT. Enzymatic digestion of squaryl-
In a similar manner, a 2-oligodeoxynucleotides may have a variety of applications (49).

Furthermore, squaryldiamide-modified oligodeoxynucleotides (ODNs) demonstrated A–T base pairing was preserved, which indicates that the squaryldiamide-modified oligomers can mimic the phosphate group, particularly that of phosphotyrosine. Developing such a more robust ODN analog that contains the squaric acid motif as a nonhydrolyzable phosphotyrosine mimetic enzymes tested, including RmlB, RmlC, and RmlD. The fact that all three enzymes modify a phosphorylated rhamnose intermediate important for Mycobacterium tuberculosis (MTB) cell wall synthesis was a possible indication that substituted rhodanines might mimic the phosphate motif, but it was unknown whether such inhibitors actually bind in the same fashion as the natural substrates. A later computational follow-up study by K. Karanadjeff et al. (57) indicated that the third rhodanine inhibitor binds at or near the phosphate-binding region of MTB. Core structure electron-density isosurfaces for these antmycobacterial compounds were generated, further hinting at the common features shared between substituted rhodanines or thiazolidinones. Core structure electron-density isosurfaces for the thiazolidinones and the diphosphate moiety.

Core structure electron-density isosurfaces for these antmycobacterial compounds were generated, further hinting at the common features shared between substituted rhodanines or thiazolidinones. Core structure electron-density isosurfaces for the thiazolidinones and the diphosphate moiety.

Cyclic phosphate mimics: thiazolidinones and rhodanines (thiothiazolidinones)

MurB, an enzyme that reduces enolglycyl uridine diphosphate N-acetylglucosamine (EP-UNAG) to uridine diphosphate N-acetylMuramic acid (UNAM) (54), is an attractive antibacterial target (55). Using crystallographic data of MurB bound to EP-UNAC, Andres et al. (55) sought a suitable surrogate for the diphosphate moiety of the natural substrate, and focused eventually on 4-thiazolidinones. Modeling studies indicated that a carbonylic acid moiety at the R1 position potentially could mimic essential interactions of the diphosphate with a lysine residue (56). Additionally, it was believed that the thiazolidinone core would orient the side chains so that they might occupy the space normally reserved for the uridine and glucosamine motifs. Although it is unlikely that the thiazolidinone core can mimic all interactions of the diphosphate, elimination of the corresponding rotatable bonds of the natural substrate was also predicted to have a positive entropic effect to binding of the thiazolidinone-based inhibitor. Only thiazolidinones that contain an n-butyl group at the R1 position exhibited any activity, with diastereomers derived from D-norleucine that exhibited a 4-fold increase in activity over those synthesized from L-norleucine (55).

In a recent screen of 8,000 compounds to identify potential drugs that target the synthesis of DTP-rhamnose from glucose-1-phosphate and dTTP, 11 inhibitors were identified; three of these contained a rhodanine (Fig 2) structural motif (56). Inhibition was found for all three dTDP-rhamnose synthetase enzymes tested, including RmlB, RmlC, and RmlD. The fact that all three enzymes modify a phosphorylated rhamnose intermediate important for Mycobacterium tuberculosis (MTB) cell wall synthesis was a possible indication that substituted rhodanines might mimic the phosphate motif, but it was unknown whether such inhibitors actually bind in the same fashion as the natural substrates. A later computational follow-up study by K. Karanadjeff et al. (57) indicated that the third rhodanine inhibitor binds at or near the phosphate-binding region of MTB. Core structure electron-density isosurfaces for these antmycobacterial compounds were generated, further hinting at the common features shared between substituted rhodanines or thiazolidinones and the diphosphate moiety.

High-throughput screening for compounds that might compete with the UDP-GlcNAc substrate of MurG also led to the identification of a rhodanine core structure as a phosphotide mimic (Fig 8c) (58). Using a fluorescein derivative of UDP-GlcNAc, compounds that compete with the binding of the fluorescent substrate were identified on the basis of anisotropy changes on incubation with the putative inhibitors. Over 48,000 compounds were screened, and of the 277 compounds that were identified as possible inhibitors of MurG,

Figure 7  (a) Dialkylphosphate similarity to squaric acid derivatives; both possess two negatively charged oxygen atoms in their tautomeric form. (b) Modified oligodeoxynucleotides that contain a squaryldiamide moiety are remarkably similar to natural oligodeoxynucleotides. 3′-5′ linked dimers can form Watson-Crick base pairs with adenine, whereas the 2′-5′ linked dimers can form both Watson-Crick base pairs with adenine and wobble base pairs with guanine. (c) Squaric acid-based inhibitors of PTPase from Yersinia are designed to mimic phosphotyrosine.

11 compounds exhibited greater inhibitory effects than the natural inhibitor UDP. 7 compounds contained a rhodanine core structure. A similar screen also revealed several compounds with rhodanine-like structures. It should be noted that these 1,3-substituted compounds are conjugate acceptors and thus potentially reactive as electrophiles; however, additional kinetic analysis indicated that no covalent modification of the enzyme was occurring. Additionally, most compounds were selective for MurG over closely related enzymes that use similar substrates. The high percentage of inhibitors with a similar core may possibly hint at a common binding mode, which reveals the ability of rhodamines to potentially serve as diphosphate mimics.

Although it is unknown whether either thiazolidinones or rhodanines actually mimic the phosphate binding site or simply have shapes that occupy the nucleotide-sugar binding site favorably, as proposed by Carlson, studies of systems that do not contain a nucleotide-sugar seem to indicate the former. Modeling studies first indicated that particular perfluoraryl compounds might mimic the overall spatial and electronic distribution of the diphosphate and triphosphate moiety. By appending a perfluoranyl moiety onto a guanosine substrate, Barber et al. hoped to mimic either guanosine...
Phosphate Mimics, Cyclic Compounds as

(a) The substituted thiazolidinone core. (b) Sometimes, thiazolidinone-containing compounds make good inhibitors of enzymes that use nucleoside diphosphates. For example, MurB, which uses EP-UNAG as its natural substrate is inhibited by the thiazolidinone derivative pictured. (c) Rhodanine-containing compounds also serve as excellent inhibitors of enzymes with natural diphosphate-containing inhibitors. For comparison, UDP (an inhibitor of MurG) is pictured next to a rhodanine derivative that exhibits good antibacterial activity. (d) Thiazolidinones have proven their usefulness as general replacements for natural substrates that contain the phosphate group. For example, 2-aryl-4-oxo-thiazolidin-3-yl-amides have replaced serine amide phosphates as more stable mimics of lysophosphatidic acid, and they have been shown to be cytotoxic in prostate cancer cell lines.

5′-triphosphate or guanosine 5′-diphosphate and thus modulate the activity of Ras. Barber et al. (67) succeeded in appending several perfluoraryl phosphate replacement moieties onto guanosine. Although no IC₅₀ values are given in the patent literature (66), the relative binding abilities of the guanosine nucleotide mimics were compared with that of GTP for the binding site of a mutant H-Ras protein using a cold chase experiment, in which either GTP or a perfluoraryl compound was used as a competitor to tritiated GTP. When experiments were performed with the natural substrate, GTP (Fig. 9a), at a concentration of 25µM, a 79% reduction in radioactivity was observed. Using the putative GDP mimic 5′-O-(2,3,5,6-Tetrafluoro-4-pyridyl) guanosine (Fig. 9a) at the same concentration, a 21% reduction in the mean c.p.m. was noted, which indicates that the perfluoraryl compound likely inhibits binding of GTP to Ras to some extent. Interestingly, when using a compound designed to mimic GTP, 5′-O-[(2,3,6-Trifluoro-5-hydroxy-4-nitrophenyl) guanosine (Fig. 9a), no reduction occurred in the binding ability of tritiated GTP (66).

Taking this concept a step further, general inhibitors for protein farnesyltransferase (FTase) (67), geranylgeranylttransferase I (GGTase-I), and squalene synthase (SqSase) (68) were also developed. In a posttranslational modification event, FTase transfers a farnesyl group to the Ras protein (69). Although not directly related to the function of Ras, SqSase uses the same substrate as FTase; thus, the compounds developed were also tested for SqSase inhibition (68). Finally, GGTase I controls the geranylgeranylation of Rho proteins and plays a role in cell motility and invasion, and also is a potential target for cancer therapy (70). Of 15 compounds tested, 5 compounds exhibited IC₅₀ values less than 10µM (68), with the best/most selective inhibitors for each enzyme illustrated in Fig. 9b–d.
Cyclic phosphate mimics: sulfhydantoins

Relatively little information exists about sulfhydantoins in the literature. Although they have been described previously as peptidomimetic serine protease inhibitors (71), Saunders et al. (72) were the first to report the use of sulfhydantoins as phosphate mimics. In an attempt to develop novel inhibitors for SHP-2, which is a tyrosine phosphatase, it was noted that general phosphate inhibitors either incorporate carboxylate or the fluorophosphonate moiety to mimic the negative charge of the phosphate at physiologic pH (71). Driven by the lack of drugs-like inhibitors in the literature, they searched for heterocyclic modulators of SHP-2 activity based on sulfhydantoins. In vitro competition assays were completed to determine the IC₅₀ values of several putative phosphate mimics, the most potent of which are illustrated in Fig. 10. Although exact IC₅₀ values were not reported in the patent literature, the compounds depicted exhibit IC₅₀ values between 1 and 100 µM (72).

Cyclic phosphate mimics: hydroxytropolones

Hydroxytropolones derived from puberulonic acid, a natural product isolated from Penicillium, were investigated for their ability to inhibit inositol monophosphatase (IMPase). Although bisphosphonic acids were developed previously as potent inhibitors of enzymes that use phosphate-containing substrates, other bimetallic, phosphate-binding metal complexes might also be targets of hydroxytropolone inhibition. Indeed alkaline phosphatase, which contains two catalytic zinc ions, the tri-zinc-containing phosphofructokinase C (75), and human immunodeficiency virus RT polymerase/ RNase H/Integrase (76), which contain essential Mg²⁺ ions, are inhibited competitively by hydroxytropolones as well.

Cyclic phosphate mimics: do they really mimic the phosphate group?

Many cyclic phosphate mimics have been developed recently, and only limited data exists about their ability to actually imitate the phosphate group. Thus, the term “phosphate mimic” simply refers to the ability of these compounds to act as potent inhibitors of enzymes that use phosphate-containing substrates. Nonetheless, a myriad of computational studies have attempted to showcase the structural and electrostatic similarities of certain cyclic phosphate replacements relative to their phosphate parents. Using the program SPA RTA N. 5.0 (Wavefunction, Inc., Irvine, CA), electrostatic charge distribution studies have attempted to show the structural and electrostatic similarities of certain cyclic phosphate replacements relative to their phosphate parents. Using the program SPA RTA N. 5.0 (Wavefunction, Inc., Irvine, CA), electrostatic charge distribution studies have attempted to showcase the structural and electrostatic similarities of certain cyclic phosphate replacements relative to their phosphate parents. interact with a phenylalanine residue, a positively charged region of the protein is proposed to interact with the carbonyl moieties of the squaric derivative (Fig 12b). Unfortunately, no direct comparison of the binding mode of phosphotyrosine versus the proposed binding of these squaric acid derivatives exists in the literature; no cocrystal structures or NMR structures of these compounds are bound to proteins. Other docking studies have been completed with tetronic acid derivatives in the active site of VHR; results indicate that on dissociation, the 3-acyltetronic acid anion can bind tightly to the active site through several hydrogen bonds in a manner similar to that of phosphotyrosine (43). Finally, rhodanine and thiazolidinone cores have been shown to bind at or near the phosphate-binding site in modeling studies of various proteins (57), and they share many commonalities with compounds believed to mimic the pentavalent transition state of phosphate hydrolysis. Core structure electron-density isosurfaces for both rhodanine and thiazolidinone cores have been shown to bind at or near the phosphoimine motif in the active site of IMPase. At this time, crystal structures of proteins complexed with these compounds are bound to proteins.

Choosing the Right Phosphate Isostere

With so many phosphate isosteres to choose from, where does one begin? Despite recent advances, it would seem that the ideal isostere must still be determined on a case-by-case basis. Ease of synthesis and compatibility of the designed synthetic route with production of a combinatorial library of compounds can be a major determining factor. Additionally, one must consider the history of each of these classes as a phosphate mimic. Much data has been generated on the “traditional” phosphate replacements, and many success stories exist with these classes of compounds. However, many published examples exist in which such replacements are biologically inactive (19, 40), and as highlighted by Fressigné et al. (78), the incorporation of phosphate replacements affects the conformational behavior of some systems strongly. In contrast, several recent publications have highlighted the potential of the cyclic compounds as phosphate mimics, but only time will tell whether many failures exist as successes.

**Choosing the right phosphate isostere: good**

Although they have been around the longest, phosphorus- and sulfur-containing replacements for the phosphate moiety present the greatest synthetic challenges. The low yields associated with appending phosphonates and fluorophosphonates make the synthesis of combinatorial libraries more difficult, which has been an obstacle in the development of potent inhibitors from these classes of molecules. Additionally, although they are certainly more stable biologically than their parent phosphates, the highly polar nature of phosphonates hinders biologic activity because of limited cell permeability (17-22). For example, one of the most potent and selective inhibitors for protein tyrosine phosphatase 1B (PTP 1B) contains an aryl difluorophosphonate group (16). Because of its anionic character at physiologic pH, it is not cell permeable and exhibits no cellular activity; only when produced in a pro-drug form do such phosphonate inhibitors become useful (16). In general, the phosphonate inhibitors that exist in the literature have slightly reduced potencies compared with their phosphate parent (3); thus, other structural and electronic analogs of the phosphate moiety often will be superior.

Progress has been made in the development of potent sulfone-containing phosphate mimetic inhibitors, but it is difficult to predict in what cases a sulfone might resemble a phosphate. Whereas a select few sulfone-based inhibitors have

Choosing the right phosphate isostere: better

Although several phosphate isosteres discussed in the previous sections demonstrate great promise, little hard data exists about their ability to actually function as a phosphate replacement. For example, only one model system has been published for both the tetrionic acid derivatives and the sulfhydantoins, and limited structural evidence exists that demonstrates phosphate-mimicking ability. Additionally, even though the sulfhydantoin or reverse sulfhydantoin core resembles the structure of biologically active the thiazolidinones and rhamnines, the only evidence for their activity is limited to the patent literature, in which no absolute IC50 values or crystal structures are presented (72). Finally, although the hydroxytropolones exhibit promising activity in a few model systems, labeling them as phosphate mimics rather than general inhibitors of bimetallic enzymes might be premature. Whereas it is possible that these three cores also function to some extent as a general phosphate replacement, more study must be completed before this can be confirmed.

Choosing the right phosphate isostere: best

Grouped in this final category are the highly desirable drug-like phosphate mimics, which include squaric acid derivatives, rhamnines/thiazolidinones, and perfluoraryl compounds; a wide range of relatively simple methods exist for the synthesis of these derivatives, and they have been demonstrated to work as phosphate mimics for at least two different classes of enzyme substrates. Squaric acid derivatives have been used in two very different phosphate-mimicking situations: in squaryl-linked oligodeoxynucleotides (48, 49) and as inhibitors of PTPases (53). Additionally, computational studies that involve electrostatic charge distribution have added to the evidence that squaric acid derivatives might be similar spatially and electronically to the highly acidic proton on the acetylsulfamate nitrogen might mimic some of the negative charge found on the phosphate, although more information is needed on this topic.

Most successful dicarboxylate-containing phosphate mimics have been based on carboxylate-rich natural products (42) that have been shown previously to have activity against the desired enzyme. Although modeling studies have shown that the negatively charged oxygens on maleate are spatially within 0.1 Å of that in the equivalent diphosphate, some malonate-, succinate-, and tartaric acid-based phosphate mimics have not been potent inhibitors of enzymatic activity (35, 38). Although dicarboxylate-containing compounds have also been developed to mimic the six-membered ring pyrophosphate-divalent metal complex that is proposed to form in many enzymes (80, 81), in those cases monosaccharide linkages have been found to be much better mimics of this chair or boat conformation (Fig. 13) (37). Carboxylate moieties can be incorporated easily into compounds through amide linkers (37) or oxidation strategies (38), but their inability to consistently function as potent inhibitors limits their applicability.
the phosphate moiety. Thiazolidinone and rhodanine derivatives can simply be prepared through a one-pot cyclocondensation reaction, which has led to their relatively high occurrence as members of commercially available compound collections. Additionally, the thiazolidinone/rhodanine core has been shown to be a valid phosphate replacement for several classes of molecules; both nucleoside diphosphates (56, 58) and phosphorylated lipids (64) have been mimicked by these heterocyclic core structures, which hints at their possible potential to serve as a general phosphate mimetic. Perfluoroaryl compounds have been demonstrated to mimic both the diphosphate and triphosphate moiety of nucleoside phosphates (67) as well as phosphoroylized isoprenoids (66, 68). Thus, it seems reasonable to believe that these strategies for phosphate mimicity could be applied successfully to other biologic targets. In the coming years, even more testing and crystallographic or computational evidence will hopefully illuminate the manner in which these compounds act as phosphate isosteres. For now, based on a few key examples these three derivatives all seem to have great potential.

Summary

Phosphonates, sulfones, and dicarboxylates are all valid replacements for the phosphate moiety, but it has become clear that several interesting alternatives to these functional groups exist. Although the squaric acid and thiazolidinone motifs have been best characterized in terms of their ability to actually mimic both the negative charge and the positional orientation provided by a phosphate group, other cyclic compounds have surfaced additionally, the thiazolidinone/rhodanine core has been shown to be a valid phosphate replacement for several classes of commercially available compound collections. Additionally, the thiazolidinone/rhodanine core has been shown to be a valid phosphate replacement for several classes of molecules; both nucleoside diphosphates (56, 58) and phosphorylated lipids (64) have been mimicked by these heterocyclic core structures, which hints at their possible potential to serve as a general phosphate mimetic. Perfluoroaryl compounds have been demonstrated to mimic both the diphosphate and triphosphate moiety of nucleoside phosphates (67) as well as phosphoroylized isoprenoids (66, 68). Thus, it seems reasonable to believe that these strategies for phosphate mimicity could be applied successfully to other biologic targets. In the coming years, even more testing and crystallographic or computational evidence will hopefully illuminate the manner in which these compounds act as phosphate isosteres. For now, based on a few key examples these three derivatives all seem to have great potential.

The discovery and optimization of small-molecule inhibitors for the treatment of human disease has been the major focus of the pharmaceutical industry for more than a century. In the last decade, they have also attracted increased attention from academia because they provide a powerful means to interrogate biological systems in an acute fashion. Although pharmaceutical companies have identified many small-molecule inhibitors for drug targets, to find a desirable small-molecule inhibitor for a specific target is still a major challenge for drug discovery and for chemical biology. Here, we present an overview of the computational approaches that can be exploited to discover small-molecule inhibitors for protein targets of interest.

Small molecule inhibitors are of special value to chemical biology and to drug discovery. Thousands of small molecules have been developed as drugs to treat various human diseases. Increasingly, small-molecule inhibitors are used to perturb the function of proteins to elucidate their biologic functions (1, 2). Complementary to the conventional genetics, small molecules allow rapid, conditional, and tunable inhibition. Furthermore, small molecules can often be identified that alter specifically one particular function of a multifunctional protein. The recent completion of the human genome sequencing project has resulted in the identification of a plethora of new protein targets for which small-molecule modulators could be developed as potential therapeutics and as biologic “tools.” Identifying a selective small-molecule inhibitor for each protein in the human genome is a formidable challenge for drug discovery and for chemical biology. Experimentally, high-throughput screening is the most widely used technology currently to identify hits for a target. On the other hand, computational methods, such as virtual screening and structure-based design, have become equally important to identify and to optimize small-molecule inhibitors. In Fig. 1, we illustrate how computational and experimental approaches can complement each other in the compound discovery and optimization process. The numbers of compounds associated typically with each method is indicated. At early stages of hit identification, high throughput methods such as virtual ligand screening (VLS) and ultra high-throughput screening (uHTS) are used frequently. At later stages, high accuracy algorithms combined with biologic assays can be used to guide the selection and the synthesis of a limited set of analogs. As shown in Fig. 1, computational and experimental approaches are not mutually exclusive processes. They are best exploited by using computation and experiment in an iterative fashion to optimize compounds progressively for a particular target of interest. Without these interactions, none of the methods can achieve its maximum potential. In this review, we focus on computational approaches depicted in Fig. 1. As will become clear later in the article, most computational methods are not associated exclusively with predefined processes or protocols. Significant redundancies exist in terms of when and what methods should be applied. The structure of the article follows the common flow of identifying small-molecule inhibitors. We will discuss the particular computational methodologies used at different stages of the process in subsequent sections.

Virtual Screening in Selecting Small Molecule Inhibitors

Virtual screening (VS) uses computational or theoretic methods to select molecules with desired biologic properties. It has broad applications in pharmaceutical industry. In this article, we limit ourselves to VS to identify biologically active small molecules. The estimated chemical space for small organic molecules is over 10^38, and the registered organic and inorganic molecules in CAS are already over 30 million. Despite advances in experimental high throughput screening technologies, currently it is impossible to screen more than a few million compounds.
With the rapid improvement of computational power and algorithms, VS methods have become an important complementary technique to experimental uHTS. It has many distinct advantages, such as investigating virtual molecules that can cover a broader area of chemical space. Compared with uHTS, VS is also a relatively inexpensive means to probe many molecular structures.

Generally, two types of virtual screening are used. One is receptor based, such as docking, and the other is ligand based, such as similarity search. In practice, both methods are often used synergistically. In Fig. 2, we illustrate how these two types of methods are used to select “hits” from a given small-molecule library.

Receptor-Based VLS

In receptor-based VLS, the atomic coordinates of receptor molecules are known experimentally or theoretically (e.g., homology models). The interactions between a small molecule and a protein are often characterized by a “lock-key” mechanism, in which high affinity small molecules often fit the protein-binding site well. The shape complementarities provide important enthalpy contributions from favorable van der Waals interactions. In addition, correctly positioned charges, hydrogen bonds, and hydrophobic contacts usually are required for higher affinity. Based on computational efficiency, receptor-based VLS can be divided into three tiers. The first tier is the popular high-throughput docking and scoring that can be computed for each ligand molecule within a few minutes on a typical desktop computer. In the rest of this article, we refer to high-throughput docking as docking and scoring for simplicity. The second tier includes the medium throughput methods that calculate the interactions more thoroughly and accurately. It often includes algorithms that account more accurately for desolvation energies, entropic penalties, and receptor flexibility. For example, detailed implicit solvent models usually are applied in these calculations. It normally takes tens of minutes for each calculation. The third tier represents the slowest method but ultimately offers more accurate results. The typical examples are atomistic molecular dynamics (MD) or Monte Carlo simulations with explicit water molecules. The details of these calculations are out of the scope of this review. Interested readers can consult recent reviews on these specific topics (3).

Among the three classes of methods, docking is the most widely used method in pharmaceutical industry. Many high throughput docking software packages are available publicly, such as Dock, Autodock, Gold, Glide, FlexX, QXP, and ICM. In addition, many companies have built their own proprietary docking technologies. A docking-based VLS calculation usually consists of three stages: preparing, computing binding modes, and scoring. Currently, most docking programs treat receptors as rigid molecules. Under this approximation, a receptor field can be calculated for the binding site. A receptor field is the interaction potential created by receptor atoms. It consists of van der Waals, electrostatic, hydrogen bonding, and solvation contributions. Without atom thermal motions, the receptor field is also static, so it can be precalculated in the absence of ligand molecules. This feature provides enormous savings of computational time over explicit atom models. Different programs employ very different algorithms to sample ligand conformations, to orient small molecules in the binding site, to retain preferred binding modes, and to increase the computational efficiency (4–7). The predicted binding configuration is selected based on molecular interaction energies or an empirical scoring function. Finally, docking ranks all ligand molecules based on binding poses that possess the highest score, and virtual “hit” molecules are selected from the top of the list. This method
The docking/scoring uses existing 3-D structures of receptors to construct binding models, and the pharmacophore searching/ranking uses known active hits, 9 of them inhibited SIGK binding with G receptor 3-D structure (i.e., docking and scoring) and the other is based on active ligand molecules alone (i.e., pharmacophore searching and ranking).

et al. (12) to identify that ranged from 100 nM to 60 µM, one chemical diversity set of 1990 compounds. Among 85 virtual actions. Bonacci et al. (11) used docking (FlexX) to screen the to discover small-molecule inhibitors for protein–protein interaction. II inhibitors (9) and BCR-ABL tyrosine kinase inhibitors (10) were also discovered by docking. Docking can also be applied to discover small-molecule inhibitors for protein–protein interactions. Banaci et al. (12) used docking (FlexX) to screen the chemical diversity set of 1990 compounds. Among 85 virtual hits, 9 of them inhibited SIGK binding with Gβδ1-2 with IC50 that ranged from 100 nM to 600 nM. It was also used by Trusset et al. (12) to identify β-Catenin inhibitors for Wnt signal pathway from 177,000 compounds. Among 22 tested virtual hits, 3 hits were confirmed as binders to β-Catenin and Tcf4 competitors. Without experimental receptor structures, docking can be carried out using carefully constructed model structures. Becker et al. (13) and Salo et al. (14) reported the successful identification of small-molecule inhibitors of several G-protein coupled receptors (GPCR) systems based on docking.

One major challenge in docking-based VLS is the accuracy of scoring functions. Conceptually, binding free energy is a rigorous measure for correct binding conformation and compound affinity. However, the inherent errors in classic force fields and the extremely lengthy computation required preclude its immediate use for VLS. In practice, an empirical function (i.e., a scoring function) normally is used to estimate free energy of binding. A few examples of commonly used scoring functions are PMF (15), Chemscore (16), Drugscore (17), Goldscore (18), and GlideScore (19). The specific mathematical forms of Chemscore, Goldscore, and PMF are shown here to highlight their similarity and difference. Other scoring functions can be found in respective references:

\[ \Delta G_{\text{chemscore}} = \Delta G_0 + \Delta G_{\text{bond}} + \Delta G_{\text{vdw}} + \Delta G_{\text{hbond}} + \Delta G_{\text{metal}}. \]

where \( \Delta G_0 \) is a fitting constant, \( \Delta G_{\text{bond}} \) is hydrogen bond energy between ligand and receptor, \( \Delta G_{\text{vdw}} \) is the energy between ligand atoms and metal ions in a receptor active site, \( \Delta G_{\text{hbond}} \) is the hydrogen receptor lipophilic interaction, and \( \Delta G_{\text{metal}} \) is for the rotatable bond penalty.

\[ \Delta G_{\text{glidescore}} = \Delta G_{\text{bond}} + \Delta E_{\text{vdw}} + \Delta E_{\text{internal}}. \]

where \( \Delta G_{\text{bond}} \) is the hydrogen bond energy between ligand and receptor, and \( \Delta E_{\text{vdw}} \) is the van der Waals energy of ligand and receptor, and \( \Delta E_{\text{internal}} \) is the van der Waals energy and torsional strain of the ligand molecule.

Figure 2. Workflow of computational algorithms used for identifying “hit” molecules from a compound library. The top panel indicates the compound collection from which the “hit” molecules are to be identified. The middle panel illustrates two virtual screening strategies. One is based on a known receptor 3-D structure (i.e., docking and scoring) and the other is based on active ligand molecules alone (i.e., pharmacophore searching and ranking). The docking/scoring uses existing 3-D structures of receptors to construct binding models, and the pharmacophore searching/ranking uses known active small molecules to construct pharmacophore models.
Small Molecule Inhibitors: Design and Selection of

\[ \Delta G_{\text{bind}}^{\text{score}} = \sum_{i<j} A_{ij}(r) + \Delta E_{\text{vdw}}, \]

where \( A_{ij}(r) = -k_B T \ln \left( \frac{\rho_{\text{seg}}(r)}{\rho_{\text{bulk}}} \right) \)

\[ \Delta E_{\text{vdw}} = -\frac{1}{3} \sum_{i<j} \frac{\rho_{\text{seg}}(r)}{\rho_{\text{bulk}}}, \]

is the ligand volume correction factor, \( \rho_{\text{seg}}(r) \) is the number density of a ligand receptor atom pair of type \( ij \) at inter atomic distance \( r \), \( \rho_{\text{bulk}} \) is the reference number density of ligand receptor pair of type \( ij \), and \( \Delta E_{\text{vdw}} \) is the van der Waals interaction between ligand and receptor. Although common features exist within different scoring functions, they often emphasize different aspects of the protein–ligand interaction. These empirical scoring functions bear significant errors because of crude approximations. Currently, no scoring functions exist that are able to rank diverse compound libraries consistently and accurately. The performance of docking based VLS varies considerably from system to system and from program to program (20). Although some programs tend to perform better than others do, it is difficult to predict the performance a priori on a specific system. In addition to ranking molecules based upon a single scoring function, combination of several scores (i.e., consensus scoring) or statistical methods (e.g., Bayesian statistics) are also used to select virtual hits.

Often, rigid receptor models provide a reasonable approximation and offer tremendous practical value. The majority of docking calculations used in industry adopt this approximation. In reality, however, receptor atoms undergo constant thermal motions, and some proteins have significant flexibility. One example is inactive and active conformations of kinases in which the activation loop moves in and out of active sites (21) with some atoms that move well over 10 Å. It is common to see a variety of conformational states for a given protein in PDB database. It is also possible that such conformations observed crystallographically represent only a fraction of the transient dynamic states that may exist in solution. Although several methods (22–24) have been developed to account for protein flexibility, considerably more computational and experimental work will be required to create algorithms that can incorporate receptor flexibility accurately. In addition to receptor plasticity, another complicating factor is the difficulty to account accurately for the enthalpy and entropic contributions of discrete water molecules in the ligand bound and unbound states. Water molecules have been observed crystallographically to play important roles in mediating hydrogen bonds between protein atoms and between protein atoms and ligands. In most docking calculations, the water molecules are removed from binding sites, which assumes that to displace these water molecules by small molecules would give favorable entropic contribution. However, the entropic gain comes at the expense of enthalpy loss if the water molecules make strong hydrogen bonds to receptor atoms or mediate ligand–protein interactions. Several programs exist that attempt to include movable water molecules in docking calculations, however, often this results in a significant loss of computational efficiency.

Besides virtual screening of ligand libraries, docking is extremely useful for lead optimization. Successful docking can elucidate the important interactions between lead molecules and the target, explain important features of the structure activity relationships (SAR), and consequently help to design new molecules. Other than docking, useful receptor based VLS tools include MD simulation, MC simulation, and QM/MM calculation.

Ligand-Based Virtual Screening

(2-D Similarity Search, 3-D Pharmacophore Search)

Another category of VLS methods is to identify ligands for targets that have unknown 3-dimensional (3-D) structures. Generally, these methods are called ligand-based VLS. The most simple and probably the most used searches involve a physical, chemical, or topological similarity search based on one or several active compounds. The similarity between two molecules can be defined in various ways. Two-dimensional (2-D) methods refer to those that only consider atom connection tables to describe molecular structures, because atom connection tables are best represented by 2-D pictures such as the ones in the top panel of Fig. 2. These methods consider topological relationships between atoms in a molecule regardless of hydrogen atoms. The simplicity of these methods allows computationally efficient comparisons. It can screen millions of molecules in seconds. Here, we outline a few representative examples.

1. Molecular 2-D fingerprints are a class of methods that use chemical substructures to characterize similarities between molecules. A fingerprint is a signature that encodes the chemical topological information of a small molecule. It is usually a long binary bit string in which each bit represents the presence 1 or absence 0 of a particular chemical substructure. For example, an ATP molecule has substructures such as a pyrimidine and imidazole heterocycle but not benzene; therefore, the bits that represent pyrimidine and imidazole would be set to “1” and the bit that represents benzene would be set “0” in the fingerprint bit string of ATP. Many variations in detailed definitions of 2-D fingerprints exist. In one straightforward way, molecular similarities are measured by the number of bits two compounds have in common.

2. Pharmacophores are defined as essential structural features in a molecule that are responsible for its binding activity, and they can also be used to generate 2-D fingerprints. Examples of commonly used pharmacophores are specific molecular fragments (i.e., an isopropyl group), hydrogen bond donors and acceptors, and negatively and positively charged atoms or groups. In two dimensions, the minimum number of bonds between two pharmacophores can be used as a distance metric. For example, the exocyclic amino
group of ATP is located 3, 4, and 5 bonds away to the three acceptor nitrogens in the purine ring. This information is coded readily in a fingerprint bit string.

3. In addition to 2-D fingerprints, the topological relationships of atoms in a molecule can be explored in high feature dimensions and nonlinear fashion by other means, such as kernel methods (25), support vector machines (26), and self-organizing maps (27).

However, molecular recognition occurs in a 3-D world. It is well known that minor chemical modifications can alter the activity of a molecule drastically. On the other hand, very different chemical structures can have similar activity against the same target. The mere existence of particular pharmacophores and/or their topological relations are not sufficient for a molecule to be active against its target. To account for 3-D information, various VLS techniques based on activities of small molecules without receptor structures have been developed, such as 3-D quantitative structure activity relationship (QSAR) models. It is commonly accepted that a small molecule must exhibit a high degree of shape complementarity to bind to its protein target with high affinity. Finding the correct superposition of active ligand molecules is the key to a successful 3-D QSAR model.

Moreover, these membrane-localized target structures are unknown with high affinity. Finding the correct superposition of active ligand molecules is the key to a successful 3-D QSAR model. Of course, shape alone does not account for all contributions of small molecules. Other factors such as locations of hydrogen bond donors and acceptors, types of functional groups, electrostatic properties, and polarizabilities all play important roles for small-molecule activities. One attempt to capture this information is 3-D pharmacophore method. Like docking, many software programs exist to develop 3-D pharmacophore models, such as DISCO (28), Catalyst (28), GASP (28), PHASE (29), and many others (30, 31). Pharmacophore features are not mutually exclusive; for instance, a hydrogen bond acceptor (i.e., donating electron pair) can be negatively charged (e.g., side chain carboxylate from Asp or Glu). Most programs provide users with the flexibility to define their own pharmacophore features. The main merit of 3-D pharmacophore models is the ability to identify lead compounds that are diverse structurally.

Although three pharmacophore models may differ in how they construct pharmacophore models, they go through the following common steps: generate conformers, enumerate pharmacophore features, generate a hypothesis, and screen the ligand library. Usually, the active conformation of a small molecule is unknown without experimental evidence. A key component of a good pharmacophore method is to sample active conformations rapidly. Studies have shown that the active conformation of a small molecule may not necessarily be the same as the lowest energy one in the unbound state (32). Therefore, a set of possible conformers within a certain energy window (e.g., 15 kcal/mol above the lowest energy conformer) are collected and clustered. The feature-enumerating step is relatively straightforward. It identifies all the possible pharmacophore features in small molecules.

Hypothesis generation is another challenging step in building pharmacophore models. In essence, this step involves finding a proper alignment of active molecules with a high degree of overlap in 3-D space in terms of their pharmacophore features. During this step, the spatial arrangements of pharmacophore features are identified so that they are common for all or a significant subset of active molecules. This step assumes that active molecules must satisfy a common pattern of pharmacophore features. However, it should not require a molecule to have all the features defined in a model to be active. The proper alignment of active molecules determines the quality of a 3-D pharmacophore model. Several algorithms have been developed to identify pharmacophore patterns (33-36) among the set of possible conformations for each active molecule. Pharmacophore hypothesis algorithms try to find and to rank the most probable pharmacophore models for known active molecules. It should also be noted that active molecules do not necessarily share a common pharmacophore pattern. Distinct binding modes have been observed in cocrystal structures (37). Moreover, different small molecules may bind to different binding sites of a receptor. Although a few algorithms exist to identify multiple pharmacophore patterns within a set of actives (29, 36), more robust methods are needed. The conformations of small molecules can be precomputed or sampled "on the fly." Once a valid pharmacophore model is constructed, it can be used to screen millions of small molecules. This strategy was used successfully by Singh et al. to identify some potent and novel VLA-4 antagonists (38). Three-dimensional pharmacophore models are used commonly for GPCR systems because generally, these membrane-localized target structures are unknown. A three-point pharmacophore model was constructed for Urotensin II receptor (39) and was used to search Avantis compound collection. Of 500 virtual "hits," 10 hits were active with the most potent compound exhibiting an IC_{50} of 400 nM. Recently, the first GPR38 specific agonist was discovered by 2-D and shape similarity in combination with a pharmacophore search (40).

Not only can active molecules be used in pharmacophore modeling, structures of inactive molecules can also provide valuable information. In common pharmacophore models, information provided by inactive compounds is captured in the concept of "excluded volume" (29, 41). A "regions that is so close to the receptor that no ligand atoms are tolerated. "Excluded volume" can be obtained automatically or defined manually. The method relies on the idea that the binding modes of the compound series are similar to each other. Although many examples from cocrystal structures and SAR have confirmed this assumption, many exceptions to this empirical observation exist. Chemical similarity does not always predict similarity in biologic activities. When active compounds consist of multiple scaffolds because of different modes of action, it is very challenging to develop pharmacophore models and to classify the actives into proper categories automatically. In addition, a compound that satisfies a good pharmacophore model is not guaranteed to have activity. For example, entropic contributions, solubility, cell permeability, and stability can also have important implications on a compound's biologic activity. Even though most pharmacophore models are built without receptor structures, binding site structures do help to construct proper pharmacophore models. The critical residues provide a complementary image of ligand pharmacophore field. This "negative image can be converted to a ligand pharmacophore model. One advantage of receptor structure-based pharmacophore models is the natural definition of "excluded volume."
Small Molecule Inhibitors: Design and Selection of...
Small Molecule Inhibitors, Design and Selection of molecular weights of between 120–250 Da to allow for subsequent additions. Usually, these compounds have weak affinities (K_d = 10 μM–10 mmol/L). To explore modifications that have the potential to increase binding affinities, the aforementioned computational methods can be applied readily. For structures with a single small molecule in a complex, the small compound can be extended automatically to maximize its interaction with target protein. During the progressive modifications, the binding mode for the initial fragment can be altered. However, certain constraints are applied to avoid drastic changes to the binding modes unless substantial modifications are introduced to the original structure. When evidence exists that multiple ligands bind to different pockets of an extended binding site in one or multiple crystal structures, computational methods can be used to propose proper linkers or fuse-disjointed fragments to yield the synergistic effects. Gill et al. (49) have used this strategy to design P38α MAP kinase inhibitors based on hits with affinities in the millimolar range. For example, they identified a lead molecule with IC_{50} = 65 nM by extending the base fragment to acquire additional interactions, and also to achieve a 100-fold increasing in potency rapidly by cojoining two overlapping fragment hits for an indole-derived compound. The structures are depicted in Fig. 4. It should be emphasized that crystal structures are extremely important in fragment-based design iterations. Because fragment hits are usually small and possess low affinity for the targets, to predict the correct binding modes by docking is difficult. In addition, the modifications to the base fragment may alter its binding modes fundamentally.

Hybrid Design Based on Known Inhibitors

Through many years of drug discovery efforts, pharmaceutical companies have synthesized millions of small-molecule inhibitors. A large amount of information has been accumulated on how these inhibitors bind to their protein targets and to the QSAR of these inhibitors. Hybrid design is an emerging technique that attempts to take full advantage of this information to design new inhibitors for existing or new protein targets (50). The essence of the hybrid design is to recombine known inhibitors for a particular target in a rational way to create new inhibitors for the same target or for a new target. In a manner analogous to the evolutionary recycling of protein domains, the hope for chemical evolution through hybrid design is to create...
new inhibitors by recombining pharmacophores derived from different classes of compounds. Hybrid design starts by using inhibitor-receptor binding information obtained experimentally from crystallography or computationally by docking to overlay multiple known ligands, and then to predict how to recombine inhibitor substructures to create new compounds. This strategy is illustrated in Fig. 5 in which a potent Aurora A kinase inhibitor can be thought of as a hybrid of two inhibitors developed originally for two other kinases. This strategy has also been applied successfully to design novel kinase inhibitors that bind to a specific inactive kinase conformation (51, 52). Gleevec is a Bcr-Abl inhibitor that has been demonstrated crystallographically to bind to the nucleotide binding cleft of Abl, which uses both the adenine binding region and an adjacent hydrophobic pocket created by the activation loop being in a unique inactive conformation (53). A hybrid strategy involved appending a 3-trifluoromethylbenzamide group to a known ATP binding site inhibitor (51). Of the hybrid compounds thus created, potent and selective inhibitors have been identified for Abl, c-Kit, p38, PDGFR, and Aurora kinases (52). Figure 5 shows how a benzamide group is attached to a quinazoline scaffold to create an inhibitor that binds to an inactive Aurora kinase conformation similar to that observed on Abl-Gleevec complex.

A computer program named BREED automates the process for hybrid design (54). The method imitates the common medicinal chemistry practice of joining fragments of two known ligands to generate a new inhibitor. The known active ligands are superimposed in their active conformation to identify all overlapping bonds, and the fragments on each side of each matching bond are swapped to generate a large set of novel inhibitors. This method has been demonstrated to have a high rate of success to identify novel inhibitors for HIV protease and protein kinases (54).

**De Novo Design**

Small molecule inhibitors can also be generated by de novo design without the prior knowledge of other active ligands. In essence, the procedures are similar to those mentioned previously. For example, LeapFrog can start without a given small molecule. It will select a core randomly and will grow a ligand from its fragment library. Although it is still rare for a computer program to generate practical and active molecules from scratch, reports of novel molecules from “raw” output of automated computer program exist. SkelGen (55) was able to generate small-molecules inhibitors for estrogen receptor binding sites without hints from known actives. Among the 17 highest scoring structures, 5 structures were active with 4 structures that possess novel structures. We have also implemented a de novo ligand design algorithm in our in-house software GRodE using an evolutionary algorithm. A molecule is represented by a unique genetic code that is subject to normal genetic operations such as mutation, addition, deletion, and translocation. The population of ligand molecules is evolved toward increasing fitness. Our retrospective studies have shown that the method can produce lead molecules that are extremely similar to experimental nanomolar inhibitors.
Small Molecule Inhibitors, Design and Selection of

If the target binding site structure is unavailable, de novo design can be carried out based on known active molecules. This circumstance may occur because none of the known actives that pose desired properties or that pose novel inhibitors are sought for patentability. However, the known inhibitors provide a basis to construct 3-D pharmacophore and other models such as Comparative Molecular Field Analysis (CoMFA) that can provide a template to guide the computational algorithm to maximize the fitness of the molecule “population” toward a given model. For example, Leapfrog can use CoMFA models in place of target binding site structures. It is also straightforward to apply pharmacophore models to novel molecular design with and without starting fragments. Novel structures are chosen based on its fitness to the given model. Unlike de novo design with known binding site structures, it is important to minimize the possibilities for resulting molecules to have steric clashes with receptor atoms. Even though these programs have produced promising results, the major drawback for such automated computer algorithms is that the “raw” computer derived molecules often are undesirable synthetically or implausible chemically. Some programs (55) have implemented chemistry rules to guide the generation of new molecules, but it is still far from satisfactory. Moreover, because a drug molecule interacts with its intended target in a complex biologic environment, a good lead molecule is selected by not only its binding affinity to its intended target, but also other properties such as crucial physical chemical properties, ability to expand SAR, selectivity relative to undesired off targets such as cytochrome P450 enzymes, and ion channels such as HERG. All are important considerations to advance a target in a complex biologic environment, a good lead molecule is selected by not only its binding affinity to its intended target, but also other properties such as crucial physical chemical properties, ability to expand SAR, selectivity relative to undesired off targets such as cytochrome P450 enzymes, and ion channels such as HERG. All are important considerations to advance a molecule toward clinical development. Various computational methods have been developed to predict these properties; however, normally they are not integrated into automated de novo design program.

Hit and Lead Optimization

Computational algorithms and modeling have advanced significantly over the last two decades in terms of accuracy, efficiency, and ease of use. Many modeling procedures are automated; however, they are far from replacing the intuition and knowledge of an experienced computational chemist. Although automated programs are used widely in early stages of lead discovery with limited human intervention, lead optimization is a process in which a computational chemist makes contributions out of his knowledge, insight, experience, and intuition. Before lead optimization, computational algorithms are designed to explore wide areas of chemical space and a wide range of activity data. During lead optimization, focus is placed on one or a few particular compound series. Small modifications are introduced to investigate local SAR and to improve other pharmacologic properties. Incremental improvements are often the objectives at this stage. Whereas the automated computational methods described previously are still important, they are not sufficiently precise to distinguish between modifications that result in 2 kcal/mol changes in binding affinities. Manual intervention, such as visual inspection and manual docking from an experienced chemist, are often of great importance for this phase.

Structure Based

As we can observe from previous discussion, protein structures have played invaluable roles in small-molecule inhibitor selection and design. Currently, over 40,000 biomacromolecular structures are deposited in RCSB protein databank. Over 5000 new structures were deposited in 2006. The atomic level structural information provides an enormous wealth of mechanistic insights with regard to protein function. A approximately 6500 protein structures in the database are in complex with an inhibitor or substrate to provide chemists with important insights into the mechanism of ligand recognition. Because biologic systems are very diverse, each system requires specialized knowledge and treatment. Successful ligand design requires an intimate knowledge of all known inhibitors, which include how their activity and selectivity is changed as a function of chemical modification (SAR), rules for which interactions are required for high affinity binding, knowledge about the potential for conformational rearrangements, and insight into what is tractable synthetically. Success therefore requires the close collaboration of computational chemists, medicinal chemists, and structural biologists. Here, we will attempt only to describe a few common techniques that computational chemists use to optimize the activity of a small-molecule inhibitor.

Visual inspection is probably one of the oldest and most powerful methods in computer modeling. Large amounts of information can be acquired by looking at the 3-D structures of an inhibitor and a protein complex, such as important hydrogen bonds, hydrophobic contacts, and strong electrostatic interactions. It allows one to design a derivative to make stronger or additional hydrogen bonds, to explore unoccupied pockets, and even to alter the scaffold while maintaining important interactions. Of course, regular molecular modeling methods are used here to ensure the proposed molecules possess sensible conformations. In contrast to the automatic molecular generating programs mentioned previously, the modifications here are proposed directly by chemists; therefore, the molecules are tractable synthetically and often follow a particular experimentally derived SAR series. The iterative use of model building, synthesis, and biologic evaluation is the most powerful and efficient means to obtain small molecules with a desired biologic activity. When multiple crystal structures with different ligands exist, one can gain even more insights into conserved interactions. This insight can be very useful to identify key interactions and to help design new compounds to maximize possible key interactions. An algorithm developed by Deng et al. (56) uses a binary string to represent ligand protein interactions. By clustering the binary strings of different small-molecule binders, the authors were able to illustrate the similarity and diversity of small-molecule binding modes. This information can be used to select correct binding modes as well as to propose new molecules.

“Anchored docking” is another common technique used in lead optimization. Unlike automated docking, “anchor” points such as particular hydrogen bonding are specified by the user to limit the configuration space sampled by docking program. This limit is to ensure that the knowledge of a chemist about the system is enforced, because usually automated docking is sufficiently accurate to find correct binding modes consistently.
The "anchor" points can be defined for a receptor, a small molecule, or both. The correct definition of "anchor" points largely relies on the users’ knowledge of the system.

**Qsar Based**

Even with an ample amount of protein structures available, many interesting protein targets without 3-D structural information exist. GPCRs are typical examples. In this case, only SAR derived from the biologic assay can be used to guide optimization. Under these circumstances, QSAR has been an important tool. It is probably one of the earliest tools for computer aided drug design. Properly choosing descriptors for QSAR models is much like an art and requires a deep understanding of the system of interest. Most common descriptors are based on physical, chemical, geometric, and topological properties. Three-dimensional QSAR models may require active ligands to be aligned properly just like the pharmacophore model building. In fact, 3-D QSAR models can be generated directly by pharmacophore models, and many pharmacophore-generating programs provide this capability. One method developed early and widely used for 3-D QSAR is CoMFA.

**Design of Selective Small Molecule Inhibitors**

For a small-molecule inhibitor to be useful as a therapeutic drug or as a tool for chemical biology study, it must have specificity for its intended target. A small-molecule drug often causes side effects or toxicity if it also modulates other proteins in the body (i.e., off-targets). Nonselective inhibitors will confound the effects or toxicity if it also modulates other proteins in the body. Therefore, the selectivity is a very important feature when considering design and selection of small-molecule inhibitors. Because ≈30,000 proteins are encoded in the human genome, which can possess multiple ligand binding sites and can be present in vastly different concentrations, finding specific inhibitors can be an extremely difficult task. Aalyzing the sequence and structural differences between a targeted protein and its closely related homologs is an effective way to design selectivity rationally.

**Targeting the Differences in the Binding Pocket**

The binding affinity of a ligand is determined by its complementarity to the size, shape, and physicochemical properties of the protein-binding site. To design selective small-molecule inhibitors rationally, the 3-D structure of the target-binding site is required. In principle, the structure of a protein-binding pocket is determined by its amino acid sequence, and it is straightforward to identify unique amino acids by sequence alignment. Once the unique residues are identified, they can be analyzed in the context of small-molecule binding to determine the residues that are important for protein ligand interaction. The inhibitors can then be designed to target them specifically for selectivity. Taunton et al. have used this approach to design selective inhibitors for p90 ribosomal protein S6 kinases (RSKs) (57). They identified two key selective determinants for RSK’s relative to other kinases. One determinant is a small "gatekeeper" amino acid, and the other is a Cys in the glycine-rich loop. Targeting these two residues, they were able to make very potent and selective inhibitors for RSKs.

Although successful for RSKs, it is often very difficult to identify unique residues suitable for selectivity for all proteins in a family. In many cases, a mono-selective inhibitor among the protein family members is not feasible, so selectivity against a subset of the family members is desired. In this case, selectivity can be achieved by targeting the sequence differences in the binding sites between the target protein and the unwanted proteins. This strategy has been applied successfully to design selective inhibitors for targets within a closely related subfamily, such as p38 kinase α, β, γ, and δ isoforms (58); protein kinase CDK2, and CDK4 (59); and COX-1 and COX-2 (60).

For protein targets that are closely related, the binding sites may look the same and no sequence difference is around the binding pocket. Therefore, a small molecule that binds to this primary site has very little selectivity. In these cases, a commonly used strategy is to search for a secondary site near the primary binding pocket. If it is less conserved, selective inhibitors can be designed by targeting the secondary site. For example, it is very difficult to develop a selective protein tyrosine phosphatase-1 B (PTP-1B) inhibitor, but a crystal structure of PTP-1B in complex with bis(para-phosphonyl) methane reveals a secondary aryl phosphate-binding pocket adjacent to the active site that can be targeted to design selective PTP-1B inhibitors (61).

Many protein structures are highly dynamic, and induced-fit effects are well known in small-molecule and protein binding (21). Although two proteins can have very similar binding pockets in static form, they can have different plasticity. Although protein flexibility is one major obstacle to predict the binding mode and the affinity of a ligand accurately, it provides a structural basis to design selective inhibitors. Usually, the conformations of the active enzymes within a family are more alike, but the inactive conformations are more different. For example, the ATP binding pockets of protein kinases in active states are highly similar, but considerable conformational variability exists among kinases in the inactive state that can be exploited for selective inhibitor design. The unique “DFG-out” inactive conformation has been applied already to the design of selective kinase inhibitors, which includes the already approved drug Gleevec and Nexavar. Lapatinib, one of the most selective kinase inhibitors, achieves its high selectivity by binding to an inactive conformation of EGFR with a methionine in the α-C helix moved away from its normal position to accommodate the beryloxy group of lapatinib (62). Exploiting differentially accessible conformational states among closely related targets has also been the structural basis for observed high selectivity of PI3K kinase inhibitors (63).
Identifying a selective small-molecule inhibitor can be time consuming. For a target in a large protein family, it is almost impossible to achieve monoselectivity. Inhibiting multiple targets by a small molecule leads to a significant complication in the analysis of target validation and studies of protein functions. To overcome the difficulty of identifying monoselective small-molecule inhibitors, a chemical genetic approach is applied to design as orthogonal receptor-ligand pairs (64, 65). In this approach, the targeted protein is mutated in the active site to create a structural distinction between the target and all other members of proteins in the same family. Then, a small molecule is designed to target the distinct structure so that it only binds the mutated protein. The first step is to study the binding mode of a small molecule to its target and identify an important interaction that is highly conserved for the ligand binding to all members in the protein family. Then, the ligand is modified in the conserved interaction region to disrupt the interaction so that it cannot bind effectively to any wild type protein, which includes the target. Two modifications are used commonly. One is to add a bulky substitute (a “bump”) at the interacting position to create steric clashes, and the other is to disrupt the critical hydrogen bonding between the ligand and the protein. The next step is to mutate the residues around the bump to smaller ones (which creates a “hole”) to accommodate the “bump” or to mutate residues to restore the critical hydrogen bonds. Although both approaches have introduced orthogonal protein-ligand pairs successfully, the “bump-hole” strategy is more suitable for design and is applicable to many different protein families. Shokat’s lab has successfully applied the “bump-hole” strategy to generate monospecific inhibitors for engineered kinases (64). The monospecific inhibitors have been used widely in kinase signaling pathway elucidation and target validation (66). Figure 6 outlines the strategies and workflows that we discussed for selective inhibitor design, in which the method details of each step in the flow chart have to be tailored towards specific systems.

**Summary**

In this review, we described briefly some common computational techniques to select and to design small-molecule inhibitors. It is not a comprehensive list of all methods available. Instead, we focused on basic methods that are used commonly in drug discovery research. Because of the size limitation, it is also impossible to discuss all the details in each method. We hope that this short review can provide some fundamental concepts used in virtual screening and rational design, and can provide the interested reader with an entry point to explore the field of computational inhibitor design and selection. Although we described the computational methods in a linear flow, the methods used in one stage of small-molecule inhibitor discovery process can be applied at different stages whenever...
appropriate. To choose the proper methods for different purposes at different stages is crucial for computational modeling to be effective. In addition, computational modeling should always interact tightly with experimental investigation in order to make significant contributions. VS and rational design is also an ever-changing field. New algorithms and strategies are emerging continuously. We believe that computational methods will play increasingly important roles in discovering new small-molecule inhibitors.

Stem cells hold great promise for the treatment of many devastating diseases and will also provide new insights into the molecular mechanisms that control developmental and regenerative processes. Realization of the therapeutic potential of stem cells will require a better understanding of the signaling pathways that control stem cell fate as well as an improved ability to manipulate stem cell proliferation, differentiation, and reprogramming. Cell-based phenotypic and pathway screens of synthetic compounds have led recently to the discovery of several small molecules that can be used to control stem cell fate. Such molecules will not only provide new insights into stem cell biology but will also facilitate the development of therapeutic agents for regenerative medicine.

Given appropriate conditions, stem cells can self-renew for long periods of time while maintaining the ability to differentiate into various functional cell types in the body (1). It is these characteristics that not only make stem cells a useful system in which to study tissue and organ development but also give them great potential for regenerative medicine. Given the success of well-practiced, cell-based therapies (e.g., hematopoietic stem cell transplantation for treating hematological diseases and pancreatic islet cell transplantation for type I diabetes), it is conceivable that this approach could be applied to many other serious medical conditions where cells are lost because of disease, injury, or aging. Current challenges in cell replacement therapy include the limited source of engraftable stem/progenitor cells and a poor ability to manipulate their functional expansion and differentiation. Alternatively, drug stimulation of the body’s own regenerative capabilities (i.e., proliferation, differentiation, migration, or even reprogramming of endogenous cells to replace the damaged cells/structures) may represent a more desirable therapeutic approach to fulfilling the ultimate goal of regenerative medicine. Although tremendous efforts have been put into these areas, it is clear that a better understanding of stem cell biology is required before these approaches can be realized.

Small molecules have long been associated with biological discoveries. Our understanding of biological processes often develops from discovering or designing ways to perturb a given process and observing the effects of the perturbation. Although genetic approaches have been widely used for this purpose, the small-molecule approach clearly offers some distinct advantages. For example, small molecules provide a high degree of temporal control over protein function, which generally acts within minutes or even seconds, and their effects are often reversible, which facilitates both rapid inhibition and activation. Their effect can also be finely tuned by varying concentrations of the compound of interest. Moreover, because of the inherent difficulty of genetic manipulation for many types of stem cells (e.g., low transfection efficiency or poor clonal expansion), small-molecule tools are especially useful for the stem cell field. In this article, recent developments in the use of small molecules (Fig. 1) on the various aspects of stem cell biology such as self-renewal, differentiation, and reprogramming will be reviewed.

Biological Background of Stem Cells

Stem cells normally are classified, based on their origin and differentiation capacity, as either embryonic or adult stem cells (1). Embryonic stem cells (ESCs) are derived from the inner cell mass of the blastocyst. ESCs can self-renew indefinitely and are pluripotent—the ability to differentiate into all cell types in the embryo proper. Adult stem cells are undifferentiated (unspecialized) cells that are found as differentiated, or specialized, tissue. They have limited self-renewal capability and generally can only differentiate into the specialized cell types of the tissue in which they reside. These cells function as the “reservoir” for cell/tissue renewal during normal homeostasis or tissue regeneration. Sources of adult stem cells have been found in most tissues, including bone marrow, blood stream, cornea...
Small Molecules to Control Stem Cell Fates

and retina of the eye, dental pulp of the tooth, liver, skin, gastrointestinal tract, lung, pancreas, heart, and brain. For example, the bone marrow is a mesoderm-derived tissue that consists of a complex hematopoietic cellular system supported by stromal cells embedded in a complex extracellular matrix. A growing body of evidence suggests that bone marrow contains at least two types of stem cells: hematopoietic stem cells (HSCs) and mesenchymal stem cells (MSCs), both of which are multipotent. HSCs have the capacity to provide life-long reconstitution of all blood-cell lineages after transplantation, whereas MSCs

Figure 1 Chemicals that control stem cell fate.

- 1972 -
have the ability to differentiate, both in vitro and in vivo, into a variety of adult mesenchymal cell types, including osteoblasts, chondrocytes, and adipocytes.

Stem cell fate in vitro is under strict control from both intrinsic and extrinsic factors, and loss of this control has been postulated to be a key step in degenerative and carcinogenic processes (2). Emerging evidence suggests cancer initiation results from an accumulation of oncogenic mutations (intrinsic loss of control) in long-lived stem cells or their immediate progenitors, followed by modification of the surrounding microenvironment (loss of extrinsic control) (3). Cancer stem cells have been detected in leukemia, breast, and brain tumors (4–7). They may originate from resident stem cells or develop as a result of a gain of self-renewal capacity in tissue progenitor cells. Therefore, the characterization of a cancer stem cell profile within diverse cancer types, and a better understanding of the biology of its counterpart, the normal stem cell, may open up new avenues for cancer treatment.

Stem cell expansion and differentiation in vitro commonly are controlled by culturing cells in a specific configuration (e.g., an attached monolayer or as suspended aggregates) with cocktails of growth factors and signaling molecules as well as genetic manipulations. However, most of these conditions are either incompletely defined or are nonspecific and inefficient at regulating the desired cellular process. Such conditions often result in inconsistency in cell culture and mixed populations of cells that would not be useful in studying specific cellular processes or in cell-based therapies. More efficient and selective conditions for homogeneous stem cell self-renewal and differentiation into specific cell types need to be developed before the various applications of stem cells can be realized. Towards this end, chemical approaches serve as excellent tools to investigate the underlying mechanism and to control the specific stem cell fate.

### Chemical Approaches to Stem Cell Research

Conceptually, two approaches exist for discovering chemical compounds in stem cell biology. The target-based approach involves development of chemical compounds for specific biological targets and the application of these compounds in order to link their targets’ modulation to the produced pharmacologic effect in cells or organisms. In the phenotype-based approach, small-molecule libraries are screened in high-throughput functional assays (in cells or whole organisms) to identify compounds that produce a desired phenotype, followed by elucidation of the molecular targets or pathways that they engage.

The success of both target-based and phenotype-based methods relies heavily on the qualities of the chemical libraries used. Although combinatorial technologies allow the synthesis of a large number of molecules with immense structural diversity, it is impossible to saturate the chemical space, which has been estimated to contain more than $10^{60}$ molecules (8). Because biological space interacts with only a fraction of chemical space, synthetic attempts to increase randomly the molecular diversity of a chemical library by introducing a high level of structural variability/complexity drastically reduce the libraries’ fitness to a given biological selection/screen, which results in most molecules being inactive. Furthermore, screening of even larger chemical collections to increase the chance of finding hits can compromise assay functionality, sensitivity, and fidelity for practical reasons (9). As a result, the screening of a highly defined set of compounds in stem cell biology becomes a critical aspect of combinatorial synthesis.

The notion of “privileged structures” describes selected structural motifs that can provide potent and selective ligands for biological targets (10). Privileged structures typically exhibit a greater tendency of interacting with biological targets and good “drug-like” properties (11, 12). One of the most straightforward and productive ways to generate “privileged” chemical libraries is to use key biological recognition motifs as the diversity elements for combinatorial synthesis (13). In this approach, a variety of naturally occurring and synthetic heterocycles that are known to interact with proteins involved in cell signaling (e.g., kinases, cell surface and nuclear receptors, or enzymes) are used as the core molecular scaffolds. Then, a variety of substituents can be introduced into each of these scaffolds to create a diverse chemical library. Using this method, a diverse heterocycle library that consists of over 100,000 discrete small molecules (representing over 30 distinct structural classes) was generated with an average purity >90%, which has proven to be a rich source of biologically active small molecules targeting various proteins involved in a variety of signaling pathways.

The screening method is another important factor for the phenotypic approach. Although the use of simple reporter systems or enzymatic activity assays would allow higher throughput in cell-based assays, the monitoring of more complex phenotypic changes (e.g., cell morphology, multiple biomarker expression and localization, and cell physiology) by high content imaging methods substantially reduces false analysis from primary screens and provides broader assay versatility (14, 15). Furthermore, informatics on the matrix of assays/compounds/genes has facilitated bioactive compound identification and deconvolution of their mechanism.

### Small-Molecule Regulators of Stem Cell Fate

#### Self-renewal

Self-renewal is the process by which a stem cell divides to generate one (asymmetric division) or two (symmetric division) daughter stem cells with identical developmental potentials as the mother cell (16). The self-renewal ability of stem cells is central to development and the maintenance of adult tissues.

Self-renewal of stem cells can be regarded as a combined phenotype of cellular proliferation and inhibition of differentiation and cell death. Consistent with this notion are the findings that self-renewal of murine embryonic stem (mES) cells can be achieved in the absence of feeder cells and serum in a chemically defined medium condition by the combined activity of two key signaling molecules: LIF/interleukin 6 (IL6)
family members and bone morphogenetic protein (BMP) (17). LIF activates STAT (signal transduction and activation of transcription) signaling through a membrane-bound gp130-LIFR (LIF receptor) complex to promote proliferation and to inhibit mesoderm and endoderm differentiations of mES cells via a Myc-dependent mechanism. BMP induces expression of Id (inhibitor of differentiation) genes via Smad signaling and inhibits differentiation of mES cells to neuroectoderm.

To gain a better understanding of ESC self-renewal, a cell-based screen for small molecules that can promote mESCs self-renewal was carried out using an established Oct4-GFP reporter mESC line and examining pluripotency marker expression (Oct4) as well as morphological analysis (undifferentiated ESCs having compact colony morphology). A novel, synthetic small molecule named pluripotin was discovered in this screen that is sufficient to propagate mESCs in the pluripotent state under chemically defined conditions in the absence of feeder cells, serum, and LIF. Long-term cultures of mESCs with pluripotin can be differentiated into cells in the three primary germ layers (ectoderm, mesoderm, and endoderm) and they can also generate chimeric mice and contribute to the germ line in vivo. Affinity chromatography using a pluripotin-immobilized matrix identified ERK1 and RacGAP as the molecular targets of pluripotin. Additional biochemical and genetic experiments confirm that pluripotin is a dual-function, small-molecule inhibitor of both ERK1 and RacGAP, and that simultaneous inhibition of both protein activities is necessary and sufficient for pluripotin’s effects on mESCs. Because pluripotin’s mechanism of action is independent of LIF, BMP, and Wnt signaling, this study suggests that ES cells may possess the intrinsic ability to self-renew and that inhibiting differentiation pathways would be sufficient for maintaining the undifferentiated state. Thus, not only did the discovery of pluripotin provide interesting insights to the mechanism of ESC self-renewal, but it also exemplified the power of small-molecule screens in that it is possible to modulate more than one target by a small single molecule to achieve a desired complex biological phenotype. In addition to the unbiased phenotypic screen described above, based on known mechanistic insights, p38 (e.g., SB203580), MEK (e.g., PD98059), or GSK3 (e.g., BIO) inhibitors have been shown to enhance self-renewal of mESCs in the presence of additional signaling inputs (18–20).

Consistent with the self-renewal model, recent studies on Notch signaling exemplified the contribution of cell survival signaling to stem cell self-renewal. Andrountelis-Theotokis et al. (19) found that activation of Notch promotes fetal neural stem cell (NSC) survival, most likely through activation of AKT, STAT3, and mTOR; this survival signal is antagonized by JAK and p38 MAPK, and applying JAK and p38 inhibitors significantly improves survival of NSCs. Interestingly, this mechanism also functions in human ESCs. Moreover, p38 inhibitors have also been shown by another independent study to promote HSC life span, which confirms even more the role of p38 in stem cell self-renewal (21). Although the details of the molecular mechanism still need to be worked out, these inhibitors clearly have had a beneficial effect on stem cell culture.

Most stem cells can divide via either asymmetric or symmetric modes (22). Because each asymmetric division generates one daughter with a stem-cell fate (self-renewal) and one daughter that differentiates, it was postulated that asymmetric division could be a barrier to stem cell expansion. Therefore, conversion of asymmetric division to symmetric division would promote self-renewal and long-term culture of stem cells. Indeed, this idea was confirmed by using one small molecule, the purine nucleoside xanthosine (Xs) (23). This small molecule promotes guanine nucleotide biosynthesis that reversibly converts cells from asymmetric division kinetics to symmetric division kinetics. It was found that Xs derived from stem cell lines exhibit Xs-dependent symmetric kinetics, and this derived stable line shows enhanced self-renewal. This study underscores the importance of balance between the two modes of division, both to stem cell expansion and to the regenerative capacity of adult stem cells.

One major challenge in hESC culture is a low survival rate after cell dissociation. Genetic manipulation (e.g., gene-targeting), and to a lesser extent, routine culture and directed differentiation are all reliant on clonal survival and/or cell association. In a small screen, a selective small-molecule inhibitor of p160 rho-associated coiled-coil kinase (ROCK), Y-27632, was found to increase hESC survival. The mechanism of action by which Y-27632 inhibits apoptosis, which is yet to be identified, should yield insights as to the causes of poor survival after dissociation (24).

Recent studies have identified multipotent isl1+ cardiovascular progenitors (MICPs) in mouse embryos, and they have also been cloned from mESCs (25). MICPs can produce the three main cell types of the heart: cardiac muscle, smooth muscle, and endothelial cells. To gain a better understanding of mechanisms that regulate the self-renewal and differentiation of MICPs, a high-throughput screen was completed to identify small molecules capable of inducing expansion of isl1+ MICPs (26). Several molecules were identified that significantly increased MICP expansion, with the potent GSK-3beta inhibitor BIO being one of the strongest. Furthermore, replacement of BIO and CMCs with a Wnt3a-producing feeder layer also facilitated MICP expansion, whereas treatment with Dickkopf-1 (DKK-1), which is an extracellular inhibitor of Wnt signaling, decreased the number of isl-1+ progenitor cells. Interestingly, BIO treatment also induced expansion of human isl1+ progenitors, which suggests a conserved role of Wnt signaling in self-renewal of MICPs.

**Lineage-specific differentiation**

Differentiation is the developmental process by which early multipotent cells acquire the features of late-stage, mature cells such as neurons, hepatocytes, or heart muscle cells. Currently, few examples of devised, highly selective, and efficient conditions for stem cell differentiation into specific homogenous cell types have been reported because of a lack of understanding of stem cell signaling at the molecular level. Small-molecule phenotypic screens provide another means to generate desired cell types in a controlled manner. Several small molecules have been identified by this method that modulate specific differentiation pathways of embryonic or adult stem cells.
Neural and neuronal differentiation

Retinoic acid (RA), forskolin, and HDAC inhibitors have been shown to induce neural differentiate of hippocampal adult neural progenitor cells. However, these factors are either pleiotropic or undefined physiologic relevance: RA has neuronal subtype patterning activity and also been reported to induce cardiac differentiation (27) as well as pancreatic differentiation (28). HDAC inhibitors are nonspecific; and forskolin activates protein kinase A and serves to increase the cellular levels of the general signaling molecule cAMP (29).

Neuropathiazol, which is a substituted 4-aminothiazole, was identified recently from a high-content imaging-based screen of chemical libraries that specifically induces neural differentiation of multipotent adult hippocampal neural progenitor cells (30). More than 90% of the neural progenitor cells treated with neuropathiazol differentiated into neuronal cells as determined by immunostaining with βIII tubulin and the characteristic neuronal morphology. Interestingly, neuropathiazol can also inhibit astroglial differentiation induced by LIF and BMP2, whereas RA cannot, which suggests that neuropathiazol functions by a different mechanism and has more specific neurogenic inducing activity. The precise molecular target(s) of neuropathiazol is still unknown, although its identification will surely provide mechanistic insights into neuronal differentiation. Additionally, neuropathiazol can be used as a specific inducer to generate homogeneous neuronal cells, and it may serve as a starting point for development of small-molecule drugs to stimulate in vivo neurogenesis.

In an elegantly devised approach, functional motor neurons were generated from mESCs by sequential treatments with RA (neutralizing and catalyzing mESCs) and a specific small-molecule agonist (Hb-Ag1.3) of Hedgehog (Hh) signaling (ventralizing the caudalized cells) (31). This experiment underscores the importance of following developmental progression through sequential induction and combinatorial factors for generating a late-stage cell type from early stem cells.

Differentiation of mesenchymal stem/progenitor cells

Mesenchymal stem cells (MSCs) are capable of differentiating into all mesenchymal cell lineages, such as bone, cartilage, adipose, and muscle, and play important roles in tissue repair and regeneration. Many small molecules have been used to control the differentiation of mesenchymal stem/progenitor cells to a variety of cell types. For example, 5-aza-C (a DNA demethylating agent) can induce C3H10 T1/2 cells (a mouse mesenchymal progenitor cell line) to differentiate into myoblasts, osteoblasts, adipocytes, and chondrocytes by enhancing cell differentiation competence via epigenetic modifications. Dexamethasone (a glucocorticoid receptor agonist) is another kind of epigenetic modifier, and its combination with other small molecules, such as ascorbic acid, β-glycerophosphate, isobutylmethylxanthine (IBMX, a nonspecific phosphodiesterase inhibitor), or peroxisome proliferator-activated receptor γ (PPARγ) agonists (such as rosiglitazone) have been used widely to modulate osteogenesis or adipogenesis of MSCs under specific conditions (32, 33). To identify small molecules that selectively induce osteogenesis of MSCs, a high-throughput screen of chemical libraries in C3H10 T1/2 cells using an enzymatic assay of alkaline phosphatase (a specific osteoblast marker) led to the identification of a novel synthetic small molecule, purmorphamine (13). Genome-wide expression profiling in conjunction with systematic pathway analysis were used to reveal that the Hh signaling pathway is the primary affected biological network by purmorphamine (34). Additionally, studies, including chemical epistasis using known Hh pathway antagonists (cyclopamine and forskolin), have confirmed that purmorphamine’s mechanism of action on osteogenesis is through specific activation of the Hh pathway, and it acts at the level of Smoothened (Smo) (35). More recently, it was shown that purmorphamine directly targets the protein Smoothened (Smo) through competitive displacement assays using fluorescently-tagged cyclopamine. Recently, a small-molecule screen completed in zebrafish embryos identified prostaglandin E2 (PGE2) synthesis as a novel modulator of vertebrate HSC function (36). Molecules that up regulated PGE2 synthesis increased HSC function, whereas those that lowered PG synthesis decreased HSC function. Moreover, treatment with a stabilized 16,16-dimethyl derivative of PGE2 improved kidney marrow recovery after irradiation in the adult zebrafish. Furthermore, PGE2 also induced an amplification of multipotent progenitors derived from mESCs, which demonstrates a conserved role in vertebrate species. These studies suggest that modulation of the PGE2 pathway could potentially be used to treat patients undergoing bone marrow transplant or to treat anemia.

Regeneration

Terminally differentiated, post-mitotic mammalian cells are thought to have little or no regenerative capacity, as they are already committed to their final specialized form and function and have permanently exited the cell cycle (36). However, it is conceivable that appropriate stimulation of mature cells to re-enter the cell cycle and proliferate may provide new therapeutically approaches for treating various degenerative diseases and injuries. The mammalian cardiomyocyte is one such mature cell type that has attracted substantial research efforts toward its regeneration. Using a target-based approach, a p38 MAPK inhibitor, SB203580, and a GSK3 inhibitor, BIO, have been shown independently to promote proliferation in both neonatal and adult cardiomyocytes indicated by BrdU incorporation and histone 3 phosphorylation (37, 38). The proliferation in adult cardiomyocytes was also observed to be associated with transient dedifferentiation of the contractile apparatus. Activation of canonical Wnt signaling by BIO also promotes proliferation of cardiac progenitor cells. The pancreatic β cell is another highly sought cell type for regeneration, the transplantation of which, in conjunction with simultaneous prevention of their immune destruction, may represent a “cure” for type 1 diabetes. Recent phenotypic screens of large chemical libraries have identified several classes of small molecules that can promote proliferation of human β cells, among which p38 inhibition was identified as the mechanism of action for one class of molecules. A major challenge lying ahead for proliferation of mature cell types is that the process typically is associated
with loss of the cell phenotype (e.g., proliferated β cells under
dergo epithelial-to-mesenchymal transition (EMT) to acquire
fibroblast-like features, and they typically do not redifferentiate
back to the mature β cells). Strategies for inducing functional
redifferentiation of the proliferated cells or for inhibiting loss
of cell identity while proliferating are highly desirable and are
under intense investigations. It should be noted that a synthetic
purine analog, myosentin, was identified previously from a
phenotypic screen, which can induce cleavage of multicellular
myoblasts to generate myoblast-like cells, which can proliferate
and redifferentiate into myotubes (39).

In the mammalian CNS, failure of axonal regeneration is
attributed not only to the intrinsic regenerative incompetence
of mature neurons but also to the inhibitory actions of CNS
myelin and molecules in the glial scar at the lesion sites. In a
cell-based screen to identify small molecules that can counteract
myelin and molecules in the glial scar at the lesion sites. In a
phenotypic screen, which can induce cleavage of multicellular
myoblasts to generate myoblast-like cells, which can proliferate
and redifferentiate into myotubes (39).

Cellular reprogramming

It was long thought that tissue/organ-specific stem/progenitor
cells could give rise only to cells of the same tissue type
but not to those of different tissue. In other words, they have
irreversibly lost the capacity to generate cell types of other
lineages in the body. However, recently several reports have
demonstrated that tissue-specific stem cells may overcome their
intrinsic lineage-restriction during exposure to a specific set of
in vitro culture or in vivo conditions. For example, recently the
Yamanaka group (41) has demonstrated that cells from mouse
embryonic fibroblast culture can be induced into a pluripotent
state during transduction with four genes (Oct-3/4, c-Myc, Sox2, and
Klf-4) in vitro. These results were extended recently to
demonstrate germline transmission of the induced pluripotent
cells (42). An extreme example is the reprogramming of a so-
matic cell to a totipotent state by nuclear transfer cloning, where
the nucleus of a somatic cell is transferred into an enucleated
oocyte or the extracts of the oocyte are fused with a somatic
nucleus (43, 44). Although in mammals neither transdifferentiation
nor dedifferentiation has yet been identified as a naturally oc-
curring process (except in certain disease states), the discovery
of cell plasticity raises the possibility of reprogramming a re-
stricted cell’s fate. The ability to dedifferentiate or reprogram
lineage-committed cells to multipotent or even pluripotent cells
might overcome many obstacles associated with using ESCs
and adult stem cells in clinical applications (e.g., immunocom-
patibility, cell isolation and expansion, or bioethics).

To identify small molecules that induce reprogramming of
lineage-committed myoblasts, a cell-based screen was designed
based on the notion that lineage-reversed myoblasts would regain multipotency. Specifically, dedifferentiated myoblasts
would acquire the ability to differentiate into (otherwise nonper-
mitted) mesenchymal cell types under conditions that typically
induce differentiation of only multipotent MSCs into adipocytes,
osteoblasts, or chondrocytes. A two-stage screening protocol
was used in which C2C12 myoblasts were treated initially with
compounds to induce dedifferentiation; compounds were then
removed, and cells were assayed for their ability to undergo os-
togenesis during addition of known osteogenic inducing agents.
Reversine, which was a 2, 6-disubstituted purine, was found to
have the desired dedifferentiating inducing activity (45). It in-
hibits myotube formation, and reversine-treated myoblasts can
redifferentiate into osteoblasts and adipocytes during exposure
to the appropriate differentiation conditions. In addition, the re-
programming effect of reversine on C2C12 cells (as well as some
other cell types) can be shown at the clonal level, which
suggests its effect is inductive rather than selective. Further-
more, reversine has also been shown to induce reprogramming
of primary mouse and human fibroblasts to a multipotent state,
which can be redifferentiated to functional myoblasts and my-
ocytes under myogenic conditions, which suggests that rever-
sine’s reprogramming mechanism might be general to different
cell types (46).

Affinity chromatography experiments revealed that nonmuscle
myosin II heavy chain (NMMII) and MEK1 are cellular
targets of reversine. Mechanistic analysis demonstrated that
reversine acts by inhibiting both NMMII and MEK1. Inhibi-
tion of NMMII induces G2/M phase accumulation/staging and
cytoskeletal remodeling, whereas MEK1 inhibition serves to
modulate signaling, including acetylation of histone H3. Addi-
tionally, PI3K signaling was found to be essential to reversine
activity (47).

Modulators of developmental pathways
and epigenetic modifiers

Developmental signaling pathways, such as Wnt, Hb, TGF/
BMP, and Notch, control embryonic patterning and cell be-
avior during development and play important roles in regu-
lating tissue homeostasis and regeneration in adulthood. Known
chemical modulators of these developmental pathways have been used widely, including GSK3β inhibitors as agonists
of a canonical Wnt pathway, fumagillin as an antagonist of a
noncanonical Wnt pathway, parmporphamine as an agonist and
cyclophosphamine as an antagonist of an Hb pathway, DAPT as an
antagonist of a Notch pathway, and SB431542 as an inhibitor of
TGFβ/Activin signaling (18, 34, 48–50).

Although activation of Wnt, Hb, and Notch pathways is in-
volved in various regenerative processes, their abberant activities
are also associated with cancer induction. Strategies to control
the activity of these pathways for regeneration while avoiding
tumor induction are highly attractive. One possible approach
would be enhancing the desired pathway activity by a syner-
gistic agonist, which would be effective only at where it is
needed (i.e., the pathway activity is inadequate), rather than
using a general pathway activator, which ectopically activates
the signaling. To identify novel compounds and pathways that
interact with the canonical Wntβ-catenin signaling pathway,
a reporter-based screen was carried out recently for molecules

Small Molecules to Control Stem Cell Fates

Developmental signaling pathways, such as Wnt, Hb, TGF/
BMP, and Notch, control embryonic patterning and cell be-
behavior during development and play important roles in regu-
lating tissue homeostasis and regeneration in adulthood. Known
chemical modulators of these developmental pathways have been used widely, including GSK3β inhibitors as agonists
of a canonical Wnt pathway, fumagillin as an antagonist of a
noncanonical Wnt pathway, parmporphamine as an agonist and
cyclophosphamine as an antagonist of an Hb pathway, DAPT as an
antagonist of a Notch pathway, and SB431542 as an inhibitor of
TGFβ/Activin signaling (18, 34, 48–50).

Although activation of Wnt, Hb, and Notch pathways is in-
volved in various regenerative processes, their abberant activities
are also associated with cancer induction. Strategies to control
the activity of these pathways for regeneration while avoiding
tumor induction are highly attractive. One possible approach
would be enhancing the desired pathway activity by a syner-
gistic agonist, which would be effective only at where it is
needed (i.e., the pathway activity is inadequate), rather than
using a general pathway activator, which ectopically activates
the signaling. To identify novel compounds and pathways that
interact with the canonical Wntβ-catenin signaling pathway,
a reporter-based screen was carried out recently for molecules
that synergistically activate signaling in the presence of Wnt3a. A 2,6,9-trisubstituted purine compound, QS11, was identified to synergize with canonical Wnt ligand both in vitro and in vivo (51). Affinity chromatography identified ARF-GAP as a target of QS11. Additional functional studies have confirmed that QS11 inhibits the ARF-GAP function, and as a consequence, it modulates ARF activity and β-catenin localization. Because ARFs play important roles in endocytosis, this study established another link between the endocytosis pathway and Wnt signaling, and it provides a useful chemical tool to modulate the Wnt pathway and explore novel functions of ARF-GAPs in cell culture and whole organisms.

Epigenetic modifications are central processes in stem cell differentiation and reprogramming that can control specific and heritable gene expression patterns in cells without altering the DNA sequence. Therefore, molecules directly regulating epigenetic machineries and changing the epigenetic status of cells should affect cell fate. Major epigenetic modifications include DNA methylation and histone modifications (acetylation, phosphorylation, methylation, and ubiquitination). S-adenosylmethionine and its analogs are widely used DNA demethylation agents, and they have been shown to increase cellular plasticity or induce differentiation of certain stem/progenitor cells (52, 53). HDAC inhibitors (e.g., TSA and VPA) have also played essential roles in studying histone acetylation and have been developed for its analogs are widely used DNA demethylation agents, and they have been shown to increase cellular plasticity or induce differentiation of certain stem/progenitor cells (52, 53). HDAC inhibitors (e.g., TSA and VPA) have also played essential roles in studying histone acetylation and have been developed for the treatment of cancers. Like all signaling/epigenetic modifiers, their effects are context-dependent; they have been shown to enhance self-renewal of HSCs, induce neuronal differentiation of NSCs, or promote myogenesis of muscle cells (54–56). In addition to these two widely used epigenetic modifiers, small-molecule inhibitors for protein arginine methyltransferases (PRMTs) (41), histone methyltransferases (HMTs, e.g., Su(var)3-9, Set1/Brm) (42) and histone demethylases (e.g., LSD1) have been identified recently via various approaches. With ongoing studies of stem cell biology and contribute to the development of regenerative medicine.

Conclusion

Stem cell research provides tremendous opportunities for understanding human development, regeneration, and diseases, and it offers great promise for developing cell-based or drug therapies to treat devastating diseases and injuries. Small molecules have proven to be useful probes of stem cell biology, from stimulating homogenous self-renewal or differentiation conditions to identifying molecules that control stem cell fate. Solid-Phase Synthesis of Biomolecules

Rolf Breinbauer, University of Leipzig, Germany
doi: 10.1002/9780470048672.wecb552

The synthesis of biopolymers, tool compounds, and molecular probes lies at the heart of any effort in chemical biology. Solution-phase strategies are well established but usually require considerable efforts in time and labor during workup and purification steps. In contrast, solid-phase synthesis, in which the substrate is covalently bound to an insoluble support, allows the simple removal of excess or consumed reagents by simple filtration. In the cases of oligonucleotides and peptides, the synthetic operations can be performed by robotic systems allowing the high-throughput synthesis of these biopolymers at low cost within a short time. The solid-phase synthesis of oligosaccharides and small-molecule probes has made significant progress during the last several years.

This article gives an overview of the main technical aspects of solid-phase synthesis and reviews the application of this technique for the synthesis of oligopeptides and proteins, oligonucleotides, oligosaccharides, and small molecules.

Biologic Background

From the mid-nineteenth century onward, researchers have made tremendous strides in understanding the molecular nature of living organisms. The discovery that cellular catalysts ("enzymes") are composed of oligomers of amino acids, that genetic information is encoded in oligonucleotides, the solving of the puzzle of metabolic pathways, and the investigation of hormonal and cellular signaling have shaped the modern view of what has become molecular and cellular biology. These discoveries have been accompanied by progress in both analytical techniques as well as in the synthesis of these molecules. Even today, the investigation of cellular organisms offers new surprises, such as the catalytic nature of RNA ("ribozymes"), the pathogenic nature of proteins ("prions"), or the silencing of genes via RNA interference. The synthesis of biopolymers and biologically active molecules remains an important task in chemical biology, as it 1) gives access to natural compounds, which otherwise could be isolated only in small and insufficient amounts; 2) allows the synthesis of modified or non-natural analogs or intermediates of natural compounds; and 3) provides tool compounds for the investigation of biologic mechanisms.

Technical Background

Although Emil Fischer had already pioneered the synthesis of sugars, nucleobases, and oligopeptides at the beginning of the twentieth century, the synthesis of these biomolecules in solution involved multistep sequences with many tedious workup and purification operations. Bruce Merrifield recognized that their syntheses can be simplified if a substrate is immobilized on an insoluble polymeric support ("resin") via a linker unit (1). Once immobilized the substrate can be easily modified by adding an excess of reagents and building blocks to ensure complete conversion. Consumed and excess reagents are then easily removed by washing the support and by simple filtration. Finally, cleavage of the linker releases the desired product into the solution allowing its isolation in pure form (Fig. 1).

Solid Support

A wide range of support materials exists for the heterogeneous immobilization of substrates in solid-phase synthesis, each offering certain advantages in different applications (2, 3). Parameters to be considered are 1) loading (mmol of functional groups per gram support), 2) bead size (measured in "mesh"), 3) swellability in solvents (degree of cross-linking and hydrophilicity), and 4) mechanical stability (mechanical abrasion interferes with filtration workup). A more than 99.99% of the substrate molecules are buried within the gel matrix of a polymeric bead, the resin must be swollen by solvent molecules to allow

access to reagents. Polystyrene (PS) resins (cross-linked with 1-2% divinylbenzene (DVB), loading up to 2 mmol functional group/g) are the resins most commonly used for oligopeptide and small-molecule solid-phase synthesis. These resins swell in most organic solvents but not in very polar solvents such as alcohols or water. If reactions need to be performed under polar conditions, the use of Tentagel (PS-resin with grafted polyethylene glycol chains), PEGA, Pepsyn, or Argogel is recommended because these substances are distinguished by polar, flexible, polymeric chains. Highly cross-linked macroporous resins (e.g., Argopore) exhibit a solvent-independent permanent pore structure and can be used in any solvent. For oligonucleotide synthesis, controlled pore glass (CPG), which is an inorganic support with well-defined, large pores, is widely used. The low loading and high cost of this material are compensated by the operational advantage of good accessibility in any solvent. Recently, the synthesis of biopolymers on planar surfaces, such as glass (DNA-chips) (4) or cellulose membranes (SPOT-synthesis), (5) has gained increasing attention.

Linker

A linker can be considered as a polymeric (or, more general, immobilized) protecting group. It is a functional group responsible for the covalent attachment of the substrate onto the support that will be cleaved from the product at the end of the synthesis sequence. The following features have to be considered when choosing an appropriate linker: 1) The attachment of substrate should proceed in high yield, 2) the linker should be stable under all reaction conditions considered for the synthetic sequence ("orthogonality"), and 3) the linker should be cleaved under mild conditions in quantitative yield without obscuring the integrity and purity of the product. More than 200 different linkers have been described exhibiting different degrees of orthogonality and releasing different functionalities at the product after cleavage (6, 7). Cleavage of the linker can be initiated by the addition of acid (commonly used in oligopeptide synthesis), base (used in DNA-synthesis), metals, oxidation, reduction, or light (photocleavable linker). Linkers that release their product without any visible functional group are named "traceless linkers." "Safety-catch linkers" require two different chemical reactions in order to undergo cleavage, which offers a unique degree of stability. In Fig. 2 some frequently used linkers and the corresponding cleavage conditions are depicted.

Automation

As solid-phase synthesis basically involves only three types of operations (addition of excess of reagent; shaking the beads in the reagent cocktail; filtration and washing) machines have been designed to perform solid-phase synthesis automatically (8). Automated oligonucleotide and oligopeptide synthesis has become routine.

Synthesis of Biopolymers

The solid-phase synthesis of biopolymers via iterative coupling of monomeric building blocks has found widespread application. It can be adapted easily for the incorporation of non-natural building blocks or labeled monomers, which will be used as probe molecules in chemical biology.
Solid-Phase Synthesis of Biomolecules

Oligopeptides are synthesized on solid phase from the C- to the N-terminus. Depending on the N-terminal protecting group of the amino acid building blocks, two different strategies can be followed. In the "Boc-strategy," the tert-butyloxycarbonyl-protecting group is cleaved by addition under acidic conditions (trifluoroacetic acid), which requires a linker that is resistant to these conditions because it is either cleaved only by very strong acids (HF, trifluoromethanesulfonic acid) or by a different agent (Fig. 3) (1). The "Fmoc-strategy" is based on the fluorenylmethoxycarbonyl-protecting group, which is cleaved by addition of 20% piperidine/DMF. It has the advantage that the important class of acid labile linkers (e.g., Wang-linker or Rink-linker) is compatible with this approach.

In addition, measurement of the UV-absorption of the cleaved protecting group allows the determination of the yield of the previous coupling operation. In practice, oligopeptides with up to 50 amino acids can be synthesized on solid phase. Instrumental for achieving reasonable yields for long oligomers is an almost perfect conversion for each deprotection and coupling step, for which a plethora of modern peptide coupling reagents are available; the coupling reagents also minimize epimerization (9). The synthesis of larger proteins (>60 aa) may be accomplished by preparation of fragments on solid phase that are then assembled using solution-phase ligation reactions (10), such as the native chemical ligation using an N-terminal Cys-residue (11). Table 1 lists representative examples of de novo synthesized proteins using solid-phase peptide synthesis. Recently, the combination of expressed protein ligation and solid-phase peptide synthesis...

Solid-Phase Synthesis of Biomolecules

**Figure 3** Flow scheme of a solid-phase synthesis of an oligopeptide following the Boc-strategy. The first amino acid is attached to the Merrifield linker by alkylative esterification of its cesium-salt. After acidic deprotection of the Boc-group and neutralization, the N-terminus undergoes DCC-mediated coupling with another Boc-protected amino acid building block. This sequence can be iterated, leading to even longer oligopeptides. Finally, the protect is released upon cleavage with HF. DCC = dicyclohexylcarbodiimide.

has emerged as a powerful tool for the preparation of proteins with unnatural modifications or labels (12). Solid-phase peptide synthesis has reached a level where the ton-scale synthesis of peptide drugs, such as the HIV drug Enfuvirtide (a 36mer peptide), has been established.

**Synthesis of Oligonucleotides**

The solid-phase synthesis of DNA oligomers has reached a high level of maturity and is extensively used for the synthesis of primers for polymerase chain reaction or the design of new genes (13). In contrast to the cellular process, the synthetic route forms the polymer in 3′-to-5′ direction. The oligomerization is carried out on CPG using a base labile linker. Typically, the nucleobases are introduced as acyl-protected phosphoramidites, which will be oxidized to phosphates after each elongation step (14). Treatment with base leads to global deprotection (nucleobase protecting groups and the cyanoethyl protecting group at phosphate) and cleavage of the oligonucleotide from the solid support. The conversion of each coupling step can be monitored by UV measurement of the dimethoxytrityl-carbocation, which is generated by the deprotection of the 5′-OH before each new coupling cycle (Fig. 4). The introduction of non-natural or modified nucleobases can be easily accomplished by using a corresponding phosphoramidite building block during the synthetic sequence.

The synthesis of RNA-oligomers (e.g., needed for applications in RNAi, aptamers, or as ribozymes) follows the steps described above for DNA but requires the protection of the

2'-OH group, for which the 2'-O-TOM - and the 2'-O-ACE-protecting groups are most often used (Fig. 5) (15). PNA-oligomers are synthesized using methodology developed for peptide synthesis. The large-scale synthesis of oligonucleotides has been established for the preparation of sufficient quantities for clinical trials of antisense drugs.

Synthesis of Oligosaccharides

The automated solid-phase synthesis of oligosaccharides is expected to have a tremendous impact in glycobiology as many natural proteins are decorated by complex oligosaccharide conjugates that strongly influence the biologic activity of the conjugate. Recently, the first examples of automatically synthesized oligosaccharides have been reported (16). The availability of appropriately protected building blocks and the creation of certain linkage patterns remain as challenges in this field.

Solid-Phase Synthesis of Small Molecules

Protein function can be modulated by small-molecule ligands. Offering complementary advantages to mutation genetics, the search for small molecules as molecular probes for the investigation of biologic systems has gained new interest ("chemical genetics"). In addition, high-throughput screening efforts in hit finding and lead optimization in drug discovery require large collections of small molecules ("molecular libraries"). Solid-phase synthesis has strongly contributed to these efforts as it gives fast access to large compound libraries.

Combinatorial Synthesis

In the early 1990s combinatorial chemistry was developed as a tool for the production of large oligopeptide libraries (17–19). Following a split–mix strategy depicted in Fig. 6, libraries with millions of different compounds can be created. This approach was extended by Ellman and colleagues for the synthesis of small-molecule libraries (20). Diversity-oriented synthesis (DOS) has been invented as a powerful tool for the synthesis of very large structurally diverse compound libraries (21). For the identification of the active compound, several strategies, such as on-bead-screening, deconvolution, or encoding, have been established. The use of "IRORI-Kans" (penetrable little containers filled with beads and labeled either with a radio-frequency tag or an optical bar code on the container lid) allows the synthesis of mg-quantities of compounds in a split–mix format, which offers the additional advantage of having the synthetic history of each kan monitored by a computer-based readout system of the radio-frequency tag or the optical bar code (22).
Solid-Phase Synthesis of Biomolecules

Figure 6: Combinatorial synthesis using a split-mix format. Building blocks are added separately in different vials, but the beads with reaction products are pooled before being distributed again before the next reaction step. Each vial contains all combined products of the previous reaction steps, but each bead contains only a single compound.

Natural Product Libraries

Several of the most useful small-molecule probes are complex natural products isolated from marine, fungal, or plant sources. As natural products have built-in biologic properties efforts in the synthesis of compound libraries increasingly use natural product scaffolds as a starting material because they promise higher hit rates in biologic screens (23). In Fig. 7 a few representative examples of molecular probes identified by screening of combinatorial libraries are depicted.

Catalytic Antibodies: Past, Present, and Future

Andrew P. Brogan, Tobin J. Dickerson and Kim D. Brogan, The Scripps Research Institute, La Jolla, California

Catalytic antibodies have emerged as powerful tools for the chemical biologist, enabling the design and realization of specific catalysts for a wide range of chemical reactions. Catalytic antibodies are grounded upon transition state theory and envisioned as programmable mimics of enzyme catalysis. Affinity maturation of the immune response for a small-molecule hapten elicits binding site complementarity within an antibody that facilitates chemical catalysis. The evolution of hapten design strategies for chemical catalysis is presented, including the transition state analog approach, strain-induced hapten design, "bait-and-switch," and "reactive immunization." The range and scope of antibody catalysis is examined by reaction class, highlighting structural and mechanistic investigations to explore the roots of chemical catalysis by these designer biocatalysts. Recently, antibodies, regardless of disposition or origin, have been shown to catalyze the oxidation of water, equipping the antibody with a mechanism for antigen decomposition. These recent developments are presented along with the utilization of this pathway in the oxidative degradation of a commonly abused drug. The achievements in antibody catalysis have enriched our scientific understanding of chemical catalysis, particularly by biological molecules in aqueous systems. However, realizing more operative rate enhancements on the same order as natural enzymes remains as the "holy grail" of this field.

Introduction

The usual paradigm in chemical biology is that chemical means lead to biological ends; however, in the case of catalytic antibodies, the reverse is the case—eliciting catalytic antibodies through biological means provides catalysts for a chemical end. The idea that antibodies could be designed to catalyze a specific chemical transformation was first proposed by Jencks (1) and was built on the foundations of enzyme catalysis originally conceptualized by Pauling (2). In this presumption, the catalytic power of an enzyme is primarily derived from the stabilization of the high energy transition state along a given reaction coordinate (Fig. 1). Therefore, a catalyst could be generated by probing the immune response for an antibody that can bind a small molecule, or hapten, that is a transition state analog of a desired chemical reaction. The first catalytic antibodies reported in 1986 independently by Lerner et al. (3, 4) and Schultz et al. (5) employed this strategy, and since these seminal reports, more than 50 chemical reactions have been catalyzed by antibodies. The technique has been refined over the years, but the general concept remains the same and numerous reviews on catalytic antibodies have appeared in the literature (6–15). Catalytic antibodies offer unique capabilities in a range of scenarios, including stereoselective organic synthesis, therapeutic potential in the treatment of disease, the elimination of toxins, the attenuation of agents used in chemical and biological warfare, and cessation of abused and/or addictive drugs. In this article, a broad overview of antibody catalysis is presented, including modern methods for eliciting catalytic antibodies, the evolution of hapten design, and advances in antibody catalysis.

Antibodies: Structure and Function

A brief introduction to the basic structure and function of an antibody is essential to understanding the catalytic power of a select few of these molecules. Immunoglobulins (Igs) are glycoproteins that can be divided into various classes and subclasses based on structure and function. Most catalytic antibodies are IgG molecules and therefore will be the focus of this review. IgG molecules consist of four polypeptide chains, two identical light chains and two identical heavy chains, that assemble...
Gene undergoing similar recombination of VL and JL genes. This recombination of three translated genes: a VH (variable) gene, a germline diversity (DH) gene, and a JH (joining) gene with the light-chain repertoire to recognize a seemingly limitless number of antigens within the genome, and the source and magnitude of the immune response after hapten hyperimmunization with no attempt to purely specific IgG molecules. Efficiency and cost-effectiveness are hallmarks of polyclonal antibody production; however, accurate characterization of this mixture is difficult. Furthermore, X-ray crystallography to examine structure-function relationships and affinity maturation to optimize the antibody is impossible with the polyclonal antibody method.

Consequently, hybridoma technology was a significant milestone enabling the isolation and production of individual antibodies (18). In this technique, antibody producing cells are isolated from the spleen after hyperimmunization with the hapten-protein conjugate. These B cells are subsequently fused with an immortal cell line, and the resultant hybrids secrete monoclonal antibodies. Monoclonal antibodies are homogenous, can be produced in large quantities, and can be rigorously purified to remove any potential contaminants. Despite greater expense and a more time-consuming process, monoclonal antibody production is the method of choice.

Phage-display technology has many uses for catalytic antibody research (19–23). Generally, phage display involves combinatorial antibody Fab or scFv (single-chain variable fragment) libraries and their expression on phage particles. One advantage to this technology is that the hyperimmunization protocol can be avoided, thereby removing the use of animals. Naïve Fab or scFv are identified in a screen for binding to a desired transition state analog. Although in theory a desired catalyst can be discovered this way, in practice this technique is more successful when an initial hyperimmunization protocol is performed followed by acquisition of the mRNA of the B cells from the spleen (19–21). The corresponding focused combinatorial antibody library is biased toward antibody fragments that recognize the hapten. Phage-display is also used as a tool in affinity maturation of a previously identified catalytic antibody. Mutagenesis of the corresponding Fab or scFv from an existing catalytic antibody can be explored using error-prone polymerase chain reaction (PCR), CDR walking, structure-guided mutagenesis, and DNA shuffling to optimize catalysis of the corresponding chemical reaction (22).

Eliciting Catalytic Antibodies

A merging of chemistry and biology is essential to effectively probe the immune system for catalytic antibodies (Fig. 3). Hapten design is critical in eliciting catalytic antibodies as variations of the central theme that transition state stabilization in the antibody combining site will yield functional catalysts for a desired chemical reaction. The evolution of hapten design will be discussed further in subsequent sections. Once the hapten is selected and synthesized, it is attached to an immunogenic carrier protein, usually via an amide bond, for hyperimmunization. A preliminary screen for antibodies that bind the hapten using an enzyme-linked immunosorbent assay (ELISA) is followed by another screen for catalysis of the reaction for which the hapten was designed. Other screening methods have also been used, including catELISA, which screens for catalysis in the antibody pool rather than hapten binding (16, 17). There are three primary methods for eliciting catalytic antibodies currently used: polyclonal, hybridomas, and phage-display.

Polyclonal antibody production is the most primitive method and has several significant limitations (6). This method inherently yields a complex mixture of antibody molecules from the immune response after hapten hyperimmunization with no attempt to purely specific IgG molecules. Efficiency and cost-effectiveness are hallmarks of polyclonal antibody production; however, accurate characterization of this mixture is difficult. Furthermore, X-ray crystallography to examine structure-function relationships and affinity maturation to optimize the antibody is impossible with the polyclonal antibody method.

Consequently, hybridoma technology was a significant milestone enabling the isolation and production of individual antibodies (18). In this technique, antibody producing cells are isolated from the spleen after hyperimmunization with the hapten-protein conjugate. These B cells are subsequently fused with an immortal cell line, and the resultant hybrids secrete monoclonal antibodies. Monoclonal antibodies are homogenous, can be produced in large quantities, and can be rigorously purified to remove any potential contaminants. Despite greater expense and a more time-consuming process, monoclonal antibody production is the method of choice.

Phage-display technology has many uses for catalytic antibody research (19–23). Generally, phage display involves combinatorial antibody Fab or scFv (single-chain variable fragment) libraries and their expression on phage particles. One advantage to this technology is that the hyperimmunization protocol can be avoided, thereby removing the use of animals. Naïve Fab or scFv are identified in a screen for binding to a desired transition state analog. Although in theory a desired catalyst can be discovered this way, in practice this technique is more successful when an initial hyperimmunization protocol is performed followed by acquisition of the mRNA of the B cells from the spleen (19–21). The corresponding focused combinatorial antibody library is biased toward antibody fragments that recognize the hapten. Phage-display is also used as a tool in affinity maturation of a previously identified catalytic antibody. Mutagenesis of the corresponding Fab or scFv from an existing catalytic antibody can be explored using error-prone polymerase chain reaction (PCR), CDR walking, structure-guided mutagenesis, and DNA shuffling to optimize catalysis of the corresponding chemical reaction (22).

Evolution of Hapten Design

The conformational changes and charge distribution along the reaction coordinate of a chemical transformation are fundamental to hapten design. Catalytic antibodies are designed to mimic the catalytic power of an enzyme, which, in part, stems from the stabilization of the high energy transition state.

---

**Figure 1** Relative energies of substrate (S) and product (P) along a reaction coordinate, revealing the energy differences between uncatalyzed (TS uncatal) and catalyzed (TS cat) transition states.
Catalytic Antibodies: Past, Present, and Future

**Figure 2** Y-shaped structure of immunoglobulin G (IgG). Disulfide linkages and sites of oligosaccharide attachment are shown. CDRs (complementarity determining regions) are the sites of high amino acid variability. Antigen binding site comprises VH (variable heavy) and VL (variable light) domains, which together make the Fab. Fv is composed of VH, VL, CH1, and CL. H is the hinge region. Fc is composed of CH2 and CH3. There are two Fab and Fv per IgG and one Fc region per IgG.

**Figure 3** Flowchart illustrating the key stages in catalytic antibody generation.

**Stable Transition State Analog Hapten Design**

A stable chemical analog that mimics the transition state of a chemical reaction was the first approach used to elicit catalytic antibodies (Fig. 4) (3–5). Acyl transfer reactions are the most studied type of catalytic antibody reaction, and a wealth of knowledge about this reaction has been garnered through antibody acyl transferases (3–5, 23–28). Using ester hydrolysis as a representative example, nucleophilic addition of water to the carbonyl carbon results in a tetrahedral transition state followed by expulsion of the alcohol leaving group. The transition state for this reaction has a delocalized negative charge that is remarkably similar to the chemically stable phosphate ester (29). The phosphorous (V) core, known to be an excellent mimic of the transition state in hydrolytic enzymes (30–33) and...
amino acids HisH35 and TyrH133 serve to stabilize the polarized body that binds the substrate in a ring-strained conformation. Hydrogen bonds from the side chains of the adjacent enzyme, because alkylation at one pyrrole nitrogen distorts the last step in the heme biosynthetic pathway (40). Interestingly, N-alkylporphyrins are known to be potent inhibitors of this enzyme, because alkylation at one pyrrole nitrogen distorts the planarity of the porphyrin macrocycle (41). This finding was used in the design of hapten 1 to catalyze the incorporation of metal ions into mesoporphyrin IX (3) by eliciting an antibody that binds the substrate in a ring-strained conformation.

The lone-pair electrons on the pyrrole nitrogen of the porphyrin ring are more accessible to chelation of metal ions in the ring-strained conformation and leads to metalation of mesoporphyrin IX. Antibody 7G12 catalyzes the incorporation of Zn2+, Cu2+, Co2+, and Ni2+ into mesoporphyrin IX, whereas ferrochelatase uses Fe3+, Zn2+, Co2+, and Ni2+ as substrates in the chelation of protoporphyrin IX. X-ray crystallography of the catalytically active 57G12-Michaelis complex revealed that the porphyrin ring adopts a nonplanar conformation that is essential for catalysis as anticipated from the hapten design (42).

**Bait-and-Switch Hapten Design**

Transition state analog hapten design has been the most universal means to elicit catalytic antibodies; however, limitations with this approach and strain-induced hapten design are realized when fractional bond orders, extended bond lengths, expanded valences, distorted bond angles, and charge distributions cannot be achieved in a stable chemical analog of the transition state suitable for immunization (7, 43, 44). Furthermore, a significant number of haptens designed for a specific chemical transformation have led to antibodies that bind the hapten with exquisite affinity yet no effective catalysis was realized. This is easily explained because the somatic mutations in the IgG molecule favor tighter hapten binding, but not necessarily more effective catalysis. Additionally, the products of a reaction may have significant similarity to the hapten used in hyperimmunization, leading to slow release of the product and/or significant product inhibition. In fact, product inhibition is thought to be the major contributing factor for low efficiency hydrolytic catalytic antibodies (45, 46).

A significant step in the evolution of hapten design was introduced by Janda and Lerner, coined the “bait-and-switch” method (47–49). This novel advancement enables electrophilic/nucleophilic and/or general acid/general base catalysis to be programmed into an antibody combining site. Specifically, a point charge on the hapten in close proximity to, or in direct substitution for, a functional group to be transformed in the respective substrate is used to induce a complementary charge on an amino acid residue in the antibody combining site during hyperimmunization (Fig. 6). The substrate lacks this charge but retains a similar overall structure and the corresponding antibody binds the substrate and acts as a general acid/general base and/or as a nucleophile/electrophile in the desired chemical reaction.

The phosphodiesterase antibody MATT.F-1 is a didactic example of bait-and-switch hapten design, illustrating differences from other hapten design approaches (49). The hydrolysis of a phosphodiester bond, such as those found in RNA and DNA, are catalyzed by ribonucleases (RNases) and deoxyribonuclease-ases (DNases), respectively. RNase A is a thoroughly studied enzyme that has two catalytic histidine residues in the active site (50). The imidazole group of HisH2 acts as a general base by protonating the 2’ oxygen, and the imidazolium group of HisH13 acts as a general acid by protonating the 5’ phosphoryl oxygen in the classic mechanism (51).

The incorporation of a general base and a general acid in the hydrolysis of a phosphodiester was hypothesized to be

elicited in an antibody combining site programmed by specific point charges designed into a bait-and-switch hapten (49). Indeed, an antibody against hapten \(6\) successfully catalyzed the hydrolysis of the corresponding substrate \(7\) (Fig. 6). In contrast to the transition state analog hapten \(8\) (52), which elicited the less-proficient phosphodiesterase catalytic antibody 2G12, the precise conformation of the high energy intermediate was sacrificed for charged moieties in specific locations of the hapten. The corresponding counterion charges from amino residues were elicited in the antibody combining site that led to catalytic antibodies with improved catalytic proficiency \((k_{cat}/K_m)/k_{uncat} = 1.6 \times 10^7 \text{M}^{-1} \text{s}^{-1}\) for MATT.F-1 versus \((k_{cat}/K_m)/k_{uncat} = 1.3 \times 10^6 \text{M}^{-1} \text{s}^{-1}\) for 2G12) for phosphodiesterase activity.

**Reactive Immunization Hapten Design**

An essential concept in enzyme catalysis, partly realized through the study of catalytic antibodies, is that the proficiency of an enzyme is not solely due to the stabilization of a high energy transition state. Enzymes are not static entities, but rather they have the dynamic ability to stabilize all possible conformations of a chemical reaction along the reaction coordinate (33, 53–55). Furthermore, many enzymes can form covalent intermediates with the substrate that are essential to catalysis. The previous hapten design methods program specific complementarity in the antibody combining site; however, the hapten is a static snapshot of a dynamic chemical process resulting in catalysts limited to noncovalent interactions that are ultimately less efficient than their enzyme counterparts. Reactive immunization is a hapten design strategy that provides a chance for catalytic antibodies to approach the catalytic efficiency of natural enzymes by using a hapten that undergoes dynamic conformational changes during hyperimmunization and traps chemical reactivity at the B-cell level (Fig. 7) (53, 56–63).

A direct comparison between reactive immunization and transition state analog hapten design was demonstrated by comparing antibody esterase activity elicited against a reactive immunization hapten, phosphonate diester \(9\), and a transition state analog hapten, phosphonate monester \(10\) (Fig. 7) (58, 61). Hapten \(9\) was originally designed for the purpose of resolving a racemic mixture of naproxen esters and contains a modestly reactive diphosphonate ester that is susceptible to nucleophilic attack during hyperimmunization. Antibody 15G2, elicited against hapten \(9\), efficiently catalyzed the hydrolysis of \(11a\) to \(S(+)-naproxen\ 12a\) and phenol \(13\). Another antibody, 5A9, from the reactive immunization panel possessed turnover numbers lower than 15G2, however, kinetically resolved the hydrolysis of racemic substrate \(11\) to the anti-inflammatory agent \(S(+)-naproxen\ 12a\) in 35% yield and 90% ee. Meanwhile, antibody 6G6, raised against hapten \(10\), catalyzed hydrolysis of \(11a\) with comparable turnover numbers to 15G2, but kinetically resolved the hydrolysis of racemic substrate \(11\) to the anti-inflammatory agent \(S(+)-naproxen\ 12a\) in 50% yield and >98% ee.
This direct comparison of hapten design approaches for the same reaction revealed that antibodies generated by each method exhibit quite different catalytic behavior. The transition state analog approach provided catalytic antibodies with good turnover numbers and enantiomeric discrimination; however, it suffered from varying degrees of product inhibition byphenol 13. Comparatively, the reactive immunization approach yielded antibodies that are ultimately better catalysts because, once an efficient catalytic mechanism evolved further complementarity did not develop, leading to broader substrate recognition with reduced product inhibition. Binding site complementarity is the selection criteria rather than chemical reactivity using the transition state analog approach and antibodies developed by this strategy are more substrate specific and yet suffer from product inhibition as a result of exquisite binding affinity.

Advances in Antibody Catalysis

More than 50 reactions have been catalyzed by antibodies (Table 1). A brief survey of the catalytic antibody landscape is presented below, highlighting creative hapten design strategies, the breadth of reactions catalyzed, and structure-function relationships.

Antibody Cationic Cyclases

Catalytic antibody technology enables the diversification of cyclization products from polyene substrates, because the programmability of antibody catalysis is not limited to the set of naturally occurring polyenes (64–69). Accordingly, hapten 14 elicited the cationic cyclase HA5-19A4 that catalyzes the tandem cationic cyclization of polyene substrate 15 to the bridge-methylated trans-decalins 16a–c (Fig. 8) (67). Cationic cyclization reactions have three components: initiation, propagation, and termination. The zwitterionic N-oxide moiety of hapten 14 mimics the initiation step of this reaction because it is isosteric and isopolar to the first carbocation formed at the beginning of the reaction cascade. The X-ray crystal structure of the Fab fragment of HA5-19A4 complexed with hapten 14 reveals a highly complementary fit in the antibody combining site (70). The hydrophobic pocket is lined with numerous aromatic residues that stabilize the postulated reactive intermediate 17 through cation–π interactions and force it into a chair–chair conformation. Propagation of cyclization proceeds via concerted attack of the C5–C6 π-bond, avoiding accumulation of the unfavorable carbocation at C1, while forming the A ring of 16a–c through the more favorable tertiary carbocation at C5. Subsequent attack on C5 by the C9-10 π-bond forms the B ring of 16a–c. Minor by-products of the reaction include compounds with incomplete closure of the B ring, resulting from either elimination or solvolysis. Termination of the cationic cyclization was programmed into the antibody by including an epoxide group to elicit an antibody residue capable of coordinating a water molecule to facilitate quenching of the terminal carbocation by solvent or to constrain the B ring of the trans-decalin into the half-chair and facilitate proton elimination. Interestingly, termination of the HA5-19A4 catalyzed reaction occurs exclusively by proton elimination because only olefinic products 16a–c are observed.

Antibody-Catalyzed Disfavored Ring Closure

An astounding aspect of antibody catalysis is the ability of these programmable biocatalysts to preferentially form the less thermodynamically favored product (66, 71–74). The intramolecular cyclization reaction of trans-epoxyalcohol 18 is an archetypal example of antibody catalysis of a disfavored transformation, which preferentially forms the tetrahydrofuran 19 under uncatalyzed conditions due to the overwhelming stereoelectronic constraints predicted by Baldwin’s rules for ring closure (Fig. 9) (75, 76).

The N-oxide and N-methyl ammonium haptens 20 and 21 were designed to mimic the stereoelectronic features of the disfavored endo transition state 22 and function as bait-and-switch haptens by programming specific complementary charges in the antibody combining site (72, 77). Antibody 26D9, elicited against only product. Additionally, hyperimmunization using the N-methyl ammonium 20, efficiently reroutes this transformation and gives tetrahydropyran 23 as the hapten 21 produced antibody 5C8 that also catalyzed the regio- and enantioselective epoxide opening of substrate 18 to yield the disfavored endo product 23 (77). The active sites in both antibodies contain a putative catalytic diad, as determined by X-ray crystallography, confirming bait-and-switch hapten design as a viable approach to catalyze this disfavored ring closure (77). The exact mechanism has not been established; however, the active site of Fab 5C8 reveals plausible general acid–base catalysis occurring by AspH95 acting as a proton donor to the epoxide oxygen assisting the formation of intermediate 22 with HisL89 serving as a base enabling nucleophilic attack by the alcohol group.

Antibody Diels–Alderases

One aspect of antibody catalysis that truly ignites the imagination of the chemical biologist is that these biocatalysts are not limited to reactions that have a natural enzymatic equivalent. The Diels–Alder reaction has immense synthetic utility; however, this chemical transformation is extremely rare in nature. Furthermore, the reaction proceeds via an entropically disfavored, highly organized pericyclic transition state (78). The programmability of a catalytic antibody has enabled the catalysis of the Diels–Alder reaction previously considered beyond the realm of possibility with a protein (79–84).

A significant hurdle in the development of a Diels–Alderase catalytic antibody was minimizing product inhibition, because based on the Curtin–Hammett principle, the transition state is markedly similar to the product of a Diels–Alder reaction. A creative solution to this problem was employed in the development of antibody 1E9 (Fig. 10) (79). The endo-hexachloronorbornene
haptens 24 elicited antibody 1E9 to catalyze the Diels–Alder reaction between diene tetrachlorothiophene dioxide 25 and N-ethylmaleimide 26. Product inhibition was overcome because, after the pericyclic reaction forming 27, SO₂ is liberated spontaneously followed by oxidation to yield the structurally dissimilar aromatic product 28; accordingly, no product inhibition was observed. X-ray crystallographic data of 1E9 Fab revealed that the antibody binding pocket is preorganized to provide significant shape complementarity with hapten 24 through van der Waals contacts, π-stacking with the maleimide functional group, and a hydrogen bond with AsnH₃⁵ (85). A recent study of noncovalent catalyzed Diels–Alder reactions by synthetic, protein, and nucleic acid hosts indicated that antibody 1E9 is the most effective of the noncovalent catalyst systems studied (86). The capabilities of this extraordinary catalytic antibody have been explained by theoretical calculations and the high degree of shape complementarity consistent with the X-ray crystallography data.

Diels–Alderase antibody 39-A11 minimizes product inhibition while generating a more conventional Diels–Alder product (Fig. 11) (80). Bicyclo[2.2.2]octane hapten 29 was designed to mimic the proposed boat-like transition state 30 of the [4π+2π] cycloaddition between diene 31 and dienophile 32. Product inhibition was circumvented by the structural disparity between the product cycloadduct and the pseudo-boat form of the hapten employed for immunization. X-ray crystallographic data of hapten 29 complexed with the 39-A11 Fab indicated that the diene and the dienophile are bound in a reactive conformation that reduces
translational and rotational degrees of freedom (83, 87, 88). The stereoselective capabilities of this antibody are accomplished by two strategically positioned hydrogen bonds (AsnH35a, ThrH50) and π-stacking of the maleimide dienophile with TrpH50, as calculated from quantum mechanical models and docking simulations (89). This unique arrangement allows reorganization of one enantiomeric transition state, facilitating formation the chiral product 33. Interestingly, sequencing and cross-reactivity studies indicate that antibodies 39-A11 and 1E9 are structurally similar and may have the same polyspecific germline origin.

A radical idea to generate Diels–Alderase catalytic antibodies employed a ferroceny moiety in hapten 34 and was designed to catalyze the reaction of diene 35 with dienophile 36 (Fig. 12) (82). Hapten 34 has two pentagonal, delocalized, π-electron ring systems stacked upon each other that were thought to be a loose transition state mimic capable of guiding the diene and dienophile into a reactive ternary complex. Additionally, the hydrophobicity of the hapten will induce a strong immune response and generate antibodies containing hydrophobic microenvironments that sequester the reactants from aqueous solution, increasing reaction rates. The freely rotating ferrocenyl moiety may enable stereoselective catalysis of all possible diastereomers; however, the immune system must be able to bind and stabilize a single conformer of 34 to elicit an effective catalyst. Antibody 13G5 was identified to preferentially catalyze the formation of the disfavored ortho-π-π-stacked product 38. This is finding remarkable considering the flexibility of hapten 34, because antibody 13G5 must preferentially stabilize the π-π-transition state 39 over the **endo**-transition state 40. Quantum mechanical modeling depicts that hapten 34 resembles the van der Waals complex between the reactants more closely than the transition state, yielding antibodies that preferentially recognize the hapten rotamer that mimics 39 (90). Furthermore, the steric restraints imposed by specific hydrogen-bonding interactions revealed in the crystal structure of 13G5 Fab complexed with the inhibitor 41 (an attenuated version of hapten 34) traps 41 in one available conformation that is a loose mimic of the early boat-like transition state for the **endo** Diels–Alder reaction (91).

**Antibody-Catalyzed Oxy-Cope Rearrangements**

The oxy-Cope rearrangement is a thoroughly studied and synthetically useful reaction in organic chemistry that proceeds through a highly organized chair-like pericyclic transition state (Fig. 13) (92, 93). The transition state analog hapten 42 elicited antibody AZ-28, which catalyzed the oxy-Cope rearrangement of substrate 43 to aldehyde 44 (94). Product inhibition was avoided by in situ chemical modification to generate the oxime. Surprisingly, the germline precursor to AZ-28 accelerated this oxy-Cope reaction 164,000-fold faster than the uncatalyzed reaction despite a much lower affinity for hapten 42. An explanation for this unprecedented discovery can be explained by X-ray crystallography of both the apo form and hapten 42-complex (95). The van der Waals and hydrogen bond interactions present in AZ-28 force the hapten into a fixed conformation that is catalytically unfavorable. In contrast, the antibody combining site for the transition state analog does not necessarily result in more efficient catalysis. Antibody-Aldolases

The aldol reaction is a fundamental C–C bond forming reaction that is ubiquitous in both chemical synthesis and nature.
Catalytic Antibodies: Past, Present, and Future

Figure 13
Hapten 42 elicited antibody AZ-28 that catalyzes the oxy-Cope rearrangement of substrate 43. (97). Class I aldolase enzymes possess a reactive lysine residue that forms an enamine intermediate with carbonyl substrates, enabling nucleophilic attack on the corresponding electrophile in the enzyme active site (98, 99). Aldolase catalytic antibodies with a similar reactive lysine residue (59, 60, 100–102) were generated using the reactive immunization hapten 45, which contains a moderately reactive β-1,3-diketone moiety (Fig. 14). Two highly efficient aldolase antibodies, 38C2 and 33F12, were obtained from the catalytic screen (59, 60). The β-1,3-diketone functionality successfully trapped a lysine residue in the antibody combining site forming Schiff base 46 and ultimately the reactive enamine 47, which directly participates in the mechanism of the aldol reaction in the antibody active site. Both 38C2 and 33F12 catalyze the aldol reaction between acetone and aldehyde 48 with enzymic catalytic proficiency $k_{cat}/k_{uncat}$ of nearly $10^9$. The X-ray crystal structure of 33F12 revealed that LysH93 is essential to the catalytic mechanism, which initiates the reaction by forming a stable enamine with the ketone substrate (60). The surrounding hydrophobic residues help to stabilize the unprotonated form of the lysine ε-amino group ($pK_a$ of 10 in bulk water). A significant perturbation of LysH93 must occur to maintain its uncharged status. Antibodies 38C2 and 33F12 are actually better catalysts of the retro-aldol reaction; however, these catalysts are extremely robust and 38C2 participated in major steps in the total synthesis of epothilones A–F (103, 104).

An attempt to improve on these antibodies employed a hybrid approach to hapten design by using a transition state mimic sulfone along with a β-1,3-diketone moiety to trap a reactive site lysine residue (Fig. 15) (62). The hybrid hapten 49 is an excellent mimic of the aldol transition state 50, eliciting two aldolase antibodies, 93F3 and 84G3. In the aldol reaction of 51 with 3-pentanone, antibody 93F3 provided syn-aldol 52 in 90% de and 90% ee, whereas antibody 38C2 only afforded the anti-isomer in 62% de and 59% ee. These second-generation aldolase antibodies 93F3 and 84G3 showed $10^3$-fold increase in proficiency over antibody 38C2.

Antibody Catalyzed Photo-Fries Rearrangement

The photo-Fries rearrangement involves the absorption of light energy by a diphenyl ether substrate resulting in homolytic C–O bond cleavage followed by radical recombination to yield biphenyl products. Multiple products can be formed in this reaction, depending on the electron withdrawing/donating characteristics of the aromatic substituents. Furthermore, the escape of free radicals from the solvent cage leads to additional phenolic products (105). For example, ultraviolet (UV) irradiation of 4-phenoxyaniline 53 forms aromatic products 54–58 (Fig. 16). The electron donating character of the amine substituent leads to preferential cleavage via path a (products 54 and 55) as opposed to path b (products 56–58) that would be favored by an electron withdrawing substituent. An antibody-mediated reaction that suppresses the escape of free radicals and primarily forms biphenyl 54 was generated against haptens 59 (antibody MT2-21 C4) and 60 (antibody MT4-3G2) (106). The rotational freedom of hapten 59 was used to explore the combinatorial power of the immune response to elicit catalysts that stabilize radicals in the combining site and seek either path a or path b. Hapten 60 is rigid and designed to assist the immune repertoire in the selection of a catalyst by limiting the conformations that can be accessed. Antibodies elicited against both haptens catalyzed the photo-Fries reaction revealing the dynamic ability of an antibody to stabilize a high energy surface in the catalysis of a reaction. Additional photochemical catalytic antibodies for the Norrish type II reaction have been developed (107–109), including an enantioselective Yang cyclization (108, 109).

Recent Developments in Catalytic Antibodies

Since the seminal discovery of chemical catalysis by an antibody, numerous complex chemical transformations have been catalyzed by these molecules. However, in biological systems, the primary function of an antibody is to serve as a mediator between recognition of a foreign substance and its destruction. Specifically, the variable region of an antibody has evolved to recognize an antigen and then recruit effector systems such as complement and phagocytic cells to destroy the foreign entity. This paradigm has been challenged by the recent discovery that antibodies have the innate ability to not only recognize foreign substances but to also destroy them (110). Lerner and coworkers have found that all antibodies, regardless of source or antigenic specificity can catalyze the oxidation of water by singlet oxygen (1O2) via a pathway that is postulated to include trioxigen species, such as dihydrogen trioxide (H2O3) and possibly ozone (O3), in the formation of hydrogen peroxide (H2O2) as the ultimate product (110–114). Further examination of this phenomenon indicated that 1O2 could be generated by
Catalytic Antibodies: Past, Present, and Future

either direct UV irradiation of the antibody molecule, by visible light and a triplet oxygen \( (\text{O}_2^\cdot) \) sensitizer like hematoporphyrin IX, or by thermal decomposition of endoperoxides. In each case, the antibody catalyzed formation of \( \text{H}_2\text{O}_2 \) was triggered.

Typically, proteins are not stable under extended exposure to UV irradiation; however, antibodies efficiently form \( \text{H}_2\text{O}_2 \) linearly up to 40 mole equivalents before an observed decrease in rate. Furthermore, \( \text{H}_2\text{O}_2 \) seems to inhibit its own production and >500 equivalents of \( \text{H}_2\text{O}_2 \) can be generated by an antibody when \( \text{H}_2\text{O}_2 \) is removed by catalase. Isotopic labeling experiments suggest that water is the electron source in this oxidation pathway. Functionally, the water oxidation pathway has been postulated to play a role in a range of clinical scenarios, including bacterial killing, inflammation, and the pathogenesis of atherosclerosis (112, 115).

The manipulation of the water oxidation pathway expands the realm of possibilities with catalytic antibodies. A specific example recently reported is the catalytic oxidative degradation of nicotine (53) by antibodies TD1-10E8 and TD1-36H10 (Fig. 17) (116). Catalytic antibodies that degrade cocaine by ester hydrolysis have been previously identified, and the use of catalytic antibodies in the cessation of drug abuse is an active area of research (37, 117–121). Developing an antibody capable of degrading nicotine has been particularly challenging because its chemical structure is not amenable to decomposition by catalytic antibodies using any of the previously outlined hapten design strategies. Many oxidative degradation products of nicotine are known (122) and antibody catalysis could parallel this pathway with a sufficient \( \text{O}_2^\cdot \) source. Riboflavin interacts with immunoglobulins, although this interaction is not completely understood (123) and is a known photosensitizer. The riboflavin-antibody interaction was exploited in the generation of reactive oxygen species to oxidatively decompose nicotine. However, the initial screen using a tight binding (\( K_d < 10\mu M \)) nicotine antibody panel elicited against hapten 54, riboflavin, and either UV or visible light led to no catalysis of nicotine degradation over the appropriate control reactions. Conversely, a weak binding panel of antibodies elicited against the less congruent nicotine hapten 55 (\( K_a > 1 \text{mM} \)) effectively catalyzed the formation of nicotine oxidation products 56 and 57. It is important to note that, in this study, a weak binding nicotine antibody was converted to a catalytic antibody using visible light and riboflavin as a photosensitizer. The inherent utility of the water oxidation pathway is an active research area, and the antibody catalyzed oxidative degradation of nicotine is the first example of manipulating this pathway for a potential therapeutic outcome.

Conclusions

Catalytic antibodies are unparalleled as tailor-made enzyme mimics of a chemical reaction and a paramount advancement in chemical biology. The scope of antibody catalysis continues to increase although enzyme-like rates have yet to be achieved. A snapshot of the reaction coordinate using transition state analog, strain-induced, or bait-and-switch hapten design has led to numerous antibody catalyzed reactions. Enzymes and catalytic antibodies share their primary mode of action by stabilizing a high energy transition state. Enzymes have a superior evolutionary advantage, and additional mechanisms that assist enzyme catalysis, like covalent catalysis, cofactors, proximity effects, and the dynamic ability to complement an infinite number of conformations along a reaction coordinate, play a larger role than originally suspected.

Perhaps the most significant contribution of the catalytic antibody field is the realization that enzyme catalysis is not simply transition state stabilization. Reactive immunization has enabled a mimic of the dynamics involved in enzyme catalysis, and an aldolase antibody that approaches enzymatic rates has been developed using this technique (59, 60). However, only a few types of reactions have been catalyzed using this hapten.
design strategy. The ability to design a de novo enzyme-like catalyst for a multitude of different reactions is an intriguing lure for the chemical biologist. The advent of catalytic antibodies was essential to the current understanding of the relationship between chemical catalysis and molecular structure; however, a better understanding of this relationship is essential for the advancement of catalytic antibody research toward the ultimate goal of readily programmed catalysts with operative rates that are inherently friendly for the environment. The discovery of naturally occurring catalytic antibodies (124) and the realization that nature uses IgG molecules for chemical catalysis provides a basis to strive toward this ultimate goal.

Enzymatic Synthesis of Carbohydrate-Containing Biomolecules

Hai Yu and Xi Chen, Department of Chemistry, University of California-Davis, California
doi: 10.1002/9780470153672.wecb153

As important biomolecules in living organisms, carbohydrates have received increasing attention in recent years. Their important roles in biologic events are being continuously unraveled. The development of synthetic methodologies, including both chemical and enzymatic methods, contributes greatly to the advance of the field of glycoscience. The involvement of regio- and stereo-selective enzymes in the synthesis of complex carbohydrate-containing molecules has become an indispensable approach. Many enzymes involved in the biosynthesis and biodegradation of carbohydrates have been characterized and have been applied for the production of carbohydrate-containing biomolecules, including oligosaccharides, polysaccharides, glycoproteins, glycolipids, and glycosylated natural products. A range of strategies for enzymatic synthesis have also been developed, such as protein engineering of glycosidases and glycosyltransferases by site-directed mutagenesis or directed evolution, one-pot multiple-enzyme synthesis, sugar nucleotide regeneration, solid-phase enzymatic synthesis, synthesis using immobilized enzymes, and cell-based synthesis. Enzymatic synthesis will continue to play critical roles in obtaining complex carbohydrate-containing biomolecules. Future efforts should focus on identifying synthetically useful enzymes such as those with flexible or novel substrate specificity and those that can form new bonds. This identification can be achieved by functional genomics and mutagenesis studies. Development of novel enzymatic synthetic methods is also critical to access diverse naturally occurring and non-natural derivatives of carbohydrates and glycoconjugates.

Biomolecules are chemical compounds that naturally occur in living organisms. They primarily contain carbon and hydrogen atoms, some with nitrogen, oxygen, phosphorus, and sulfur. A wide range of biomolecules exists. Major types are carbohydrates, nucleic acids, lipids, and peptides/proteins. Due to their important roles in bioprocesses and their potential use as drugs or drug targets, synthesis of biomolecules has been a subject of enormous interest. Most active biomolecules are chiral compounds. Although new synthetic reagents, catalysts, and strategies have been developed, chemical synthesis of complex biomolecules continues to pose substantial challenges. Therefore, environmentally benign, highly efficient, and highly selective enzymatic synthesis has been and will continue to play indispensable roles in obtaining many biomolecules. This is especially true for the synthesis of complex carbohydrates or glycoconjugates. The enzymatic synthesis of carbohydrate and carbohydrate-containing biomolecules will, therefore, be the subject of discussion here.

Enzymatic Synthesis of Oligosaccharides

Terminal carbohydrate moieties of naturally occurring glycoconjugates are usually the oligosaccharide synthetic targets. They are generally the key determinants recognized by carbohydrate-binding proteins and are directly involved in many important biologic and bioprocesses, including cell adhesion, differentiation, development, and regulation (1). Enzymatic synthesis of these molecules has been extensively studied.
Both glycosidases and glycosyltransferases have been widely applied.

**Glycosidase-catalyzed synthesis of oligosaccharides**

Glycosidases, including endoglycosidases and exoglycosidases, are enzymes that catalyze the cleavage of glycosidic bonds. Under certain conditions, glycosidases can be used for the formation of glycosidic links in which a carbohydrate hydrazyl acts as a more efficient nucleophile than as a water molecule.

Oligosaccharide formation catalyzed by wild-type glycosidases can be accomplished by either a thermodynamically (shifting the equilibrium by using a large excess of acceptors, adding organic solvent, or increasing reaction temperature) or a kinetically (using activated glycosyl donors and exogenous nucleophiles) controlled process (2, 3). Many wild-type glycosidases have been studied. Some are readily available and with low cost. They are relatively stable and have been used in the enzymatic synthesis of oligosaccharides. More recently, with a better understanding of the catalytic mechanism of glycosidases, mutants of glycosidases with high efficiency in catalyzing the formation of glycosidic bonds have been constructed. These mutants, which are mainly of retaining-type glycosidases, are called glycosynthases. They have been increasingly used in synthesis.

**Endoglycosidase-catalyzed synthesis of oligosaccharides**

Endoglycosidases have mainly catalyzed the hydrolysis of internal glycosidic bonds. Many endoglycosidases, however, have transglycosylation activity and have been used for the synthesis of oligosaccharides of varied lengths. For example, the β-glucosidase from *Glucosaminiurn galactaricium* has transglycosylation activity and has been used for the synthesis of a wide range of oligosaccharides, including LacNAc, Gal, and GlcNAc, with yields ranging from 7% to 44% (16). The enzyme showed a preference for the 1,3-α-D-glucosidases from glucosamine (13). Another Bacillus circulans β-galactosidase, however, was specific for the cleavage of the 1,3-β-link (12). It was used to synthesize Gals1.3GalNAc, Gals1.3Gal, and GlcNAc, and their pNP derivatives in 10–46% yields using GalNp as a donor (14). β-Galactosidases from *Penicillium multicolor*, *Aspergillus oryzae*, *Bifidobacterium bifidum*, and *Escherichia coli* have been widely studied and used to synthesize β-linked oligosaccharides, including LacNAc, Galβ1,4Gal. Kragl et al. used 25% of 1,3-di-methylimidazole methyl sulfate (a water-miscible ionic liquid) in water to decrease the hydrolysis of the formed product in a kinetic-controlled manner (13). Another Bacillus circulans β-galactosidase, however, was specific for the cleavage of the 1,3-β-link (12). It was used to synthesize Gals1.3GalNAc, Gals1.3Gal, and GlcNAc, and their pNP derivatives in 10–46% yields using GalNp as a donor (14). β-Galactosidases from *Penicillium multicolor*, *Aspergillus oryzae*, *Bifidobacterium bifidum*, and *Escherichia coli* have been widely studied and used to synthesize β-linked oligosaccharides, including LacNAc, Galβ1,4Gal. Kragl et al. used 25% of 1,3-di-methylimidazole methyl sulfate (a water-miscible ionic liquid) in water to decrease the hydrolysis of the formed product in a kinetic-controlled manner (13). Another Bacillus circulans β-galactosidase, however, was specific for the cleavage of the 1,3-β-link (12). It was used to synthesize Gals1.3GalNAc, Gals1.3Gal, and GlcNAc, and their pNP derivatives in 10–46% yields using GalNp as a donor (14).

**Exoglycosidase-catalyzed synthesis of oligosaccharides**

The native function of exoglycosidases is to cleave a terminal monosaccharide unit, but exoglycosidases can be used to add a monosaccharide in the oligosaccharide synthesis. Many types of exoglycosidases from bacterial, fungal, animal, and plant sources have been reported and have been used in the formation of glycosidic bonds, including sialidases, galactosidases, glucosidases, fucosidases, mannosidases, xylosidases, N-acetylhexosaminidases, and more.
Old World monkeys. Humans naturally produce anti-Gal antibodies that specifically recognize α-Gal epitopes (17). Although in low yields, α-galactosidases from A. oryzae, A. parasiticus, A. flavipes, A. terreus, Talaromyces, and coffee beans have been used to construct Galα1,3Gal (18–20). A highly specific α-galactosidase from Penicillium multicolor was able to catalyze the synthesis of α-Gal disaccharides and trisaccharides from Galα1,3GalP donor in 25–46% yields. The yield of the reaction can be increased by decreasing the concentrations of the substrates (21). Interestingly, a coffee bean and a Thermomyces lanuginosus α-galactosidase could catalyze the galactosylation of a cyclic glucosetetrasaccharide to form an α1,6-linkage (22).

Li et al. used a CLONEZYME thermophilic glycosidase library (Diversa Corporation, San Diego, CA) in the synthesis of Galα1,4Gal, Galα1,6Gal, Galα1,3Gal, and Galα1,3Galα. Some enzymes can use lactose as a donor and transfer two Gal residues in tandem to the hydroxyl group of the acceptor (23).

Glucosidases

Glucosidases have been commonly used as catalysts for the formation of alkyl glucosides, which are surface-active compounds that have applications in the pharmaceutical and the food industry. Alcohols are usually used as both solvent and acceptors. For example, glucoamylase and β-glucosidase have been used to catalyze the synthesis of α- and β-glucosides, respectively. Maximum yields were obtained when the reaction solution consisted 10% (vol/vol) of water in primary alcohol or 15% (vol/vol) of water in diol (24). Kosary et al. used an immobilized β-glucosidase in preparative scale synthesis of alkyl and aryl β-D-glucopyranosides in moderate yields ranging from 12% to 19%. They found that the alcohol solvent component of the reaction mixture can be replaced by 1,2-diacetoxyethane (25).

An α-glucosidase from Xanthomonas campestris was used to synthesize α-arabinosyl (hydroquinone-1-α-glucopyranoside), an important cosmetic ingredient, in 93% yield using maltose as donor and hydroquinone as acceptor (26).

Glucosidases have also been widely used as catalysts for the formation of various oligosaccharides. A thermostable β-glucosidase from Thermus thermophilus was used to transfer the glucose or fucose residue from Glc1PαNP or Fuc1PαNP to a glucose acceptor for the synthesis of Glc1,3(6OEt) and Fuc1,3(6OEt) in an 88% and a 58% yield, respectively (27). β-Glucosidases from Sclerotinia sclerotiorum and Aspergillus niger were both used to synthesize gluco-oligosaccharides, such as gentiose, cellotriose, and cellotetraose, from cellobiose (28). α-Glucosidases from a different source can catalyze the formation of gluco-oligosaccharides with different links. For example, an α-glucosidase from Aspergillus Niger favors the formation of an α1,6-linkage; a Penicillium purpurogenum enzyme yields mostly α1,4-linked maltotriose from maltose (29). An α-glucosidase isolated from fungal keratinases illacinius prefers to catalyze the synthesis of α1,2- and α1,3-linked gluco-oligosaccharides from maltose (29). A thermostable β-glucosidase from Bacillus, strain S-A 1606 shows very broad substrate specificity. Site-directed mutagenesis of this enzyme generates mutants with altered specificity for oligosaccharide formation (30).

Mannosidases

Mannosyl-terminated oligosaccharides are commonly found in the carbohydrate moieties of N-linked glycoproteins of the eukaryotic system. For example, Manα1,2Man and Manα1,3Man are terminal structures of high-mannose type and hybrid type N-glycans. Athanassopoulos et al. (31) reported that incubating mannosylase with a novel α-D-mannosidase from A. phomitis afforded Manα1,6Man and Manα1,8Man an in 21% and 5% yield, respectively.

β-Mannoside links, which are considered one of the most challenging synthetic glycosidic bonds, can be achieved by the catalysis of β-D-mannosidases from Aspergillus oryzae and Helix pomatia (32).

Jack bean α-mannosidase has also been able to catalyze the transglycosylation of rhamnose residue. It has been used in the synthesis of a disaccharide Rhaα1,2ManSEt in 32.1% yield from Rhaα1PαNP and ethyl L-thio-D-thiamorphosyranose. The disaccharide product is a derivative of the common oligosaccharide unit of antigenic lipopolysaccharides from Pseudomonas (33).

Fucosidases

α-L-Fucose is commonly found as the terminal unit in the carbohydrate moiety of many important glycoproteins involved in a variety of biologic events. For example, α1,2-fucosylated LacNAc is the determinant of blood-group type O antigen. Disaccharides Fucα1,3GlcNAc and Fucα1,4GlcNAc are part of Lea and Leb antigens, respectively.

By using α-L-fucosidases from Penicillium multicolor (34), Aspergillus niger (35, 36), Corynebacterium sp. (35), and other sources (37–39), α1,3-linked L-fucosides have been obtained. By using an α-L-fucosidase from Ampullaria niger (35), α1,6-linked disaccharide Fucα1,6GalSEt has been produced in 14% yield from Fucα1PαNP and Galα1PαNP. With Fucα1PαNP as the donor, α1,4-disaccharide Fucα1,4(6OEt)GlcNH2 SEt has been obtained in 50% yield using an α-L-fucosidase from bovine kidney (40) and in 33% yield using an enzyme from bovine testes (41). Compared with α-L-fucosidases, only a few β-D-fucosidases were reported to form β-D-fucosides (42–44).

For example, β-glucosidase from Thal rosewood and almond both catalyse transglycosylation of alcohols to synthesize α-L-fucosyl fucosides with high yields using PNP-Fuc as the donor (43).
Sides to afford sulfated disaccharides with intermediate is involved (displacement mechanism in which a covalent glycosyl-enzyme rect displacement, whereas retaining glycosidases use a double inversion or inversion of stereochemistry, and thus they are classified glycosidase Agrobacterium sp catalytic carboxylate nulceophile mutant of a retaining glycosynthase was reported by Withers et al. on a single synthesis of oligosaccharides but no hydrolytic activity. Since the glycosynthase-catalyzed formation of the glycosidic bond (51). An \( \alpha \)-linked tri saccharide unit of xylo glucan resulted in 15% yield when \( \alpha \)-xylosyl fluoride was used as a glycosyl donor and pNP-\( \beta \)-cellobioside was used as an acceptor.

**Glycosynthases — glycosidase mutants**

Glycosylation or transglycosylation reactions catalyzed by wild-type glycosidases inevitably suffer from low yields and unpredictable regioselectivity because of the hydrolytic nature of the glycosidases and the lack of regioselectivity of many glycosidases. The creation of glycosynthases, a class of glycosidase mutants, has greatly advanced the field of glycosidase-catalyzed synthesis of oligosaccharide.

Glycosynthases are a new class of glycosidase mutants developed based on the mechanistic understanding of glycosidases. Glycosidases hydrolyze glycidosidic links with net reten- tion or inversion of stereocchemistry, and thus they are classified into retaining glycosidases and inverting glycosidases. Inverting glycosidases proceed via a general acid-base-catalyzed direct displacement, whereas retaining glycosidases use a double-displacement mechanism in which a covalent glycosyl-enzyme intermediate is involved (Fig. 3a and b). A glycosynthase is formed by replacing a single active site nucleophile (usually a glutamate or an aspartate residue) of a glycosidase with a neutral alanine or serine residue. An activated glycosyl donor, usually a glycosyl fluoride of the opposite anomeric configuration to that of the natural substrate, is used for the glycosynthase-catalyzed formation of the glycosidic bond (Fig. 3c). These mutated enzymes have increased activity for the synthesis of oligosaccharides but no hydrolytic activity. Since the first glycosynthase was reported by Withers et al. on a single catalytic carboxylate nucleophile mutant of a retaining glycosidase Agrobacterium sp. \( \beta \)-glucosidase (Abg) E358A mutant (52), many glycosynthases have been generated by Withers et al. and others. The first glycosynthase of an endoglycosidase was a \( \beta \)-lactamase mutant of the retaining L.\( \beta \)-1,4-glucanase from Bacillus licheniformis reported by M alet and Planas (53). Currently, about 20 glycosynthases from ten different glycosidase families have been produced. Except for a recently reported mutant of an exo-oligoxylanase (Rex) from Bacillus halodurans (54), which is the first glycosynthase derived from an inverting enzyme, all others are mutants of retaining glycosidases. Despite the development of glycosynthases, many naturally occurring carbohydrate structures have not been obtained by the glycosynthase-catalyzed reaction, because the strategy relies on the availability of gene sequence and on the understanding of the catalytic mechanism of the glycosidases, and this information is not available for all glycosidases known to date.

**Glycosyltransferase-catalyzed synthesis of oligosaccharides**

Leloir-type glycosyltransferases are enzymes that catalyze the transfer of a monosaccharide from activated sugar nucleotide donor to an acceptor. Because of their high efficiency and rego- and stereo-specificities, they offer significant advantages in the formation of glycosidic bonds, and thus, they have been widely used in the synthesis of carbohydrate-containing structures. Glycosyltransferases have been classified based on the carbohydrate residue that they transfer.

**Sialyltransferases**

Chemical synthesis of sialosides is considered one of the most difficult glycosylation reactions because of a hindered tertiary amionic carbon and the lack of a participating auxiliary functional- ity in the carbon next to the amonic carbon in sialic acids (55, 56). Sialyltransferase-catalyzed glycosylation is believed to be the most efficient approach for the production of sialic acid-containing structures.

Sialyltransferases catalyze the transfer of a sialic acid residue from CMP-sialic acid to a galactose, GalNAc, or another sialic acid residue. Sialyltransferases from bacterial and mammalian sources have been extensively studied and used in the enzymatic synthesis of sialosides, sialylglycoconjugates, and enzymatic modification of cell surface.

Rat liver \( \alpha \)2,3SiaT and \( \alpha \)2,6SiaT have been the most widely used mammalian sialyltransferases for the synthesis of sialo- sides. Both enzymes have broad donor and acceptor substrate specificity. They can tolerate a variety of modifications at the Neu5Ac moiety of CMP-Neu5Ac (57–59) and Gal on accep- tors (60–62). Four SiaTs from rat liver or porcine submaxil- lary glands were studied for their abilities to transfer synthetic 9-substituted sialic acid analogs onto N- or O-linked glyco- protein glycans. They all accepted CMP-9-alpha-Neu5Ac as the donor substrate. In contrast, 9-amino-Neu5Ac was only ac- cepted by \( \alpha \)2,6SiaT form rat liver (63).

Wong et al. have studied the acceptor specificity of a recom- binant \( \alpha \)2,3SiaT from Neisseria gonorrhoeae by using several synthetic oligosaccharides, glycolipids, and glycopeptides. Lac- tose, its \( \beta \)-lactosyl derivatives, sulfated oligosaccharides, and the \( \Delta \)54L-1 glycopeptide carrying a sulfotyrosine residue were all excellent acceptors for the enzyme. However, most glycolipids were poor substrates for this bacterial enzyme (55).

Using genes cloned from Neisseria meningitides, a fusion protein has been constructed that has both CMP-Neu5Ac synthetase and \( \alpha \)2,3SiaT activities. This fusion protein could sialylate various oligosaccharide acceptors with Neu5Ac, as well as Neu5Gc and \( \beta \)-propionyl-neuraminic acid, in high yields. A 100 gram-scale of \( \alpha \)2,3-sialylactose was produced using this protein with the regeneration of sugar nucleotide CMP-Neu5Ac.
Enzymatic Synthesis of Carbohydrate-Containing Biomolecules

(a) Retaining glycosidase

(b) Inverting glycosidase

(c) Glycosynthase

(d) Thioglycoligase

(e) Thioglycosynthase

Figure 1 Catalytic mechanisms for wild-type and engineered glycosidases. (a) Retaining glycosidase, to hydrolyze glycosidic links using the double-displacement mechanism; (b) inverting glycosidase, to hydrolyze glycosidic links via a general acid/base-catalyzed direct displacement; (c) glycosynthase, mutation of the catalytic nucleophile allows transfer an activated sugar donor (such as a glycosyl fluoride) to suitable acceptors; (d) thioglycoligase, mutation of the catalytic acid/base allows transfer of an activated \( \beta \)-glycoside to suitable acceptors; (e) thioglycosynthase, mutation of both the catalytic nucleophile and the acid/base residues allows transfer of glycosyl fluoride donor to acceptors.

Very recently, the fusion protein and a recombinant human \( \alpha \)2,6-sialyltransferase (hST6Gal-I) have been used in gram-scale synthesis of sialosides (65).

A bifunctional sialyltransferase Cst-II from \( C. \) jejuni OH4384 carrying both \( \alpha \)2,3- and \( \alpha \)2,8-sialyltransferase activities has been used in the enzymatic synthesis of ganglioside mimic GD3 (66).

Another multifunctional bacterial enzyme that has been reported recently is Pasteurella multocida sialyltransferase (PmST1 or tPm0188Ph) (67, 68). It has four different activities, including an \( \alpha \)2,3,6,8-sialidase, \( \alpha \)2,3-sialidase, and trans-sialidase activities. PmST1 is a highly active sialyltransferase with broad donor and acceptor substrate specificity; therefore it is a powerful tool.
in synthesizing diverse sialosides that contain structurally modified sialic acids.

As more than 50 different sialic acids derivatives have been found in nature, sialyltransferases with flexible donor and acceptor specificity are preferred by chemists. A α2,6SiaT cloned from Photobacterium damsela (Pd2,6ST) can efficiently transfer Neu5Ac, KON, Neu5Gc, and their derivatives with extensive modifications at C-5 and C-9 in the sialic acid residues from their CMP-activated forms to the acceptors (8). Pd2,6ST also has very relaxed acceptor specificity. For example, this bacterial enzyme has been applied for the enzymatic sialylation of glycosyltransferases and glycoconjugates (70). The exhaustively studied glycosyltransferases and has been the most firmly established enzyme responsible for the biosynthesis of a galactan core in the major structural component of mycobacterial cell wall, which has been reported (85). Ga1T transfers Ga1 residues from UDP-galactofuranose (UDP-Galf) to several OST-linked to the neuraminic acid residue in the sequence with 71% yield. More interesting, Pd2,6ST has shown activity in transferring sialic acid to N- and O-linked glycoproteins (69).

Galactosyltransferases

Galactosyltransferases are a family of enzymes that catalyze the addition of a galactose residue from activated sugar nucleotide donor uridine diphosphate galactose (UDP-Gal) to different acceptor substrates in different links.

_Gal1,4Galα1,3Galβ1,4Glcα1_ (1) is one of the most exhaustively studied galactosyltransferases and has been the most commonly used glycosyltransferase in the synthesis of oligosaccharides and glycoprotein units (70). The Galα1,4GalT exhibits poly-functional donor specificity and can transfer modified galactose from their activated UDP form to acceptors to afford corresponding LacNAc analogs (71, 72). The Galα1,4GalT is equally relaxed in respect to its acceptor specificity, and the modified Ga1NAc acceptor can be tolerated by the Galα1,4GalT. As this enzyme has a highly relaxed substrate specificity, it has been exploited in the synthesis of many non-natural LacNAc-based structures. Pdα1,4GalT from bacterial sources such as N. pylori (73) and N. meningitidis (74) have also been cloned, but examples of their application in the synthesis of galactosides have been limited (75).

Carbohydrate structures bearing a Ga1α1,3Galβ1 terminus are α-Galactosyl epitopes. The interaction of these epitopes on the surface of animal cells with anti-α-Galactosyl antibodies in human serum is believed to be the main cause in antibody-mediated hyperacute rejection in xenotransplantation. The unique enzyme responsible for the formation of α-Gal epitopes is α1,3Galactosyltransferase (α1,3GalT). Fang et al. (76) reported that a truncated bovine α1,3GalT (80-368) can be produced as a soluble recombinant enzyme on a large scale with highly specific activity. A variety of α3,4galactosylated oligosaccharides were synthesized using such a recombinant enzyme.

The 2° and 6° donor analogs of globotriose Ga1α1,4Galβ1,4Glcα1,4GlcOAcOR, which is the known receptor for Shiga and Shiga-like toxins, were prepared using UDP-2-deoxy-Gal and UDP-6-deoxy-Gal along with α1,4GalT from N. meningitidis in 11% and 95% yield, respectively (77). The inexpensive galactosyl fluoride has also been used as a donor for an α1,4Ga1T to produce an α1,4-linked galactoside in the presence of a catalytic amount of UDP (78).

Various α1,3GalTα1 have been cloned and expressed from bacterial (46, 79) and mammalian sources (80-82). Core 1, Ga1α1,3GalNAc α1-3mannosyltransferase, is the major constituent of O-glycan core structures in many cells. The core 1 structure is also called T antigen in pathologic studies. Core 1 β1,3galactosyltransferases (core 1 β1,3Galα1T), which are responsible for the synthesis of core 1 disaccharides, have been purified recently (83, 84).

Compared with galactopyranosyltransferases, a few studies on galactofuranosyltransferase (GalT), which is responsible for the biosynthesis of a galactan core in the major structural component of mycobacterial cell wall, have been reported (85). Ga1T transfers Ga1 residues from UDP-galactofuranose (UDP-Galf), instead of UDP-Gal, to the growing galactan chain. Very recently, Lorary et al. (86) reported the high-level expression and purification of a novel bifunctional recombinant galactofuranosyltransferase from Mycobacterium tuberculosis H37Rv, which can produce both α1,5- and α1,6-galactofuranose links in an alternating fashion.

_N-acytylgalactosaminyltransferase

The human blood group A glycosyltransferase (α1,3N-acetylgalactosaminyltransferase) is responsible for the biosynthesis of blood group A antigens. It catalyzes the transfer of a Ga1NAc from UDP-Ga1NAc to the C-3 hydroxyl of Gal residue in (Fucu1,2Ga1α1,6GlcOR) to form blood group A antigen Ga1NAcα1,3Fucα1,2Ga1α1,6GlcOR. α1,3-3Ga1NAcCT from N. meningitidis was reported to transfer a Ga1NAc to 1-thio-D-galactose to produce a trisaccharide, which was further used to synthesize lacto-N-neotetraose (87). Wang et al. (88) had constructed α1,3-N-acetylgalactosaminyltransferase UDP-N-acetylglucosamine C4 epimerase fusion protein and had synthesized a variety of globotetraose and isoglobotetraose derivatives using this fusion protein and UDP-GlcnAc. This construction alters the donor substrate requirement of the reaction from the high-cost UDP-GalNAc to UDP-GlcnAc. Recently, gram-scale synthesis of GD3, GT3, GM2, GD2, GT2, and GM1 gangoside oligosaccharides was reported by Blixt et al. using α1,4-N-acetylgalactosaminyltransferase (α1,4GalNAcCT) from Campylobacter jejuni along with other glycosyltransferases (89).

_N-Acetylgalactosaminyltransferases

N-Acetylgalactosaminyltransferases (Ga1NAcTs) play important roles in the synthesis of 0-glycan core structures and in the branching and subsequent elaboration of N-linked glycans on glycoproteins. GlcNAcTs I-VI (differing in their specificities and glycosidic bonds formed with trimannose core-containing N-glycans) have been studied on their substrate specificity and their application. For example, Core 2 Ga1NAc (β1,6Ga1NAcCT) has been used in the synthesis of 0-linked core 2-type 6° blood type (90). Norberg et al. (91) had investigated the donor and acceptor substrate specificity of β1,3Ga1NAcCT from N. meningitidis. This enzyme can use both UDP-GlcnAc and UDP-GalNAc as donors. It is also capable of tolerating deoxy derivatives at any position other than C-3 of the Gal residue in Ga1/2LacNAcOAcOR acceptor.

Fucosyltransferases

Several mammalian fucosyltransferases (FucTs) have been characterized, and their application to the synthesis of fucose-
noting oligosaccharides has been well studied. Recently Drumliard et al. (92) developed an efficient bioengineering method for large-scale production of fucosyl α1,2-linked oligosaccharides from lactose. 2-Fucosyl lactose and lacto-N-neofucopentaose-1 (LNF1), an H-2 antigen oligosaccharide were produced by expressing Helicobacter pylori α1,2-fucosyltransferase in metabolically engineered E. coli cells. Trisaccharide 2’-fucosylactose could be synthesized industrially on a multiton scale for nutraceutic applications. The pentasaccharide LNnF-1, which contains the H-2 antigen structure, could be used as a precursor for the synthesis of other antigens of the ABH histo-blood-group system.

Mannosyltransferases

The β1,4-mannosidic linkage is common to most asparagine-linked oligosaccharides (N-glycans) in glycoproteins as part of their pentasaccharide core structure. The formation of the glycosidic link in Manα1,4GlcNAc is particularly challenging for chemical synthesis. Glycosidases have been used, but they require a large excess of the expensive chitobiose acceptor and produce low yields. A highly active recombinant β1,4-mannosyltransferase was reported (93), and this enzyme was used to produce the core triasaccharide of N-glycans with a yield of 80% using UDP-mannose as donor and the synthetic chitobioyl phosphatidyl as acceptor. A recombinant α1,2-mannosyltransferase was recently reported to use GDP-S-thio-Man as a sugar nucleotide donor to produce the corresponding S-mannosides (94). S-Glycans are expected to have potentially stronger affinity for receptors compared with their natural counterparts, and they may also find other applications in hydrodase-resistant vaccines.

Enzymatic formation of S-glycosidic bonds

Natural occurring carbohydrates contain monosaccharides linked through O-glycosidic bonds. Thioglycosides, in which the glycosidic oxygen atom has been replaced by the sulfur atom, can be tolerated by most biological systems and are less susceptible to acid/base or enzyme-mediated hydrolysis. They are invaluable in the studies of glycosidases and are gaining interest as targets for pharmaceutical industry. Many efforts have been focused on the synthesis of thioglycosides by conventional chemical synthetic methods. Only recently, mutants of glycosidases and glycosyltransferase have been constructed and applied to form S-linked oligosaccharides using thiolated acceptors.

Glycosidase mutants (thioglycoligase and thioglycosynthase) in the synthesis of S-linked oligosaccharides

A glycosidase mutant, in which the acid/base carboxyl residue was replaced by a catalytically inactive residue, was recently developed by Wilthers et al. as a novel strategy for the synthesis of S-linked oligosaccharides (95). This new class of glycosidase mutants is named “thioglycoligase” (Fig. 3a). Two different alanine acid/base mutants of retaining β-glycosidases, a β-glucosidase from Agrobacterium sp. Abg E171A and a β-mannosidase from Cellulomonas fimi Man2A, were used for the formation of thioglycosidic bonds. The readily available dinitrophenyl glycoside donor DNP-Glc or DNP-Man was incubated with the mutant enzyme and the acceptor to provide corresponding thioglycosaccharides in good yields. With this new methodology, Stick and Stubbs (96) have synthesized various types of S-linked disaccharides using glycosidase mutant Abg E171A. Incubation of the glucose donor DNP-Glc and various thiol acceptors with Abg 171A provided corresponding β1,4-, β1,3- and β1,6-S-linked disaccharides, but it did not work for the formation of β1,2-thio-linkage. More recently, the generation of α-thioglycosides has been successfully achieved for the first time using thioglycoligases derived from glycoside hydrolase family 315. solütARIOculos α-glycosidase and E. coli α-mannosidase (97).

The thioglycoligase technology was further extended with the advent of thioglycosynthases (Fig. 3a), double-mutants of retaining glycosidases which lack both catalytic nucleophile and catalytic acid/base residues and can efficiently catalyze the thioglycosidic bond formation using glycosyl fluoride donors and thioglycoside acceptors (98). Reaction of the synthetic α-glycosyl fluoride with the acceptors in the presence of the double mutant Abg E171A, E558D at neutral pH afforded two β1,4-S-linked disaccharides with 51% and 45% yields, respectively.

Glycosyltransferase mutants in the synthesis of S-linked glycodies

Rich et al. (99) have reported a new enzymatic method for the synthesis of thioglycosides using glycosyltransferase. Incubation of a mixture of thiol acceptor and UDP-Gal with unit quantities of a recombinant bovine α1,3-galactosyltransferase in the presence of DTT afforded the thio-linked tetrasaccharide in 92% yield instead of the expected trisaccharide product because of the second glycosyl transfer that occurred after the initial transfer of a galactosyl residue to the thiolated acceptor. The desired trisaccharide, which is an analog of the Clostridium difficil toxin A binding ligand, was obtained in near-quantitative yield after treatment with an α-galactosidase from green coffee beans. Furthermore, their initial results confirmed that a β1,3-N-acetylglucosaminyltransferase from N. meningitides can catalyze the transfer of UDP-GlcNAc to a thiol donor to afford a thio-linked trisaccharide. This is the first example of using glycosyltransferases in synthesizing thioglycosides. Such thioglycosides could serve as important immunogens and components of conjugate vaccines.

Enzymatic Synthesis of Polysaccharides

Polysaccharides, along with nucleic acids and proteins, belong to three major important classes of naturally occurring biopolymers. Polysaccharides are important biomacromolecules with unique physical properties that lead to advanced biomaterials and biomedical applications (100). For example, glycosaminoglycans (GAGs) are linear polysaccharides containing repeating disaccharide units of a hexosamine and a uronic acid.
Heparin, heparan, and chondroitin are three prevalent glycosaminoglycans. Vertebrates use glycosaminoglycans in structural, recognition, adhesion, and signaling roles. Chemical synthesis of naturally occurring polysaccharides is considered to be impractical. Most polysaccharides, especially those from bacteria origins, are obtained by purification from natural sources or from cell culture, enzymatic approaches have been increasingly applied to obtain some structures.

Heparin/Heparan Sulfate

Heparin and heparan sulfate are linear polysaccharides with a repeating disaccharide unit of 1,4-linked uronic acid (D-glucuronic or L-iduronic acid) and D-glucosamine residues. Both uronic acid and glucosamine can contain sulfo groups at different positions including 2-O-sulfo substitution of the uronic acid residue and 2-N-, 3-O-, and 6-O-sulfo substitution in the glucosamine residue. Heparin and heparan sulfate are structurally related glycosaminoglycans that participate in numerous important biologic processes, such as blood coagulation, viral and bacterial entry and infection, angiogenesis, and cancer development.

The enzymatic synthesis of heparin and heparan sulfate is currently under extensive investigation using glycosyltransferases of E. coli (101, 102) and heparanase synthase of P. multocida (103, 104). Rosenberg et al. reported an approach to rapidly assemble anti-coagulant III-binding classic and nonclassic anti-coagulant heparan polysaccharides using the enzymes involved in the heparin sulfate biosynthesis (105). Recently Chen et al. (106) have described a method for the enzymatic sulfation of multigram amounts of heparin sulfate with specific functions using immobilized sulfotransferases combined with a 3-phosphoadenosine 5′-phosphosulfate regeneration system. Because the recombinant sulfotransferases are expressed in bacteria and the method uses a low cost sulfo donor, it can be readily used to synthesize large quantities of anti-coagulant heparin drug or other biologically active heparan sulfates.

Hyaluronan

Hyaluronan (hyaluronic acid, HA) is a highly anionic unbranched linear polymer containing a (1→4)-linked uronic acid (β-D-gluconic or α-L-iduronic acid) repeating unit, which plays important roles in modulating cell adhesion, signaling, and motility. Several enzymes responsible for HA synthesis, namely Hyaluronidases A and B Synthases, have been cloned from bacteria and mammals (107, 108). HA synthase from Streptococcus equisimilis was employed for milligram-scale synthesis of HA (109). In this reaction system, UDP-sugars (UDP-GlcA and UDP-GlcNAc) were effectively regenerated by the catalyses of several enzymes, synthetic HA was produced in 90% yield. In addition, mutated HA synthase from Type A Pasteurella multocida (PmHA S1-703 aa) was recently used for the stepwise synthesis of HA, which has a monodisperse molecular mass of up to 20 sugar units (110). On the other hand, using hyaluronidase (HAase) to synthesize HA has also been reported (111, 112). HA oligomers of up to 22 sugar units were synthesized by enzymatic reconstruction of HA chains using the transglycosylation reaction of Bovine Testicular HAase (111).

Chondroitin

Chondroitin (Ch) and chondroitin sulfate (ChS) are naturally occurring heteropolysaccharides belonging to the family of GAGs. Ch is a nonsulfated derivative of ChS, which consists of a G(A)1,3GlcNAc2 disaccharide repeating unit connected through β-N-acetylglicosamido bonds. ChS exists predominantly as polysaccharide side chains of proteoglycans in extracellular matrixes where it plays important roles in the bioactivities of living systems. Ch is widely used as a therapeutic material for the prevention or alleviation of symptoms of diseases.

The enzymatic polymerization to provide synthetic Ch and its derivatives catalyzed by hyaluronidase has been reported by Kobayashi et al. (113). Synthetic oxazoline monomers were recognized and catalyzed by ovine testicular HAase (OTH) to produce Ch and the polymerization behaviors greatly depend on the reaction conditions. The Mn value of synthetic Ch reached 4600, which corresponds to that of naturally occurring Ch.

Polysialic acids

Polysialic acids (PSA) are linear homopolymers of N-acetyllactosaminic acid and N-glycolylneuraminic acid joined by α2,8- and α2,9-ketosidic linkages. Polysialic acids play many important biologic roles. For example, polysialylation of mammalian neural cell adhesion molecules affects cell-cell adhesive interactions during embryogenesis (114). Polysialic acid is also a component of many bacterial capsular polysaccharides that are important virulence factors. Sialyltransferases catalyze the addition of sialic acid to form diverse carbohydrate molecules. The substrate specificity of α2,8 and α2,8/α2,9-polySiaT toward glycolipids and sialylated polysaccharides has been characterized (115–117). For example, the neu5 gene product from E. coli K92 that exhibits α2,8/α2,9-polySia transferase activity both in vitro and in vivo has been described for the first time by Wong et al. (116).

Cellulose

Cellulose is a linear polysaccharide of β-D-glucan linked dehydration β-glucose repeating units. Cellulose is the most abundant polysaccharide on earth. It is a major component in higher plant cell walls and has been used as raw material in paper, fibers, and lumber industries.

Enzymatic synthesis of cellulose has been achieved by cellulase. For example, incubation of β-cellobiose fluoride with a cellulase from Trichoderma viride can produce cellulose in 54% yield with DP around 22 after 12h. In addition, change of the reaction conditions (substrate concentration or organic solvent concentration) enabled the selective synthesis of the water-soluble cellobiosepolysaccharides (118).

Amylose

Amylose is a linear polymer of glucose mainly linked with an α-(1,4)-glycosidic bond. Amylosepolysaccharides have been effectively prepared by polycondensation of α-D-maltosyl fluoride using an α-amylase from Aspergillus oryzae as the catalyst in a mixed solvent of methanol-phosphate buffer (119).
Amylose was also prepared via in vitro polymerization of D-glucosyl phosphate catalyzed by a potato phosphorylase (120). A large excess amount of Glc-1-P is required in this equilibrium-controlled reaction.

Xylan

Xylan, a xylose polymer having a β(1,4)-glycosidic linkage in the main chain, is the important component of hemicellulose in plant cell walls. Kobayashi et al. (121) reported that synthetic xylan that consists exclusively of xylose units can be prepared by the crude cellulase (containing xylosidase polymerization of β-xylosyloxy fluoride as a monomer in a mixed solvent of acetonitrile/acetate buffer. The reaction proceeded to produce β(1,4)-linked synthetic xylan with a degree of polymerization of 23.

Chitin

Chitin is a β(1,4)-linked polymer of N-acetyl-D-glucosaminopyranose. It is used as structural material in nature, such as the main component in the cell walls of fungi, the exoskeletons of insects and other arthropods, as well as in some animals. It attracts much interest in several scientific and application areas as a multifunctional substrate.

Enzymatic Synthesis of Glycoproteins

Many biologically important proteins are carbohydrate-containing glycoproteins. Two major types of glycoproteins are O-linked glycoproteins (a sugar moiety is linked to the β-hydroxy group of either a serine or a threonine residue in the polypeptide) and N-linked glycoproteins (an oligosaccharide is linked to the amide-side chain of asparagine residue of the polypeptide). For O-linked glycosylation, three different ways can occur: 1) A single GlcNAc residue may be reversibly added to proteins in the cytoplasm or nucleus, 2) initiation of synthesis of proteoglycans may occur by the addition of xylose in the Golgi, and 3) mucin-type O-linked glycosylation is initiated in the ER. As glycoproteins usually present a mixed population of glycan structures, the isolation of homogeneous glycoproteins from natural sources in significant quantity is impossible. The chemical method for the de novo synthesis of large glycoproteins is currently unavailable. Although challenging, enzymatic synthesis of structurally defined glycoproteins is feasible.

O-GlcNAc-modified glycoproteins

Many nuclear and cytosolic proteins are ρ-O-GlcNAc-modified, which is the covalent attachment of ρ-GlcNAc to Ser/Thr residues in the proteins. Nearly 80 proteins bearing the O-GlcNAc group have been identified to date (124). Understanding the functional roles of O-GlcNAc requires the development of new strategies for the detection and study of O-GlcNAc-modified proteins. Khodde et al. (125) reported the direct, high-throughput analysis of O-GlcNAc-proteins using a chemoenzymatic approach. An engineered galactosyltransferase was exploited to selectively label O-GlcNAc-proteins with a ketone-based tagged Gal, which permitted the enrichment of low-abundance O-GlcNAc species and the localization of the modification site. Another chemical strategy was developed by Bertozi et al. for identifying O-GlcNAc-modified proteins from living cells. O-GlcNAcase is capable of transferring azidoacetylgalactosamine (GlcNAz) from UDP-GlcNAz to known protein substrates, such as recombinant nuclear pore protein p62. These O-GlcNAz-modified proteins can be covalently derivatized with various biochemical probes at the site of protein glycosylation using the Staudinger ligation reaction (126). Such a strategy for in vivo modification of target proteins can provide a rapid means for the identification of sites of O-GlcNAc modification on purified recombinant protein. However, so far no reports exist on enzymatic synthesis of O-GlcNAc-linked glycoproteins by directly transferring GlcNAc to proteins. Zhang et al. (127) developed a novel strategy for the generation of homogenous glycoprotein by selective incorporation of glycosylated amino acids (GlcNAc-c-c1-0-) into proteins. An orthogonal M. jannaschii RNA synthetase (TyRS) mutant was identified that selectively incorporated GlcNAc-c-c1(1-0-) into myoglobin. With the evolved TyRS synthetase, milligram quantities of homogenous glycoprotein was obtained upon coexpression of the synthetase, suppressor tRNA, and TAG-mutated myoglobin genes in E. coli in medium that contained the glycosylated amino acid. This approach has advantages of high selectivity, efficiency, and high yield without the generation of other glycoforms or unmodified forms of myoglobin.

O-GalNAc-modified glycoproteins

Mucin-type O-linked glycoproteins that are involved in biologic interactions in higher eukaryotes are ρ-O-GalNAc modified. Strategies for the detection and study of O-GalNAc-modified proteins have been developed (128-131). Bertozi et al. have developed a metabolic labeling approach toward proteomic analysis of mucin-type O-linked glycosylation, a unique azido chemical tag introduced permits the identification of O-GalNAc-modified proteins from complex cell lysates (128).

O-GalNAc-linked glycopeptides have been synthesized using glycoenzymes. Aijikara et al. (132) recently used the transglycosylation activity of an endo-β-N-acetylgalactosaminidase from Streptomyces sp. for the synthesis of O-linked glycopeptides. Using Galp1,3GalNAc-Cl as the glycosyl donor, this enzyme can transfer the disaccharide to a serine in a hexapeptide and produced a Galp1,3GalNAc-linked hexapeptide in 11% yield.
proteins prepared by conventional chemical methods (137). Greater structural homogeneity as compared with PEGylated enables the manufacturing of long-acting protein drugs with sialic acid-PEG to oligosaccharides, G-CSF, IFN-α, and GM-CSF. Selective addition of sialic acid conjugated with PEG to the introduced GalNAc expressed in specific serine and threonine residues in non-glycosylated proteins (134). The process involves enzymatic GalNAc glycosylation at specific sites and threonine residues in non-glycosylated proteins expressed in Escherichia coli, followed by the enzymatic transfer of sialic acid conjugated with PEG to the introduced GalNAc residues. The strategy was applied to three therapeutic polypeptides, GM-CSF, IFN-α, and GM-CSF. Selective addition of sialic acid-PEG to O-linked GalNAc on a protein provides a novel, highly site-selective mechanism for PEGylation, which enables the large-scale manufacturing of long-acting protein drugs with greater structural homogeneity as compared with PEGylated proteins prepared by conventional chemical methods (137).

N-linked glycoproteins

N-linked glycoproteins are found in a wide range of organisms ranging from archaea to mammals and other eukaryotes (138). The major method for enzymatic synthesis of N-linked glycoproteins is to elaborate the existing sugar moieties on the proteins. Glycosidases are used to trim the existing glycan structures, other sugars can then be put back on by glycosyltransferases (this process is called glycoprotein remodeling). For example, the synthesis of homogeneous unnatural glycoform of ribonuclease B (RNase-B, which presents a mixture of high-mannose glycoforms) was achieved by endo H degradation to GlcNAc2-Man9GlcNAc2 (139) followed by elaboration with a galactosyltransferase, a fucosyltransferase, and a sialyltransferase to form the desired glycoform (140).

Some endo-2-3 sialidase/glycosidase (ENGase), such as Endo A from Arthrobacter protophormiae (141) and Endo M from Mucor hiemalis (141), have transglycosylation activities. They can transfer a large intact oligosaccharide to a GlcNAc-peptide acceptor in a single step. This methodology has also been successfully employed in constructing glycoproteins. Incubation of the tetra- or hexasaccharide oxazoline with homogeneous GlcNAc-Rnase B in the presence of Endo-A afforded the glycoproteins in 82% and 96% yield, respectively (143).

Hamilton et al. (149) reported a new approach to produce complex human N-glycoproteins using yeast-based expression systems. They observed that Man9GlcNAc-Rnase B expression in endogenous yeast glycosylation pathways, five active eukaryotic proteins were properly expressed and localized in the yeast Pichia pastoris. Targeted localization of the enzymes enabled the generation of human glycoproteins with homogeneous N-Glycan structures. This is a big step toward producing therapeutic glycoproteins. Glycoengineered yeast Pichia pastoris was also employed to produce human antibodies with specific human N-glycan structures (150) and human glycoproteins with complex terminally sialylated N-glycans (151).

Enzymatic Synthesis of Glycolipids

Glycolipid synthesis (GSL) is a field that has experienced significant advancements in recent years. Enzymatic synthesis of GSLs using recombinant glycosyltransferases has become a powerful tool for the production of complex glycosphingolipids, mimics of native GSLs, and GSL analogs with modified structures. This technique allows for the precise and controlled synthesis of GSLs, which are important in various fields such as pharmacology, biology, and medicine.

Glycosphingolipids (GSL) are amphiphilic molecules that are synthesized by sequential actions of glycosyltransferases. They consist of a glycosphingolipid backbone linked to a carbohydrate moiety. The synthesis of GSLs is typically initiated by the transfer of a sialic acid-containing glycosphingolipid, called ganglioside, to a glycosphingolipid acceptor. The phosphorylation of GSLs can be achieved by the catalysis of a series of glycosyltransferases to provide targeted glycopeptides. Glycosyltransferases are also often used in the elaboration of the existing glycan structures on glycopeptides and glycoproteins. For example, a sulfated N-terminal fragment of PSGL-1 (P-selectin glycoprotein ligand 1, which is an important cell-surface glycoprotein on vascular endothelial cells) has been prepared using this method (134).

Modification of protein drugs by covalent attachment of polyethylene glycol (PEG) can prolong the half-life and enhance the pharmacodynamics of therapeutic proteins. Defrees et al. (136) recently developed a novel approach for site-directed PEGylation using glycosyltransferases to attach PEG to O-glycans. The process involves enzymatic GalNAc glycosylation at specific serine and threonine residues in non-glycosylated proteins expressed in Escherichia coli, followed by the enzymatic transfer of sialic acid conjugated with PEG to the introduced GalNAc residues. The strategy was applied to three therapeutic polypeptides, GM-CSF, IFN-α, and GM-CSF. Selective addition of sialic acid-PEG to O-linked GalNAc on a protein provides a novel, highly site-selective mechanism for PEGylation, which enables the large-scale manufacturing of long-acting protein drugs with greater structural homogeneity as compared with PEGylated proteins prepared by conventional chemical methods (137).

N-linked glycoproteins

N-linked glycoproteins are found in a wide range of organisms ranging from archaea to mammals and other eukaryotes (138). The major method for enzymatic synthesis of N-linked glycoproteins is to elaborate the existing sugar moieties on the proteins. Glycosidases are used to trim the existing glycan structures, other sugars can then be put back on by glycosyltransferases (this process is called glycoprotein remodeling). For example, the synthesis of homogeneous unnatural glycoform of ribonuclease B (RNase-B, which presents a mixture of high-mannose glycoforms) was achieved by endo H degradation to GlcNAc2-Man9GlcNAc2 (139) followed by elaboration with a galactosyltransferase, a fucosyltransferase, and a sialyltransferase to form the desired glycoform (140).

Some endo-2-3 sialidase/glycosidase (ENGase), such as Endo A from Arthrobacter protophormiae (141) and Endo M from Mucor hiemalis (141), have transglycosylation activities. They can transfer a large intact oligosaccharide to a GlcNAc-peptide acceptor in a single step. This methodology has also been successfully employed in constructing glycoproteins. Incubation of the tetra- or hexasaccharide oxazoline with homogeneous GlcNAc-Rnase B in the presence of Endo-A afforded the glycoproteins in 82% and 96% yield, respectively (143).

Hamilton et al. (149) reported a new approach to produce complex human N-glycoproteins using a yeast-based expression system. They observed that Man9GlcNAc-Rnase B expression in endogenous yeast glycosylation pathways, five active eukaryotic proteins were properly expressed and localized in the yeast Pichia pastoris. Targeted localization of the enzymes enabled the generation of human glycoproteins with homogeneous N-Glycan structures. This is a big step toward producing therapeutic glycoproteins. Glycoengineered yeast Pichia pastoris was also employed to produce human antibodies with specific human N-glycan structures (150) and human glycoproteins with complex terminally sialylated N-glycans (151).

Enzymatic Synthesis of Glycolipids

Glycolipid synthesis (GSL) is a field that has experienced significant advancements in recent years. Enzymatic synthesis of GSLs using recombinant glycosyltransferases has become a powerful tool for the production of complex glycosphingolipids, mimics of native GSLs, and GSL analogs with modified structures. This technique allows for the precise and controlled synthesis of GSLs, which are important in various fields such as pharmacology, biology, and medicine.

Glycosphingolipids (GSL) are amphiphilic molecules that are synthesized by sequential actions of glycosyltransferases. Regarding the structural variation of GSLs, the expression of enzymes acting on lactosylceramide (LacCer) is the rate-determining step. Several genes that code for enzymes responsible for the synthesis of the carbohydrate moiety of glycosphingolipids have been recently identified.

Sialic acid-containing glycosphingolipids, called gangliosides, have various important biologic functions. In vertebrates, almost all gangliosides are synthesized from a common precursor, ganglioside 

1,4GlcNAc could serve as a substrate for ENGase-catalyzed transglycosylation. Wang et al. then explored sugar oxazolines as donor substrates for Endo A and Endo M in the N-glycopeptide synthesis using large peptides and partially deglycosylated Rnase-B as model systems (146–148). They found that Endo-A and Endo-M both can effectively catalyze the reaction between the synthetic oligosaccharide oxazoline and the GlcNAc-heptapeptide to form the glycopeptide in 82% and 78% yields, respectively. The newly formed glycosidic bond was indicated to be a 1,4-type by NMR analysis, which confirms that the ENGase-catalyzed transglycosylation using sugar oxazoline as the glycosyl donor proceeded in a stereo- and regiospecific manner to form the desired glycopeptide (147). The ENGase-catalyzed transglycosylation method has also been successfully employed in constructing glycoproteins. Incubation of the tetra- or hexasaccharide oxazoline with homogeneous GlcNAc-Rnase B in the presence of Endo-A afforded the glycoproteins in 82% and 96% yield, respectively (148).

Hamilton et al. (149) reported a new approach to produce complex human N-glycoproteins using a yeast-based expression system. They observed that Man9GlcNAc-Rnase B expression in endogenous yeast glycosylation pathways, five active eukaryotic proteins were properly expressed and localized in the yeast Pichia pastoris. Targeted localization of the enzymes enabled the generation of human glycoproteins with homogeneous N-Glycan structures. This is a big step toward producing therapeutic glycoproteins. Glycoengineered yeast Pichia pastoris was also employed to produce human antibodies with specific human N-glycan structures (150) and human glycoproteins with complex terminally sialylated N-glycans (151).
Glycosylation of Natural Products

Many biologically active natural products are glycospides. It is becoming more and more obvious that glycosylation affects bioactivity or selectivity of natural products, such as anticancer drugs and antibiotics (160, 161). Altering glycans has become a focus within natural product chemistry and pharmaceutical sciences. Recent developments in molecular glycobiology make it possible to develop new and more effective glycodrugs. The glycosides vancomycin and teicoplanin are clinically important antibiotics. As the carbohydrate portions of these molecules affect biologic activity, developing efficient strategies to make carbohydrate derivatives is of interest in searching for vancomycin and teicoplanin analogs. Glycosyltransferases from Amycolatopsis orientalis were used by the Walsh group to produce variant sugar forms on both vancomycin and teicoplanin classes of glycopeptide antibiotics using nucleotide diphospho-sugar (NDP-sugars) as the glycosyl donors (162). Although GaTs are generally perceived as unidirectional catalysts, very recently, Thomson et al. (163) reported that four glycosyltrans-ferses from two distinct natural product biosynthetic pathways (calicheamicin and vancomycin) readily catalyzed reversible re-actions, allowing sugars and aglycons to be exchanged with ease. Using these new reactions, more than 70 differentially glycosylated calicheamicin and vancomycin variants were pro-duced.

The glycosyltransferase DesVII can catalyze the attach-ment of TDP-D-desosamine onto 12- and 14-membered macro-lactone rings to make methymycin/methemymycin and nar-bormycin/pikromycin, respectively, in Streptomyces venezuelae. The purified DesVII is active only in the presence of another protein, DesVIII, at high pH. Y-C17 (10-deoxy-D-methylmycin) was synthesized in preparative scale using TDP-D-desosamine as the donor and 10-deoxy-D-methylmycin as aglycon acceptor (164).

Steroidal glycosides constitute a structurally and biologically diverse class of molecules such as cardenolides or saponins. They have received considerable recent attention because of their physiologic and pharmacologic activities. Synthesis of steroidal glycosides via enzymatic systems is still rare as most enzymes are not available. β-Galactosidosidase from Aspergillus oryzae was used in the synthesis of various cardiac glycosides which are unstable under basic or acidic condition during chemi-synthetic synthesis (165). A peripllogenin β-D-glucoside was prepared in 37% yield using the biotransformation of digitoxigenin by hybrid cells (166). Thiem et al. have re-port ed the enzymatic synthesis of the β-glucosidories of estradiol and ethynylestradiol on a preparative scale by incubating bovine liver UDP-glucuronol transferase with corresponding phenolic aglycone substrates (167).

Peptidoglycan is a polymer of carbohydrate chains connected by peptide crosslinks. It is the major component in bacterial cell wall. The enzymes that synthesize peptidoglycan layers have received special attention because many known antibiotics function by blocking peptidoglycan synthesis (168). Among these enzymes, bacterial transglycosylases (GTases) are located on the external surface of the bacterial membrane where they polymer-ize lipid II, a disaccharide anchored to the membrane by a 55 carbon undecaprenyl chain (169, 170). Terrak et al. re-port ed that the penicillin-binding protein (PBP) 1b of E. coli catalyzes the conversion of C55H89 lipid-transported disaccha-ride pentapeptide units into polymeric peptidoglycan (171).
bifunctional enzyme catalyzes both glycosylation for the formation of the carbohydrate backbone of murein and transpeptidation for the formation of the interstrand peptide links (172).

Strategies in Enzymatic Synthesis of Carbohydrates and Glycoconjugates

Protein engineering of glycosidases and glycosyltransferases

Other than protein crystal structure-based construction of glycosidase mutants, such as glycosylases, thioglycosylases, and thioglycoligases discussed above, for the synthesis of carbohydrate-containing structures, protein crystal structure-based rational design of glycosyltransferase with altered substrate specificity has also been performed. In addition, directed evolution has emerged as a powerful tool in generating mutants with designed function.

Crystal structure-based rational design of glycosyltransferase mutants

Many X-ray crystal structures have been reported for glycosyltransferases, which makes the structure-based redesign of glycosyltransferases feasible. For example, crystallographic analysis of the Y289L mutation of β1,4GalT predicted that such a mutation should provide space for a C-2 N-acetyl group (173). Using the GalT tolerating the C-2 donor sugar substrates, Khidekel et al. (174) reported that Y289L mutant β1,4GalT could efficiently transfer a Gal analog with a ketone functionality at C-2 from donor to the O-GlcNAc glycosylated protein CREB. The ketone functionality on the Gal was used as a tag to identify O-GlcNAc posttranslational modified proteins.

Directed evolution

Wild-type enzymes are powerful tools in the synthesis of carbohydrates. Enzymatic synthesis using wild-type enzymes, however, is limited by the enzyme instability and the restriction on the substrates that can be recognized by the wild-type enzymes. Protein crystal structure-based rational design and mutants generated by site-directed mutagenesis provide some solution for the problems. Some properties of the mutants, however, cannot be obtained by rational design because of the limited information available about the structure-function relationship of proteins. Directed evolution has emerged as a promising approach to obtain enzymes with broader or altered substrate specificity. The key for a successful directed evolution process involves an efficient screening system to identify randomly generated mutants with desired properties. This has been a challenge for applying directed evolution approaches for glycosyltransferases. A recent report by Mayer et al. describes the development of a novel agar plate-based coupled-enzyme screen to select an improved glycosynthase form a library of mutants (175). Withers et al. developed a novel fluorescence-based high-throughput screening methodology for the directed evolution of sialyltransferases. Using this methodology, a library of >10^6 SaT mutants was screened and a new sialyltransferase variant was discovered, which had more than 400-fold higher catalytic activities than the parent enzyme (176).

Feng et al. (177) reported the converting a β-glycosidase of Thermus thermophilus to a β-transglycosidase by directed evolution. Mutants possessing high transglycosase activity are identified by using a simple screening procedure. Using these mutants, self-condensation of nitrophenyl glycosides can reach nearly quantitative yield, whereas transglycosylation of maltose and cellobiose can reach 60% and 75%, respectively.

One-pot multiple-enzyme synthesis

Glycosyltransferases have been used in combination with other enzymes such as sulfotransferases, proteases, lipases, and acetyltransferases to synthesize complex oligosaccharides. Most of these enzymatic reactions can be successfully achieved under similar conditions, which makes it possible to carry out a multiple-enzyme reaction in one-pot system to produce oligosaccharide and their derivatives. One-pot multiple-enzyme reaction can simplify the product purification process without the necessity of isolation of intermediates, thus avoiding the compound loss during the multiple purification steps. More important, it avoids the use of high cost sugar nucleotides and their analogs by using less-expensive starting materials.

Yu et al. (8, 67) recently reported a highly efficient and convenient one-pot three-enzyme chemoenzymatic approach for the synthesis of libraries of α2,6-linked and α2,3-linked sialosides containing naturally occurring as well as non-natural sialic acids. In this method, sialic acid modifications can be chemically introduced at the very beginning, onto the six carbon sugar precursors (ManNAc or mannose) of sialic acids. These ManNAc or mannose analogs can then be directly converted to naturally occurring and non-natural sialosides in one-pot using three enzymes, including a sialic acid aldolase, a CMP-sialic acid synthetase, and a sialyltransferase, without the isolation of intermediates. (Fig. 2) Such process takes advantage of the relaxed substrate specificity of all the enzymes involved in the synthesis.

Sugar nucleotide regeneration

The application of glycosyltransferases in the glycosidic link formation is limited because of the high cost of sugar nucleotides. This limitation has led to the development of sugar nucleotide recycling systems in enzymatic glycosylations. These regeneration systems require the use of only catalytic quantities of the sugar nucleotides, which can be regenerated continuously from inexpensive precursors, making the large-scale enzymatic synthesis of complex carbohydrates economically viable.

Sugar nucleotide regeneration systems have been developed by mimicking their biosynthetic pathways. For example, Wang et al. reported the incorporation of a UDP-GalNAc-4-epimerase in a UDP-GalNAc regeneration system, which in combination with a GalNAcT, was used in the synthesis of globotetraose and its derivatives (Fig. 3) (88).
Enzymatic Synthesis of Carbohydrate-Containing Biomolecules

Figure 2: One-pot three-enzyme chemoenzymatic synthesis of sialosides containing sialic acid modifications. In this strategy, mannose or ManNAc derivatives are chemically or enzymatically synthesized. These compounds are then used by a recombinant E. coli K-12 sialic acid aldolase to obtain sialic acids and their derivatives followed by an N. meningitidis CMP-sialic acid synthetase for the formation of CMP-sialic acids. From which, sialic acids can be transferred to lactose, LactNAc, galactose, GalNAc, or their derivatives by a multifunctional P. multocida sialyltransferase (PmST1) or a P. damsela α2,6-sialyltransferase (Pd2,6ST) to form α2,3- or α2,6-linked sialosides in one pot without the isolation of intermediates.

Figure 3: Enzymatic synthesis of globotetraose with in situ UDP-GlcNAc regeneration. The system contains UDP-GlcNAc pyrophosphorylase (GlmU), pyruvate kinase (PykF) and inorganic pyrophosphatase (PPase) from E. coli K12; GlcNAc-phosphate mutase (Agm1) from S. cerevisiae; and GlcNAc kinase (GlcNAcK) from C. albicans.

Other examples of multi-enzyme systems with sugar nucleotide regeneration for large-scale economic synthesis of many oligosaccharides have also reported (76, 178). Trisaccharide Galα1,3Galβ1,4GlcNAcβO(CH2)8CO2Me was enzymatically synthesized by combining four enzymes (sucrose synthase, UDP-Glc 4-epimerase, β1,4-GalT, and α1,3-GalT) in one pot using acceptor GlcNAcβ1-O(CH2)8CO2Me with in situ UDP-Gal regeneration (Fig. 4). This is an efficient and convenient method for the synthesis of Galα1,3Galβ1,4GlcNAc epitope, which plays an important role in various biologic and immunologic processes.

Solid-phase enzymatic synthesis

Solid-phase synthesis of oligosaccharides is a practical and convenient method as it simplifies the product purification and makes combinatorial process feasible (179). Combining the highly efficient enzyme-catalyzed glycosylation with solid-phase techniques offers a particularly convenient approach for the synthesis of oligosaccharides and glycoconjugates.
solid-phase enzymatic synthesis has been applied for sLe\(^\alpha\) tetrasaccharide (180) and a biomedically important tetrasaccharide Neu5Ac\(\alpha_2,3\)Gal\(\beta_1,4\)GlcNAc\(\beta_1,3\)Gal (an inhibitor of the attachment of H. pylori to mucous cells) (181). Other polymer supported syntheses of oligosaccharides have also been reported. Nishimura et al. reported a new approach for highly efficient chemoenzymatic synthesis of glycopeptide using a combination of solid-phase and water-soluble supports (Fig. 5) (182). This approach was efficient and versatile for the synthesis of a glycopeptide library.

**Immobilized enzymes in the synthesis—superbeads**

The use of immobilized enzymes in bioprocesses offers greater productivity because the same enzyme molecules can be used multiple times over a long period of time. Wang et al. reported a novel approach that transfers in vitro multiple enzyme sugar nucleotide regeneration systems onto solid beads (the superbeads) that can be used and reused as common synthetic reagents for production of glycoconjugates. First the multiple
enzymes involved in the biosynthetic pathway for the regeneration of UDP-Gal were expressed as N-terminal His-tagged enzymes; these enzymes were then co-immobilized on Ni-NTA beads by taking the advantage of the affinity of the histidine tag and nickel-nitrilotriacetic acid (NTA) resin. The sugar nucleotide regeneration superbeads can then be conveniently combined with glycosyltransferases for the synthesis of specific oligosaccharides. Using the UDP-Gal regeneration beads (containing galactokinase, galactose-1-phosphate uridylyltransferase, glucose-1-phosphate uridylyltransferase, and pyruvate kinase), which are required for the regeneration of UDP-Gal from UTP, with a truncated bovine α1,3-galactosyltransferase, the triasaccharide Galα1,3LacOBn was synthesized in 72% yield in gram-scale (183). Thse beads were reused three times during a three-week period and still retained 90% enzyme activity. Also the nickel beads can be recharged for more use after removing the deactivated enzymes. The superbeads can also be used in combination with multiple immobilized glycosyltransferases to generate target oligosaccharides. For example, using 2 equiv of galactose as the starting sugar and GlcNAc(1→3)Galα1→3Galβ1→4GlcNAc as the glycosyl acceptor, a combination of α1,3GalT and β1,4GalT immobilized on the UDP-Gal superbeads was used to produce a pentasaccharide with an overall yield of 76% (183). Combined with galactosyltransferase, the superbeads become a very useful reagent to synthesize a variety of oligosaccharides and their derivatives.

Another approach by Chen et al. (186) used a single product-producing E. coli strain (superbug) containing all the genes required for the synthesis of complex oligosaccharides, including fucosylated oligosaccharides, sialylated oligosaccharides, and lipooligosaccharides. Another approach by Chen et al. (186) used a single product-producing E. coli strain (superbug) containing all the genes required for the synthesis of complex oligosaccharides, including fucosylated oligosaccharides, sialylated oligosaccharides, and lipooligosaccharides. This superbug technology has been used in the synthesis of αGal epitope, P1 trisaccharide antigen, globotriose, and their derivatives. The superbug technology is cost effective because only catalytic amounts of the high energy phosphates are required. The use of a single bacterial strain instead of multiple strains avoids transport of reaction intermediates among strains and prevents the complication of maintaining the growth of different strains.

**Conclusion And Perspective**

Significant progress has been made over the past two decades for the application of enzymes in the synthesis of complex carbohydrate-containing biomolecules. Challenges are still exist. Taking advantage of the increasingly available genomic data, advancement in enzymatic synthesis of biomolecules relies on the identification and characterization of enzymes with better stability and novel or more flexible substrate specificity, a better understanding of the enzyme mechanism, genetic manipulation for tailor-made enzymes, and new methodology development.

The biologic significance of glycans (i.e., carbohydrates and saccharides) and the need to obtain structurally defined material for study have resulted in a proliferation of strategies for the synthesis of this extraordinary class of biomolecules. Each strategy carries with it both advantages and disadvantages. The two major approaches, chemical and enzymatic synthesis, will be discussed with an emphasis on the former.

Linear synthesis

The glycosylation reaction is fundamental to glycan synthesis (see the article "Key Reactions in Glycan Synthesis"). The iterative addition of monosaccharide units in a synthetic sequence constitutes a linear glycosylation strategy. With respect to overall synthetic efficiency, this strategy is not optimal, particularly for large targets (5). The classic Koenigs-Knorr reaction, which was discovered in 1901, signaled the advent of chemical oligosaccharide synthesis (6). The preparation and use of glycosyl bromides and chlorides as glycosyl donors in combination with appropriately protected glycosyl acceptors and heavy metal activators/promoters (typically silver or mercury salts) remains to date a formidable methodology for glycan construction despite toxicity and high cost. Because of the general instability of these intermediates, coupled with the harsh conditions necessary for their preparation, glycosyl bromides have been limited largely to a linear strategy, as opposed to a more efficient convergent (block) approach.

Convergent synthesis

The development of novel glycosylation methodologies in the 1970s and 1980s featuring more stable glycosyl donors such as orthoesters (7), fluorides (8), trichloroacetimidates (9), thio-glycosides (10), N-pentenyl glycosides (NPGs) (11), glycals (12), and sulfoxides (13), among others, enabled access to larger oligosaccharides by virtue of a convergent approach. Mild preparation methods of these donors coupled with chemical stability (for purification and storage) greatly increased the overall efficiency of glycan synthesis. Routine conversion of oligosaccharide intermediates (blocks) into glycosyl donors and subsequent coupling with various acceptors has enabled chemists to access more complex structures in an efficient manner; for example, Schmidt et al. (14) have efficiently applied the block synthesis strategy in the preparation of various glycans.

Chemical Synthesis of Glycans

Glycans encountered in nature in the form of glycoconjugates (glycoproteins and glycolipids) mediate a remarkable variety of biologic events, including inflammation, fertilization, cell growth and development, tumor growth and metastasis, host-pathogen interactions, and the storage and transfer of information (see the article "Glycans in Information Storage and Transfer") (2, 3). To study the structure and function of these biomolecules, they must be obtained in pure form. As isolation from natural sources often yields impure material by virtue of microheterogeneity (4), recourse is made to either chemical or enzymatic synthesis (or a combination of the two referred to as chemoenzymatic synthesis).
Selective, two-stage and latent-active strategies

The necessity to recruit and use protecting groups on both the glycosyl donor and acceptor is synthetically cumbersome (see the article “Glycan Synthesis, Protection and Deprotection”). A distinct advantage of manipulations of oligosaccharide intermediates before coupling lowers overall yield. In an ideal synthesis, the number of protecting group operations should be held to a minimum. Toward this goal, various strategies have been introduced that take advantage of selective activating conditions. A generalized example of this method is the selective activation of a glycosyl donor (halide, trichloroacetimidate) in the presence of an acceptor bearing a leaving group (thioglycoside or NPG). After the coupling event, the disaccharide is reacted with another acceptor in the presence of a suitable activator. This strategy cuts down the number of protecting group operations in the synthesis. Thioglycosides and N-pentenyl glycosides are unique donors in that they are stable to traditional protecting group manipulation and can be activated selectively in the glycosylation event under appropriate conditions. A recent example of this strategy was Barchi’s preparation of a tumor-associated T antigen building block (15).

In 1984, the Nicolaou group introduced a two-stage glycosylation strategy (16), which is also represented in Fig. 1. In this approach, thioglycoside intermediates are converted into glycosyl fluorides with N-bromosuccinimide (NBS) and (diethylamino)sulfox trifluoride (DAST) and are coupled subsequently (Stage 2) with a thioglycosyl acceptor. This process can be repeated, offering quick access to large structures. The Nicolaou group (17) has leveraged this methodology to prepare a host of complex glycans. A more powerful two-stage glycosylation approach is K. Ahn’s glycosyl sulfoxide methodology wherein a phenyl thioglycosides is used as a stable anomer protecting group, which is oxidized to the anomic sulfone with m-chloroperbenzoic acid (MCPBA). Subsequent triflation activates the anomic center for glycosylation. The K. Ahn group (18) has demonstrated the utility of this method in the synthesis of several blood group antigens.

Roy (19) introduced a latent-active glycosylation strategy in 1992 to describe the use of a stable (latent) anonic group that can be converted into a reactive (active) anonic group. In this context, a 4-nitrophenyl thioglycoside bearing a free hydroxyl (acceptor) can be coupled selectively with a 4-N-arylphenyl thioglycoside donor. The nitro group can then be reduced and acetylated, and this procedure can be repeated. By modulating the electronics of the thioarane, selective glycosylation can be accomplished. A further example of this strategy is the use of O-allyl glycosides (latent) by Boons (20), which are converted into O-vinyl glycosides (active) and activated subsequently with trimethylsilyl triflate (TMSCl) in the presence of a suitable acceptor (Fig. 1).

Orthogonal strategy

An orthogonal glycosylation strategy was outlined in 1994 by O’Gara (21) that featured the use of two glycosyl donors (phenyl thioglycosides and fluorides) meeting the following two criteria: (1) Either anomic group should be activated selectively in the presence of the other; and (2) both anomic groups should remain compatible with subsequent protecting group manipulation (Fig. 1). This strategy was utilized in the highly efficient synthesis of an extended blood group B determinant (22).

In 1997, Boons (23) reported a highly convergent and efficient synthesis of Group B Type III Streptococcus hexacarhide using three unique donor sets (ethyl thioglycosides, cyanoethylidene, and NPGs) that required no protecting group steps beyond those used in building-block synthesis.

Chemoslective glycosylation

Fraser-Reid (24) introduced a chemoselective strategy (armed–disarmed glycosylation) in 1988 after making the observation that NBS-promoted hydrolysis of NPGs bearing electron-donating protecting groups (alkyl ethers such as benzyl) on the C-2 hydroxyl proceeded much faster relative to those bearing electron-withdrawing protecting groups (esters such as acetyl). This strategy led to the experiment in which two monosaccharides bearing identical leaving groups (4-pentenylxoy) are coupled wherein a “disarmed” monosaccharide bearing a free hydroxyl bears an ester on the C-2 position and an “armed” donor possesses an alkyl ether substituent on the C-2 position. In the event, no self-coupled product was formed (Fig. 2). This strategy differs from the orthogonal strategy in that the same anomic group is used. Chemoslectivity is achieved by modulating the electronics of the incipient oxocarbenium ion. By proximity, the C-2 ester of the coupled product into an alkyl (benzyl) ether. More specifically, the less-reactive promoter iodonium dicollidine perchlorate (IDCP) can be used in the first coupling, whereas the more powerful N-isodosuccinimide (NIS)/triflic acid (TfOH) or NIS/trithylsilyl triflate (TESOTf) combination is sufficient to glycosylate disarmed donors (25).

In addition to changing the electronics of the C-2 protecting group, Fraser-Reid et al. have introduced the use of cyclic acetal protecting groups (1,3-dioxanes and 1,3-dioxolanes) to “disarm” glycosides. This process works by placing torsional strain on the pyranose scaffold, as the oxocarbenium ion is best stabilized by a d/hedral angle of 0° (C6D6–C5H5). Conformational restraints placed by cyclic protecting groups on the saccharide preclude achieving the desired angle (26). Ley et al. have expanded on this torsional control element with the introduction of dipropionate (27) and cyclohexane-1,2-dicarboxylic acids (28). By using different promoters in the sequencing of these glycosylations (mild promoters for early coupling, stronger promoters for later coupling), the number of synthetic operations performed on advanced intermediates is reduced (Fig. 2). Friese and Danielczyk (29)

has applied the chemoselective strategy to glycals for the preparation of 2-deoxyglycosides.

Chemoselective glycosylations can also be realized by changing the steric environment about the anomeric center (aglycon). Boons and colleagues (30) have shown that ethyl thiglycoside donors can be activated selectively in the presence of sterically encumbered dicyclohexylmethyl thiglycoside acceptors with IDCP. This methodology has been exploited in the synthesis of various glycan targets. The resulting coupled product can be activated again with the more powerful NIS/TfOH system in the presence of a suitable acceptor (Fig. 2).

One-pot glycosylation

The assembly of complex glycans via either a linear or a block approach is often subject to tedious purification (chromatography) steps that lower the overall chemical yield. It would be desirable to use an approach that strives to lower the number of purifications, particularly as the synthesis advances. Toward this end, many groups have developed and refined one-pot...
Key Strategies for Glycan Synthesis

Chemoselective Glycosylation

One-pot glycosylations (OPGs) fall into three different categories. Each category is based on the particular strategy being employed, which includes reactivity-based (chemoselective), selective (including orthogonal donor sets), and iterative one-pot glycosylations. Historically, Kahne and coworkers in 1989 disclosed the first OPG strategy for the synthesis of a cyclamycin trisaccharide, which was based on 1) the relative reaction rates (chemoselectivity) of electronically distinct phenyl-sulfoxides and 2) the use of a TMS ether as a latent acceptor in the second glycosylation. The desired trisaccharide was isolated in 25% overall yield. In 1994, Ley and coworkers demonstrated that various glycosyl donors could be sequenced in a one-pot strategy; namely, glycosyl bromides, fluorides, or trichloroacetimidates were first coupled with a thioglycosyl acceptor. The addition of a second, reducing end acceptor and a thiophilic promoter (NIS) resulted in trisaccharide formation. Yields as high as 84% for the overall process were realized, showcasing the efficiency of this strategy as well as the promoter compatibility, which can be a problem. The method has been extended to branched structures as well. Takahashi has advanced the orthogonal OPG strategy in an impressive synthesis of the heptasaccharide phytoalexin elicitor (HPE) in 24% overall yield.

Ley and coworkers were the first to quantify the reactivity of various ethyl thioglycosides. In 1999, Wong and coworkers disclosed a programmable one-pot glycosylation strategy in which a database of relative reactivity values (RRVs) was established for numerous monosaccharides and disaccharides bearing the p-methylthiophenyl (STol) anomeric group. With this information in hand, they could optimize a one-pot synthetic sequence in which a series of donors bearing free hydroxyls (with the exception of the first unit, which is fully protected) would be sequentially reacted in the order of decreasing RRV terminating with a “reducing end” cap. Disaccharides (or larger oligosaccharides) can be sequenced to offer access to branched oligosaccharides. A software program, OptiMer, was developed to select the appropriate building blocks from the database to perform an optimal one-pot oligosaccharide synthesis. Coupling of STol glycosides can be affected with a variety of thiophilic reagents. This software program has enabled the synthesis of a variety of important glycans, including poly-N-acetylactosamines, Fucose...
Key Strategies for Glycan Synthesis

**Selective (including Orthogonal) One-Pot Glycosylation**

- X = Br, OC(NH)CCl₃, F
- X = SR, OH

**Reactivity-Based (Chemoselective) One-Pot Glycosylation**

GM₁ (small-cell lung cancer epitope) (39), the Lewis Y hexasaccharide (colon cancer epitope) (40), and Globo H (breast cancer epitope) (41) in addition to combinatorial carbohydrate libraries (42). As of 2005, 600 thioglycoside building blocks have been entered into the database with RRVs ranging from 1 to >10⁶ (43). Wong and colleagues have introduced a novel activator, N-(phenylthio)caprolactam/Tf₂O, for programmable one-pot synthesis (44).

Yu and co-workers synthesized several saponins in a one-pot fashion using monosaccharide and disaccharide trichloroacetimidates and thioethyl glycosides (45). In 2000, Mukaiyama and colleagues established that glycosyl fluorides or phenylcarbonates could be used in concert with thioglycosides for the synthesis of several trisaccharides (46). This methodology was used in the synthesis of HPE using fluorides and thioethyl glycosides (47).

**Iterative One-Pot Glycosylation**

The iterative OPG strategy combines favorable elements of both chemoselective and orthogonal approaches in that it uses similar activating conditions for each coupling step yet does not rely heavily on differentiating building blocks with protecting groups to modulate and optimize reactivity (armed–disarmed concept), respectively. Danishefsky et al.'s glycal assembly method (48), Gin’s chemoselective dehydrative glycosylation (49), and Yamago et al.’s bromine-activated selenoglycosides (50) all reflect the utility of the iterative glycosylation strategy in glycan synthesis.

Crich and colleagues have demonstrated elegantly that the stereoselective synthesis of β-mannosides with glycosyl sulfoxides proceeds via anomeric α-triflate intermediates (51). Crich and Sun (52) observed that premixing the mannosyl sulfoxide with the promotor system (triflic anhydride and a hindered pyridine base) before the addition of the acceptor, as opposed to direct triflation of both donor and acceptor, led to higher β:α ratios. The authors theorized that the increased selectivity originated from an S₄N₂ displacement reaction of the acceptor and that the α-triflate derived from the sulfoxide. Crich et al. (53) also showed that when thioglycosides and aromatic bromides were subject to triflation, the same α-triflate intermediate was observed via low-temperature NMR studies. In summary, Crich and colleagues had demonstrated the viability of the donor pre-activation concept. These findings account for the feasibility of the iterative OPG strategy, which is generalized in Fig. 3.

Yu and co-workers synthesized several saponins in a one-pot fashion using monosaccharide and disaccharide trichloroacetimidates and thioethyl glycosides (45). In 2000, Mukaiyama and colleagues established that glycosyl fluorides or phenylcarbonates could be used in concert with thioglycosides for the synthesis of several trisaccharides (46). This methodology was used in the synthesis of HPE using fluorides and thioethyl glycosides (47).

**Reactivity-Based (Chemoselective) One-Pot Glycosylation**

GM₁ (small-cell lung cancer epitope) (39), the Lewis Y hexasaccharide (colon cancer epitope) (40), and Globo H (breast cancer epitope) (41) in addition to combinatorial carbohydrate libraries (42). As of 2005, 600 thioglycoside building blocks have been entered into the database with RRVs ranging from 1 to >10⁶ (43). Wong and colleagues have introduced a novel activator, N-(phenylthio)caprolactam/Tf₂O, for programmable one-pot synthesis (44).

Yu and co-workers synthesized several saponins in a one-pot fashion using monosaccharide and disaccharide trichloroacetimidates and thioethyl glycosides (45). In 2000, Mukaiyama and colleagues established that glycosyl fluorides or phenylcarbonates could be used in concert with thioglycosides for the synthesis of several trisaccharides (46). This methodology was used in the synthesis of HPE using fluorides and thioethyl glycosides (47).

**Iterative One-Pot Glycosylation**

The iterative OPG strategy combines favorable elements of both chemoselective and orthogonal approaches in that it uses similar activating conditions for each coupling step yet does not rely heavily on differentiating building blocks with protecting groups to modulate and optimize reactivity (armed–disarmed concept), respectively. Danishefsky et al.'s glycal assembly method (48), Gin’s chemoselective dehydrative glycosylation (49), and Yamago et al.’s bromine-activated selenoglycosides (50) all reflect the utility of the iterative glycosylation strategy in glycan synthesis.

Crich and colleagues have demonstrated elegantly that the stereoselective synthesis of β-mannosides with glycosyl sulfoxides proceeds via anomeric α-triflate intermediates (51). Crich and Sun (52) observed that premixing the mannosyl sulfoxide with the promotor system (triflic anhydride and a hindered pyridine base) before the addition of the acceptor, as opposed to direct triflation of both donor and acceptor, led to higher β:α ratios. The authors theorized that the increased selectivity originated from an S₄N₂ displacement reaction of the acceptor and that the α-triflate derived from the sulfoxide. Crich et al. (53) also showed that when thioglycosides and aromatic bromides were subject to triflation, the same α-triflate intermediate was observed via low-temperature NMR studies. In summary, Crich and colleagues had demonstrated the viability of the donor pre-activation concept. These findings account for the feasibility of the iterative OPG strategy, which is generalized in Fig. 3.

In iterative OPG, the glycosylating species (donor) is treated with the promoter system in the absence of the acceptor. A priori, the activated species must be sufficiently stable so as not to decompose before glycosylation and yet reactive enough to undergo reaction with the acceptor. In the event, a glycosyl donor is first activated with the promotor, followed by the addition of an acceptor bearing a stable anomeric group (alkylthio moiety). The glycosylation occurs irrespective of the protecting group ensemble of the acceptor. This process removes the burden of electronically tuning each glycoside via protecting group manipulation; moreover, protecting groups can be selected so as to streamline deprotection steps (endgame). The process can be repeated (iterated) and terminated with a final “cap” acceptor (Fig. 3).

In 2003, the van Boom/van der Marel group cleverly used 1-hydroxy and thioglycosides in a sequential OPG strategy in
which the powerful Ph₃SOTf₂O/TTBP (2,4,6-tri-tert-
butylpyrimidine) (54) promoter system was leveraged to syn-
thesize an α-Gal epitope trisaccharide in 80% yield (stepwise
synthesis was accomplished in 69% overall yield) (55). Initial
activation of the 1-hydroxy donor with the above promoter sys-
tem followed by reaction with a thioglycoside acceptor yielded
a disaccharide intermediate. As a by-product of the reaction is
Ph₂O, more Tf₂O was introduced to activate the thioglycoside
in the presence of an acceptor to furnish the target trisaccharides
(56, 57).

In 2004, Huang et al. outlined a general, iterative OPG stra-
tegy based on “pre-activation” of the glycosyl donor for the syn-
thesis of several trisaccharides and tetrasaccharides using 2,701
glycosides and a P-TolSO/AgOTf/TMS-AW300 (in situ prepara-
tion of p-TolSOII) promoter system. This approach obviates the
need to tune electronically or torsionally each donor, which is
critical in reactivity-based OPG (58). This strategy was applied
in a four-component, one-pot synthesis of α-Gal Pentasaccha-
ride, which is a glycan epitope responsible for the shortcomings
of p-Gal to human xenotransplantation. Yields for the one-pot se-
quence ranged from 39% to 41% (59). Recently, Huang et al.
(60) introduced a novel α-thiophenylamine, benzene sulfimyl
morpholine (BSM), for iterative OPG processes. The novel reagent
was used in the synthesis of several trisaccharides.

Solid-phase synthesis

The advent of automated oligopeptide and oligonucleotide syn-
thesizers revolutionized the fields of protein and nucleic acid
chemistry, respectively. These technologies have greatly en-
abled the study and understanding of structure and function by
making routine access to these structures straightforward.

At the heart of these methodologies lies a solid-phase strat-
egy (61) for which Merrifield was awarded the 1984 Nobel
Prize in Chemistry. Solid-phase methodologies possess sev-
eral advantages: purification is made easy (filtration as op-
posed to chromatography), excess reagents can be employed
to drive reactions to completion via mass action as purifica-
tion is rendered trivial, and the process lends itself well to
automation. Critical to a successful solid-phase oligosaccha-
ride synthesis are the proper selection of the following items:
1) polymer support such as insoluble polyurethane or solu-
ble polyethylene glycol (PEG), 2) orthogonal protecting groups
sets, 3) linker (which can be regarded as a resin-bound pro-
tecting group), and finally 4) building blocks. In addition,
it is desirable to have “on-resin” analytical techniques avail-
able so as to monitor the progress of the synthesis. Toward
that goal, various techniques, including high-resolution magic
angle-spinning NMR (62), gated-decoupling 13C NMR spec-
troscopy using 13C-enriched protecting groups (63), fluorinated
protecting groups and 19F NMR spectroscopy (64), FT-IR (65),
MALDI-TOF MS (66), and colimetric assays have been de-
vloped (67).

Solid-phase strategies for glycan synthesis can be broken
down into three types: donor bound, acceptor bound, and bidi-
rectional (Fig. 4). In the donor bound mode, an excess acceptor
is used to drive the reaction to completion (or to maximize
yields). As the donor in a typical glycosylation reaction is the
“reactive intermediate,” unproductive side reactions correspond
to a direct loss in overall yield as the material is bound to the
solid support. The acceptor bound approach, which is the most
popular of the three, uses an excess of donor in solution. This
parallels Merrifield’s strategy for peptide synthesis in which
the reactive species is in solution (and in excess); hence, any
undesired side reactions along with unreacted donor are sim-
ply washed away. The bidirectional strategy represents a hybrid
of the two approaches and is well suited for the synthesis of
branched glycans (68).

With the success of solid-phase methods for peptide synthe-
sis, early studies of solid-phase oligosaccharide syntheses were
launched in the 1970s with the pioneering work of F Rechert
and Schurig (69) who prepared several disaccharides and triac-
tehrides using Merrifield’s resin and glycosyl bromides. Van
Boom and colleagues (70) reported on the solid-phase synthesis
of a heptaglycosylfuranoside in 1987 using Merrifield’s resin and
glycosyl chlorides in an impressive 23% overall yield. Both ap-
proaches used an acceptor bound strategy. The field underwent
a renaissance in the 1990s as powerful new glycosylation meth-
ods and protecting group strategies for oligosaccharide synthesis
emerged (71).

Danzhafsky and coworkers (72) have used the glycal as-
sembly method in a donor bound approach for the solid-phase
synthesis of various glycans, including among others the Lewis
B hexasaccharide, a blood-group determinant that has been iden-
tified as a mediator in the binding of pathogen Helicobacter
pylori to human gastric epithelium and is implicated in the
onset of peptic ulcers (73). A attachment of a glycal monosac-
charide to a polyethylene resin via a silyl linker was followed by
epoxidation with dimethyldioxirane (DMDO) and reaction with
a glycal acceptor in the presence of ZnCl₂. Protection (ester-
ification) of the newly formed C2 hydroxyl (or coupling with
another glycosyl donor, which is a unique advantage of the gly-
cal assembly method) and subsequent iteration of this process
leads to a resin-bound, fully protected glycan. Cleavage or re-
moval of the material from the resin and final protecting group
removal steps furnishes the desired oligosaccharide. To address
the issue of slower reaction rates on the solid-support as com-
pared with solution-phase, Krepinski et al. (74) used soluble
polyethylene glycol (PEG) polymer in an acceptor-bound ap-
proach with glycosyl bromides. The PEG strategy was used by
van Boom et al. (75) to prepare the heptasaccharide phytoalexin
elicitor (HPE).

As the solid-phase paradigm began to attract interest, a host
of research groups began transferring their respective glycosy-
lization technologies onto the solid-support, with each using
the acceptor-bound strategy. K. Ahmed et al. (76) prepared a triac-
tehride on Merrifield’s resin with glycosyl sulfonates and a
thiophenyl linker, and they demonstrated that sulfonides could
be used to install stereoselectively α-fucosidic linkages. The
power of this technology was demonstrated in the combinational
synthesis of a library of 1300 disaccharides and triacchorides
(77). Rademann and Schmidt have shown that trichloroacetim-
ides, which is one of the most powerful and popular donors
to date, have been effective in the solid-phase paradigm (78).
Schmidt et al. have introduced a variety of linker systems (79)
and have used different supports over the past decade (80).
Recently, they disclosed the synthesis of a library of N-glycans

(81). Nicolaou et al. (82) used phenolic polystyrene as a solid support to synthesize several oligosaccharides. Thioglycosides were employed as donors as well as a photolabile linker for the synthesis of HPE and a protected dodecasaccharide related to the phytoalexin elicitor family with a block strategy. Fraser-Reid et al. (83) translated the NPG method to the solid support (polystyrene) functionalized with a photolabile linker. A trisaccharide was prepared in which the chloroacetyl (ClAc) was used as the temporary protecting group between couplings. Seeberger et al. (84) have leveraged glycals for the rapid preparation and utility of glycosyl phosphates, which is a powerful class of glycosyl donors. A series of glycans has been prepared with this method (85). In 1999, Seeberger et al. (86) reported on the development and application of a 4(3)-1,8-octenediol linker, which was used in the preparation of several linear oligosaccharides. Cleavage from Merrifield’s resin with Grubbs et al.’s first-generation ruthenium catalyst (87) under an atmosphere of ethylene performed a cross metathesis reaction to yield an NPG, which can be used for additional glycosylation in solution or can be modified to access neoglycoconjugates (88).

The development of an automated oligosaccharide synthesizer would be highly beneficial to glycobiologists and would serve to drive glycomics, as the synthesis of glycans has been largely restricted to specialized groups. It would allow for routine assembly of desired targets and would accelerate the pace of discovery in glycoscience. Toward this end, Seeberger and coworkers (89) used their solid-phase methodology and disclosed the first automated oligosaccharide synthesizer in 2001. A modified ABI peptide synthesizer was used to prepare a protected heptasaccharide (HPE) and a protected dodecasaccharide using monosaccharide and disaccharide phosphate donors. The synthesis of the latter was accomplished in 16 hours after purification by high-performance liquid chromatography. The synthesizer has also been used to prepare glycans related to the branched Leishmania cap tetrasaccharide (90), a synthetic anti-toxin malaria vaccine (91), a core N-linked pentasaccharide that is common to all N-linked glycoproteins (92), the Lewis X pentasaccharide, the Lewis Y hexasaccharide, and the Le\(^\text{a}\)-Le\(^\text{b}\) nonasaccharide (93). Glycosyl phosphates and trichloroacetimidates have emerged as privileged donors in this regime.
Key Strategies for Glycan Synthesis

Enzymatic Synthesis

Nature has evolved carbohydrate-processing enzymes for the efficient assembly of glycans. Glycosyltransferases and glycosidases perform highly regioselective and stereoselective glycosylations, which thus obviates the need for tedious protecting group manipulation and controls the stereospecific installation of glycosidic linkages (two key issues in chemical glycan synthesis) (94). Moreover, the reactions are carried out under mild and green (nontoxic, environmentally friendly) conditions. As such, a growing trend has occurred in the synthetic carbohydrate community to leverage these enzymes in order to streamline glycan synthesis (95). These reactions are particularly useful for difficult chemical glycosylations (e.g., installation of sialic acid residues).

Glycosyltransferases

The biosynthesis of oligosaccharides is mediated by glycosyltransferases, which transfer either monosaccharide nucleotide monophosphates (e.g., CMP-Neu5Ac) or monosaccharide nucleotide diphosphates (e.g., Glc-UDP) to acceptors with either retention or inversion at the donor’s anomeric center (Fig. 5). These enzymes have evolved to be highly regiospecific and stereospecific. The high cost and availability of both enzyme and substrate are major drawbacks of the enzymatic approach. In addition, nucleotide diphosphate generated during the enzymatic glycosylation inhibits the enzyme. The issue of substrate cost has been addressed with elegant nucleotide donor recycling strategies introduced by Wong et al. (96), which have been translated to other glycosyltransferase systems (97). Feedback inhibition has been tackled by including a phosphatase (98). Wong et al.’s (99) synthesis of sialyl Lewis X, which is a glycan involved in the inflammation cascade, is a testament to the power of this strategy. The enzymatic glycosylation of sialic acid has found widespread use in glycan synthesis, as the chemical installation of this monosaccharide is difficult. Many glycans have been prepared enzymatically, including one-pot and solid-phase enzymatic approaches (100).

Glycosidases

During glycoprotein synthesis, glycosidases are involved in processing the glycans via hydrolysis of glycosidic linkages. These enzymes have been used for in vitro glycan synthesis under the appropriate conditions and make use of readily available, inexpensive donors such as nitrophenyl glycosides (Fig. 5). In addition, glycosidases are more stable than glycosyltransferases and more compatible with organic solvents. Although highly stereospecific, glycosidase are not regiospecific and hence result in a lower yield of desired oligosaccharide. Nevertheless, these highly useful biocatalysts have been employed in the synthesis of various glycans (101). Finally, a considerable amount of effort has gone into the engineering of novel glycosyltransferases and glycosidases that feature desirable characteristics (e.g., thermostability) as well as in preparing novel structures (e.g., thioglycosides). These strategies will certainly strengthen the ability to prepare more efficiently complex structures enzymatically (102).

Other strategies

To address issues of large-scale oligosaccharide synthesis, Koizumi et al. (103) at Kyowa Hakko (Kogyo Co. Ltd.) disclosed the utility of multiple metabolically engineered microorganisms containing all of the necessary genes for nucleotide generation and glycan synthesis; moreover, inexpensive orotic acid was used as a UTP precursor. The strategy resulted in a highly efficient synthesis of the globotriose epitope. Wang and coworkers (104) have also addressed the sugar nucleotide issue with the development of “superbeads,” in which enzymes involved in the glyconjugate biosynthetic pathway are expressed in recombinant Escherichia coli strains, isolated, and immobilized on an agarose resin. Additional glycosyltransferases could be used in solution as well. In 2002, Wang et al. (105)

![Figure 5](image-url)  
Glycosyltransferases and glycosidases in enzymatic glycan synthesis.
engineered an E. coli strain, which they termed "superbug," containing all of the biosynthetic genes necessary for the synthesis of α-Gal epitopes. This process obviates issues associated with isolating the individual enzymes (as in the superhead approach). The "superbug" technology was used in the large-scale synthesis of globotriose trisaccharide Gb3 (106).

Finally, the hybrid chemical and enzymatic approach (chemoenzymatic strategy) has also been popular for the synthesis of many glycans (107). The chemical approach with its drawbacks still allows for greater flexibility in the synthetic scheme (e.g., carbohydrate-based drugs and unnatural glycans). Moreover, relatively straightforward components of the glycan can be assembled readily with chemical synthesis, which leaves the difficult glycosylations (sterically and/or stereochemically demanding) to be carried out enzymatically. A highly illustrative example of this strategy is Unverzagt's chemoenzymatic synthesis of dodecasaccharide (108). Recently, Chen and co-workers (109) reported on an efficient one-pot, three-enzyme delivery of the target dodecasaccharide (108). Recently, Chen and co-workers (109) reported on an efficient one-pot, three-enzyme chemoenzymatic synthesis of various sialic acid-containing trisaccharides.

Future Outlook

The biologic significance of glycans and their potential as therapeutic agents has energized the field of glycochemistry. The prognosis for the development and implementation of novel strategies for the synthesis of glycans is very good as no general solution has been uncovered. Discoveries made in the chemical and enzymatic/biologic arenas will continue to "raise the bar" as the need to procure glycans for study persists.

Synthetic Sphingolipids as Bioactive Molecules: Roles in Regulation of Cell Function

Robert Bittman, Queens College of The City University of New York, Flushing, New York
doi: 10.1002/9780470048672.wecb576

Sphingolipids are a highly diverse class of lipids, which encompasses thousands of different structural combinations of the polar head group, amino group or amide chain, and sphingoid long-chain base. Initially regarded as inert structural components of eukaryotic cell membranes and plasma lipoproteins, sphingolipids now are recognized as key participants in the life of virtually all cell types. They influence a myriad of biological processes, including cell growth, cell death, and susceptibility to inflammation and infections. The number of known sphingolipid-dependent cell signaling systems is increasing rapidly as research efforts in this field progress. Sphingolipids stabilize transient microdomains in membranes known as “rafts.” Signaling proteins and receptors partition into membrane rafts, and some toxins, pathogen, and viruses bind to sphingolipids that are concentrated in rafts and subsequently undergo endocytosis (see also Extracellular Lipid Signals and Lipid Rafts). Synthetic, non-natural analogs of sphingolipids hold promise as drug candidates for treatment of various disease states via their ability to perturb cell signaling, membrane trafficking, and binding of infectious agents. The repertoire of synthetic sphingolipids includes analogs that target enzymes in the sphingolipid biosynthetic pathway and those that act as antiproliferative agents, immunomodulators, and regulators of lipid raft formation (and resultant receptor function). This review is intended to bring attention to selected synthetic analogs of sphingosine, ceramide, and glycosphingolipids that may lead to therapeutic intervention in certain pathophysiologic conditions.

Chemical Structures of Sphingoid Long-Chain Bases and Their Glycosylated and Phosphorylated Derivatives

Sphingolipids contain a sphingoid base backbone, which often is referred to as the long-chain base. The long-chain base is an...
Sphingolipids with modifications at C-1 and C-2

Many examples of sphingolipids exist in which the C2-amino and/or terminal hydroxy group is modified. N,N-Dimethyl-D-erythro-sphingosine is a naturally occurring sphingolipid that, like D-erythro-sphingosine, inhibits the ubiquitous signal transducer protein kinase C (PKC) (11). At high concentrations (10µM), N,N-dimethylsphingosine also inhibits sphingosine kinases, the enzyme that is responsible for the formation of sphingosine 1-phosphate (S1P), but at low concentrations (<1 µM) it activates sphingosine kinase in the cytosol via a PKC-dependent mechanism (12).

The C-1 hydroxy group of sphingosine is replaced by a hydrogen in 1-deoxy-D-erythro-sphingosine (25,3R)-2-amino-3-decanol. Because no functional group is present at the terminal carbon, chemical/biochemical modification at that site is precluded. This naturally occurring sphingosine analog, which is called spisulosine or ES-285, was isolated from the clam Macromeris polyacantha and was found to induce an atypical form of apoptosis in murine leukemia cells (13). A cyclodextrin-based formulation of spisulosine is being used in Phase I clinical trials as an anticancer agent (14).

Sphingolipids with a sulfate group esterified to the C-1 position were isolated from marine invertebrates and shown to possess various bioactivities, such as the inhibition of neuraminidase and telomerase activity (15).}

Ceramides are N-acyl-D-erythro-sphingosines (compound 1, Fig. 2). Thus, ceramide is a 2-amido-1,3-diol. The fatty amide group in ceramide is structurally heterogeneous, differing in the length and extent of saturation and hydroxylation of the alkyl chain. In some species the fatty amide bears an α-hydroxy group. Typical fatty acids that are prevalent in the fatty amide group in ceramide is structurally heterogeneous, differing in the length and extent of saturation and hydroxylation of the aliphatic chain.

Sphingomyelin is a naturally occurring sphingolipid that, like D-erythro-sphingosine, inhibits the ubiquitous signal transducer protein kinase C (PKC) (11). At high concentrations (10µM), N,N-dimethylsphingosine also inhibits sphingosine kinases, the enzyme that is responsible for the formation of sphingosine 1-phosphate (S1P), but at low concentrations (<1 µM) it activates sphingosine kinase in the cytosol via a PKC-dependent mechanism (12).

The C-1 hydroxy group of sphingosine is replaced by a hydrogen in 1-deoxy-D-erythro-sphingosine (25,3R)-2-amino-3-decanol. Because no functional group is present at the terminal carbon, chemical/biochemical modification at that site is precluded. This naturally occurring sphingosine analog, which is called spisulosine or ES-285, was isolated from the clam Macromeris polyacantha and was found to induce an atypical form of apoptosis in murine leukemia cells (13). A cyclodextrin-based formulation of spisulosine is being used in Phase I clinical trials as an anticancer agent (14).

Sphingolipids with a sulfate group esterified to the C-1 position were isolated from marine invertebrates and shown to possess various bioactivities, such as the inhibition of neuraminidase and telomerase activity (15).
Synthetic Sphingolipids as Bioactive Molecules: Roles in Regulation of Cell Function

Figure 1 The structural feature common to all sphingolipids is a long-chain sphingoid base. Sphingoid bases are 2-amino-1,3-diols that bear an aliphatic chain. The chain length varies from about 14 to 24 carbon atoms, and the extent of unsaturation, hydroxylation, and methyl-branching in the chain also varies. 1, (2S,3S,4R)-sphingosine; 2, (2S,3R)-dihydrosphingosine; 3, (2S,3S,4S)-phytosphingosine; 4, 4E,6E-sphingadiene.

Figure 2 The structures of ceramide: 1, a schematic structure of ceramide that illustrates the sites at which structural modifications may be introduced by chemical synthesis, and the structure of a representative ceramide found in human skin (2). Structural changes in the ceramide molecule have been introduced at many sites. Alterations include the configuration at C-2 and C-3, the lengths of the fatty amide chain and of the aliphatic chain attached to C-5, the positions of the unsaturation and the secondary hydroxy group, the replacement of the hydroxyl groups with other atoms (hydrogen or fluorine) or functionalities (methoxy, methylthio, and keto), the incorporation of aromatic, heteroaromatic, and other rings in place of the alkenyl side chain of the sphingoid base, and the replacement of the carbonyl group of the carboxamide group. In addition, the 2-amino-1,3-diol functionalities have been incorporated into cyclic structures.

Other examples of sphingolipids with modifications at C-1 are glycosylated and the following phosphorylated derivatives.

Phosphorylated sphingolipids

Sphingomyelin (ceramide 1-phosphocholine, compound 1, Fig. 3) is a phospholipid in which the terminal hydroxyl group of ceramide is esterified to phosphocholine. Sphingomyelin and the glycerocephospholipid phosphatidylycholine have the same polar head group; together, the two choline-containing phospholipids account for >50% of the total phospholipid content of many mammalian membranes. Sphingomyelin is one of the most abundant phospholipids in the plasma membranes of mammalian cells and plasma lipoproteins, and its metabolism...
provides a source of sphingolipid second messengers. Sphingomyelin is a typical example of the stability of sphingomyelin in the formation of ceramide and phosphocholine (Fig. 3). Hydrolysis by sphingomyelinase catalyzes the phosphodiester bond, and the amine group transfers the phosphocholine to the lipid mediator lysophosphatidic acid. Autotaxin (ATX), an enzyme that catalyzes the hydrolysis of lysophosphatidic acid, is subject to product inhibition by two important lysophospholipid signaling molecules, lysophosphatidic acid and sphingosine-1-phosphate. Therefore, this enzyme is an attractive drug target that may be inhibited by synthetic lysosphingo- and/or glycosphingolipids.

In mammalian cells, the predominant long-chain base in sphingomyelin is D-erythro-C18-sphingosine. Dihydrosphingosine is a minor long-chain base of sphingomyelin of most mammalian membranes; for example, the dihydrosphingosine content of egg (chicken) and milk (bovine) sphingomyelin is 1% and 15-20%, respectively (23). An exception, however, is the adult human eye lens membrane, in which dihydro sphingosine comprises about 50% of the total phospholipid and about 80% of the total sphingomyelin content (24). The absence of unsaturation in the long-chain base results in modified physical properties. The double bond of sphingomyelin is essential in maintaining the transbilayer asymmetry of a glycosphingolipid in phospholipid vesicles (25) and in inhibiting protein-mediated glycosphingolipid transfer between membranes (26), as demonstrated by replacing sphingomyelin with dihydro sphingomyelin in bilayer membranes.

The C-3-hydroxy group and the C-4,C-5-double bond of sphingomyelin and other sphingolipids are localized in the lipid-water interfacial region. These groups play a role in organizing interfacial water via hydrogen bonding with the surrounding water molecules and neighboring lipids. Intramolecular hydrogen bonding (with the participation of strongly bound water molecules) between the C-3-hydroxy group of the long-chain base and the bridging oxygen of the phosphate results in restricted polar head group mobility (27). The trans-double bond of the sphingoid base plays a role in the extent of hydration of the interfacial region of sphingomyelin-containing bilayers. Dihydrosphingomyelin has been proposed to promote stronger intermolecular hydrogen bonds with neighboring dihydrosphingomyelin, cholesterol, and other lipid molecules than does sphingomyelin (28), whereas sphingomyelin may form more stable intermolecular hydrogen bonds (27). Dihydrosphingomyelin has a higher affinity for cholesterol than sphingomyelin and protects cholesterol and unsaturated phosphatidylcholines from oxidation better than sphingomyelin (29).

A heterogeneous mixture of fatty amide chains is found in natural sphingomyelins and other sphingolipids, varying with the source and age (30). The fatty acyl chain content of milk sphingomyelin, for example, is 33% C23:0, and 20% each of C16:0, C22:0, and C24:0. About 50% of the N-acyl chain composition of bovine brain sphingomyelin is C18:0, with about 20% C24:1 and 8% C22:0. Egg sphingomyelin is an exception, being relatively homogeneous with respect to N-acyl content—largely C16:0 (80–85%) and C18:0 (12%). An abundance of long, saturated amide chains exists in sphingomyelin compared with the fatty acyl chains of glycerophospholipids, which provides a marked disparity in the intramolecular chain lengths of the sphingoid chain and the N-acetyl chain. A long, saturated N-acetyl chain in sphingomyelin is conducive to tight packing between sphingomyelin and cholesterol, which may result in the formation of ordered microdomains in bilayer membranes. Synthetic sphingomyelin bearing a N-oleyl chain is not incorporated into cholesterol-rich domains (31), probably because of its high miscibility with phosphatidylcholine (32).

The lengths of both the long-chain base and fatty amide chain tend to be shorter in the sphingolipids isolated from invertebrate sources than from mammalian sources. For example, the major long-chain base of the sphingolipids of Drosophila (33), the moth Manduca sexta (6), and honey bees (34) is C14-D-erythro-sphingosine (the 14-carbon homolog of the long-chain base, with smaller amounts of the C15-C17 sphingoid bases), and the N-acetyl chains of their sphingolipids are also shorter (35). Incidentally, the fatty acyl chains of their glycosphingolipids are also shorter than those of glycosphospholipids in mammalian cell membranes; thus the temperature of the main gel to liquid-crystalline phase transition is lower in invertebrate membranes than in mammalian membranes.

Invertebrates also contain ceramide phosphoethanolamine, an analog of sphingomyelin in which the choline is replaced by ethanolamine, as the major sphingolipid of Drosophila and other invertebrates. Ceramide phosphoethanolamine seems to have an antioxidant function in Drosophila (33) similar to sphingomyelin in mammalian cells (36, 37). Little information is available regarding the other functions of ceramide phosphoethanolamine because most physical studies of sphingophospholipids have been focused on sphingomyelin. Sphingomyelin isolated from natural sources partitions efficiently into highly ordered lateral domains of lipid bilayers enriched in cholesterol and interacts preferentially with cholesterol (38), but ceramide phosphoethanolamine seems to form less tightly packed bilayers with cholesterol (39).

Sphingophospholipids are another type of sphingophospholipid in which the polar head group contains a carbon-phosphorus bond. Ceramide 2-aminoethylphosphonate is a typical example (compound 2, Fig. 3). In some species, the head group also bears an N-acryloxycarboxylic acid or an N-methyl group. Sphingophosphonolipids are minor constituents of mammalian cell membranes but are abundant in the bacterium Bacteriovorax stolpii, in which the long-chain fatty acids are mostly C17 iso-branched phytoceramide and dihydrosphingosine backbone and an inositol phosphate head group. Inositol phospholipids are formed in a reaction catalyzed by InsPcCer, compound 3, Fig. 3, which has a phytoceramide or dihydrosphingosine backbone and an inositol phosphate head group. InsPcCer is subject to product inhibition by two important lysophospholipid signaling molecules, lysophosphatidic acid and sphingosine-1-phosphate. Therefore, this enzyme is an attractive drug target that may be inhibited by synthetic lysosphingoi-and/or glycosphingolipids.
Synthetic Sphingolipids as Bioactive Molecules: Roles in Regulation of Cell Function

Figure 3: The structures of sphingomyelin (1), ceramide aminoethylphosphonate (2), and inositol phosphorylceramide (InsPCer) (3).

PCer synthase, which transfers inositol phosphate from phosphatidylinositol to the C-1 hydroxy group of dihydroceramide or phytoceramide and therefore liberates diacylglycerol (42). Glycosylated derivatives of InsPCer constitute the lipid moiety of most glycosylphosphatidylinositol-(GPI)-anchored membrane proteins of eukaryotic cell membranes (43, 44). As no mammalian analog of InsPCer synthase exists, this enzyme is a potential therapeutic target for the development of selective antifungal and antiprotozoal agents that interfere with sphingolipid biosynthesis in fungal and protozoan cells but not in mammalian cells (45, 46). Microbial natural products that inhibit InsPCer synthase include the cyclic peptide aureobasidin A, an amphipathic lipid known as khafrefungin, and a macrolide called galbonolide A or rustmicin (46, 47). The structures of the latter two compounds are shown in Fig. 4.

The phosphorylated metabolites of sphingomyelin are sphingosylphosphocholine (lyso-sphingomyelin, the N-deacylated derivative of sphingomyelin), sphingosine 1-phosphate, and ceramide 1-phosphate. These sphingolipid metabolites are signaling molecules that regulate diverse cellular functions (48–53).

Glycosylated sphingolipids

The terminal hydroxy group of sphingosine is linked to at least one carbohydrate moiety in glycosphingolipids. In mammalian cells, the sugar moiety is in a β-glycosidic link to the sphingoid base, as in β-glucosylceramide (Fig. 5). Cerebrosides are one subgroup of glycosphingolipids in which a galactose or glucose is linked to ceramide (compound 1, Fig. 5). Sulfatides are a subgroup of galactocerebrosides in which a sulfate group is esterified to the C-3 position of the sugar; the sulfatide group of 3′-phosphodiestersilane 5′-phosphosulfate is transferred to the galactocerebroside in a reaction catalyzed by a sulfotransferase. β-Galactosylceramide and its 3′-sulfate ester bind to the gp-120 envelope protein of HIV-1; this interaction allows HIV-1 to infect CD4-negative cells (54). Globosides have at least two saccharide units linked by the anomeric hydroxy group of one sugar to the terminal hydroxy group of the sphingoid base. Plants and fungi contain inositol-linked phosphophytoceramides (InsPCer) such as compound 3 (Fig. 3), a major glycosphosphatidylcholine of yeast, and mannosylated and dimannosylated derivatives. Gangliosides (compound 2, Fig. 5) are ubiquitous components of vertebrate cells and are abundant in nervous tissues. They are localized in the outer leaflet of plasma membranes and form clusters in lipid microdomains, where they participate in various recognition and cell signaling processes (55). The oligosaccharide head group of gangliosides contains at least one N-acetylneuraminic acid residue. This monosaccharide, which is a sialic acid and is abbreviated as NANA, NeuAc, or Neu5Ac, is recognized (together with uncharged saccharide units) by many carbohydrate-related proteins (56). Thus gangliosides are sialylated glycosphingolipids. The predominant N-acyl chain of the ceramide backbone in gangliosides is stearoyl (C18:0). Figure 5 shows the structures of the gangliosides GM1 and GM3. In ganglioside nomenclature, the subscript letter “M” refers to “mono,” which is the number of NANA residues in GM1. The difference between 5 and the number after the “M” indicates the number of uncharged sugar residues present in the ganglioside: four in Ga2, and two in Ga3. Ga4 is the principal...

2: Gangliosides

an oligosaccharide head group with one or more sialic acid residues

Gangliosides affect a multitude of cellular processes, including binding specifically to viruses and many bacterial toxins. A well-known example is the binding of cholera toxin, the enterotoxin produced by *Vibrio cholerae*, to GM1 on the surface of human intestinal epithelial cells (57). The development of artificial receptors for the toxin may form the basis for the design of a potential anticholera drug (58). Another example of a specific interaction between a protein and a ganglioside is the binding of GM1 to α-synuclein, a presynaptic protein with a propensity to form fibrils and aggregates that have been implicated in Parkinson's disease and other neurodegenerative diseases (59). Ganglioside GM3 binds to insulin receptors; in fact, the accumulation of GM3 in membrane microdomains (rafts) of adipocytes results in the development of insulin resistance, apparently because of the dissociation of the insulin receptor from its complex.
with caveolin-1 in rafts (68). Because \( G_{\alpha 3} \) is a negative regulator of insulin signaling, the inhibition of \( G_{\alpha 3} \) biosynthesis may offer a novel therapeutic approach for insulin-resistant type 2 diabetes.

**Role of Chemical Structure in the Biological Activity or Biophysical Behavior of Ceramide**

The presence of two chiral carbon atoms in sphingosine results in the possible formation of four stereoisomers (Fig. 6). Only the D-erythro stereoisomer occurs naturally, and this stereoisomer is the only form that is used efficiently as the substrate for sphingolipid-using enzymes such as ceramidase (63, 62) and protein phosphatases (63). The "D" nomenclature is based on the Fischer projection and its relationship to the Fischer projection of D-glyceraldehyde (Fig. 6). Many studies have been carried out to assess how the various bioactivities of the unnatural stereoisomers of ceramides differ from that of D-erythro-ceramide. Short-chain ceramides (having a C2 to C8 \(-\)acyl chain) were used in many of these studies because they are water soluble and cell permeable. In general, the D-erythro form was found to be the most effective with regard to bioactivity. For example, only the D-erythro isomer of C8-acyl-ceramide was capable of promoting the fusion of an alpha virus with target liposomes; the other three isomers were inactive (64). However, in some studies the D-threo isomer had equal or higher activity than the D-erythro isomer (65), and in still other studies both the D-threo and D-threo isomers had higher activity than did the D-erythro or D-erythro isomer (66). In other studies, a lack of stereospecificity was found, as all four stereoisomers exhibited approximately equal activity (67-69).

Short-chain analogs of D-erythro-ceramide trigger apoptosis, thereby mimicking the activity of endogenous ceramide. However, biophysical studies indicate that short-chain ceramides perturb the physical properties of model membrane bilayers differently than their long-chain counterparts. For example, they did not form the ceramide-rich domains that are observed characteristically with C16:0- and C18:0-ceramide (70). A study of the ability of ceramide analogs to displace sterols from rafts indicated that C12:0- and C16:0-ceramides are faithful mimics of natural ceramides in model bilayers (71). The presence of the trans-double bond between C-4 and C-5 contributes to the close packing of D-erythro-ceramide molecules at the lipid-water interface (72). The unsaturation is required for most bioactivities of ceramide that have been studied, as dihydroceramide generally exhibits much lower activity than the natural ceramide. How- ever, biophysical studies indicate that short-chain ceramides can mimic the activity of endogenous ceramide. In the anabolic pathway of ceramide biosynthesis, N-acylation of a sphingoid long-chain base takes place in the endoplasmic reticulum and Golgi apparatus. In the catabolic pathway of ceramide biosynthesis, degradation of sphingomyelin and glycosphingolipids takes place at the plasma membrane and lysosomes, respectively. The enzymes in both the anabolic and catabolic pathways of sphingolipid metabolism are important determinants of cell survival, growth, and differentiation. Because sphingolipids have been implicated in a wide range of human diseases and neurological syndromes, sphingolipid-using enzymes represent potential targets for therapy of a variety of diseases characterized by an accumulation of sphingolipids or an improper balance among growth-supporting (such as sphingosine 1-phosphate, ceramide 1-phosphate, and glycosylceramides) and growth-inhibiting sphingolipids (such as ceramide and sphingosine).

A defect in a single lysosomal enzyme or cofactor results in substrate accumulation in one or more organs. This imbalance between the formation and breakdown of glycosphingolipids is associated with neurodegeneration and high mortality (see also Lipid Homeostasis, Chemistry of). Partial reduction in the rate of biosynthesis of the glycolipid that accumulates in a lipid storage disease is known as substrate reduction therapy, which is an alternative therapeutic approach to enzyme replacement. An inhibitor of an enzyme in an anabolic glycosphingolipid pathway is used to reduce a key glycosphingolipid partially to a level at which the residual catalytic activity is capable of preventing excessive substrate accumulation. The imino sugar N-butyldexosamine (NB-DNJ), which is marketed as miglustat or Zavesca, is a synthetic sphingolipid deriva- tive that selectively modulates cellular glycosphingolipid levels. It inhibits the ceramide-specific glycosyltransferase that catalyzes the first committed step in glycosphingolipid synthesis and shows promising results in the management of some an- imal models of glycosphingolipid storage diseases because it offsets the accumulation of glucosylceramide and more complex glycosphingolipids (82).

Dihydroceramide exhibits different physical and biochemical effects compared with the corresponding ceramide bearing the same \(-\)acyl chain. For example, channel formation in mitochondrial membranes (78) and protein phosphatase activity in pancreatic beta cells are inhibited by dihydroceramide but are activated by ceramide (63, 79). Dihydroceramide is less effective than ceramide in inducing apoptosis (68).

The terminal hydroxy group of ceramide has also been modified. 1-O-Methoxyceramide did not inhibit mitochondrial ceramide (69), and 1-fluroceramide was a weak inhibitor of glucosylceramide formation in cultured murine neuronal cells (80). The 1-methylthio analog of dihydroceramide activated sphingomyine kinase and disrupted neuron axonal growth in cell cultures (81).

**Biological Background**

In the anabolic pathway of ceramide biosynthesis, N-acylation of a sphingoid long-chain base takes place in the endoplasmic reticulum and Golgi apparatus. In the catabolic pathway of ceramide biosynthesis, degradation of sphingomyelin and glycosphingolipids takes place at the plasma membrane and lysosomes, respectively. The enzymes in both the anabolic and catabolic pathways of sphingolipid metabolism are important determinants of cell survival, growth, and differentiation. Because sphingolipids have been implicated in a wide range of human diseases and neurological syndromes, sphingolipid-using enzymes represent potential targets for therapy of a variety of diseases characterized by an accumulation of sphingolipids or an improper balance among growth-supporting (such as sphingosine 1-phosphate, ceramide 1-phosphate, and glycosylceramides) and growth-inhibiting sphingolipids (such as ceramide and sphingosine).
myriad of cell signaling events, a great deal of attention has been devoted to the study of ceramide metabolism and function in the past two decades. The direct targets of ceramides that have been identified are the protease cathepsin D, ceramide-activated protein phosphatases, ceramide-activated protein kinases, the kinase suppressor of Ras (KSR), isoforms of protein kinase C (PKC), c-Jun N-terminal kinase (JNK), Akt, and PTEN (83, 84). The phosphorylation state of proteins with pro- and antiapoptotic activities is modulated by intracellular ceramide levels.

**Regulation of the endogenous levels of ceramide with naturally occurring inhibitors of sphingolipid-using enzymes**

The structures of some naturally occurring compounds that act on sphingolipid-metabolizing enzymes are shown in Fig. 7. These compounds include 1) sphingols, which inhibit serine palmitoyl-CoA transferase, 2) fumonisin and australifungin, which inhibit sphingomyelinase, 3) scyphostatin, which inhibits neutral-pH optimum isomerase of sphingomyelinase, 4) 2-acetyl-4-tetrahydroxybutylimidazole (THI), which inhibits S1P lyase, and 5) aureobasidin A, kahrefungin, and gaibondide A, which inhibit lysIP cer synthase (Fig. 4).

**Overview of sphingolipid biosynthesis**

The de novo synthesis of ceramide takes place in the endoplasmic reticulum and begins with the decarboxylative condensation of L-serine with palmitoyl-CoA, catalyzed by serine palmitoyl-CoA transferase (SPTase) (Fig. 8). As the name of the enzyme implies, palmitoyl-coenzyme A is recognized preferentially by mammalian SPTase, and the palmitoyl chain is transferred to the amino group of L-serine with the formation of 3-ketosphinganine. In this reaction, carbon dioxide is released from serine, with the other two carbon atoms of serine providing the source of C-1 and C-2 of the long-chain base. Therefore, the 18-carbon long-chain base predominates in the sphingolipids of mammalian cells. Although most prokaryotic cells do not contain sphingolipids, some bacteria such as the Sphingomonas species synthesize glycosphingolipids. The SPTase of these bacteria is a cytoplasmic homodimer, in contrast to the membrane-bond heterodimeric form found in eukaryotes (85); as mentioned above their sphingoid long-chain bases tend to have fewer than 18 carbons, which implies that their SPTase prefers an acyl-CoA with fewer than 16 carbons in the acyl chain.

Inhibition of the first step in sphingolipid biosynthesis with sphingols, L-cycloserine, or p-chloro-L-alanine results in the depletion of all sphingolipids. Sphingolipids such as myriocin (also known as ISP-1, Fig. 9) and sphingofungin (Fig. 9) have been isolated from fungal cultures and often are used as biochemical tools to examine the roles of sphingolipids in vitro. Growth inhibition of cultured cells by myriocin and sphingofungin B was rescued by exogenous sphingolipids (86).

Myriocin treatment of apoE1 knockout mice decreased the sphingomyelin content of lipoproteins and lowered the levels of plasma cholesterol and triglycerides, which indicates that sphingoid biosynthesis may be a therapeutic target for treating dyslipidemia and atherosclerosis (87). Myriocin is a competitive inhibitor of SPTase, which forms an aldimine adduct with the active site of the enzyme. However, cycloserine and p-chloro-L-alanine inhibit SPTase by a different mechanism; they react with the coenzyme of SPTase, pyridoxal 5′-phosphate, inhibiting the enzyme irreversibly and thereby downregulating the biosynthesis of sphinganine (88). As shown in Fig. 9, myriocin and sphingofungin B (both of which inhibit SPTase in the nanomolar range) bear a structural resemblance to sphinganine and its biosynthetic intermediates and may also mimic the transition state of the SPTase-catalyzed reaction. The configurations at C-2, C-3, C-4, and C-5 of sphingofungin B are important for its inhibitory potency on SPTase; however, the 14-hydroxy epimer of sphingofungin B is as potent as the natural 14S stereoisomer, which indicates that the configuration at C-14 is not critical (89).

**Inhibition of other enzymes in the sphingolipid metabolic pathway by natural products**

In the second step of the sphingolipid biosynthetic pathway, the carbonyl group of 3-ketosphinganine is reduced with NADPH to form sphinganine (Fig. 9). Biological activities of sphinganine may be due to its ability to downregulate the biosynthesis of sphinganine (88). As shown in Fig. 9, sphingofungin B was rescued by exogenous sphingolipids (86). Growth inhibition of cultured cells by myriocin and sphingofungin B (both of which inhibit SPTase) was rescued by exogenous sphingolipids (86). Myriocin is a competitive inhibitor of SPTase, which forms an aldimine adduct with the active site of the enzyme. However, cycloserine and p-chloro-L-alanine inhibit SPTase by a different mechanism; they react with the coenzyme of SPTase, pyridoxal 5′-phosphate, inhibiting the enzyme irreversibly and thereby downregulating the biosynthesis of sphinganine (88). As shown in Fig. 9, myriocin and sphingofungin B (both of which inhibit SPTase in the nanomolar range) bear a structural resemblance to sphinganine and its biosynthetic intermediates and may also mimic the transition state of the SPTase-catalyzed reaction.
form D-erythro-sphinganine. No naturally occurring inhibitors of 3-ketosphinganine reductase have been reported yet.

The N-acylation of sphinganine with a fatty acyl-CoA is catalyzed by acyl-CoA-dependent ceramide synthases (also called dihydroceramide synthases; at least six genes for this enzyme exist in mammalian cells), which produces dihydroceramide. The fungal natural products fumonisin and australifungin (Fig. 7) are specific inhibitors of N-acylsphinganine transferase activity in mammalian and fungal cells, respectively. The structure of fumonisin resembles the structures of both the sphingosine base and fatty acyl-CoA cosubstrates of dihydroceramide synthase. Therefore, the aminopentol portion of fumonisin may compete with the long-chain base for binding to the enzyme, and the polar region that contains the two TCA substituents may block binding of the fatty acyl-CoA. Fumonisin-induced disruption of sphingolipid metabolism resulted in neurotoxicity, birth defects, cancer, and renal and liver failure (90, 91). γ-Tocopherol, the predominant form of dietary vitamin E, also raises the levels of dihydroceramide and dihydrophosphonosine in human prostate cancer cell lines (92). Although the mechanism by which these sphingolipids are elevated has not been established, this result is another example of how an interruption in the de novo sphingolipid pathway can culminate in cell death.

Dihydroceramide desaturase catalyzes the last enzyme in the de novo biosynthetic pathway, which is the introduction of the C-4,C-5-trans-double bond into the long-chain base. No naturally occurring inhibitors of this enzyme have been reported yet. In plants and fungi, dihydroceramide is hydroxylated at C-4 instead of undergoing dehydrogenation. The hydroxylated product, phytoceramide, is the precursor of complex sphingolipids such as Ins PCer and various glycosyl-InsPCer derivatives such as mannose-IPC, mannose diinositolphosphorylceramide, dimannose inositolphosphorylceramide, and galactose-dimannose inositolphosphorylceramide.

**Metabolism of ceramide**

Ceramide formed in mammalian systems is metabolized to sphingomyelin, glucosylceroglipids, and ceramide 1-phosphate by the actions of sphingomyelin synthase, glucosylceramide synthase, and ceramide kinase on ceramide, respectively. Ceramide synthesized in the endoplasmic reticulum is transported to the Golgi apparatus for synthesis of complex sphingolipids (93). Sphingomyelin is synthesized from ceramide by transfer of the
Figure 8: Outline of the sphingolipid biosynthetic pathway. Natural and synthetic inhibitors of sphingolipid-metabolizing enzymes are shown adjacent to the inverted T bars.

Figure 9: Structures of naturally occurring inhibitors of SPTase.

phosphocholine head group of phosphatidylcholine. As mentioned above, sphingomyelin synthase catalyzes this reaction, and diacylglycerol (an activator of PKC) is released. InsPCer synthase carries out the analogous process in yeast and plants, transferring inositol phosphate to phytoceramide or dihydroceramide. Cerebrosides and gangliosides are synthesized from ceramide and nucleotide sugars in the presence of glycosyl transferases.

Hydrolysis of the amide bond of ceramide by ceramidases generates sphingosine, which has broad antibacterial and antifungal activity in addition to its PKC inhibitory activity (94). Phosphorylation of sphingosine at the terminal hydroxy group by sphingosine kinases affords S1P. S1P lyase, a pyridoxal 5'-phosphate dependent enzyme that has a potential role in controlling cell fate and stress responses (96, 97), cleaves S1P between C-2 and C-3 to produce an α,β-unsaturated fatty aldehyde and phosphoethanolamine. Pyridoxal 5'-phosphate forms a Schiff base with the amino group of S1P. S1P lyase plays a role in determining the balance between the intracellular levels of S1P and ceramide.

S1P is dephosphorylated by S1P phosphatases. The S1P phosphatase-1 isozyme decreases the transport of ceramide from the endoplasmic reticulum to the Golgi, as determined by the visualization of a fluorescent analog of ceramide that accumulates in the ER (98). S1P phosphatase type-2 is upregulated by inflammatory stimuli (99).

Interrelationships Among Sphingolipid Metabolites

Ceramide also is formed by sphingomyelinase (SMase)-catalyzed hydrolysis of sphingomyelin. Acidic and neutral SMases are activated by stress stimuli and external agents such as the Fas ligand (FasL), tumor necrosis factor-α (TNF-α), growth factors, and chemotherapeutic agents, which produces a transient rise in intracellular ceramide levels by hydrolysis of the phosphocholine moiety of sphingomyelin. SMases play important roles in cell signaling pathways that regulate cell growth, differentiation, cell cycle arrest, and apoptosis. A secretory form of acidic SMase is important in sphingomyelin catabolism, generating ceramide from sphingomyelin in plasma membrane domains. The resulting coalescence of ceramide-rich domains leads to the initiation of apoptosis, internalization of pathogens, and secretion of cytokines (100, 101).

The fungal metabolite scyphostatin (Fig. 7) is a potent, reversible inhibitor of membrane-bound Mg2+-dependent neutral sphingomyelinase (nSMase), thereby interfering with the generation of ceramide (102, 103). The activity of nSMases is sensitive to the cellular redox state, for example, the ratio of glutathione in the reduced versus the oxidized form (104, 105). The farnesyltransferase inhibitor manumycin A, a polyenamide produced by the Streptomyces species, also inhibits nSMase irreversibly (106).

The lysosomal acid sphingomyelinase (aSMase) isoform is inhibited by L-carnitine, a cofactor of acyl-coenzyme A transport in mitochondria (107, 108), and by phosphatidylinositol polyphosphates, which occur in plant, yeast, and mammalian cells (109).

A caramel food colorant and component of coffee, 2-acetyl-4-tetrahydroxybutylimidazole (THI, Fig. 7), inhibits S1P lyase, which causes S1P to accumulate in the lymph nodes (110).
by glycosylceramide synthases; it is converted to ceramide 1-phosphate by ceramide kinase and to sphingosine by ceramidases (Fig. 10a). The interplay between the kinases and phosphatases may control the concentrations of these sphingolipid mediators. Figure 10b shows the interconversions among the sphingolipid metabolites, together with the natural and synthetic inhibitors of enzymes in the sphingolipid pathway.

Elevating the ceramide content of cells

Stimulating ceramide biosynthesis and inhibiting the conversion of endogenous ceramide to other sphingolipid metabolites is a strategy that may be applied to block key steps in cancer progression such as cell growth and cell survival. The intracellular level of ceramide can be elevated by 1) activating neutral...
and acid SMases, 2) stimulating the de novo synthesis of ceramide, and 3) blocking the metabolic conversion of ceramide to other sphingolipids (for example, by inhibiting enzymes that use ceramide as a substrate, such as sphingomyelin synthase, glycosylceramide synthases, ceramidases, ceramide kinase, and O-acyltransferases).

Lowering the ceramide content of cells
Inhibitors of the enzymes that participate in the de novo biosynthesis of ceramide may be used to treat pathologies associated with elevated intracellular ceramide levels, such as chemotherapy-induced cell death and insulin resistance in muscle.

Designing Sphingolipid Analogs to Modulate Sphingolipid Metabolism
Synthetic analogs of sphingolipids offer advantages over natural sphingolipids

1. The extensive hydrophobicity of some natural compounds can be reduced by synthesizing compounds with shorter hydrocarbon chains or with more polar groups, thereby enhancing the aqueous solubility and cellular uptake (which may be directed to different intracellular compartments). Many cell-permeable analogs of ceramide mimic the effects of TNF-α, chemotherapeutic agents, oxidants, and ionizing radiation, which activate SMases to produce ceramide. Moreover, the subcellular localization of the analog may be dependent on the lipophilicity and/or net charge of the analog. N-Hexanoyl- and N-octanoyl-D-erythro-ceramide are examples of cell-permeable analogs of natural ceramide that induce cell cycle arrest or apoptosis in A549 cells (111, 112).

2. As discussed above, altering the stereochemistry of the sphingosine backbone has produced, in many instances, stereoisomers with altered bioactivity compared with the natural stereoisomer, for example, in activating the catalytic subunit of serine-threonine protein phosphatase 2A (63) or in inhibiting mitochondrial ceramidase (69).

3. The chemical and metabolic stability of labile natural compounds can be enhanced by incorporating stabilizing groups such as a phosphonate in place of a phosphodiester bond or a C-glycosidic bond, thereby creating new agents that resist phosphatase (113–115) and glycosidase action in cells (116).

4. The toxicity and bioavailability can be varied by conjugation to form new derivatives such as glucuronides that are metabolized differently than the parent compound. An example is a glucuronide derivative of the aminophanolamide of all-trans retinoic acid, fenretinamide (N-(4-hydroxyphenyl)-retinamide, 4-MPR) (117).

5. Structure-activity relationships may be established if several analogs are available. This step is a necessary step in drug design that leads to optimizing the properties of the therapeutic agent and developing a lead compound.

Many non-natural sphingolipid analogs have been synthesized with the aim of achieving a potential therapeutic advantage with respect to one of the following bioactivities: 1) to manipulate the activity of enzymes in the sphingolipid biosynthetic pathway and thus alter the balance between the pro-survival and antiproliferative sphingolipid metabolites, 2) to alter the stability of lipid nets and cause aberrant localization of signaling molecules, 3) to produce immunosuppression via alteration of the number of circulating lymphocytes, or 4) to activate natural killer T cells to produce a desired array of cytokines.

Elevating Intracellular Ceramide Levels with Unnatural Sphingolipid Analogs
Irradiation (UV and γ rays), chemotherapy, pathogenic infections, and many other external stress stimuli activate SMases and elevate the endogenous levels of ceramide in tumor cells, which promotes apoptosis. However, tumor cells may counter these treatments by activation of ATP-dependent efflux pumps and by converting endogenous ceramide to other sphingolipid metabolites, which thereby evades apoptosis.

Use of unnatural sphingolipid analogs to elevate endogenous ceramide levels in tumor cells by interfering with ceramide trafficking
After the de novo synthesis of ceramide in the endoplasmic reticulum, additional biosynthesis of sphingolipids continues in the Golgi apparatus and plasma membrane. Sphingomyelin synthase uses ceramide as a substrate for sphingomyelin production in the lumen of the Golgi. A cytosolic ceramide transfer protein, CERT, transports ceramide in a nonvesicular manner from the endoplasmic reticulum to the Golgi complex (118). Ceramide transport is required for the synthesis of sphingomyelin and presumably other sphingolipids. A Drosophila mutant that lacked the functional CERT gene had a depressed content of ceramide phosphoethanolamine (the sphingomyelin analog in Drosophila) and ceramide, which resulted in altered membrane trafficking.
permeability behavior and an enhanced susceptibility to oxidation of cellular components (13). A synthetic analog that resembles ceramide with respect to structure and stereochemistry, (1R,3R)-N-(3-hydroxy-1-hydroxymethyl-3-phenylpropyl)dodecamide (1R,3R)-HPA-12 (Fig. 11), inhibited sphingomyelin biosynthesis by blocking ceramide trafficking (119).

Use of synthetic sphingolipid analogs to modulate endogenous ceramide levels

1. Inhibition of neutral SMases. Mg²⁺-dependent nSMases in plasma membranes hydrolyze sphingomyelin to yield ceramide and phosphocholine. As ceramide is a key signaling molecule in the apoptotic and inflammation response to stress signals, inhibitors of SMase isoforms may provide lead compounds for the treatment of inflammation, ischemia, neurodegenerative diseases, and infarction. The following examples are representative of efforts to develop synthetic sphingophospholipid analogs with antiapoptotic activity.

   - 3-O-Methyl- and 3-O-ethyl-sphingomyelin (Fig. 11) inhibited nSMase without markedly affecting the activity of the acid isoform (120). Inhibition of nSMase also was observed with hydrolytically stabilized tert-butylcarbamate and urea derivatives of sphingomyelin, which also prevented apoptotic neuronal cell death in an ischemic model (121, 122). S1P analogs with a difluoromethylene phosphonate link instead of the phosphate group (SMA-3 and SMA-7, Fig. 12) inhibited nSMase in pheochromocytoma PC-12 cells and inhibited cerebral infarct in mice (123). Phosphonocho line analogs of sphingomyelin, in which an oxygen atom in the phosphate ester head group was replaced by a carbon, nitrogen, or sulfur atom, were also inhibitors of nSMase (124) as was a lactone derivative of ceramide (125) (Fig. 11).

   - Inhibition of SM synthase. Tricyclodecan-9-yl xanthogeneate (D609, Fig. 12) is a known inhibitor of phospholipase C (which hydrolyzes phosphatidylcholine) (127). It inhibited SM synthase and induced apoptosis in U937 human monocyte leukemia cells (128) and rat PC12 cells (129).

   - Inhibition of glucosylceramide (GlcCer) synthase. This enzyme incorporates a glucosyl residue from UDP-glucose into ceramide to form β-glucosylceramide, which is a precursor of complex glycosphingolipids that participate in many physiologic and pathophysiologic processes. Therefore, this enzyme is a potential drug target. NB-DNJ (Fig. 12) is a competitive inhibitor of GlcCer synthase with respect to ceramide and is a noncompetitive inhibitor with respect to UDP-glucose; molecular modeling studies (indicated that NB-DNJ) is structurally similar to ceramide but not to glucose (130). NB-DNJ reduced the level of GlcCer that accumulates in Gaucher disease and also acted as a chemical chaperone for the acid β-glucosidase that is defective in this disease. Other competitive inhibitors of GlcCer synthase are ceramide analogs with a cyclic amino head group such as morpholine or pyrrolidine instead of the primary hydroxy group at C-1. They also have a phenyl group in place of the aliphatic chain of the sphingosine backbone. A lead compound that was developed to inhibit GlcCer synthase is (1R,2R)-1-phenyl-2-amino decanoyl-3-morpholino-1-propanol (D-threo-PDMP, Fig. 12), which has an...
Synthetic Sphingolipids as Bioactive Molecules: Roles in Regulation of Cell Function

N-decanoyl amide chain (131). This ceramide analog leads to the accumulation of ceramide in neuroblastoma and other cell types and also possesses antitumor activity (132). The inhibitory potency on GlcCer synthase was enhanced by the elongation of the N-acyl group from C10 to C16, by the introduction of electron-rich aromatic substituents, by the replacement of the morpholino with a pyrrolidino head group, and by the addition of water-soluble links. In addition to inhibiting the activity of GlcCer synthase, D-threo-PDMP exerts several other effects, including the alteration of the structure and function of membrane domains in late endosomes, the inhibition of LDL degradation, and the enhanced uptake of paclitaxel (133). Administration of high doses of L-PDMP increases GlcCer synthesis in the brain (134).

4. Inhibition of ceramidases. Ceramidases specifically hydrolyze the amide bond of ceramide to form sphingosine and a fatty acid without acting on the amide bond of other sphingolipids. Enzymatic forms of ceramidase with acidic, neutral, and alkaline activities have been studied. The enzyme with an acidic pH optimum is localized primarily in lysosomes and thus is important in catabolism. It is activated by the glycoprotein sphingolipid activator protein D (SAP-D) (135, 136).

N-Oleoyl ethanolamine (Fig. 12), the first known inhibitor of this enzyme, has a low potency (IC₅₀ > 0.5 mM) and a low specificity (137, 138). Point mutations in the gene encoding acid ceramidase lead to the lysosomal storage disease known as Farber disease. As acid ceramidase is overexpressed in several human cancers, currently a great deal of interest exists in developing new inhibitors of this enzyme to induce an accumulation of endogenous ceramide and a suppression of cell growth (139). Ceramidase also catalyzes the reverse of the hydrolysis reaction, for example, the condensation of sphingosine with a fatty acid without the participation of cofactors (140). N-(2-Oxo)-acylsphingosines inhibited acid ceramidase with a low selectivity and low potency (138). D-erythro-2-(N-Myristoylamino)-2-phenyl-1-propanol (D-e-MAPP, Fig. 12) inhibited alkaline ceramidase, which raises the intracellular levels of ceramide and arrests cell growth (141). A ceramide analog in which a 4-nitrophenyl group replaces the aliphatic chain (denoted as B13, Fig. 12) is a potent inhibitor of acid ceramidase; it induced apoptosis in prostate and colon cancer cell lines (142, 143). A urea derivative of ceramide also inhibited mitochondrial ceramidase (69). Analogs of D-e-MAPP and B13 affect the levels of ceramide, sphingosine, and S1P in MCF7 cells (144). Examples of other potent and specific inhibitors of acid ceramidase are LCL-204 (Fig. 12) and LCL-102, which are lysosomotropic analogs of B13.
5. Inhibition of ceramide synthase. A short-chain cyclopropenyl-containing ceramide analog called GT-11 (145) (also called CB-cyclopropenylceramide) (146) inhibits ceramide synthase.

6. Inhibition of dihydroceramide desaturase. The last enzyme in the de novo biosynthesis of ceramide is inhibited by GT-11, but at high concentrations this compound also inhibited S1P lyase and SPTase (147, 148). Fenretinide (4-HPR, Fig. 12) also inhibited dihydroceramide desaturase (147, 148). This synthetic retinoid and its analogs have apoptogenic activity, which elevates intracellular ceramide levels and induces cell death in a variety of cell types in vitro and in vivo by multiple mechanisms (117, 149, 150).

7. Inhibition of S1P lyase. S1P lyase is inhibited by sulfhydryl reagents, FTY 720 (151), and by racemic 2-vinyldihydrosphingosine 1-phosphate (152) (Fig. 12). When S1P lyase is overexpressed, ceramide levels are increased and apoptosis is induced (153).

Other Structural Analogs of Ceramide with High Antiproliferative Activity

The bioactivity of many synthetic ceramide analogs that bear modifications in the long-chain base or in the fatty amide chain has been studied.

Modifications in the sphingosine backbone
(25,3R,4E,6E)-N-Octanoylamidococadecadiene-1,3-diol, a ceramide analog with an additional double bond (between C-6 and C-7), induced accumulation of endogenous ceramide in multidrug-resistant breast cancer cells and induced apoptosis by the mitochondrial pathway without inhibiting the growth of normal epithelial cells (76).

Modifications in the length of the N-acyl chain
In vitro and in vivo studies have shown that short-chain ceramides induce growth arrest (154). A fluorescent analog of C6-ceramide partitioned into caveolin-enriched microdomains of rat aorta vascular smooth muscle cells and led to growth arrest via activation of PKC-ζ, which is recruited to lipid microdomains and subsequently reduces the activity of Akt (155).

Additional polar groups
Ceramide analogs with an additional hydroxyl group in the long-chain base, as in 6-hydroxyceramide (76) and phytoceramide (156), are more effective than ceramide in arresting proliferation of some tumor cell lines. The introduction of a uracil or thiouracil group at C-1 of ceramide provided an effective apoptotic agent (157).

Reduction of the carboxamido group of ceramide to a methylene group
An analog called ceramine induced apoptosis in leukemic cells, which indicates that the carbonyl group of the amide group of ceramide is not required for in vitro cytotoxicity (66, 158). Ceramide analogs with an arylsulfonamido group had higher cytotoxicity activity than the corresponding alkylsulfonamide analogs (159).

N-acylated 2-amino-1,3-diols
Reaction of amino diols with a fatty acid afforded a series of simple ceramide analogs with pro-apoptotic activity in human cancer cell lines (160). An example is N-oleylserinol, which induced apoptosis in cells expressing the pro-apoptotic protein PAR-4 and was used to purify transformed cells from embryonic stem cells before implantation into mouse brain (161).

Targeting of ceramide analogs to specific cell organelles
Short- and long-chain ceramides form channels in the outer mitochondrial membrane, which enables proteins in the intermembrane space to be released (162). An aromatic "ceramidoid" in which the N-acyl chain terminates in an N-alkylpyridinium group bears a net positive charge (163) (Fig. 13). This ceramide analog preferentially targets mitochondria, where it accumulates and induces apoptosis by triggering the release of cytochrome c into the cytosol, activating the apoptotic cascade, and blocking the growth of cell carcinomas in vitro and in vivo (164). LCL-204 (also called AD2646) accumulates in lysosomal membranes, inhibiting acid ceramidase, inducing the release of cathepsins, and triggering apoptosis of prostate cancer cells (165) and head and neck squamous cell cancer cells (166). LCL-204 also reduced resistance to Fas.

Ceramide analogs that inhibit protein kinase C isozymes and induce downstream loss of extracellular signal-regulated kinase (ERK1/ERK2)
Inhibition of the PKC isozyme superfamily elicits apoptosis in tumor cells. Phenethyl isothiocyanate (PEITC) conjugates of sphingosine and sphinganine (Fig. 13) exert potent antiproliferative effects in human leukemia HL-60 cells by the inhibition of conventional PKC and novel PKC activity and ERK1/ERK2 activity (167). The activity of these derivatives surpassed that of safingol (L-threo-sphinganine), a non-natural analog of the natural
Sphingolipid Regulation of Signaling via Control of Raft Formation and Stability

Sphingomyelin and glycosylated sphingolipids (GSLs), together with sterols and glycerophospholipids, are key lipid building blocks of rafts. As rafts are considered to represent sites for the initiation of many receptor-mediated signaling events including the uptake of pathogens, sphingolipids play pivotal roles in a variety of dynamic cellular events such as membrane trafficking and the activity of membrane proteins.

Disruption of plasma membrane microdomains by sphingolipid analogs that cannot pack tightly with neighboring lipids

Fluorescent analogs of D-erythro-(or 25,3S)-lactosylceramide and D-erythro-sphingomyelin undergo endocytosis from the plasma membrane via caveolae, whereas non-natural analogs such as L-threo-(or 25,3S)-lactosylceramide and L-threo-sphingomyelin follow a predominantly clathrin-dependent route of endocytosis (16). These observations suggest that the stereochemistry at the C-3 position of the sphingosine backbone plays a role in the internalization pathway of the sphingolipid. Studies with a fluorescent, excimer-forming derivative of lactosylceramide (BODIPY-LacCer, Fig. 14) indicated that the D-erythro stereoisomer forms clusters in membranes, from which caveolar endocytosis is initiated. The corresponding L-threo stereoisomer was excluded from these domains; molecular modeling indicated that it does not pack as tightly with neighboring lipids as the natural stereoisomer.

A non-natural glycosphingolipid inhibited caveolar uptake, viral binding and infectivity, and β1-integrin signaling

The addition of D-erythro-N-octanoyl-lactosylceramide (CD-D-e-LacCer, Fig. 14) to human skin fibroblasts at low temperature promoted the formation of plasma membrane microdomains as shown by confocal fluorescence microscopic studies. The addition of CD-D-e-LacCer to cells also initiated the clustering of β1-integrins within these domains and the activation of β1-integrins. On warming to 37°C, β1-integrins were internalized rapidly via caveolar endocytosis in cells treated with CD-D-e-LacCer, whereas little β1-integrin underwent endocytosis in untreated fibroblasts. The incubation of cells with CD-D-e-LacCer followed by a brief warm-up also caused src activation and a reorganization of the actin cytoskeleton (16).

Conversely, addition of C8-L-threo-LacCer (Fig. 14) inhibited the formation of microdomains in the plasma membrane, which resulted in the inhibition of both endocytosis and β1-integrin signaling (170). Thus, non-natural sphingolipids that can block the formation of microdomains in the plasma membrane may offer a novel means for interfering with the cell entry mechanism that is employed by various pathogens and viruses.

Synthetic Immunomodulatory Sphingolipids: Analogs of the Immunosuppressant FTY720 and the Immunostimulator α-Galactosylceramide

FTY720 interferes with S1P signaling and modulates lymphocyte function

Sphingosine 1-phosphate (S1P) mediates numerous biological processes; therefore, potential new drug candidates may be specific agonists and antagonists of S1P receptors. Chemical manipulation of myriocin led to the development of a new immunosuppressive sphingosine analog known as FTY720 (2-amino-2-(4-octylphenylethyl)-1,3-propanediol), which is phosphorylated in vivo to form the (S)-phosphate (FTY720-phosphate, Fig. 15) (173). This synthetic analog of S1P is a potent agonist of the S1P-type 1 receptor but does not activate the S1P-type 2 receptors on the surface of thymocytes and lymphocytes. FTY720 possesses more potent immunosuppressive activity than myriocin without inhibiting sphingolipid biosynthesis and host immune defense responses to many infectious agents. FTY720 inhibits lymphocyte trafficking in vivo, which promotes the sequestration of lymphocytes into lymph nodes and impairs the S1P-type 1 receptor-mediated migration of lymphocytes between secondary lymphoid tissues and the blood. Thus, the cells become unresponsive to S1P and external signals that direct these cells to sites of inflammation (172). In addition, FTY720 has other potent suppressive effects on T cells unrelated to migration, including the inhibition of the S1P-evoked generation of cytokines that promote autoimmune inflammation such as IL-17 (173). (S)-FTY720-phosphate and other FTY720 analogs that activate S1P receptors and stimulate various signaling pathways seem to be useful for the treatment of a variety of pathologic conditions, including angiogenesis, inflammation, respiratory distress syndrome, and autoimmune diseases.

Promotion of myelination by FTY720 and (S)-FTY720-phosphate

Although FTY720 failed to improve efficacy for preventing renal allograft rejection in Phase III clinical studies (174), a different purpose has been found for its potential use. Phase III clinical trials are underway to examine the use of FTY720 for...
Synthetic Sphingolipids as Bioactive Molecules: Roles in Regulation of Cell Function

Potential treatment of systemic lupus erythematosus and autoimmune demyelinating diseases such as multiple sclerosis (175). (S)-FTY720-phosphate stimulated, via induction of ERK1/2 and Akt phosphorylation, the survival of progenitor cells that give rise to myelin-producing oligodendrocytes (176). Therefore, in addition to its immunosuppressive function, FTY720 shows promise as a therapeutic agent in the treatment of multiple sclerosis via the protection of oligodendrocytes and the replenishment of lost oligodendrocytes, thus promoting remyelination.

Other potential clinical applications of FTY720

The combination of FTY720 with a tyrosine kinase inhibitor induced apoptosis in melanoma cells (177). (R)-AAL, an ether analog of FTY720 (which also has a methyl group in place of a hydroxymethyl group) (Fig. 15), was phosphorylated in vascular cells and blocked vascular endothelial growth factor (VEGF)-induced vascular permeability in vivo (178). (S)-FTY720-phosphate also may regulate calcium ion channels in smooth muscle cells in an S1P-receptor independent manner (179). FTY720 also enhances pulmonary endothelial cell barrier integrity by a mechanism that seems to be different than that used by S1P, which also augments endothelial cell vascular barrier integrity (180).

Glycosphingolipid-Based Immunotherapies: Presentation of Glycosphingolipids to a Subset of T Cells

A naturally occurring α-anomer of galactosylceramide known as KRN7000 (Fig. 16), was isolated from the marine sponge Agelas mauritianus in 1992 and was subsequently identified as an antitumor agent and a potent immunostimulant of invariant natural killer T (iNKT) cells. These cells are an innate subset of T lymphocytes that express a semi-invariant T-cell receptor (TCR). They rapidly produce immunoregulatory cytokines on recognition of glycolipid ligands bound to the CD1d glycoprotein on the surface of antigen-presenting cells, which results in the activation of dendritic cells, NK cells, B cells, and T cells. The function of CD1d is related to the nonclassical major histocompatibility complex (MHC) class I molecules. CD1d presents glycolipid antigens to the TCR of NKT cells (181). A synthetic analog of KRN7000 known as α-galactosylceramide (α-GalCer, Fig. 16) is the most extensively studied lipid antigen that binds to CD1d. Although α-GalCer is a highly potent glycolipid antigen for cells that express CD1d, it is not a natural product of mammalian cells. The identity of the natural mammalian glycolipid antigen that binds to CD1d for presentation to iNKT cells has remained elusive despite intense study. X-ray crystallographic studies showed that the phytosphingosine backbone and fatty amide chain of α-GalCer reside in the two CD1d clefts, with hydrogen bonding between residues in CD1d and the 2’, 3’, and 4’-hydroxy groups of galactose and the 3-hydroxy group of phytosphingosine (182). The 4’- and 6’-positions of the sugar head group are exposed for recognition of the αGalCer/CD1d complex by the TCR. CD1d is recycled through the endosomal and/or lysosomal pathway, and this trafficking is essential for the loading of CD1d with glycolipid antigens (183).

Manipulation of the Th1 versus Th2 polarization with α-GalCer analogs

Although the therapeutic potential of α-GalCer as an immunomodulator for treating autoimmune and infectious diseases, cancer, hepatitis B, and malaria is well established, several limitations to its therapeutic use have been recognized. These include the production of both T-helper 1 (Th1) and T-helper 2 (Th2) cytokines, long-term iNKT cell unresponsiveness in mice on repeated administration, and a very low solubility of the glycolipid in aqueous media. Therefore, many α-GalCer analogs with modifications in the two lipid chains or in the galactose head group have been synthesized and studied. The balance between the levels of Th1 and Th2 cytokines secreted may be crucial to attaining therapeutic efficacy of the immunostimulant because Th1 and Th2 have opposing actions (184). For example, a glycolipid agonist that stimulates NKT cells to produce Th1-type cytokines (such as interferon-γ and the interleukins IL-2 and IL-12) would be beneficial for...
the treatment of intracellular infections caused by viruses and some bacteria and for the stimulation of antihuman immunity. Several α-GalCer analogs have been synthesized that modulate the NKT cell responses by polarizing them to produce a desired cytokine profile. An N-acyl analog of α-GalCer that has a C20:2 cis-double bond in place of the C20:0 amide chain of the natural agelasphins induced a Th1-type response (185) as did analogs that have an aromatic group at the ω-terminus of the N-acyl chain (186). However, an analog of α-GalCer with a truncated phytosphingosine chain stimulated NKT cells to selectively produce Th2-type cytokines, such as IL-4, and suppressed autoimmunity in animal models of multiple sclerosis (187), collagen-induced arthritis (188), and autoimmune diabetes (189). An α-GalCer analog with an elongated phytosphingosine chain induced NKT cells to produce a weaker cytokine response, which resulted in the suppression of an arthritis disease model in mice (190).

A increased production of Th1 cytokines has also been achieved in mice with a C-glycosidic analog of α-GalCer, in which the linker region between the sugar and the backbone was altered by replacing the α-anomeric oxygen atom of galactose with a methylene group (isosteric C-α-GalCer, Fig. 16 (191). A nonisosteric C-glycoside of α-GalCer also was prepared in which the anomeric carbon is bonded directly to C-1 of the phytosphingosine backbone (nonisosteric C-α-GalCer, Fig. 16 (192). This analog elicited a higher ratio of Th1-type cytokine/Th2-type cytokine response in human NKT cells in culture than α-GalCer and the isosteric C-α-GalCer. The mechanism of the Th1 bias remains to be elucidated, but factors such as aqueous solubility, access to lipid transfer proteins, the stability of the CD1d:glycosphingolipid-TCR ternary complex, and receptor-mediated uptake may be involved. Thus, new α-GalCer analogs may have therapeutic relevance.

**Conclusion**

Many natural compounds, dietary constituents, and chemotherapeutic agents alter the activities of enzymes in the de novo biosynthetic pathway of sphingolipids, which thereby modifies the relative concentrations of endogenous sphingolipid species present in cells. During the last two decades the importance of sphingolipids in cell signaling pathways has been recognized, and many bioactivities of sphingolipid metabolites have been studied. The mechanisms by which sphingolipids exert their biological activities on intra- and extracellular targets have been elucidated, but the roles of sphingolipid-metabolizing enzymes and their isozymes in disease processes are not yet understood. The attention that has been devoted to the enzymes that metabolize sphingolipids has resulted in an improved understanding of the pathways for interconversions among sphingolipid messengers with opposing bioactivities. Manipulation of the levels of sphingolipid metabolites seems to be a means of determining cell fate. In vitro and in vivo studies have shown that several enzymes are potential targets for therapeutic applications, including sphingomyelinases, ceramidases, GlcCer synthase, sphingosine kinases, and S1P lyase. Other enzyme targets probably will be identified in future research, such as ceramide synthase, ceramide kinase, autotaxin, and dihydroceramide desaturase. In addition to enzymes involved in sphingolipid metabolism, lysosphospholipid GPCRs hold promise as attractive pharmacologic targets. Agents that disrupt lipid microdomains may also have therapeutic applications. Several human clinical trials have been undertaken to date with synthetic sphingolipids in the hope of assessing their efficacy and safety as chemotherapeutic agents for various diseases: with α-GalCer (193, 194), safingol (195), NB-DNJ (miglustat) (196–198), and FTY720 (175, 199, 200). It remains to be shown whether synthetic sphingolipids will be successful agents for the treatment of infectious and autoimmune diseases and hyperproliferative diseases such as cancer.

Glycolipids, Synthesis of Lipidomics
The discovery of natural RNA catalysts has prompted chemical biologists to pursue artificial nucleic acids that have catalytic activities. Such artificial nucleic acid enzymes may comprise either RNA (ribozymes) or DNA (deoxyribozymes). The term “ribozyme” was first used in 1982, when Kruger et al. reported natural catalytic activity by RNA (1). This term is now used universally for catalytic RNAs, whether artificial or natural (see also the WECB review on natural ribozymes). The term “deoxyribozyme” was first used in 1994, when Breaker and Joyce reported the first artificial DNA catalyst (2); no natural deoxyribozymes have been identified. With current knowledge, we cannot design nucleic acid enzymes that have completely new catalytic activities from first principles or by rational modification of known enzymes. Instead, we must use combinatorial search techniques to identify functional RNA and DNA sequences by sifting through a large number of random sequences using an appropriate search strategy. This process of “in vitro selection” has proven useful for identifying nucleic acid enzymes with a wide range of catalytic activities. In certain cases, we can apply ribozymes and deoxyribosymes for practical purposes such as sensing the presence of an analyte and providing a visible response. This review describes how artificial nucleic acid enzymes are increasingly used in practical applications ranging from analytical chemistry to biology.

**Scope of Ribozyme Catalytic Activities**

The first artificial ribozyme was reported in 1990 (3). Since that time, in vitro selection has been used to discover many artificial ribozymes with a wide range of catalytic activities. The known natural ribozymes catalyze phosphodiester cleavage or ligation, with the exception of the ribosome—made of both RNA and protein—that catalyzes peptide bond formation. Many artificial ribozymes also catalyze phosphodiester exchange reactions (RNA/DNA cleavage or ligation), although a growing number of ribozymes catalyze other reactions. Artificial ribozymes for phosphodiester cleavage or ligation have been emphasized in part because nucleic acid catalysts can readily bind via Watson-Crick base pairs to oligonucleotide substrates. By segregating the binding and catalysis functions to distinct regions of the nucleic acid enzyme (Fig. 1), the difficulty of achieving catalysis is reduced. The substrate binding energy is designed directly into the system, and the enzyme needs only to catalyze the reaction. The scope of artificial ribozyme activities identified to date is provided in Table 1 (4–52); representative examples of ribozymes and the reactions that they catalyze are shown in Fig. 2. Such a compilation indicates that many different types of reactions are amenable to nucleic acid catalysis, which includes such prototypical “organic” reactions as the aldol reaction and the Diels–Alder cycloaddition, which form carbon–carbon
In vitro selection and application of nucleic acid enzymes (ribozymes and deoxyribozymes)

Figure 1 Schematic view of nucleic acid enzyme catalysis, showing separate binding and catalytic regions of the ribozyme or deoxyribozyme (lower strand). At the outset of selection, the binding regions are fixed in sequence, whereas the catalytic region comprises a random sequence. In this example, the two substrates (upper strands) are oligonucleotides, which interact with the binding regions by Watson–Crick base pairs; X and Y are the two functional groups that react with one another (solid arrows). Substrates may be small molecules rather than oligonucleotides, and some nucleic acid enzymes break rather than form bonds in the substrate. During most selection procedures, one substrate is attached covalently to the enzyme strand (e.g., via dashed loop at right), which enables selection to occur by linking genotype (sequence) to phenotype (catalysis). However, for practical application such attachment may not be required, particularly when the substrates are oligonucleotides.

General Considerations for In Vitro Selection Procedures

The identification of new artificial ribozymes is impossible without carefully designed in vitro selection methodologies. Although the details and even the fundamental elements of the selection procedure can differ for each ribozyme, some general considerations are common. (See also the WEBC review on construction and selection of nucleic acid combinatorial libraries.) An early approach to ribozyme selection was to identify RNA sequences that bind to a transition-state analog, as has been done for catalytic antibodies. Although such approaches do work in certain cases (45, 48, 51), in other cases the approach was unsuccessful (53), and it was suggested that selecting directly for catalysis is superior (8). Indeed, most ribozyme selections now aim directly for selecting catalytic RNA sequences using the desired substrates rather than transition-state analogs.

Sequence Space and Length of the Random Region

A ribozyme selection experiment almost always begins with solid-phase synthesis of a long DNA oligonucleotide that has two types of sequence elements: constant and random (Fig. 1). The constant regions either serve as primer binding sites for a polymerase chain reaction (PCR) step or—as after conversion to RNA—provide binding sites for nucleic acid substrates. The random region constitutes the nucleotides that, as RNA, will compose the catalytic portions of any functional ribozymes that emerge from the selection process. For some but certainly not all ribozymes, RNA nucleotides from the constant regions can also contribute to catalysis.

One critical consideration for any selection effort is the nucleotide length of the random region. This length directly determines the possible number of nucleotide sequences—i.e., the size of the “random pool”—in a mathematically straightforward way. Because N is the common designation for a random nucleotide (versus A, G, U, and C for the four standard RNA nucleotides), the random region is usually denoted as, for example, N20 for a 20-nucleotide region. For a statistically random N20 region, there are $4^{20} \approx 10^{6}$ possible nucleotide sequences. Successful ribozyme selections have used random regions that range in length up to N25, for which sequence space has the unimaginably large value of $4^{25} \approx 10^{77}$. The number of random-pool molecules actually used to initiate selection is limited by technical considerations such as a manageable PCR volume and is on the order of $10^{13}$–$10^{15}$, which corresponds to 0.01–10 nmol. Therefore, for all but the shortest random regions ($<N20$), sequence space is vastly undersampled. For a relatively small 40-nucleotide random region and starting with $10^{14}$ molecules, only $10^{-10}$ of the $10^{44}$-molecule sequence space is represented, for a typical N20 pool, only $10^{-28}$ of the $10^{44}$-molecule sequence space is covered. Despite the sparse sampling, many selection experiments are quite successful, which implies that catalytically active RNA sequences are relatively common in sequence space, at least for the investigated catalytic activities. Such a conclusion has been reached on the basis of experimental data numerous times (8, 23).

It can be difficult to choose the proper random-region length. This choice requires a compromise between coverage of sequence space (always favoring small random regions) and achieving the structural complexity necessary to support catalysis (probably but not necessarily favoring large random regions; note that excess sequence elements can inhibit catalysis). In selections for identifying aptamers (ligand-binding RNAs), the optimal random-pool length was found to reflect a balance between these factors (54). In ribozyme selections, the structural complexity of the catalytic motif was found to influence strongly the optimal pool size, with complex motifs particularly benefiting from long random pools (55). Of course, before undertaking a new selection effort, one does not necessarily know the structural complexity of the ribozymes that will be identified. Therefore, in practice, the random-pool length is usually chosen based on experience and educated guesswork. To handle the uncertainty, parallel selection experiments that use more than one random-pool length may be performed. Several random pools of various lengths may also be allowed to compete directly with one another in the same tube (19, 56).

NOTES: This tabulation is not intended to be exhaustive, in that other examples of ribozymes with the indicated activities may have been reported, nd = not determined in published report. When the reaction type is marked with "(novo)," the ribozyme required nonstandard nucleotides for activity. The entry "# Rand nt" is the total number of original random nucleotides in the sequence pool, these may have been in two or more portions interspersed with constant regions. The entry "Rate enh" is the highest rate enhancement reported, often calculated as the ratio of rate constants for the observed versus background reactions (Fig. 4). In some cases, the authors reported the rate enhancement as the ratio of $k_{obs}/k_{0}$ for the ribozyme and the analogous value for the uncatalyzed reaction. The listed rate enhancement may be a lower limit on the true value, for at least one of two reasons: (1) Only an upper limit was possible on the uncatalyzed rate. (2) The uncatalyzed rate represents a spectrum of reactions, only one of which corresponds to the particular reaction catalyzed by the ribozyme. Under "Selection method," the entry "(beads)" is included if noncovalent binding to beads (or other solid support) of the tagged nucleic acid sequences was an integral part of the key selection step. In some other cases, the substrate was presented on beads to avoid aggregation, but the key selection step did not involve a solid support. The entry "(corex") is included if a photosensitizer release step was used.

8The experiment started with a known aptamer or ribozyme sequence, which in some cases was partially randomized. In some cases, a new random-sequence domain of indicated length was also included.

9The experiment used rational redesign of a known ribozyme sequence.
Tolerance of Ribozymes to Variation in Sequence

Many artificial ribozymes do not seem to require specific nucleotides at every position within their initially random regions. This is similar to how many proteins tolerate amino acid changes at numerous sites but not at certain key residues. Due to the hierarchical nature of RNA folding, in which a complex tertiary structure forms on a foundation of Watson–Crick secondary structure elements such as stem-loop structures (57), a ribozyme can probably tolerate nucleotide changes at certain positions as long as Watson–Crick interactions are maintained (see Reference 58 for similar findings with aptamers). At other positions, the identities of the nucleotides may not matter at all. These considerations increase substantially the possibility that a particular ribozyme will emerge from a selection experiment, because many variants of a ribozyme that differ at noncritical nucleotides are essentially equivalent in terms of catalytic activity.

Overview of Experimental Selection Strategies

In general, a successful in vitro selection experiment must physically link the information in the catalytic nucleic acid sequence with the desired reaction chemistry, such that the successful sequences can be isolated. Therefore, an experimental strategy must be devised by which the majority of catalytically incompetent random-pool sequences are discarded, whereas the small minority of functional random-pool sequences are retained. Many strategies have been used, and many variations are possible even within the framework of a single general strategy. One possible selection approach is represented by the strategy used to identify the first RNA ligase ribozymes (Fig. 3) (8). As a means of illustrating a selection process, the key aspects of the procedure are discussed below, using the RNA ligase ribozyme selection as the specific example.

Preparation of the Random-Pool DNA

The random-pool DNA is prepared by solid-phase synthesis (SPS), with the random (N) nucleotides provided simply by mixing the four standard DNA nucleotide phosphoramidites together in one bottle. During SPS, random coupling to each growing oligonucleotide chain ensures that the collection of synthetic oligonucleotides has an effectively random region that encompasses all N positions. In practice, random coupling to each growing oligonucleotide chain ensures that the collection of synthetic oligonucleotides has an effectively random region that encompasses all N positions. In practice, the phosphoramidites are mixed in non-1:1:1:1 mole ratio, because each phosphoramidite reacts during SPS with a different rate constant. After correcting for these known unequal coupling efficiencies, the random pool will have an approximately equal proportion of each standard DNA nucleotide at each position. Once the random-pool DNA has been synthesized, the random-pool RNA is made using this DNA as a template for in vitro transcription using T7 RNA polymerase (59).
...ribozymes (8), the selections were performed primarily at pH 7.4, 600 mM KCl, and 60 mM MgCl₂ at 25 °C for 16 h, at least for the initial selection rounds. Due to the large number of independent variables, selection experiments often take advantage of parallel processing. Multiple selection experiments that each use a specific set of incubation conditions are performed. By comparing the outcomes of several selections performed in parallel where the only difference is in the incubation conditions, one may gain information on which aspects of these conditions are essential to achieving the desired catalytic activity.

Once the catalytically active nucleic acid sequences have been separated by an appropriate physical method, the selection round must be completed by synthesizing the DNA pool for input into the next selection round, now enriched in those sequences that (as ribozymes) are competent for catalysis. For the RNA ligase ribozymes, this was achieved by reverse transcription and PCR amplification followed by transcription (Fig. 3). Similar steps are common to most ribozyme selection procedures.

The overall selection cycle is iterated multiple times until the activity of the pool is sufficiently high that identifying individual sequences within the pool is warranted. The necessary number of rounds can vary greatly but is typically between 5 and 15 (only rarely greater than 20). The need for multiple selection rounds may initially seem mysterious—how come catalytically active sequences do not emerge after just one selection round? The reason is that most of the astronomically large number of possible random-pool sequences are not truly catalytically active, yet they may accidentally survive a particular selection round merely by chance. Only by requiring reproducible catalysis over multiple selection rounds can active ribozyme sequences dominate the selection pool.

A hazard of any selection experiment is that certain nucleic acid sequences may be able to survive even though they do not actually catalyze the desired chemical transformation. There is no general solution to this problem, other than to take great care in designing the selection procedure to avoid giving such opportunistic sequences a means of survival. Occasionally “negative selection” pressure can be applied, in which sequences that catalyze an undesired reaction are intentionally discarded before the remaining sequences are offered the opportunity to catalyze the desired reaction.

Testing the Catalytic Activities of Individual Ribozymes

Once the activity of the pool has reached an acceptable level after multiple rounds, individual ribozymes are cloned (but not yet...
Ribozyme Optimization

After individual catalytically active ribozyme sequences have been identified, a “minimal” ribozyme is often devised by systematically deleting portions of the sequence. Usually this is guided by computer folding algorithms such as mfold (60) that can predict RNA secondary structure with good reliability, particularly for small RNAs. Empirically, it is often found that certain regions of an initially identified ribozyme (such as a large single-stranded loop) can be shortened or even eliminated without damaging catalysis. This is advantageous because smaller ribozymes are easier to synthesize and less likely to suffer out damaging catalysis. This is advantageous because smaller ribozymes are easier to synthesize and less likely to suffer nonspecific degradation, and they are also easier to study mechanistically because fewer nucleotides must have their chemical roles explored. However, as shown with the natural hammerhead ribozyme (61), one must not be overzealous in removing nucleotides that may be catalytically critical. A newer approach to determining a minimal ribozyme motif is to use nonhomologous randomization (typically changing the concentrations of divalent metal ions Mg^{2+} and Mn^{2+}) can intentionally elevate the polymerase error rate considerably, thereby introducing substantial variation during the DNA amplification step. An important consideration is the types of mutations that are made; some conditions favor certain nucleotide changes, whereas other conditions provide more randomness. Instead of altering the polymerase error rate, nonstandard nucleotide triphosphate analogs may be used to promote random mutations during PCR (64).

Second, a selection effort can be restarted from the beginning using a partially randomized sequence pool. In this “reselection” approach, a new pool is prepared by SPS on the basis of a known ribozyme sequence and with an enzyme region that is partially randomized, meaning that a marked asymmetry or mixture of the four nucleotide phosphoramidites is used for each N position. A typical reselection experiment might use a partially randomized pool in which all enzyme region nucleotides have the appropriate nucleotide of the parent ribozyme with 70% probability, or one of the other three nucleotides with 10% probability each. As for consideration of initial random-pool length, the extent to which each nucleotide position is randomized is based on both experience and guesswork. As a guide, one can compute the distribution of nucleotide changes relative to the “parent” sequence for any set values of randomization probabilities (65, 66), thereby knowing how many nucleotides (on average) will be changed relative to the parent sequence.

Continuous Evolution as an Alternative Method

One principal drawback of many conventional in vitro selection procedures is their tediousness, particularly when individual selection rounds are time-consuming. This also limits the number of selection rounds that may be performed. To obviate such issues, investigators have performed “continuous evolution” experiments. In continuous evolution, samples of replicating molecules are diluted serially (e.g., 10^3-fold dilution, often with >100 serial transfers) and at constant temperature (isothermal amplification), rather than selected in discrete rounds and with temperature cycling that is characteristic of PCR. The history of continuous evolution goes back to Spiegelman’s work in the 1960s on Qβ replicase, in which self-replication by minimal nucleic acid sequences was sought (67). More recently, Wright and Joyce broadened the approach of continuous evolution to encompass evolution of catalytic function (68). In one experiment, a continuous evolution approach was used to evolve an RNA ligase ribozyme that is “resistant” to the activity of an RNA-cleaving deoxyribozyme (69). The application of continuous evolution to ribozymes has advantages in terms of both speed and amplification power, but there are disadvantages in terms of susceptibility to contamination and limitations on the types of reactions that may be catalyzed (70).
Multiple Turnover Using In Vitro Compartmentalization (IVC)

An inherent limitation of most selection approaches is the absolute requirement for a covalent linkage between the catalytic nucleic acid and its substrate during selection. Although in many cases the emergent ribozymes can be converted into intermolecular (trans-acting) forms, during the selection process each candidate ribozyme is restricted to two possible chemical yields, 100% or 0%: i.e., each molecule has either performed or not performed the desired chemical reaction. Consequently, selection for multiple turnover is not possible. (In some cases, artificial ribozymes are capable of multiple turnover anyways, but this must be considered as fortuitous.) To alleviate this difficulty, candidate ribozymes have been encapsulated along with unattached substrates within individual droplets in a water-in-oil emulsion. This process is termed in vitro compartmentalization (IVC) (71, 72). If the system is arranged such that each droplet contains just one type of ribozyme candidate, then the encapsulation serves the same conceptual purpose as a covalent bond in terms of linking information (“genotype”; the ribozyme sequence) to catalytic ability (“phenotype”). An IVC strategy has been applied to develop several ribozymes with multiple turnover ability (73, 74).

Fundamental Insights Into Nucleic Acid Catalysis from Artificial Ribozymes

A primary motivation for studying artificial nucleic acid enzymes is to gain insight into natural nucleic acid catalysis. These insights include implications for prebiotic chemistry and the RNA World hypothesis, as well as a fundamental mechanistic understanding of nucleic acid enzymes.

Implications for Prebiotic Chemistry and the RNA World

The RNA World hypothesis posits that before the advent of proteins, there was a period of prebiotic evolutionary history in which RNA both carried information and performed catalysis (75) (see also the WECB review on the origins of life: emergence of an RNA world). Although it is probably impossible to reconstruct a complete RNA World in the modern laboratory, exploring the capabilities of artificial ribozymes can provide information and constraints. For example, the identification of a ribozyme for processive template-directed RNA polymerization (21) provides evidence that relatively small RNA molecules (although they do have hundreds of nucleotides) are capable of catalysis that would have been important in a prebiotic RNA-based era. Many studies have focused on similar considerations (e.g., see References 76 and 77).

Mechanisms of Artificial Ribozymes

Little is known about the mechanisms of most artificial ribozymes. The catalytic rate and other basic features of each new ribozyme are generally determined as part of its initial characterization. Detailed mechanistic analyses are infrequent, although on occasion the tools of physical organic chemistry (e.g., kinetic isotope effects (78)) have been applied. Artificial ribozymes are usually, but not always, selected in the presence of divalent metal ions such as Mg$^{2+}$ or many others (Table 1). Not surprisingly, artificial ribozymes typically require a modest-to-high concentration of such metal ions for their function. The catalytic tasks of these metal ions are often unknown, and a major challenge is to separate the roles of metal ion participation in structure versus catalysis.

For each ribozyme, it is usually possible to identify an appropriate “background” reaction that has a relatively low rate. For an RNA ligase ribozyme, a relevant background reaction is the analogous ligation reaction when the functional groups are held together by a complementary splint that has no enzyme region whatsoever (Fig. 4). The rate enhancements determined for various ribozymes in comparison with suitable background reactions can be low (∼10$^2$), but they can also be as high as 10$^{10}$ (Table 1). Although ribozyme rate enhancements are often modest relative to those of protein enzymes, the appropriate benchmarks are the natural ribozymes, and on this basis, artificial ribozymes compete well with their natural counterparts.

The substantial rate enhancements observed for artificial ribozymes imply that they do more than passively hold together their substrates. Therefore, ribozyme catalysis is more than an “effective molarity” phenomenon. Consistent with this, almost all ribozymes make just one product even when multiple products are possible. For example, although the initially reported RNA ligase ribozymes could potentially have made either 3′-5′ or 2′-5′ linear RNA linkages, each particular ribozyme was observed to make just one linkage (8). Depending on geometrical constraints, effective molarity alone could lead to a mixture of products, which is not observed. In most cases, it is not yet clear whether ribozymes generally work by preferential lowering of transition-state energies or by precise positioning of the reacting molecules.
moieties, i.e., orientation effects. Given that such issues are not yet settled for most of the natural ribozymes [such as the ribosome (79, 81)], mechanistic studies of all kinds of ribozymes will continue to be an active research field.

Structural Biology of Artificial Ribozymes

Most (but not all) natural ribozymes have X-ray crystal structures available, and nuclear magnetic resonance (NMR) spectroscopy has also been extensively applied (see also the WECE Reviews on crystallographic techniques: nucleic acids and on NMR: nucleic acids). Perhaps surprisingly, only two artificial ribozymes have been studied using these methods. First, the Phe-dependent RNA-cleaving “leadzyme” has been examined by both X-ray crystallography (82, 83) and NMR spectroscopy (84, 85). Second, a ribozyme for the Diels–Alder reaction has been studied by X-ray crystallography (86), revealing a pre-formed hydrophobic substrate-binding pocket that is capable of enantioselective catalysis. The application of structural biology methods to understand artificial ribozyme function is a field ripe for increased activity.

Evolving New RNA Catalytic Activities Starting From Known Ribozymes

One interesting issue that is relevant both for a fundamental appreciation of RNA catalysis and for practical applications is to understand the circumstances in which a known ribozyme activity may be evolved to provide a different type of catalysis. In one report, evolving a self-aminoacylating ribozyme into a self-phosphorylating ribozyme required a substantial number of mutations, such that the new ribozyme could adopt a distinct structure (14). This implies that escape from the parent ribozyme’s fold is required for evolution of new activity. Another study found that one designed RNA sequence can adopt either of two different folds, each of which catalyzes a different reaction (87). In nature, bifunctional sequences presumably represented transitional structures for the evolution of one catalytic activity into another. However, most bifunctional sequences would probably not exist today, because they are likely suboptimal for the emergent ribozymes. For example, artificial variants of the hammerhead ribozyme are resistant to ribonuclease due to 2′-amino and 2′-fluoro modifications (88). Increased stability to natural RNA-cleaving enzymes is useful for certain practical applications, particularly in vitro (see below).

Ribozymes with Nucleotides Other Than \( A, G, U, \) and \( C \)

The first in vitro selection effort with nonstandard nucleotides identified RNA that catalyzes the Diels–Alder reaction (23, 24). In this work, a pyridine-modified uridine derivative replaced all uridines throughout the RNA. The pyridine moieties were presumed to assist catalysis by some combination of hydrogen bonding, hydrophobic and dipolar interactions, and metal coordination. Most of the new ribozymes were strictly Cu(II)-dependent, suggesting a role for Lewis acid catalysis. Other artificial ribozymes with nonstandard nucleotides (each of which has an unmodified Watson–Crick face that permits use with T7 RNA polymerase and reverse transcription) include an RNA ligase ribozyme with N6-amino-modified adenosines (11), amide syntheses ribozymes that incorporate 5-imidazolyl-U (34), and a urea syntheses ribozyme that also incorporates 5-imidazolyl-U (35). One of the most intriguing artificial ribozyme activities is the ability to induce palladium nanoparticle crystallization using pyridine-modified uridine nucleotides (49). The various ribozymes create different crystal shapes such as hexagonal plates versus cubes, and they require the pyridine-bearing RNA nucleotides for their activities (50). Presumably the pyridines interact directly with metals during crystal formation. Such ribozymes present an intrinsic mechanistic challenge due to the heterogeneous nature of their reaction.

Incorporating nonstandard RNA nucleotides into a selection effort can enhance the chemical (or biochemical) stability of the emergent ribozymes. For example, artificial variants of the natural hammerhead ribozyme are resistant to ribonuclease due to 2′-amino and 2′-fluoro modifications (88). Increased stability to natural RNA-cleaving enzymes is useful for certain practical applications, particularly in vitro (see below).

Ribozymes with Fewer Than Four Kinds of Nucleotide: Minimal Informational Systems

In the opposite of adding nonstandard functional groups to RNA’s chemical repertoire, ribozymes having three or fewer kinds of nucleotide have been investigated. In one study, RNA ligase ribozymes were identified that exclude cytidine (C) from the enzyme region (89). When one such ribozyme was re-selected with inclusion of C, the catalytic rate improved about 20-fold (90), providing a quantitative measure of the importance of variety in ribozyme components. Going to the extreme, an RNA ligase ribozyme was identified that uses only two different nucleotides—a binary informational system (91) comprising only uridine (U) and 2,6-diaminopurine (D) nucleotides (Fig. 5). This ribozyme was inefficient, with only about 8% ligation yield in 80 h at pH 9.0 and 23°C (4.0 × 0.05 h−1). Nevertheless, its activity demonstrates that a dramatically minimized and biologically related informational system can encode catalysis. Such types of ribozymes could have been relevant in an RNA World, at a point in time when only one base pair had evolved.
Practical Synthesis of Ribozymes

For practical synthesis of a ribozyme, two options are generally available. The first method is SPS, which is readily available to nonexperts via several commercial sources and via some academic service facilities. When nonstandard RNA nucleotides are desired, SPS is generally the best approach. The second method is in vitro transcription from a DNA template (59), which in most cases is limited to the four standard RNA nucleotides. A new method (albeit one that requires organic synthesis of the components of a nonstandard base pair) allows enzymatic transcription of RNA with unnatural nucleotides (92).

In Vitro Selection of Deoxyribozymes

Many considerations that are important for ribozymes also apply to deoxyribozymes, which differ solely by the lack of a 2′-hydroxyl group at each nucleotide. Natural DNA is almost always found in double-stranded form, which is structurally uniform and does not support catalysis. In contrast, artificial deoxyribozymes are largely single-stranded, and their conformational flexibility allows catalytic activity. Because RNA already seems to have a paucity of functional groups relative to proteins, early speculation was that the lack of a 2′-hydroxyl would render DNA catalytically inferior to RNA (93), if not altogether incompetent. Nevertheless, experiments have shown that DNA is quantitatively as functional as RNA in terms of catalysis. This is particularly evident when comparisons are made between RNA and DNA enzymes that catalyze the same type of reaction. For example, deoxyribozymes that cleave RNA are at least as competent as analogous ribozymes, if not better (94). This similarity between RNA and DNA may relate to common classes of mechanisms. Evidence increasingly suggests that ribozymes often rely on acid-base catalysis involving the nucleobases (95), which are present in both RNA and DNA. Combining this observation on catalysis with the finding that both RNA and DNA aptamers are highly competent for binding to ligands (96), it is unsurprising that the lack of 2′-hydroxyl groups on DNA is still compatible with its catalytic activity.

Scope of Deoxyribozyme Catalytic Activities

To date, many fewer types of reactions have been explored with deoxyribozymes than ribozymes. This reflects both the later discovery of DNA catalysis and possibly the greater fundamental appeal of RNA catalysis as more relevant to the RNA World hypothesis. Nevertheless, when they have been examined, deoxyribozymes have proven quite competent catalytically (Table 2) (97–122). This extends not only to the types of reactions that have been investigated but also to important characteristics such as rates. For example, the RNA-cleaving 10–23 deoxyribozyme can achieve a kcat of 10 min⁻¹ (rivaling natural ribozymes) and a kcat/Km of 10⁵ M⁻¹ min⁻¹, which is higher than that for the protein enzyme ribonuclease A (97).

Other Considerations for Deoxyribozymes

The same experimental selection approaches that are used for ribozymes are generally applicable to deoxyribozymes. For deoxyribozymes, there is no need to transcribe a sequence pool from DNA to RNA and then reverse-transcribe the successful RNA back into DNA for amplification during each selection round. Instead, the DNA is both the information and the catalyst throughout the selection process. Mechanisms of deoxyribozymes have been probed even less often than for ribozymes; in general, much work remains to understand how DNA catalyzes reactions. Intriguingly, one RNA-cleaving deoxyribozyme uses ascorbate as a cofactor (116) and another uses histidine (123), indicating that nucleic acid enzymes can use cofactors to expand their limited functional group repertoire. Structural biology efforts have also been very modest for deoxyribozymes. In the sole published experiment, the 10–23 deoxyribozyme crystallized in a catalytically inactive 2:2 stoichiometry complex with its RNA substrate (124). Although this was an interesting four-way structure with implications for understanding Holliday junctions, it highlights the need for future efforts to understand the structure of catalytic DNA.

Structural data on DNA aptamers show that they can form ligand-recognition motifs that resemble their RNA counterparts, even without 2′-hydroxyl groups (125).

NOTES: See Table 1 legend for description of column headings.

As for ribozymes, several deoxyribozymes that incorporate nonstandard DNA nucleotides have been identified. For example, an RNA-cleaving deoxyribozyme with three imidazole functional groups has been obtained (100); other examples include RNA-cleaving deoxyribozymes that have both imidazole and amine nonstandard functionalities (101, 102). DNA can be completely modified by incorporation of solely nonstandard nucleotides during PCR (126). This suggests that future efforts should be able to expand considerably the use of chemically modified DNA for in vitro selection. A different purpose of nonstandard nucleotides is for regulation of catalytic activity. For example, appending an azobenzene moiety onto an RNA-cleaving deoxyribozyme allows the catalytic activity to be switched photochemically (127, 128).

An interesting conceptual question is whether a ribozyme and deoxyribozyme can be active with the same nucleotide sequence (with, of course, the U nucleobases of RNA replaced with T in DNA). In one study in which a deoxyribozyme with hemin-dependent peroxidase activity was identified, exchanging all DNA for RNA reduced but did not destroy the catalysis (129). More recently, a selection approach was used to convert a known ribozyme sequence into a deoxyribozyme (130). Curiously, this deoxyribozyme was nonfunctional when made as either RNA or DNA is intriguing for its implications regarding “crossover” between two types of informational macromolecule.

For practical synthesis of deoxyribozymes (i.e., single-stranded DNA), SPS is the typical approach. If nonstandard nucleotides must be incorporated, SPS is generally the sole viable approach. In contrast, for DNA containing only the four standard nucleotides, conventional PCR may be used. If so, a main challenge is to separate the desired single-stranded DNA product from its complement. This may be achieved by using one primer with a nonamplifiable 5'-tail, such that the two product strands are of unequal length and therefore separable by PAGE (131). Asymmetric PCR that includes only one primer may instead be applied (132), although because DNA synthesis is linear and not exponential in this process, only a limited amount of single-stranded DNA can be generated. As another option, methods have been described for taking advantage of biotin-streptavidin technology to isolate single-stranded DNA from conventional PCR reactions (133, 134).

Terminology for Nucleic Acid Enzymes

An alternative definition of “nucleic acid enzyme” is a protein enzyme that modifies nucleic acids, e.g., T4 polynucleotide kinase (T4 PNK) for phosphorylation of RNA and DNA. Unfortunately, the term “nucleic acid enzyme” can therefore refer either to ribozymes and deoxyribozymes or to protein enzymes.
that modify RNA and DNA. In practice, both definitions of nucleic acid enzymes are used by different groups of authors, and the intended meaning must be gleaned from context.

Occasionally, the term “RNA enzyme” is used as a synonym for ribozyme. In contrast, the contraction “RNAz” is rarely used, perhaps because “ribozyme” is approximately the same length and is just as simple to write. Similarly, “DNAz” is often used as a synonym for deoxyribozyme. The contraction “DNAzyme” is used by some authors to replace the polysyllabic “deoxyribozyme.” However, there is often confusion about the capitalization (i.e., DNAzyme, dNAzyme, or DNAzyme), with only the first of these variants generally considered proper.

RNA and DNA molecules with catalytic activity are related to aptamers. Ribozymes and deoxyribozymes bind to their substrates and catalyze chemical reactions, whereas RNA and DNA aptamers simply bind to their ligands (135, 136). Aptamers are most commonly identified by a procedure originally termed “systematic evolution of ligands by exponential enrichment” or SELEX (135). SELEX is a form of in vitro selection, but not all in vitro selection is SELEX. In particular, SELEX is not generally used to identify nucleic acid enzymes—note the word ligands (not catalysts) in the full form of the acronym. Therefore, except when SELEX is performed on a transition-state analog, RNA and DNA catalysts are identified by “in vitro selection.”

One relatively subtle but important distinction for identifying catalytic nucleic acids is the difference between screening in vitro and in vitro selection. In a screen, all candidates (such as small-molecule compounds from a combinatorial library) are surveyed individually for a desired property. This requires an efficient screening procedure, which for small-molecule combinatorial chemistry often involves multi-well plate experiments or miniaturized systems that allow parallel examination of thousands of spatially segregated samples. (See also the WECB reviews on screening of chemical libraries and on high-throughput screening.) However, statistical considerations for nucleic acid enzymes—e.g., 10^15 sequences examined in a single experiment—obviate any realistic possibility of screening individual sequences one at a time. Instead, selection approaches must be used. The distinguishing feature of a nucleic acid enzyme selection is that a successful candidate sequence must survive through a stringent experimental step based on its catalytic ability. Even though most random-pool sequences have no catalytic activity, the sequences that are functional emerge due to their immense selective advantage, magnified over multiple selection rounds.

Finally, for in vitro experiments, the difference between “selection” and “evolution” is that evolution requires the introduction of variation after the start of the experiment. In many selection procedures, all variation is present within the random region of the initial pool at the outset of the experiment. Because such procedures merely serve to discard inactive sequences and retain active ones without introducing new variation, they are in vitro selection and not in vitro evolution. In contrast, when variation is introduced intentionally by mutagenic PCR or by restarting the experiment with a partially randomized pool, in vitro evolution is being performed.

**Practical Applications of Nucleic Acid Enzymes**

As the field of artificial nucleic acid enzymes continues to develop, attention has increasingly turned from conceptually oriented experiments to those with more immediate practical utility. Ribozymes and deoxyribozymes have been used for analytical, biochemical, biological, and chemical applications. In addition to several specific applications that are described below, ribozymes and deoxyribozymes have been used for many additional purposes in biochemistry, nanotechnology, and even molecular computation (94).

**In Vitro Engineering of Signaling Ribozymes and Deoxyribozymes as Analytical Sensors**

Analyte detection is one of the primary research motivations in many disciplines. Numerous efforts have focused on nucleic acid enzymes as the basis for sensors (see also the WECB review on biosensors). One of the most productive approaches combines in vitro selection with rational design to create allosteric nucleic acid enzymes. In such a case, catalytic activity is regulated by binding of a small-molecule ligand remote to the catalytic site in a modular fashion (Fig. 6b). Many artificial allosteric ribozymes have been identified, such as several hammerhead ribozyme variants (Fig. 6b) (137–141). Additional work has shown that nuanced behavior such as responsiveness to more than one ligand is possible (142), as is catalysis that is regulated by oligonucleotides (143–145). Laboratory exploration of allosteric ribozymes presaged the discovery of riboswitches, which are naturally occurring RNA regulators of gene expression that generally function by allosteric mechanisms (146). Allosteric deoxyribozymes may be even more practical than their ribozyme counterparts, due to the increased chemical and biochemical stability associated with DNA. A small number of deoxyribozymes have been reported that use various strategies to achieve allosteroy (147–150).

Many systems have been engineered specifically to optimize their practical signaling properties, often on the basis of regulated RNA cleavage activity. Liu et al. have developed deoxyribozyme sensors for metal ions and small organic molecules whose sensing ability is based on fluorescence or colorimetric signals (Fig. 6c) (151–154). Li et al. placed a fluorophore and a quencher close together on the substrate, thereby identifying new RNA-cleaving deoxyribozymes that synchronize fluorescence signaling with catalysis (Fig. 6d) (147) and collectively function at a wide range of pH values (155). These deoxyribozymes are advantageous because they were developed specifically to cleave the fluorophore-containing substrate, and therefore catalysis is optimal with the substrate that is directly relevant to sensing applications. Two research groups (156, 157) have placed ribozymes into arrays that offer the potential for investigating complex biochemical phenomena such as gene expression patterns.
In Vitro Selection and Application of Nucleic Acid Enzymes (Ribozymes and Deoxyribozymes)

Figure 6. Artificial ribozymes and deoxyribozymes as sensors. (a) Schematic depiction of an allosterically regulated nucleic acid enzyme. (b) Examples of allosterically controlled hammerhead ribozymes that cleave RNA in response to binding of the depicted ligands (137, 139); other examples are known (140, 141). The communication modules are highlighted in gray. (c) Example of a signaling ribozyme that is sensitive to adenosine binding with a colorimetric response due to gold nanoparticle dissociation (153). (d) Example of a signaling deoxyribozyme that synchronizes ligand (ATP) binding and catalysis with a fluorescence response (147).

Cleavage of RNA In Vitro and In Vivo by Deoxyribozymes

RNA-cleaving deoxyribozymes have been particularly useful as in vitro laboratory reagents for RNA cleavage (94). Because such deoxyribozymes bind to their RNA substrates via extensive Watson–Crick base pairs (e.g., 10–23 deoxyribozyme in Fig. 2), selectivity for the substrate sequence is an inherent part of each interaction. With the development of a nearly complete collection of related RNA-cleaving deoxyribozymes (158), it is now possible to cleave almost any desired RNA target sequence with an appropriate DNA enzyme. In some experiments, the secondary structure within the RNA target can interfere with binding of the deoxyribozyme. Measures to improve the RNA–DNA interactions by chemical modification of the DNA can enhance the cleavage yield (159), as can inclusion of “disruptor” oligonucleotides that interfere with the target’s secondary structure. DNA is not susceptible to the cellular ribonucleases that quickly destroy RNA. Due to this stability and to other advantages in cost, toxicity, and potency, deoxyribozymes are particularly useful for in vivo mRNA cleavage (see summary in Reference 94), although chemically modified ribozymes may also be employed (160). Such approaches using nucleic acid enzymes are a valuable counterpart to other mRNA-targeting strategies, most notably the application of small interfering RNA (siRNA) or antisense oligonucleotides (see also the WECB reviews on gene silencing techniques and on the chemistry of small interfering RNAs).

RNA Ligation by Deoxyribozymes: Synthesis of Linear and Branched RNA

Several studies from the Silverman research group have identified deoxyribozymes that ligate two RNA substrates. Several deoxyribozymes join an RNA 3′-hydroxyl group with an RNA 5′-triphosphate, forming a native 3′–5′ linear RNA linkage (105). Synthesis of RNA incorporating internal chemical modifications often requires ligation of two or more fragments (see also the WECB review on labeling techniques: nucleic acids). Therefore, RNA ligation deoxyribozymes should be an important alternative to methods such as “splicing ligation” using T4 DNA ligase (161), which often does not work well in particular systems. Other deoxyribozymes create 2′,5′-branched RNA or lariat RNA by mediating the reaction of an internal RNA 2′-hydroxyl group with a 5′-triphosphate (108, 111). In addition to the very high site-selectivity exhibited by these deoxyribozymes (which
is interesting in a fundamental sense), the branched RNA products can be applied to enable biochemical experiments that would otherwise be impossible (162).

**Catalysis of Bimolecular Small-Molecule Reactions by Ribozymes and Deoxyribozymes**

A particularly desirable yet challenging goal is to identify nucleic acid enzymes that mediate bimolecular reactions between two small molecules, i.e., when the substrates are not themselves nucleic acids. For this purpose, no substrate should be covalently attached to RNA or DNA. Very few nucleic acid enzymes have been identified by selection for binding to a transition-state analog (Tables 1 and 2), the resulting catalysis requires no covalent attachment to the substrate. However, in most selections for small-molecule catalysis, one substrate is tethered covalently to the RNA or DNA. This tether can be very short (17, 20, 28, 30), or a long flexible tether such as PEG can be used to mimic a substrate free in solution (25, 34, 35, 73). In either case, most of the resulting nucleic acid enzymes are nonfunctional when the substrate lacks the tether. Indeed, for only two types of in vitro-selected nucleic acid enzymes has catalysis of small-molecule chemistry been achieved with no tethering whatsoever (in trans). First, an RNA capping ribozyme is active when the reacting nucleotide is not attached to the remainder of the ribozyme (17). Second, several Diels–Alder ribozymes (25, 26, 73) are active when the PEG tether that links the anthracene substrate to an oligonucleotide is absent. These limited examples are insufficient to draw general conclusions about what is necessary to achieve bimolecular catalysis of small-molecule reactions by nucleic acid enzymes.

**Perspective on Artificial Ribozymes and Deoxyribozymes**

As noted by Joyce, in the arena of nucleic acid enzymes, “you get what you select for... and sometimes a whole lot more” (163). (Battled-hardened experimentalists might add, “...but if things don’t work, a lot less.”) Currently, the study of artificial ribozymes and deoxyribozymes is just under 20 years old and about to leave behind its teenage years. The original motivation to study nucleic acid enzymes was for the fundamental purpose of exploring the scope of nucleic acid catalysis. Artificial ribozymes and deoxyribozymes have already offered substantial insight into such catalysis, and we may expect additional success from ongoing research in this area. As more types of reactions well beyond nucleic acid cleavage and ligation are increasingly the goal of artificial nucleic acid enzymes, including efforts toward catalysis of small-molecular reactions, a practical and important question is to decide what are the most appropriate reactions to be targeted by RNA and DNA catalysis? Which reactions truly need nucleic acid catalysts, and how can nucleic acid enzymes be developed as practical chemical reagents? In contrast, what reactions are best performed by other catalysts such as protein enzymes or more traditional organic and organometallic catalysts? The responsibility falls to those of us working actively on selection experiments to develop and demonstrate the synthetic utility of ribozymes and deoxyribozymes for the broader chemical biology community. In parallel with these considerations, elegant experiments have already shown that practical applications such as analytical sensing can be accomplished in spectacular fashion using nucleic acid enzymes. Such techniques will surely be refined and extended in the near future.

Locked Nucleic Acids

Zenia M. Starling and Troels Koch, Santaris Pharma A/S, Hørsholm, Denmark
doi: 10.1002/9780470048672.wecb516

The intensive research and development of antisense oligonucleotides in the past decades has refined our knowledge of this class of molecules, and they are now recognized as potent reagents for gene-target validation and therapeutic uses. Within this field, a very promising class is locked nucleic acid (LNA). In recent years, the number of applications for LNA in basic research, molecular diagnostics, and therapeutics has expanded continuously. In this article, the general biophysical, biochemical, and pharmacological properties of LNA will be summarised. The ability of LNA oligonucleotides to target both coding and noncoding RNAs effectively and specifically via different modes of action will be discussed. Several LNA oligonucleotides have completed preclinical toxicology and are now tested in clinical trials. The status of one drug candidate will be presented briefly at the end of the article.

Background

Native oligonucleotides cannot be used as active antisense reagents and therefore in the history of antisense, a variety of chemically modified nucleotides has been developed to improve properties such as target affinity, nuclease resistance, and pharmacokinetics of the oligonucleotides. The first generation of chemically modified antisense drugs was the phosphorothioates (PSs). The phosphorothioate internucleoside link showed improved nuclease stability and bioavailability, but it resulted in lower RNA affinity. To compensate for that, the length of PS was kept rather long and 18–20-mers were frequently used. This is significantly longer than the antisense principle requires for specific mRNA recognition. The ideal antisense reagent ought not to be longer than required for specific mRNA recognition which is dependent on sequence typically 12–16-mers. However, PSs have been used extensively to inhibit mRNA targets in vitro, but the combination of a relatively low target affinity and limited nuclease stability reduce the in vivo potential of PS via specific antisense mechanisms. On the contrary, the therapeutic significance of PS is high in combination with other chemical modifications (see below) or via their mode of action other than classical antisense.

The second-generation antisense drugs are represented classically by the nucleotides where the 2′ position has been modified. Examples of this class are the 2′-O-Me, 2′-O-MOE, and 2′-F-modified nucleotides (Fig. 1). By incorporating these modifications into oligonucleotides, the affinity was improved—compared with the PSs—but to get sufficient potency and efficacy, the length of the second-generation antisense drugs was unchanged compared with the first generation (18-20-mers) drugs illustrating that the second-generation antisense oligonucleotide did not increase the affinity adequately.

Locked Nucleic Acid (LNA) was presented in 1998. LNA represents a true member of the third generation of antisense drugs. When LNA nucleotides were incorporated into oligonucleotides, they induced the highest binding affinity for both complementary RNA and DNA reported in the field (2). This opened completely new perspectives for the development of antisense drugs. The remaining part of this article will focus on LNA and its therapeutic aspects.
Locked Nucleic Acids

Biophysical Properties of LNA

LNA oligonucleotides obey Watson-Crick hydrogen bonding rules and form right-handed helices, and actually the most intriguing property of the LNA nucleotide is that it fits perfectly in the Watson-Crick framework. LNA nucleotides can be included in any combination with DNA/RNA nucleotides, and any analog thereof that fits within the Watson-Crick framework. The immediate property described for LNA was an extraordinary high affinity (2)—a property later confirmed in numerous papers and recently reviewed (7). When LNA monomers are incorporated in either DNA or RNA each residue adds to affinity in an additive manner. insertions of few LNA-ribonucleotides lead to increase of melting temperature (T_m) of 6-7 °C per modification; however, the largest increase is observed when LNA nucleotides are included in PS, which provides a record high increase of 9-10 °C per modification (8). This feature of LNA is unique because PS modification is known to reduce the affinity of DNA and 2'-modified oligonucleotide analogs. However, when PSs are used as internucleoside link in LNA oligonucleotides affinity is almost not affected and therefore, the affinity of LNA diesters and LNA PSs is almost the same.

The affinity increase per LNA modification is the greatest when only few LNA nucleotides are incorporated into oligonucleotides because LNA nucleotides direct the conformation of nearby desoxyribose-nucleotides to attain a greater degree of the high affinity North conformation. Therefore, the affinity increase is driven by both the LNA nucleotides and the North-directed DNA nucleotides. Fully modified LNA oligonucleotides—with no RNA nucleotides—do have the highest affinity, but the affinity per LNA modification is lower. This unique property of LNA is called "structural saturation." Structural saturation is a very important property of LNA because only a few LNA modifications can transform the entire oligonucleotide into a high-affinity structure.

The high affinity of LNA makes it possible to design shorter antisense oligonucleotides with retained high potency, and it means that the "hit rate" of LNA antisense oligonucleotides designed to complement different sequences along the mRNA are greatly compared with traditional antisense chemistries (9). This finding indicates that the lead identification process in drug discovery becomes faster and that fewer LNA antisense oligonucleotides are needed to find highly potent mRNA binders.
LNA Oligonucleotide Designs

LNA and most LNA-analogs can be mixed in any combination with nucleic acids and analogs. Depending on the application of LNA, the design may be divided in five categories: mixmer, gapmer, headmer, tailmer, and fully modified (Fig. 3, a–e). In the mixmer, the LNA residues are dispersed along the sequence of the oligonucleotide (a), whereas in the gapmer two continuous LNA segments are attached in the 5′- and 3′-ends of a central nucleic acid fragment (b). A headmer is a continuous nucleic acid fragment with a continuous LNA segment in the 5′-end (c) and vice versa for a tailmer (d). The fully modified LNA oligonucleotide is self-explanatory (e) (Fig. 3).

The length and specific design, however, may vary depending on the intended use and on how important the affinity, nuclease resistance, and the RNase H/RISC recruitment (see below) is for the proposed application. In the classic designs described above, the total length of LNA oligonucleotides is 16 mers, and the oligonucleotides are fully PS-modified.

In conclusion, freedom of design offered by LNA has enabled the development of LNA oligonucleotides with the ability to target both coding and noncoding RNAs effectively and specifically in vivo, using different modes of action, such as target cleavage, steric block of translation and inactivation by sequestration.

Biochemical Properties of LNA

Nuclease resistance

One important aspect of antisense technology is the stability of antisense agents against extracellular and intracellular endonucleases and exonucleases. A series of studies has investigated the serum and nuclease stability of LNA-modified oligonucleotides, and the studies have shown that incorporation of LNA segments into oligonucleotides increases their stability against nucleases. It is the number and the position of the LNA residues as well as insertion of other stabilizing entities—such as PSs—that determines the rate of degradation of the oligonucleotides. For example, a single LNA residue at the 3′-end is not sufficient to increase stability substantially against exonucleolytic attack, whereas one LNA residue at the 3′-penultimate position or two LNA modifications at the ultimate position of the 3′ end efficiently stabilize against 3′-endonucleases (10, 11). An effective way to secure exonucleolytic protection is obtained with the gapmer design, but the central DNA segment is sensitive to endonucleolytic activity. If the central DNA segment becomes longer than four nucleotides, then cleavage starts to occur and the cleavage rate increases as the DNA segment increases.

A preferred way to protect degradation of the central DNA segments is to use PS internucleoside links. The PS link is easy to introduce during LNA synthesis and it serves as a substrate for RNase H (see below). A series of fully PS-modified gapmers with gap-sizes that range from 9 to 11 PS links have been examined in human and rat plasma and they showed no sign of endonucleolytic activity (7). Fully modified LNA is essentially resistant to exonucleolytic and endonucleolytic degradation either with fully diester or PS internucleoside links (11).

RNase H recruitment

It is well established that oligonucleotides targeting mRNA are most potent if they are designed to recruit RNase H. Under normal circumstances, this enzyme cleaves mRNA hybridized to a DNA complement. Nevertheless, because LNA nucleotides adopt an RNA-like structure, they cannot recruit RNase H. However, LNA gapmers, which contain a stretch of DNA—or PS—nucleotides, can recruit RNase H. More specifically, several studies have investigated various LNA/DNA gapmers and concluded that a gap of six DNA nucleotides is necessary for initiating RNase H activity, and that a gap of seven DNA nucleotides allows for high RNase H activity (11–14). The conclusion is that antisense LNA oligonucleotides can be designed to elicit RNase H activity while still containing LNA monomers for improved binding and target accessibility (15). Furthermore, it has been shown that the highest activity was observed if the entire LNA gapmer was phosphorothioate (not just the DNA segment) (11).

LNA Applied In Vitro

Most antisense experiments made with LNA have been focused mechanistically on mRNA inhibition by RNase H recruitment (7). Expression studies in a wide variety of human epithelial and cancer cell lines are made and the overall picture of these experiments is that LNA antisense oligonucleotides are very potent with IC₅₀ values for mRNA inhibition obtained frequently in the low to sub nanomolar range—and actually more potent than competing oligonucleotide analogs (7).

The potency of LNA oligonucleotides is related to the design of the oligonucleotide and to the target site. Several studies have found that the gapmer design is slightly more potent than the mixmer design, in which inhibition of mRNA in the translational start site is required (7). However, when the target site is in the coding region, the gapmer design is superior (16).
This finding is caused by the fact that a high-affinity LNA oligomer can prevent ribosome binding to mRNA and thereby stop translation initiation; but once the ribosome is bound and initiates translation, mRNA has to be cleaved by RNase H to stop its action (17). LNA gapmers have been used intensively in cellular-based assays to inhibit mRNA expression. This work has been reviewed recently (7), and the conclusion is that LNA gapmers ranging from 12–16mers inhibit gene expression with IC₅₀ values in the low to sub-nanomolar range (18).

Another mechanistic action for mRNA inhibition is a non-RNase H based mechanism in which the LNA antisense oligonucleotide acts via very tight binding to the mRNA and thus, interferes with its additional processing. This mechanism is called "steric block." Steric block includes prevention of ribosome binding by blocking the 5'-UTR that acts as a "road block" during translation by binding to the message or by redirection of splicing sites to alter the production of splice variants (19). When antisense oligonucleotides act according to this mechanism, the mRNA remains intact. LNA oligomers have been used effectively as steric blocks to inhibit the expression of several therapeutically interesting targets for instance inhibition of viral replication (11,20) and redirect splicing in samples from patients with Duchenne muscular dystrophy (21,22).

Pharmacology

Currently, pharmacological activity of LNA antisense oligonucleotides has been demonstrated in many different tissues (liver, kidney, colon, jejunum, small intestine, lung, spleen, and brain) and species (mice, rats, and monkeys) using a variety of administration routes (subcutaneous infusion, intravenous injection, intraperitoneal injection, and direct injection into brain) (7). Using different designs of LNA oligonucleotides, it has been possible to target both mRNAs and noncoding miRNAs effectively (see below), which causes either a reduction in protein synthesis, a shift in the splicing pattern, or inactivation by biochemical sequestration.

The pharmacological effect of LNA oligonucleotides depends on biodistribution and cellular uptake of the LNA and LNA-analog oligonucleotides. Biodistribution studies have shown equal uptake of LNA and ω-LNA, except in kidneys, where the uptake of ω-LNA is greater than for LNA. Amino- and thio-LNA have increased uptake in liver, whereas the amino-LNA has the broadest distribution showing significantly greater uptake in heart, lung, muscle, and bone compared with other analogs (23). Once absorbed by tissues, LNA oligonucleotides are taken up by cells by internalization, and a strong relationship between tissues uptake and endogenous effects have been demonstrated (7).

The first in vivo antisense experiment with LNA-antisense involved two different 15-mer LNA designs that target the delta 16-mer LNA, which targeted the RNA polymerase II gene product, inhibited tumor growth in mice at low doses (less than 5 mg/kg/day) and was tolerated well (24). Since these early studies, the pharmacological properties of LNA have been documented in numerous publications. Many improvements have been made, and the LNA oligonucleotide design and how LNA oligonucleotides interact with the intracellular molecular machinery are better understood. The conclusion of these works is that pharmacological relevant doses of LNA range typically from 0.5-5 mg/kg, and that the oligonucleotides are generally well tolerated (7).

An interesting observation is that the pharmacological potential can be increased with reduced size of the LNA oligonucleotides. A shorter design (oligonucleotides shorter than 16-mers) has been used to inhibit ApoB-100 expression in liver and jejunum. ApoB-100 is the major cholesterol-carrying protein in low-density lipoprotein (LDL) and plays a central role in cholesterol metabolism and atherosclerosis. The study showed that 12-14mers reduced the target expression with 80-90% where a reduction of only 30-40% was seen with the 15 and 16mers. The reduction in ApoB-100 expression was followed almost linearly with reduction in plasma cholesterol levels (25). These data suggest that use of shortmers may become a new approach for systemic gene targeting with significantly improved pharmacological effects.

Inhibition of MicroRNA

MicroRNAs (miRNAs) are an abundant class of short endogenous noncoding RNAs that act as posttranscriptional modulators of gene expression. To date, more than 5000 miRNAs have been identified in invertebrates, vertebrates, and plants according to the miRBase miRNA database release 10.0 in August 2007. Growing evidence shows that miRNAs exhibit a wide variety of regulatory functions and exert significant effects on cell growth, development, and differentiation.

A major obstacle to specific and sensitive detection of mature miRNAs in animals is their small size (~19-23 nucleotides). Endlabeled LNA-probes, in which every third position is an LNA residue, have been used in Northern blot analysis to detect miRNAs with high specificity and showing at least 10-fold increased sensitivity compared with DNA probes (26), which is a major achievement in miRNA research. Furthermore, LNA probes with uniform Tₘ values of 72°C have been used in high-sensitivity arrays for miRNA expression profiling (27).

Such arrays allow discrimination between single nucleotide variations as demonstrated by the specific discovery of related miRNA family members. LNA probes have been used successfully to enhance the sensitivity and specificity of in situ hybridizations to miRNAs in zebrafish (28,29) and in human brain (30).

The expanding list of human miRNAs along with their highly diverse expression patterns and high number of potential target miRNAs suggest that miRNAs are involved in a wide variety of human diseases. Perturbed miRNA expression patterns are reported in many human cancers (31), and more than 50% of the human miRNA genes are located in cancer-associated genomic regions or at fragile sites (32).
Several studies have shown that LNA oligonucleotides can be used to inhibit miRNA function specifically and effectively (LNA-anti-miRs). One study showed inhibition of miR-21 activity with an LNA gapmer that leads to induction of apoptosis in glioblastoma cell lines, which illustrates that aberrantly expressed miRNAs can function as oncogenes (33). Another study showed inhibition of the bantam miRNA in Drosophila by a complementary LNA-modified oligonucleotide resulting in sequence specific derepression of Hid protein synthesis in cell culture (34). Recent findings by Elmén et al. (35) show that high-affinity antagonism of the liver-specific microRNA 122 (miR-122) in mice, by steric hindrance using LNA-anti-miRs, can result in potent functional inhibition. This finding suggests that oligonucleotides composed of LNA may be valuable tools for identifying miRNA targets in vivo and for studying the biological role of miRNAs and miRNA-associated gene-regulatory networks in a physiological context. In addition, the high metabolic stability of LNA-anti-miRs, caused in part by increased nuclease resistance, their small size and apparent lack of acute toxicity or changes in liver morphology (35), imply that LNA-anti-miRs may be well suited as a novel class of potential therapeutics for disease-associated microRNAs.

Three other LNA-based compounds are at preclinical development studies. ENZ3042 is a specific inhibitor of survivin, which plays a vital regulatory role in both apoptosis and cell division. Survivin is overexpressed heavily in many cancers and in newly formed endothelial cells engaged in angiogenesis but almost absent in normal adult differentiated tissue. Clinically, survivin expression is associated with poor prognosis, increased cancer recurrence, and resistance to therapy. The compound therefore has the potential to improve the response to therapy in a wide variety of malignant solid tumors. SPC3833 is in preclinical development and it is designed to effectively affect the expression of apolipoprotein B100 (ApoB100). The drug effectively down-regulate ApoB100 synthesis leading to a reduction of VLDL secretion from the liver. The down-stream effect of this is that SPC3833 efficiently lowers LDL and cholesterol levels (37). Finally, SPC3649 is the first LNA oligonucleotide developed as a microRNA inhibitor. SPC3649 is a lead candidate targeted to the liver-specific microRNA-122. The LNA anti-miR is developed for treatment of Hepatitis C and hypercholesterolemia and is expected to commence human clinical pharmacology and safety studies in 2008.

LNA Drugs in Clinical and Preclinical Development

In 2006, the LNA oligonucleotide SPC2996 completed its first human clinical trial, which was a Phase I/I study in patients with chronic lymphocytic leukemia (CLL). SPC2996 acts by inhibiting the synthesis of B-C1, which is a key sensor protein that protects cells against apoptosis. The protein is expressed in most cancers including CLL, and high expression levels have been firmly correlated with low response rates, resistance to chemotherapy, faster time to relapse, and shorter survival time (36). Thus, downregulation of B-C1 expression provides an attractive means by which CLL and other cancers can be resensitized to natural apoptotic stimuli and to chemotherapeutic agents that provoke apoptosis.

The results of this study are encouraging for such an early stage trial. All patients who received the top dose of the drug had a rapid reduction in the number of cancerous white blood cells in circulation, and expression of B-C1 was reduced with 33% as measured by qPCR in total blood RNA.

The results of this first human clinical trial provide the basis for additional development of SPC2996, and it underlines that repeated doses of the drug can be administered safely.

The second LNA oligonucleotide that entered a human clinical Phase I/I trial in patients with solid tumors is ENZ2968—a potent inhibitor of HIF-1α. HIF-1α serves as the key sensor of cellular hypoxia in response to which it transcriptionally upregulates a host of genes that play important roles in promotion of cancers, which include angiogenesis, apoptosis, cell migration, and metastasis. HIF-1α is essentially undetectable in normal cells, but it reaches high intracellular concentrations in a variety of cancers in which it is correlated strongly with poor prognosis and resistance to therapy.

Three other LNA-based compounds are at preclinical development studies. ENZ3042 is a specific inhibitor of survivin, which plays a vital regulatory role in both apoptosis and cell division. Survivin is overexpressed heavily in many cancers and in newly formed endothelial cells engaged in angiogenesis but almost absent in normal adult differentiated tissue. Clinically, survivin expression is associated with poor prognosis, increased cancer recurrence, and resistance to therapy. The compound therefore has the potential to improve the response to therapy in a wide variety of malignant solid tumors. SPC3833 is in preclinical development and it is designed to effectively affect the expression of apolipoprotein B100 (ApoB100). The drug effectively down-regulate ApoB100 synthesis leading to a reduction of VLDL secretion from the liver. The down-stream effect of this is that SPC3833 efficiently lowers LDL and cholesterol levels (37). Finally, SPC3649 is the first LNA oligonucleotide developed as a microRNA inhibitor. SPC3649 is a lead candidate targeted to the liver-specific microRNA-122. The LNA anti-miR is developed for treatment of Hepatitis C and hypercholesterolemia and is expected to commence human clinical pharmacology and safety studies in 2008.

Final Remarks

The remarkable hybridization properties of LNA, both with respect to affinity and specificity, position LNA as an enabling molecule for molecular biology research, diagnostic applications, and therapeutics. The fact that LNA nucleotides can be mixed in any combination with DNA/RNA residues and phosphorothioate internucleoside linkages is a very attractive property. Of particular relevance for the therapeutic aspects of LNA is the combination of LNA/DNA residues and PS residues. These “chimeric” oligonucleotides exert their action via the individual components: The LNA residue mediates very high target affinity and stability, and the PS’s provide the necessary PK properties and cellular uptake. We believe that the combination of these properties in one oligonucleotide—such as we have described here—provides enabling properties of LNA as RNA inhibitor.

Nucleosides in RNA, Modified

N. Dinuka Abeydeera and Christine S. Chow, Wayne State University, Detroit, Michigan
doi: 10.1002/9780470048672.wecb688

Natural and unnatural modified nucleosides play important roles in chemistry and biology. Over 100 different functional group modifications occur on natural nucleosides, which range from sugar methylations to base isomerization reactions. Unnatural modifications are also broad in their range of possible structures and applications. Both types of modifications have been incorporated site specifically into RNAs to understand their biological roles or to be used as biophysical, structure, and mechanistic probes. More recently, modified RNAs have been applied as therapeutic agents. This article summarizes the approaches toward generation of modified nucleosides and their incorporation into RNA using chemical, biochemical, or combined (semisynthesis) approaches. Some examples of applications with modified RNAs will also be discussed.

Background to Modified Nucleosides in RNA

The expansive array of RNA functions discovered to date is highly dependent on the ability of RNA to fold into unique structures, undergo large conformational changes, or participate in specific interactions with macromolecules (e.g., RNA and proteins), metal ions, and small organic ligands. Although the core nucleotide structures are sufficient for many biological roles of RNAs, over 100 natural modifications in RNA have been discovered over the past six decades, which seem to modulate RNA function (1, 2). In addition, a wide variety of unnatural nucleosides has been synthesized and incorporated into RNA. These modifications often provide RNA with unique properties, such as expanded or altered hydrogen-bonding; van der Waals, base-stacking, or electrostatic interactions; as well as unique metal-binding sites, chemical reactivity, or fluorescent characteristics. The synthetic routes to generate modified nucleosides vary considerably, as do the routes for incorporation of the nucleosides into small oligonucleotide fragments or large, full-length RNAs. The syntheses of modified RNAs serve many purposes, such as developing a better understanding of the biological roles of natural modifications, generating tools for studies of RNA structure and function, and producing novel therapeutic agents.

The types of nucleoside or nucleotide modifications range from alterations of the base component to changes in the sugar or phosphate moieties. The natural modifications include pseudouridylation (generation of a C-glycoside), methylation, deamination, thiolation, and alkylation (1, 2). Hypermodifications also exist in which multiple components of the nucleotide are altered. Some unnatural modifications include fluorescent bases, such as 2-aminopurine, or novel nucleobases to expand the genetic code. This review summarizes some of the most common approaches taken by chemical biologists toward generation of modified nucleosides and their incorporation into RNA using chemical, biochemical, or combined (semisynthesis) approaches. It is possible to use these techniques to construct RNA molecules with a wide variety of functional groups at highly specific positions. Although the applications of modified RNAs are numerous and far reaching, it is not possible to give a comprehensive view in this short article; therefore, representative or recent examples of applications have been selected for discussion.

Synthesis of Modified Nucleosides

The chemical synthesis of novel nucleosides or those that mimic natural modifications will provide biologists with new probes for RNA function. Thousands of modified bases have been described in the literature, which range from synthesis of both natural and unnatural nucleosides to their incorporation into short oligonucleotides and full-length nucleic acids. Numerous different approaches have been taken to generate modified nucleosides (3–6), which clearly cannot all be described in this brief review. Therefore, several examples have been selected to highlight some general strategies for preparing nucleoside analogs. Traditional methods for modified nucleoside synthesis...
Nucleosides in RNA—Modified

Nucleosides—coupling strategies

Most nucleosides contain N-glycosidic linkages (i.e., linkages through the base nitrogen atom). The N-glycosides can be generated by reactions with a suitably protected and activated sugar component and a silylated base (purine or pyrimidine) fragment. The most commonly used reaction in N-glycoside synthesis is the Hillbert-Johnson-type sugar-base condensation in the presence of a Friedel-Crafts catalyst, such as SnCl₂, which can be used to produce pyrimidine, purine, as well as sugar and/or base-modified nucleosides (Fig. 1a, b, i). Several improvements to these methods have been made since the original reports, which include the use of microwave-assisted reactions to generate nucleoside libraries (9). Maydanovych et al. (10) have used similar coupling strategies to generate adenine analogs for the study of RNA editing, and they reported the detailed procedures in a recent review article. The less-common C-glycosides contain a C-C linkage between the carbohydrate moiety and the heterocyclic base. A wide range ofaryl C-glycosides can be generated by using the Heck coupling reaction, as recently reviewed by Wellington and Bennet (11). Pseudouridine (Fig. 2a, c), which is the most abundant natural modification found in RNA, is a C-glycoside generated by posttranscriptional isomerization of uridine residues at specific sites along the oligonucleotide chain. Although numerous groups have reported on the synthesis of pseudouridine, Hanesian, and Machaalani’s stereocentered synthesis is the most convenient and efficient route to date (12). Their synthesis involves a reaction between a suitably protected D-ribose aldehyde and lithiated pyrimidine, followed by sequential ring-opening and ring-closing steps to produce either α or β pseudouridine in high yields. The ratio of α/β anomers is controlled by the presence of L-selectride and zinc chloride.

Nucleoside modifications

An alternative route to modified nucleosides involves derivatization of the standard nucleosides, guanosine, adenosine, cytidine, and uridine. Among the large repertoire of modifications identified to date, the methylated nucleosides are highly abundant and occur frequently in the functionality important regions of RNA (1, 2). Methylation typically occurs on the sugar or base portion of the nucleoside. Although many approaches have been taken to methylate nucleosides, site-selective introductions of a methyl group can be challenging. A recent report by Höbarth et al. (13) showed the synthesis of a wide variety of methylated ribonucleosides, which included 1-methylguanosine (m2G), 1′-methylguanosine (m1E), 2′-methylguanosine (m2G), 1-methylinosine (m1I), 3-methyluridine (m3U), N²-methylcytidine (m2C), N²-methyladenosine (m2A), and N²,N⁶-dimethyladenosine (m2A). Guanosine methylation at the amino nitrogen to yield m1G can be achieved by treatment of guanosine with NaI in DM SO followed by addition of methyl iodide (Fig. 2a, steps i, ii) (13). Methylations at the N⁷ position on guanosine to yield m2G and m22G can be achieved following sugar and O³ protection and generation of a 2-fluoro intermediate. The 2-fluoro intermediate is treated with CH₃NH₂ or (CH₃)₂NH to yield m2G or m22G, respectively (Fig. 2a, steps iii–viii) (13). Alternatively, m2G can be generated through reduction of a suitably protected p-thiocresol intermediate (Fig. 2a, steps iii, viii-x) (14). Methylated adenosine analogs can be obtained using isonine as a starting material. Generation of the 6-chloro intermediate allows for conversion into m2A or m22G with CH₃NH₂ or (CH₃)₂NH, respectively (Fig. 2b, steps xi, vii, viii, ix) (13).

Methylated cytidine analogs can be obtained from 5-methyluridine (m1U) as the starting material (15). Suitable protected m1U is reacted with P₂S₅ to yield a 4-thio intermediate that is then converted to 5-methylcytidine (m2C) during treatment with NH₃ (Fig. 2c, steps xiii–xiv). Uridine can be used as a starting material for the synthesis of N⁴-methylcytidine (m⁴C), N⁴,2′-O-dimethylcytidine (m⁴Cm), and 2′,O-methyl-cytidine (mC) (Fig. 2d, steps xv–xx). A tetrazole intermediate is generated (16, 17) that can be converted to m2C or m6Cm with the appropriate methylating agent. The Z-2′-O-methyl group is installed through an anhydronucleoside intermediate and opening with Mg(OH)₂, in methanol (18).

Methylated uridine analogs can be generated using related methods, such as treatment of uridine with NaI and MeI (Fig. 2e, steps i, ii) (12) to give m2U or conversion to 2′-O-methyluridine (mU) through an anhydronucleoside intermediate and opening by the appropriate nucleophile (18).

Several unnatural nucleoside phosphate modifications (Fig. 3) have been generated, which include phosphorothioate, phosphororoamidate, phosphorothioate, and methylphosphonate derivatives. The syntheses of these modifications have been reviewed by Verma and Eckstein (19). A modification of those procedures can be used for the generation of phosphoroxyenolate RNAs (20).

Convertible nucleotides

Convertible nucleotides are modified nucleotides that contain reactive functionalities. They are incorporated into RNA at specific locations and allow for convenient posttranslational introduction of chemical probes, isotope labels, or cross-linking agents, such as disulfide linkages. In this approach, the nucleotide derivative contains a leaving group on its base moiety and is incorporated into the oligonucleotide at a defined location (21). Once the preparation of the desired precursor RNA is completed, the oligonucleotide is treated with an appropriate nucleophile (e.g., amine), which can displace the leaving group and become attached to the specific base moiety (Fig. 3). As will be discussed in more detail later, the convertible nucleosides have many applications, and they can be used to control the RNA structure and function, as well as to regulate RNA conformational switching and dynamics.

Enzymatic approaches to nucleoside triphosphate synthesis

Nucleosides can also be prepared by using enzymatic reactions. Modified nucleoside triphosphates are useful as precursors for
the synthesis of RNA through a modified DNA template and T7 RNA polymerase. The chemoenzymatic synthesis of nucleoside triphosphates was recently reviewed by Wu et al. (22). A recent example is the synthesis of β-azaguanosine (BetaGuo), which is a guanosine analog with N8 in place of C8 that displays fluorescent properties, and the conversion to the corresponding triphosphate (BetaGTP) (23). The strategy for BetaGTP synthesis involves the use of enzymes from the pentose phosphate and nucleotide salvaging pathways, many of which are commercially available. The presence of the triphosphate allows for the incorporation of BetaGuo into RNA using a DNA template and T7 RNA polymerase.

Single site incorporation

\[ \text{Nu (amine, probe, etc.)} \]

Multiple site incorporation

\[ \text{Nu-S-S-Nu} \]

**Figure 3** The convertible nucleoside approach is shown (21). On the left, a single convertible nucleoside that has been incorporated site-specifically into the RNA is treated with a nucleophile to displace the leaving group, X. On the right, an RNA with multiple convertible nucleosides can be used to generate a cross-linked analog.

Incorporation of Modified Nucleosides into RNA

Through a combination of chemical and biochemical approaches, modified nucleosides can be incorporated into RNA either globally (i.e., at many sites) or in a site-specific manner. Depending on the particular application of interest, either a global or site-specific incorporation strategy may be desirable.

**Enzymatic incorporation**

Modified nucleotides in RNA can be generated by using site-specific enzymes. Several naturally occurring modifying enzymes have been isolated and used to modify either small oligonucleotides or full-length RNA templates at specific sites (Fig. 4a) (24). The enzyme reactions are useful for understanding the biological roles of the modified nucleosides; however, they are not as useful for generating modified RNAs for biophysical studies or as therapeutic agents because the reactions do not go to completion, and the modified RNAs are often difficult to separate from the unmodified RNAs. RNAs in bacteria and eukaryotes are modified by different pathways. Individual modifications in bacterial RNAs are mediated by one of many unique protein enzymes that are typically site specific and target particular structures or sequences of RNA (24). The most common enzymes are methyltransferases and pseudouridine synthases. Because of the greater number of modifications in RNAs from higher organisms, an alternative pathway of insertion is used that employs fewer site-specific enzymes. Noncoding RNAs known as small nucleolar RNAs (snoRNAs) combine with a set of proteins to generate a small nuclear ribonucleoprotein (snRNP) complex that guides the site of enzyme modification on the target RNA (25). The discovery of snoRNAs has been extremely important for understanding the biological roles of RNA modifications, but the use of snoRNPs is not as convenient for generation of site-specifically modified RNAs for biophysical studies.

RNA segments can be modified at their 3'-ends by using a bisphosphate analog of the modified nucleoside and T4 RNA ligase (Fig. 4b) (26). This reaction is general and essentially can be applied to any RNA sequence and modification type that can be converted into a bisphosphate. The 3'-modified RNA segment can then be dephosphorylated with calf intestinal phosphatase and ligated with another 5'-phosphorylated RNA fragment to generate larger RNAs with site-specific modifications (Fig. 4b) (26). Methods for ligation include the use of a DNA "splint" with either T4 RNA ligase or T4 DNA ligase (27, 28). The presence of the complementary DNA fragment promotes formation of the desired RNA product and minimizes dimer or circular RNA formation.

A second enzymatic approach employs T7 RNA polymerase and a DNA template that directs the addition of specific ribonucleotides according to standard Watson-Crick base-pairing rules. This transcription method can be used to generate RNAs of any length and sequence. The T7 RNA polymerase will often accept modified nucleoside triphosphates. The method is useful for global modification, but typically it does not allow for site-specific incorporation of modified nucleotides. This limitation has been overcome in several cases, in which nonstandard nucleotides are used to direct the insertion of modified nucleotides through alternative base-pairing schemes (Fig. 4c) (29).

**Chemical approaches**

The chemical synthesis of RNA has the distinct advantage of allowing for site-selective incorporation of modified nucleosides into the oligonucleotide chain. The early phosphodiester method developed by Khorana (30) was followed by the H-phosphonate and phosphoramidite approaches (31). Although the phosphodiester approach has distinct advantages over phosphoramidite synthesis, it is not as widely used. Therefore, the focus of this section will be on the more commonly employed methods.
Nucleosides in RNA, Modified

(a) Modifying enzymes (E) convert standard nucleotides (N) into modified versions (N-X) (e.g., methylation, pseudouridylation) (24). Eukaryotes require a snoRNP complex along with the modifying enzyme to direct the site of modification, whereas bacteria use unique enzymes to modify each site (25). (b) T4 RNA ligase is used to add a single modified nucleotide (X) in the form of a bisphosphate (pXp), or to ligate a modified fragment to another piece of RNA (26, 27). (c) Enzymatic incorporation employs T7 RNA polymerase and a modified DNA template, in which deoxynucleotide Y makes a unique base pair with ribonucleotide X (in the form of XTP) to incorporate the modified nucleotide at a single, specific site on the RNA chain (29). (d) The steps for incorporation of modified nucleotides by solid-phase oligonucleotide synthesis are shown (32–34). (e) The most common protective groups for the phosphoramidite building blocks are highlighted.

Figure 4: The site-specific incorporation of modified nucleotides into RNA is depicted. a) Modifying enzymes (E) convert standard nucleotides (N) into modified versions (N-X) (e.g., methylation, pseudouridylation) (24). Eukaryotes require a snoRNP complex along with the modifying enzyme to direct the site of modification, whereas bacteria use unique enzymes to modify each site (25). b) T4 RNA ligase is used to add a single modified nucleotide (X) in the form of a bisphosphate (pXp), or to ligate a modified fragment to another piece of RNA (26, 27). c) Enzymatic incorporation employs T7 RNA polymerase and a modified DNA template, in which deoxynucleotide Y makes a unique base pair with ribonucleotide X (in the form of XTP) to incorporate the modified nucleotide at a single, specific site on the RNA chain (29). d) The steps for incorporation of modified nucleotides by solid-phase oligonucleotide synthesis are shown (32–34). e) The most common protective groups for the phosphoramidite building blocks are highlighted.
Nucleosides in RNA, Modified

The chemical synthesis of RNA occurs on a solid support, such as a controlled-pore glass or polystyrene bead (Fig. 4d). The synthesis typically goes in the 3′ to 5′ direction, building from the 5′-hydroxyl group at each cycle. The 5′-OH is protected with a suitable organic moiety that can be removed quickly and efficiently. The 2′-hydroxyl is also protected until the end of the synthesis. The monomer unit that reacts with the 5′-OH is a nucleoside with a phosphoramidite moiety at the 3′ hydroxyl. The phosphoramidite method involves four major steps after deprotection of the 5′-hydroxyl group from the 3′ nucleoside attached to the solid support: 1) coupling at the 5′-OH with a suitably protected phosphoramidite, 2) capping the unreacted 5′-OH groups, 3) oxidation of the phosphite linkage to generate a phosphate, and 4) removal of the 5′-protecting group of the newly added nucleotide unit (Fig. 4d). The final steps involve removal of the oligonucleotide product from the solid support and deprotection of the 2′-OH groups and phosphate moieties. The final RNA product is then purified using standard methods, such as polyacrylamide gel electrophoresis or high-performance liquid chromatography.

The choice of 5′ and 2′ protecting groups is critical for the successful generation of an oligonucleotide product. The chosen phosphoramidites must have high coupling efficiencies and be stable during the entire oligonucleotide synthesis, yet easily removed at the end of the synthesis. The synthetic route to generate the phosphoramidites should also be efficient in order to reduce the cost of the oligonucleotide synthesis. A wide range of protecting groups has been introduced for RNA synthesis over the past three decades; however, only the most commonly used methods will be discussed. One of the first 2′-OH protecting groups to be employed was tert-butyldimethylsilyl (TBDMS or TBS) (32). More recently, [(triisopropylsilyl)oxy]methyl (TOM) (33) and benzhydryloxy-bis(trimethylsilyloxy)silyl (BzH) (34) have been developed for 2′-OH and 5′-OH protection (Fig. 4e).

Whereas each method has distinct advantages and disadvantages, they complement one another because unique chemical modifications on the nucleoside may be more compatible with one particular method. Modifications that are chemically incompatible with these protecting groups would require alternative methods. Several key factors in choosing the type of phosphoramidite to use include: 1) fast coupling times (<2 minutes), 2) high coupling efficiencies (>99.8%), 3) high stability in solution, and 4) the ability to generate long RNA fragments (>20 nucleotides in length). Many recent reviews on RNA synthesis protocols are available that provide more details regarding phosphoramidite preparation (6, 34).

The rationale for choosing chemical synthesis to generate modified RNAs is that a wide range of both natural and unnatural modifications can be incorporated at single or multiple points in the RNA sequence.
sites, and highly pure RNAs can be produced on a large scale (>mg). As mentioned earlier, convertible nucleotides can be generated in which a group of modified nucleosides that contain reactive functionalities are incorporated into RNA and allow for subsequent attachment of chemical probes, such as isotopic labels, tools for disulfide cross-linking, or fluorescent moieties (21). This postsynthetic modification allows for generation of site-specifically modified RNAs in fewer steps compared with complete enzymatic or chemical synthesis (Fig. 3).

Semisynthesis approaches
The enzymatic and chemical approaches can be easily combined to generate >100-nucleotide-length RNAs that contain either natural or unnatural modifications at specific sites. Either chemically or enzymatically produced fragments can be joined or ligated with T4 DNA ligase or T4 RNA ligase along with a DNA split, as mentioned above (27, 28). Together, these methods can be applied to generate large, full-length RNA molecules, such as 235 ribosomal RNA (approximately 3000 nucleotides in length), with site-specific modifications to study RNA function (35).

Applications of Modified RNAs
Numerous motivations can be cited for generating site-specifically modified RNAs. The first reason is to use modified RNAs for structure-function studies in either natural or model systems. For this purpose, many different biophysical approaches are employed, such as fluorescence spectroscopy, NMR spectroscopy, and X-ray crystallography. For mechanistic studies, site-specific changes to the oligonucleotide allow for single-atom or functional-group changes and subsequent biochemical studies to be conducted and compared with wild-type RNA. A second major reason for constructing modified RNAs is to use them as therapeutic agents with enhanced stability or improved biological activity. Antisense oligonucleotides were recognized long ago as having potential therapeutic properties for downregulating gene expression. More recently, RNA interference (RNAi) has been discovered as another tool for regulation of RNA activity. Other therapeutic agents include RNA aptamers and ribozymes. A topic of recent interest is the use of modified nucleosides to expand the genetic code, as well as to understand the basic principles of Watson-Crick base pairing and catalysis. A variety of nucleoside modifications can be used to monitor RNA folding, stability, and structure, as well as ligand interactions. Fluorescent analogs, such as 2-aminopurine (2-AP) (Table 1), have proven to be highly useful to monitor RNA conformational changes and dynamics in solution (40-42). The 2-AP modification causes very little perturbation to the RNA structure, and it has been used to monitor drug (e.g., aminoglycoside antibiotic) interactions with target RNA (53). In contrast, attachment of a bulky substituent, such as 8-bromoguanosine (8-BG) (Table 1), to the RNA base may limit rotation about the glycosidic bond, favoring one conformation (e.g., syn) over another (e.g., anti). Such an approach has been used to stabilize YNMG RNA hairpin motifs and enhance the RNA folding rate, because of preorganization of the denatured state of the RNA (43).

Biophysical probes
A variety of nucleoside modifications can be used to monitor RNA folding, stability, and structure, as well as ligand interactions. Fluorescent analogs, such as 2-aminopurine (2-AP) (Table 1), have proven to be highly useful to monitor RNA conformational changes and dynamics in solution (40-42). The 2-AP modification causes very little perturbation to the RNA structure, and it has been used to monitor drug (e.g., aminoglycoside antibiotic) interactions with target RNA (53). In contrast, attachment of a bulky substituent, such as 8-bromoguanosine (8-BG) (Table 1), to the RNA base may limit rotation about the glycosidic bond, favoring one conformation (e.g., syn) over another (e.g., anti). Such an approach has been used to stabilize YNMG RNA hairpin motifs and enhance the RNA folding rate, because of preorganization of the denatured state of the RNA (43).

Generation of site-specifically modified RNAs that can perform disulfide cross-linking allows for RNA folding pathways to be examined (21, 54). Photoactivated cross-linking is another strategy that uses naturally occurring or synthetic modifications, such as 4-thiouridine, 6-thioguanosine, 5-bromouridine, and 5-iodouridine (Table 1), to study RNA-RNA interactions in folded RNAs (19).

Modified nucleosides incorporated into small RNA model systems can also be used to investigate the global versus individual effects of modified nucleotides on natural RNAs, such as rRNA or tRNA. For example, in some early studies, Yarian et al. (44) demonstrated that pseudouridine (Table 1) leads to increased thermal stability of the tRNA anticodon stem-loop region. Later, Meroueh et al. (45) demonstrated that pseudouridines have opposing effects on rRNA helix 69 stability, which depends on their specific locations and sequence contexts. These effects on stability may be important for conformational switching mechanisms in functional RNAs (46, 47).

Mechanistic probes

Site-specifically modified RNAs have been used in many applications to examine RNA structure-function relationships, RNA–protein interactions, RNA–ligand interactions, and RNA-catalysis mechanisms. Some earlier studies demonstrated the use of synthetic oligonucleotides to probe the roles of specific functional groups and detailed mechanisms in ribozyme catalysis (55). The synthesis of nucleoside analogs allows for a full range of chemical diversity (e.g., inductive effects, space-filling capacity, etc.) to be explored, such that quantitative structure activity relationships can be determined for RNA enzymes and other biologically important RNAs (56).

Nucleotide analog interference mapping (NAIM) is an alternative method to conventional single-atom substitution experiments, which provides biochemical information related to the RNA structure and function (48). NAIM has the ability to screen rapidly the effects of chemical group substitution rapidly on RNA function. This method uses an array of modified 5′-O-(1-thio)-nucleoside triphosphates (Table 1) to assess concurrently the contributions of functional groups at every nucleotide position along the RNA backbone. The applications of this method range from mapping of RNA tertiary contacts and substrate contacts in ribozymes to quantification of the energetic contributions of RNA–ligand interactions.

Functional RNAs

RNAs have an enormous range of functions. Those functions have been the subject of numerous publications over the past several decades. One example is RNA aptamers, which are oligonucleotides that have been selected for and tailored to bind with high affinity and selectivity to a variety of ligands, which include nucleotides, peptides, proteins, vitamins, and drugs (57). Aptamers are engineered from random nucleic acid libraries through repeated rounds of in vitro selection. Modified nucleotides play important roles in aptamer function, because they provide enhanced stability to the RNA-based aptamers and can also endow them with desirable chemical reactivities or control of their folded structures, which would be beneficial for the development of novel targeting agents. Several modified aptamers have already been developed as potential therapeutics (57).

Nucleic acid selection methods have also been exploited for the development of novel RNA enzymes or ribozymes (58). An in-vitro-selected RNA that contains the modified nucleotide 5′-(4-pyridylmethyl)-uridine (Table 1) can catalyze carbon–carbon bond formation in a Diels-Alder cycloaddition, with an 800-fold rate acceleration compared with a random RNA (49). Modified RNAs that contain the same uridine modification have also been selected to mediate metal–metal bond formation in the synthesis of palladium nanoparticles (59). Modified RNAs are likely to have many other applications as novel ribozymes that catalyze important biological reactions or can be used to create novel materials.

RNAi/siRNA

Short interfering RNA (siRNA) is a class of molecules composed of double-stranded RNA molecules (20–25 nucleotides) that are involved with the interference of specific genes (i.e., RNA interference or RNAi). During the RNAi process, the siRNA is incorporated into a protein complex, which unwinds the siRNA by an ATP-dependent mechanism to generate an
active RNA-induced silencing complex (RISC) (60). The unwound antisense strand of RNA will then guide the RISC to the target mRNA and bind according to standard Watson-Crick base-pairing schemes. Strand scission of the target mRNA is induced by RISC, which leads to a decreased level of protein expression by the corresponding mRNA. The overall success of gene downregulation depends on the stability and structure of the duplex formed between the siRNA and target mRNA. This idea has led to the design and synthesis of numerous modified siRNAs with the anticipation that appropriate changes in the nucleoside composition will lead to enhanced stability, both in terms of chemical stability (i.e., to avoid nuclease degradation) and thermal stability (i.e., to generate a duplex with more favorable free energy, enthalpy, and/or entropy contributions). The modified oligonucleotides are also designed to have increased cellular uptake and properties that will enhance their biodistribution or entry into specific cell types (61, 62). Another type of nucleotide modification involves the addition of a photocurable moiety (Table 2), such that temporal and spatial control of siRNA targeting is possible (50).

Other applications

RNAs that employ the four standard bases have more limited opportunities for hydrogen-bonding interactions and functionality, even though the range of tertiary interactions is broad (63). The use of additional base pairs would not only increase the structural complexity of RNA but would also allow for enzymatic replication. This concept has been exploited by several research groups to expand the genetic code, as well as to generate novel, site-specifically modified RNAs (e.g., biotinylated, fluorescent, cross-linked RNAs) (6, 29, 64).

Summary and Outlook

This article highlights methods for synthesis of modified nucleosides and their site-specific incorporation into RNA. RNAs of practically any size can now be engineered with a broad range of natural or unnatural modifications to the base, sugar, or phosphate portions of the nucleotides. Using chemical, biochemical, or combined approaches, a change of a single atom at a desired location can be accomplished, as well as global modification. Because of the diversity of modifications accessible through chemical or enzymatic synthesis, the modified RNAs also have a tremendous range of applications, some of which have been summarized in the last portion of this review. Future efforts will continue to give researchers a better understanding of the importance of natural modified RNAs, provide new tools for biophysical and structure analysis for structure-function studies of RNA, and lead to novel RNA therapeutics or catalysts. On a more practical note, novel methodologies for cost-effective, large-scale preparation of highly pure modified RNAs will also be of importance (65), and improved catalysts for RNA ligation (66) will allow for larger, biologically relevant RNAs to be generated with greater ease.

Peptide nucleic acid (PNA) is a chimeric molecule that consists of hydrogen-bonding purine and pyrimidine heterocycles attached to a pseudopeptide backbone. The bases allow the recognition of specific DNA or RNA sequences, which results in hybrid multihelical structures. The lack of a negative charge on the PNA backbone eliminates Coulombic repulsion from target DNA and RNA strands, which results in high affinity hybridization. These properties have led to a diverse set of applications for PNA, which includes antisense/antigene inhibition of gene expression, various DNA/RNA detection assays, nucleic acid labeling and purification technologies, and programmed assembly of nanoscale materials. The modular design of PNA has led to the synthesis of several “next-generation” analogs that promise to improve PNA’s performance in many existing applications as well as to open doors to new applications. Although most prior research on PNA has focused on its nucleic acid-like character, recent developments of the peptide-like aspects of PNA promise to stimulate additionally the work on this fascinating DNA mimic.

The DNA double helix is the first molecular icon, a structure that is readily associated with its function, even by people with little or no science education. Over the past half century, the structure has inspired chemists along three lines that are familiar to those who have worked at the interface between chemistry and biology. The first group of chemists synthesized in the laboratory what nature produces enzymatically, and they were motivated by both fundamental and practical needs. The second group of chemists understood the relationship between structure and function, where synthetic chemistry allows atomic-scale changes in the DNA structure. The third group of chemists identified DNA as a potential target for molecular recognition, with the ability to regulate gene expression using synthetic compounds as the ultimate goal. These lines of inquiry are not necessarily parallel, but rather they become intertwined at various points, most notably in the area of synthetic oligonucleotides. A variety of DNA analogs have been synthesized and characterized, which feature modifications to the deoxyribose ring, the phosphodiester linkage, and the heterocyclic nucleobases. Many of these modifications have been combined within the same structure to optimize the oligonucleotide for a specific application.

Most synthetic DNA analogs represent logical departures from the natural structure. However, one of the most radical structural modifications of DNA to appear in the literature is peptide nucleic acid (PNA, Fig. 1), in which the sugar-phosphate backbone is abolished entirely in favor of a pseudopeptide. PNA was first reported by Nielsen et al. in 1991 from the University of Copenhagen (1). The structure is reminiscent of both proteins and nucleic acids, hence the name, and has led to considerable interest in its possible role in prebiotic chemistry.

An intriguing molecular structure and origins-of-life scenarios hardly explain the intense research effort dedicated to PNA, whereas the original 1991 Science article has been cited over 1100 times as of September 2006. Rather, it is what PNA does in the presence of DNA and of RNA that has captured the imagination of chemists and of biologists. Although PNA was conceived originally as a triplex-forming oligomer that would bind in the major groove of double-stranded (ds) DNA, the earliest reports demonstrated that homopyrimidine PNA binds to ds DNA by a strand invasion mechanism. First, one PNA strand displaces the homologous homopyrimidine DNA strand locally and forms Watson-Crick base pairs with the complementary homopurine DNA target (Fig. 2) (1, 2). A second PNA strand then binds to the major groove of the hybrid to form a very stable PNA-DNA triplex. This discovery was very exciting because...

targeting ds DNA opens the door to the regulation of gene expression at the transcriptional level. Several variations on this “strand invasion” recognition mechanism that ease the sequence requirements have been reported in the ensuing 15 years, and research is ongoing (see Further Reading).

PNA is also capable of binding to complementary single-stranded (ss) DNA and to RNA mixed-sequence (i.e., purine-containing and pyrimidine-containing) targets by Watson-Crick base pairing to form hybrid duplex structures (Fig. 2) (3). As with the triplex structures mentioned above, these hybrids exhibit high thermodynamic stability partly because of the lack of electrostatic repulsion between the PNA and DNA/RNA. High affinity and excellent mismatch discrimination led to many PNA applications that range from the inhibition of mRNA processing and translation to sensing, diagnostics, and imaging. The original Nature article (3) that describes Watson-Crick PNA–DNA and PNA–RNA duplex formation has been cited over 700 times to date.

PNA recognition of DNA and RNA has been extended recently to a new binding mode, named “homologous hybridization” (4, 5). In this format, guanine-rich PNA probes recognize homologous DNA or RNA targets by forming hybrid guanine quadruplexes. Great interest exists in G-quadruplexes for their suspected roles in the regulation of gene expression at the transcriptional and translational levels, so this added binding mode could expand the range of biologic targets for PNA.

This article focuses on the interplay between chemical properties and biologic applications of PNA. Besides strategies to regulate gene expression, PNA-based biotechnologies will be presented. Although the vast majority of these studies have used the original PNA structure, the next-generation PNAs that feature backbone and nucleobase modifications are likely to be used in future applications. Finally, to illustrate the versatility of this fascinating molecule, the use of PNA in materials science will be summarized. The growing footprint of nanotechnology in biologic research warrants careful consideration of the opportunities presented by PNA’s unique properties. As space limitations prevent an exhaustive description of PNA research, readers are referred to several recent reviews for additional information (see Further Reading).

PNA as Antisense and Antigene Agents

Compounds that bind sequence selectively to single-stranded RNA or double-stranded DNA have the potential to regulate gene expression by antisense or antigene mechanisms, respectively. The high affinity and sequence selectivity exhibited by PNA sparked much interest in the possible use of DNA in these applications. Furthermore, the biochemical stability of PNA, as it is not susceptible to cleavage by nuclease nor by protease enzymes, raised hopes that PNA's could be effective in vivo as well as in vitro. Experiments in which the PNAs were targeted either to RNA or to DNA, are described in this section.

Antisense applications

In the classic antisense approach, the binding of an oligonucleotide to a complementary region of a mRNA prevents translation via three possible mechanisms: 1) binding of the antisense agent blocks ribosome assembly on the mRNA, 2) an actively translating ribosome cannot proceed past the steric block presented by an antisense agent bound within the coding region of the mRNA, or 3) the hybrid duplex formed by the antisense agent and the mRNA recruits RNase H, which degrades the mRNA strand. PNA–RNA hybrids are not substrates for RNase H, which leaves the first two mechanisms available for PNA antisense agents. Scattered reports indicate that PNAs targeted to the coding region of an mRNA can inhibit translation, presumably by mechanism 2). However, two separate groups have reported that PNAs targeted to either the translation start codon or the 5′-untranslated region exhibited antisense effects, whereas PNAs targeted to the coding region did not (6, 7). The failure of the latter PNAs to block translation could be caused by the weak binding of the PNA to its target sequence, which could occur if the target sequence is part of a stable, folded region of the mRNA. Alternatively, the PNA could bind but be displaced by the ribosome as it translates through the PNA binding site. Regardless of the explanation, these studies indicate that PNAs that interfere with ribosome assembly are most likely to be effective antisense agents.
Three other examples of RNA-targeted PNAs that block gene expression should be mentioned. In the first case, the PNA is not targeted to the mRNA but to the unspliced pre-mRNA present in the nucleus immediately after transcription. Splicing eliminates introns from the pre-mRNA and results in the ligation of exons to produce the mature mRNA. Alternative splicing, in which the same pre-mRNA produces different RNAs based on the use of different splice sites, increases the complexity of the genome. This process has been implicated in certain genetic diseases, whereas the use of a splice site leads to a normal protein, whereas the use of a different splice site can lead to a defective protein (and the absence of the normal protein). Cell culture experiments with complementary PNAs targeted to a splice site used in place of adenine and thymine (12). (See the “Nucleobase Modifications” section.) A significant challenge to using homopyrimidine PNAs in vivo is the basic process that underlies several biotechnologic techniques that constitute a multibillion-dollar-per-year industry. DNA/RNA microarrays, polymerase chain reactions (PCRs), single nucleotide polymorphism (SNP) assays, and fluorescence in situ hybridization (FISH) are only some techniques that rely on Watson-Crick base pairing. Although each of these methods works when using a synthetic DNA oligonucleotide as a capture or detection probe, the higher affinity and nuclease stability of PNA offers obvious advantages (except in PCR, where a pure PNA oligomer cannot serve as a primer). Besides allowing lower concentrations of probe to be used, which helps to minimize hybridization to unintended targets that have a similar sequence, PNA can invade stable secondary or tertiary structural elements to gain access to its target. These folded structures impose thermodynamic and kinetic penalties to any hybridization probe; the higher affinity of PNA combined with its lack of electrostatic repulsion from DNA and RNA leads to significant advantages of PNA over most oligonucleotides based on polyanionic backbone chemistries. This section illustrates a few applications of PNA in biotechnology.

Fluorescent PNA probes

PNA probes have been used for FISH experiments, and commercial kits are available for microbial targets (17). Typically, the probes present in these kits hybridize to the abundant ribosomal RNA from bacteria. A recent paper illustrated the value

Probes, Labels, and Sensors

Hybridization between complementary oligonucleotide strands is the basic process that underlies several biotechnologic techniques that constitute a multibillion-dollar-per-year industry. DNA/RNA microarrays, polymerase chain reactions (PCRs), single nucleotide polymorphism (SNP) assays, and fluorescence in situ hybridization (FISH) are only some techniques that rely on Watson-Crick base pairing. Although each of these methods works when using a synthetic DNA oligonucleotide as a capture or detection probe, the higher affinity and nuclease stability of PNA offers obvious advantages (except in PCR, where a pure PNA oligomer cannot serve as a primer). Besides allowing lower concentrations of probe to be used, which helps to minimize hybridization to unintended targets that have a similar sequence, PNA can invade stable secondary or tertiary structural elements to gain access to its target. These folded structures impose thermodynamic and kinetic penalties to any hybridization probe; the higher affinity of PNA combined with its lack of electrostatic repulsion from DNA and RNA leads to significant advantages of PNA over most oligonucleotides based on polyanionic backbone chemistries. This section illustrates a few applications of PNA in biotechnology.
of PNA as a hybridization probe to detect Legionella pneumophila (18). Discrimination between this and other species of Legionella bacteria required a probe that could bind to sites that typically are classified as “low affinity” because of the poor hybridization of DNA probes. PNA probes showed absolute specificity, which identified correctly 47 different strains of bacteria and distinguished between pneumophila and other Legionella species.

PNA FISH probes also have been used for telomere analysis (19). Telomeres consist of hundreds of repeats of a short sequence (e.g., 5′-TTAGGG-3′ in humans). Therefore, many copies of a complementary nucleic acid probe can hybridize to each telomere in a cell, which leads to a bright fluorescence signal. The high affinity of PNA allows the use of probes shorter than DNA probes, which means that more copies of the probe can hybridize to the telomeres.

A third application for fluorescent PNA probes is to introduce fluorescent labels into the mRNA site specifically (20). For example, PNA probes have been hybridized to exonic sites that flank consecutive splice sites in a pre-mRNA from yeast. Förster resonance energy transfer (FRET) donor and acceptor dyes were attached covalently to the PNA, and low FRET efficiencies were observed when the PNAs were hybridized to the pre-mRNA. However, when hybridized to the mRNA produced by splicing, large increases in FRET have been observed in both in bulk solution and on a glass slide where single-molecule measurements could be made. As in the FISH applications, the ability to use short PNA probes to deliver the fluorescent dye to a desired location decreased the likelihood that the PNA will disrupt the structure and the function of the RNA that is under investigation.

PNA can also be functionalized with “fluorogenic” dyes, that is, dyes that exhibit enhanced fluorescence in response to a change in the environment. Unsymmetrical cyanine dyes developed originally as DNA stains can be attached covalently to PNAs to create fluorogenic probes, and chemistries have been developed that allow attachment of the dye at internal (21) as well as at terminal positions (22).

Finally, the intrinsic properties of PNA led to an interesting variation on the molecular beacon concept. As devised originally, a DNA probe that bears a 5′-terminal and 3′-terminal fluorophore (F) and quencher (Q) groups, respectively, can be designed to fold into a hairpin in which the fluorescence is quenched because of the close proximity of F and Q (23). Subsequent hybridization with a complementary DNA opens the hairpin and the increase in distance between F and Q restores the fluorescence. This design necessitates that the terminal DNA sequences are complementary to stabilize the hairpin conformation by Watson-Crick base pairing. If F and Q groups are attached to a PNA probe, the terminal sequences are not required (24), which is most likely caused by the tendency of PNA to adopt a compact rather than an extended structure in the absence of a complementary strand. These “stemless” PNA beacons ease the sequence constraints that complicate the DNA molecular beacon design.

### Probes for nonfluorescent DNA/RNA detection

PNA has been tested in a wide variety of DNA detection modes where unmodified DNA can also be used. However, besides the standard advantages noted above for PNA (high affinity, good mismatch discrimination), many of these assays exploit the ability of PNA to hybridize at low ionic strength, conditions that can denature competing secondary/tertiary structure in the target nucleic acid. Moreover, use of PNA with its neutral backbone as a probe for hybridization at surfaces eliminates the substantial charge repulsion between the DNA/RNA target and immobilized DNA probes.

An interesting new approach to DNA detection involves probes attached to polymer microspheres loaded with a scintillator (25). The hybridization of a complementary, radiolabeled target DNA leads to strong signal amplification because of the close proximity of the scintillant and the radiolabel. Another appealing aspect of this method is that the PNA probe can be synthesized directly on the scintillant-loaded microspheres.

PNA probes have also been used for in vivo imaging of mRNAs (26). In this application, the PNA is functionalized with a cell-penetrating peptide and a magnetic resonance imaging (MRI) contrast agent. Cell uptake and hybridization to the mRNA target allowed MRI imaging of gene expression both in cell culture and in live rats.

Another method for nonfluorescent detection of DNA involves the noncovalent binding of an inexpensive cyanine dye to PNA–DNA duplexes (27). The dye assembles into a helical aggregate in the presence of PNA–DNA, which results in a vivid blue-purple color change. This phenomenon has been used in SNP detection assays.

### PCR clamping

An early application for PNA is in a method known as “PCR clamping,” which improves the detection of single nucleotide polymorphisms (SNPs) in samples where mutant DNA of interest is present in a very low amount relative to wild type (28). This situation can occur, for example, when only a few mutant cancer cells are present along with a large excess of healthy cells in a tissue biopsy. The challenge is to detect the low abundance of mutant sequence against the high background of wild-type sequence. One approach to improve the signal-to-noise ratio in such situations is to amplify selectively the mutant DNA by PCR. This is where PNA is particularly helpful. PCR primers are designed to overlap the SNP site present in the cancer cells and then a PNA oligomer that is fully complementary to the wild-type DNA (and therefore has a single mismatch to the mutant DNA) is synthesized. The PNA preferentially hybridizes to the wild-type DNA in competition with the PCR primer that is complementary to the same site, which reduces the amplification of the wild type relative to the mutant DNA. This method allows SNP detection when the wild-type DNA is present in up to 20,000-fold excess relative to the mutant.
Bioseparations

A growing need exists to develop sequence-specific means to purify nucleic acids, both for genomic analysis and for the larger scale purification of plasmid DNA for gene therapy. The sequence-specific binding properties of PNA can be used in affinity separations of DNA as an alternative to standard DNA purification methods such as anion-exchange chromatography and density-gradient techniques. This section describes several such applications of PNA.

Analytical applications

The hybridization of PNA to a complementary DNA or RNA leads to changes in the properties of the nucleic acid. One of these changes occurs in the electrophoretic mobility, where the perturbation in the charge: size ratio because of the PNA hybridization causes significant shifts in the rate at which a given DNA or RNA migrates in an electric field. Adjusting conditions such as temperature allows preferential hybridization of the PNA to fully complementary targets versus those bearing even single mismatches, and it results in large separation during electrophoresis.

Purification applications

In addition to the analytical-scale applications described above, large-scale purification of nucleic acids using PNA probes has also been explored. Applications range from the purification of plasmid DNA to be used in gene therapy to the isolation of RNA and RNA–protein complexes from complex biologic samples. One approach to using PNA in this way is to link it to a solid support such as a polymer bead and then use the PNA-functionalized support to capture complementary DNA from solution. However, both biosensor and surface plasmon resonance data point to a reduction in the specificity and the binding kinetics to PNA probes that are attached directly to solid surfaces. The most effective “purification by hybridization” strategies circumvent this by two-step methods, in which PNA probes with some attachment functionality (e.g., hexahistidine peptide or biotin) bind targets in solution and the resulting PNA–DNA (RNA) hybrids are captured on beads or surfaces. The most effective “purification by hybridization” strategies circumvent this by two-step methods, in which PNA probes with some attachment functionality (e.g., hexahistidine peptide or biotin) bind targets in solution and the resulting PNA–DNA (RNA) hybrids are captured on beads or surfaces. The target DNA thereby is modified with a nonpolar tag that may adsorb selectively to nonpolar media, including alkyl-modified Sepharose and surfactant micelles (Fig. 3). In general, the covalent attachment of n-alkanes and other lipophiliic materials impacts neither the duplex stability nor the sequence selectivity of PNA–DNA duplexes. The attachment of a 12-carbon alkane to PNA provides adequate resolution to separate 60-mer DNA targets from both noncomplementary oligomers and calf thymus DNA in hydrophobic interaction chromatography (HIC), an aqueous-based method. The resolution is improved greatly when 18-carbon alkanes are attached to PNA probes, even when the PNA is targeted to internal sequences of the target. The strand-invasion ability of PNAs can also be leveraged to purify dsDNA oligomers in HIC. Far greater resolution can be achieved when targeting dsDNA because DNA in duplex form interacts very weakly with the HIC media unless the alkylated PNA is attached.

Finally, using PNA as an affinity capture reagent recently was extended to probing RNA–protein complexes (RNP)s in cells (33). In this application, the PNA is functionalized with a peptide that allows uptake into cells and is complementary to an RNA component of an RNP. The PNA also bears two affinity tags, the first of which is a benzophenone-modified phenylalanine residue that can photodissociate the PNA to a protein present in the RNP. The second tag is a biotin group, which allows the purification of the cross-linked PNA–protein. Subsequent analysis by mass spectrometry identifies both the protein and its cross-linking site. As is the case for PNA used to deliver a fluorophore to a specific site in an RNA, this method requires that the PNA not disrupt the structure being probed.

PNA-encoded libraries

Another application of PNA that has emerged recently is a tag to encode and to screen combinatorial libraries of small molecules (34). For example, fluorescent PNA tags have been attached to individual members of a library of potential protease inhibitors. After incubating the library with a target protein, bound versus free compounds were separated by size-exclusion chromatography and the PNAs obtained from the bound fraction were hybridized to a DNA microarray. Any DNA to which fluorescent PNA was bound allowed decoding of first the PNA and then the compound from the library tagged by the respective PNA. The authors suggested alternative screening, profiling, and assay formats for this promising technology.

Next-Generation PNAs

PNA and its structural analogs are synthesized conveniently by standard solid-phase methods (35). The backbone chemistry of PNA allows the attachment of a diverse array of fluorescent dyes, metal-binding ligands, cell-penetrating peptides, and many other moieties that increase the functional capacity of the PNA. In addition to PNAs that simply are modified by attaching functional groups to the N-terminus or C-terminus, large numbers of PNA analogs that feature integral modifications, i.e., alterations in the backbone or nucleobase components, have been reported (36). Most of these analogs were made in attempts to better understand the structure-function relationship of PNA so that the hybridization, solubility, and/or cellular uptake properties of PNA could be improved. In this section, we introduce several second-generation PNAs, classified as either having backbone or nucleobase modifications, and discuss their potential impact on the applications described above.

Backbone modifications

Most backbone-modified PNA analogs fall into one of four classes (Fig. 4). The first class was made by inserting a methylene group into the PNA backbone or the linker that connects the nucleobase to the backbone (Fig. 4, I). These modifications were made to assess the effect of chain length, in the backbone...
Peptide Nucleic Acids

Figure 3 PNA amphiphiles (representative structure shown) can form mixed vesicles with surfactants such as SDS. Hybridization to complementary DNA or RNA allows separation from complex mixtures using open channel capillary electrophoresis.

Figure 4 Examples of backbone-modified PNAs.

as well as in the linker, on the hybridization properties of PNA. Both structural changes induced significant destabilization of the PNA–DNA and PNA–RNA hybrid duplex. A single backbone modification lowered the $T_m$ of a PNA–DNA duplex by 8–20°C and a PNA–RNA by 6–15°C, depending on where the modification was made. These results suggest that the original PNA design, N-(2-aminoethyl) glycine backbone and carboxymethyl linker, which has the same number of atoms in the backbone and in the linker as the DNA, is optimal for hybridization to DNA and RNA.

The second group of backbone modifications was made by introducing methylene bridges that connect the various functional groups in the backbone and in the linker (Fig. 4 II). These modifications were made in attempts to introduce structural preorganization into an otherwise randomly folded PNA backbone structure (37) and led to improvements in the binding affinity (38) and RNA versus DNA selectivity (39). Although this result supports the hypothesis that preorganization of the strands reduces the entropy penalty for duplex formation, additional structural analyses will be required to determine whether these backbone modifications do preorganize PNA into helical structures and whether these helical structures bear close resemblance to that of the targeted molecules, DNA and RNA.

The third group of backbone modifications was made by installing amino acid side chains with R or S configuration at the α-position of the N-(2-aminoethyl) glycine unit (Fig. 4 III) (40). Generally, these chiral PNAs were found to form slightly less stable PNA–DNA complexes than the original unsubstituted PNA for backbones that contain amino acid side chains with bulky, apolar groups. PNAs that contain negatively charged amino acid side chains, such as aspartic or glutamic acid, were shown to induce even greater destabilization, presumably because of the electrostatic and/or steric repulsion. On the other hand, incorporation of positively charged amino acid side chains, such as lysine or arginine, led to the stabilization of the PNA–DNA duplex, with R having a larger effect than S.
amino acids. Furthermore, the arginine-modified PNAs, also referred to as "GPNAs" because of the presence of guanidinium groups on the PNA backbone, exhibited substantially improved cell uptake relative to unmodified PNAs (41). This is likely because of the similarity between GPNAs and various natural and synthetic compounds that feature multiple guanidinium groups and readily enter mammalian cells.

The fourth and perhaps most intriguing class of backbone modifications feature amino acid side chains installed at the γ-position of the N-(2-aminoethyl) glycine unit (Fig. 4 IV). Unlike the unmodified PNA or other PNA derivatives that have been developed so far, generally that do not fold into well-defined conformations, γ-modified chiral PNAs assume helical conformation (42). These chiral PNAs preorganize into either a right-handed or left-handed helix, which depends on the backbone configuration of the amino acids from which the PNA analogs were derived. Those PNAs that are derived from naturally occurring (and less costly) L-amino acids preorganize into a right-handed helix and bind to DNA and RNA with high affinity and sequence selectivity, whereas those derived from unnatural D-amino acids preorganize into a left-handed helix and do not bind effectively to either DNA or RNA.

**Nucleobase modifications**

Several modified nucleobases have been incorporated into PNA—many of which have been covered in a recent review (36). In general, any modified nucleobases can be incorporated into PNA as long as they can withstand the conditions used commonly in Boc or Fmoc solid-phase peptide synthesis. One of the first modified nucleobases to be incorporated into PNA was pseudo-isocytosine (J, Fig. 5). J is a synthetic analog of N-3 protonated cytosine and forms Hoogsteen base-pairs with guanine in triplexes at neutral pH. This enhances the stability of PNA2–DNA triplex invasion complexes significantly under physiologic conditions, although the kinetics of strand invasion at physiologic ionic strength is relatively slow.

Another important nucleobase to be incorporated into PNA was 2,6-diaminopurine (D, Fig. 5). D is a synthetic analog of adenine (A) that contains an extra exocyclic amine. When base-paired with the complementary thymine nucleobase, D forms three H-bonds as opposed to two H-bonds in base pairs of T with A. The extra H-bond provides additional stability to the hybrid duplex, with a gain in $T_{m}$ of 3–5°C/bp for PNA–DNA. In addition to providing duplex stability, D has been exploited, in combination with another modified nucleobase, 6-thiouracil (sU), in the recognition of mixed-sequence, double helical DNA in a binding mode called “double-duplex invasion” (12). In this binding mode, both strands of the ds DNA are targeted simultaneously by two PNA strands. Replacement of the naturally occurring T and A nucleobases with D and sU, which form a less stable base pair than T-A and T-U, prevents the two complementary PNA strands from hybridizing to one another to form a PNA–PNA complex. This strategy has been used successfully in the sequence-specific recognition and cleavage of mixed-sequence, ds DNA (43).

More recently, another modified nucleobase termed “guanidino G-clamp” (X, Fig. 5) has been incorporated into PNA (44). Guanidino G-clamp is an analog of cytosine, but unlike cytosine, which can form only three H-bonds with guanine, it can form five H-bonds—three through Watson-Crick and two through Hoogsteen base pairing. Besides the extra H-bonds, the guanidino G-clamp stack effectively with the adjacent nucleobases because it contains a tricyclic phenoxazine ring, and thus, it provides additional stability to the bound complex. No binding studies have been performed on guanidino G-clamp, but the introduction of a similar nucleobase analog that contains an amino instead of a guanidino group enhanced the stability of PNA–DNA and PNA–RNA duplexes by 23°C and 18°C per modification, respectively (45). Guanidino G-clamp is expected to confer even greater stabilization because of its ability to form five H-bonds as opposed to four in the case of amino G-clamp.

**Nanotechnology and Materials Science**

The information storage ability conferred to PNA by the nucleobases together with the chemical and biologic robustness of this synthetic nucleic acid have made PNA appealing particularly for use in the organization of chemical objects ranging
in size from molecular-scale to nanoscale. The outcome of the interaction between PNA and these chemical entities are materials whose chemical composition and three-dimensional structure are encoded in the nucleobases and/or in the secondary structure of the PNA. The information stored in the PNA is “expressed” into the new structures by relatively weak chemical and physical forces, such as hydrogen or coordination bonding and hydrophobic interactions. The synthesis and the study of the properties of these pre-programmed materials provides information relevant for the understanding of fundamental biologic processes, such as molecular recognition and self-assembly, and of the rules based on which artificial enzymes and molecular electronic devices can be built. The PNA-based materials have the potential of being useful in biology, diagnostics, and therapeutics.

Toward the molecular end of the scale range, PNA has been shown to act as scaffold for transition metal ions situated at the core of PNA duplexes (46) (Fig. 6). The metal ion incorporation was realized by the chemical substitution of nucleobases with ligands. This process is site specific because the ligands have higher affinity for metal ions than the nucleobases. The existence of the metal ions within the PNA duplex opens the possibility of directional electron transfer mediated by the metal ions, in a manner similar to that in which electron transfer metallo-proteins work in Nature. Also, some of the metal ions enhance electrochemical, optical, or magnetic resonance detection of the PNA strands or duplexes. At the nanoscale end, the predictable molecular recognition process based on hybridization of ssPNA attached covalently to carbon nanotubes (47) or shell cross-linked nanoparticles (48) has been used to achieve controlled mechanical manipulation of nanosize objects and to organize them in large-scale architectures or on surfaces. The strong interaction between PNA and DNA has also been exploited in the synthesis of DNA-based nanostructures. For example, bisPNAs have been used as tools for rational design of nanosize, DNA-based locked pseudorotaxanes or on surfaces. The strong interaction between PNA and these chemical entities are materials or on surfaces. The strong interaction between PNA and DNA has also been exploited in the synthesis of DNA-based nanoscale structures. For example, bisPNAs have been used as tools for rational design of nanosize, DNA-based locked pseudorotaxanes and catenanes. The strand invading ability of homopyrimidine bisPNAs allows them to be used as sequence-specific “openers” of DNA duplexes (49). The resulting single-stranded region of the DNA can in turn bind opposite ends of another single-stranded DNA that is circularized by DNA ligase to produce a catenane-like structure (50).

Biotinylated PNA oligomers have also found use as cross-linking agents to connect avidin with DNA three-way junction nanostructures, which yield hydrogels that grow and shrink in a temperature-dependent manner (51). Avidin-linked enzymes can be integrated into the hydrogel structure, where they can catalyze reactions of small substrates that diffuse into the pores of the gel (52). Cooling below room temperature led to precipitation of the gel and allowed the separation of the product and recovery of the enzyme.

**Conclusion**

The early reports of PNA’s abilities to bind to single-stranded and double-stranded nucleic acids with high affinity and selectivity generated much excitement that led to both in-depth characterization of the binding process as well as an impressive array of biologic, biotechnologic, and nanotechnologic applications. The pace of PNA research as measured by number of publications has grown steadily for the past 15 years and shows no sign of abating. Additional advances are expected to come as next-generation PNAs are developed, particularly those that feature backbone modifications and take advantage of the peptide-like character of PNA. Recent successes in improving antigenic/antisense activity and cell uptake bode particularly well for future use of this most versatile of DNA mimics in chemical biology.

Engineering of artificial metalloproteins is an expanding field with potential impacts in many areas from fundamental understanding of protein structure and function to industrial production of specialty chemicals such as chiral drug intermediates. Incorporation of unnatural amino acids and non-native metal cofactors into proteins is an emerging field in the area of protein design, as it offers the tantalizing prospect of introducing new functionality and provides exquisite probes for and fine-tuning of native protein properties. Although it is a relatively young field, engineering of non-native metalloproteins boasts a myriad of techniques for design, construction, and/or expression of the desired artificial protein. Additionally, many groundbreaking studies exist in this field that have enhanced basic scientific understanding of protein function or generated promising artificial enzymes. Discussion of the techniques prominent for incorporation of unnatural amino acids and non-native cofactors is followed by some of the most interesting applications of these techniques reported to date.

Approaches to Unnatural Amino Acid Incorporation into Proteins

Many methods have been developed to incorporate unnatural amino acids into metalloproteins, and these methods can be classified as either biological or synthetic in nature. Biological approaches rely on cellular machinery for placement of the unnatural amino acid or cofactor with its unnatural analog, while altering a specific structural or electronic element, may be accomplished without gross perturbation of the protein site it replaces. As the title suggests, metal-containing proteins are the focus of this article, and although many wonderful examples of protein incorporation of unnatural amino acids and cofactors exist, only those for metalloproteins will be considered in this review. Because the elementary nature and function of amino acids and cofactors differ, it is sensible to discuss them separately. Furthermore, discussion of the techniques prominent for incorporation of unnatural amino acids and non-native cofactors will be followed by some of the most interesting applications of these techniques reported to date.

Approaches to Unnatural Amino Acid Incorporation into Proteins

Many methods have been developed to incorporate unnatural amino acids into metalloproteins, and these methods can be classified as either biological or synthetic in nature. Biological approaches rely on cellular machinery for placement of the unnatural amino acid within the protein sequence. Recent advances in molecular cloning and biology are the essence of these techniques. The simplest of these is cavity complementation in which a metal ligand is mutated to Gly or Ala to create a cavity that can then be titrated by exogenous ligands. The use of auxotrophs (bacteria lacking the ability to produce a specific amino acid) can be used for global replacement of a natural amino acid with a structurally similar unnatural analog. Finally, and more excitingly, it is now possible to use the amber stop codon and tRNAs that have been specially

selected to charge with an unnatural amino acid to place the unnatural amino acid exactly at the coded position in the peptide sequence (13).

Synthetic approaches use chemical transformations on either native proteins, peptides obtained by solid-state synthesis, or both. Chemical modification is the simplest of these and requires the treatment of the selected peptide with a chemical reagent that alters reactive amino acid side chains such as Ser, Lys, or Cys (14). Because that particular amino acid at all positions of the protein is modified, it is difficult to make the chemical modification site-specific. Total solid phase peptide synthesis allows for site-specific incorporation of unnatural amino acids at any specific location (13), but it is limited in length, because the synthesis efficiency decreases with increased length of the peptide chain. This limitation has been eased by native chemical ligation which exploits the reactive properties of an N-terminal cysteine to connect two or more shorter synthetic peptides covalently via a peptide bond (16). The biological and synthetic approaches are complimentary and the combination of these two approaches has proven very useful. One excellent example is the semisynthetic technique of expressed protein ligation that couples a bacterially expressed peptide with a synthetic peptide in a fashion similar to that used for native chemical ligation (17). This hybrid of synthetic and biological techniques allows easy site-specific introduction of unnatural amino acids into much longer peptide sequences (18).

**Design and engineering of metallocproteins that contain unnatural amino acids using the biological approach**

The method of cavity complementation has been employed effectively to introduce unnatural amino acids as metal ligands into the oxygen storage protein myoglobin (11, 19) and into the electron transfer protein azurin (20). In the case of myoglobin, the proximal histidine that coordinates to the iron atom was removed, which generated a cavity that was titrated by neutral thiol and thioether ligands. Introduction of these unnatural amino acids demonstrated that ferrous heme iron proteins can be ligated by a neutral cysteine. These observations are important because they demonstrate that ferric heme proteins that apparently lose cysteinate ligation on reduction may in fact be ligated by neutral cysteines. Thus, ligation of the heme iron by unnatural amino acids has demonstrated the existence of a ligation state previously only hypothesized to exist and which significantly alters our understanding of the electronics and reactivity of the very important P450 class of enzymes. In the case of azurin, removal of one of the copper ligating histidines generated a cavity near the solvent exposed surface of the protein. It was shown that altering the type of unnatural amino acid titrated into the protein produced variations in the spectroscopic characteristics that encompass the known range of mononuclear copper-thiolate proteins. From this study, it became apparent that the protein scaffold has a preference for a few distinct geometries of the metal center. It is also important that the spectroscopic properties of the native protein could be restored by titration of the cavity with imidazole, which indicates that the introduction of the cavity had not altered the protein structure irreversibly. The use of unnatural amino acids has thus demonstrated that despite the wide variation in naturally occurring copper proteins, a few specific metal ligand geometries may be responsible for all variations in function.

The auxotrophic method has been used in the study of the monoxygenase P450 enzymes to replace all of the methionine residues with norleucine (Nle) (21). Although the Met to Nle substitution resulted in decreased thermal stability of the enzyme, a roughly two-fold increase in peroxysyngase activity was observed. This was noteworthy because peroxysyngase activity, which is the oxidation of organic substrates using hydrogen peroxide, is normally inefficient in the monooxygenase P450s. The increase in activity was attributed to the removal of the methionine residues, which are oxidized easily by hydrogen peroxide, resulting in enzyme inactivation. This study demonstrates the power of unnatural amino acids to tune the properties of native enzymes by introducing novel properties without sacrificing natural catalytic function.

The incorporation of unnatural amino acids into metallocproteins via RNA by using the amber stop codon has also contributed to the design of artificial metalloproteins. Using this technique, a para-cyano-L-phenylalanine was incorporated into myoglobin in place of the distal histidine (22). The cyano group on this unnatural amino acid proved to be a probe of ligand binding and local electronic environment, which distinguishes between linear and bent configurations of different diatomic heme ligands (i.e., O2, NO, and CO). This report demonstrated site-specific incorporation of a very useful probe via unnatural amino acids that might also find application in the study of protein folding and conformation, electronic fields within proteins, or biomolecular interactions. Site-specific modification of cytochrome c3 with a redox mediator was also accomplished using the amber stop codon encoding for unnatural amino acids (23). To achieve this goal, a para-propargyloxyphenylalanine unnatural amino acid introduced on the surface of the protein was reacted with an azido-viologen. The covalent anchoring of the redox active viologen near the hemes of cytochrome c3 was shown to increase the amount electron transfer both to the solution and the protein cofactor by three fold. This report expands the number of modifications that can be made site specifically in a metalloprotein because the unnatural amino acid used can react with any azide-bearing molecule. The development of a system for introducing a selectively reactive unnatural amino acid near a c-type heme is important and applicable to the study of other heme proteins. These studies demonstrate the use of the RNA method for incorporating unnatural amino acids, and an increase in the number of studies using this technique is anticipated.

**Design and engineering of metallocproteins that contain unnatural amino acids using synthetic techniques**

An excellent example of unnatural amino acid introduction via a synthetic technique may be found in work performed on the protease subtilisin. Chemical conversion of a catalytically active serine to a selenocysteine altered the catalytic activity...
significant (24). Instead of native hydrolysis activity, which is greatly suppressed, selenosubtilisin catalyzes the reduction of peroxides in a highly enantioselective fashion, and it has even been used for resolution of functionalized racemic peroxides with up to 99% enantiomeric purity in the alcohol produced (25). The methodology for incorporation of selenium on the catalytically active serine position has even been extended down the periodic table to incorporate tellurium (26) at this position. The new tellurometallase displays similar reactivity to selenosubtilisin but with altered kinetic properties. The dramatic changes in reactivity observed in subtilisin on incorporation of unnatural amino acids. Although limited by the size of protein it can make, the total synthesis of proteins has contributed significantly to the study and the design of metalloproteins. Replacement of two histidine residues in a de novo designed four-a-helix bundle with 4-L-(pyridyl)-L-alanines resulted in −6 × 104 weaker binding of the ferric heme and a near 300 mV increase in the reduction potential (28). Changing this same position to 1-methyl-L-histidine causes >7 × 103-fold decrease in ferric heme affinity but only 125-fold decrease for ferrous heme (29). The methylated histidine unnatural amino acid also prevented the favored heme coordination geometry and resulted in a five-coordinate high-spin ferrous heme similar to decysmyoglobin that could bind CO reversibly but not O2 (28). These substitutions of unnatural amino acids reveal the preferential binding of different redox states of the heme cofactor and provide insight into the importance of the protein environment for the reduction potential (28). A stabilizing effect of such a hydrogen bond on the reduced form of the protein had been predicted to increase the reduction potential. The replacement of the amide in question with an ester linkage lowered the reduction potential of the iron cluster by ∼100 mV, in agreement with the predicted stabilizing effect for this hydrogen bond. A gain, the use of unnatural amino acids confirmed the existence of subtle interactions between the protein environment and the metal center, and it emphasizes the necessity of including such interactions in protein design and engineering efforts. It is also important to note that an alteration such as exchanging an amide for an ester was impossible with conventional mutagenesis because all natural amino acids contain an amide linkage.

Artificial Metalloproteins: Design and Engineering of

Design and engineering of metalloproteins containing unnatural amino acids using semisynthetic techniques

Expressed protein ligation (EPL) has been used recently to introduce unnatural amino acids into metalloproteins to examine the effect of individual amino acids on fine-tuning the properties of the metal binding site. In the first report of EPL on a metalloprotein, the Cys in the type 1 blue copper electron transfer protein azurin has been replaced with selenocysteine, which resulted in marked changes in the electronic absorption and electron paramagnetic resonance (34, 35). However, little change was observed in the reduction potential. Conversely, when the axial methionine ligand in azurin is substituted by its structural analogs selenomethionine, norleucine, oxomethionine, trifluoromethionine, or difluoromethionine (Fig. 3), very little change is observed in the spectroscopic properties, but large changes in reduction potential are reported (>200 mV) (36, 37). A linear relationship between the reduction potential and the hydrophobicity of the axial ligand demonstrates that hydrophobicity is the dominant factor contributed by the axial ligand to tuning the reduction potential (36). Extrapolation of these results to studies with conventional mutagenesis demonstrate nearly identical effects of the axial ligand hydrophobicity on the reduction potential in all type 1 blue copper proteins (36). Type 1 blue copper proteins are one of the most common classes of electron transfer proteins, which play critical roles in processes such as photosynthesis and oxidative respiration. The role of the conserved axial methionine has been probed by mutagenesis using all other 19 natural amino acids, but the exact role remained undefined because conventional mutagenesis changes more than one factor, such as electronic and steric factors, at the same time. Using isostructural amino acids, the exact effect of the methionine is more readily defined, and observation of the above trend is only possible by introducing unnatural amino acids using EPL.

Although it is not used to study the metal binding site, EPL has been used to expand the DNA recognition abilities of a zinc-finger protein (32) by replacement of arginine with citrulline (Cit) (Fig. 2b). DNA-binding specificity of a zinc-finger is determined primarily by three amino acids. One such amino acid residue, Arg, recognizes the 5′-most guanosine (G) via donation of two hydrogen bonds. Replacement of the Arg with natural amino acids resulted in similar (as with Lys, which like Arg has only hydrogen bond donors) or decreased specificity.
Similar imidazole terminated rhenium molecular wires of a photogenerated radical with the active site of P450cam covalent electron tunneling wire that allows direct interaction between the heme and ruthenium complex, intermediates that are very difficult to see using the protein’s native redox partners were observed. Implementation of these unnatural cofactors may be far reaching, and it may allow detailed study of many biological electron transfer processes by removing the diffusion limits and time resolution restrictions of more conventional techniques.

An artificial catalyst that consists of a monoclonal antibody, 1G8, and the achiral rhodium complexes against which it was raised, exploits noncovalent interactions to promote enantioselective catalysis (41). Not only did the antibody bind tightly to the non-native cofactor, but it also provided a chiral environment. Hydrogenation of 2-acetamidoacrylic acid proceeded with 98% ee. The substrate specificity was also very high, and the antibody prevented the hydrogenation of larger substrates. Inclusion of a substrate mimic during antibody generation should improve the activity and substrate scope for the artificial catalyst. Additionally, rational design of the original antibody isolated is also possible. As the first report of asymmetric hydrogenation by a transition metal-immunoglobulin complex, this approach holds promise for future development of tightly bound non-native cofactors as catalysts.

The noncovalent approach has been used to replace the native heme in heme proteins such as myoglobin, with non-native protoporphyrin IX modified at the propionate groups. Removal of the native heme followed by reconstitution with the propionate-modified protoporphyrin IX has led to myoglobins that display increased negative charge (42), flavin redox cofactors (43), and glycosylation (44) on the heme edge (Fig. 4). These modified hemes modulate a host of properties such as protein-protein interactions, protein-protein recognition, and electron transfer. Extensive reviews that contain the specifics of each heme modification are recommended to the reader (9). The propionate-substituted porphyrins allow much more direct contact between the heme and the solution outside the protein than occurs with only native heme. In a similar strategy, introduction of a porphycene in place of the native heme led to a myoglobin with dramatically enhanced dioxygen affinity (45). These authors show that direct alteration of the cofactor may be more effective than conventional mutagenesis for improving the properties of a native metalloprotein. The role of the formyl substituent on heme a has also been probed by comparing heme b and a heme a mimic inside a four-α-helix bundle (46). It was demonstrated that a major function of the formyl substituent is to raise the reduction potential of the heme, which it does by destabilizing the binding of the ferric state (47). This work with non-native cofactors is valuable because it is difficult to probe the thermodynamics of binding, oxidation reduction events, and variance of the heme type simultaneously in the native system. Lastly, a four-α-helix bundle that binds a nonbiological metalloporphyrin selectively over native heme has been reported, which demonstrates that proper design can actually favor the non-native cofactor (48, 49). The design of a peptide that can bind a non-native cofactor selectively takes us closer to the rational design of a metalloprotein from the ground up and provides an important testing ground for our knowledge of protein structure and function.

Figure 4 Introduction of non-native metal Schiff base and substituted heme cofactors by noncovalent attachment in myoglobin. (Adapted from Reference 8, p. 6, 7, copyright 2007 with permission from Elsevier.)

Reconstitution of heme proteins with modified hemes relies heavily on the strong protein-heme interaction and incorporation of non-native cofactors that bear less structural similarity to heme is more challenging. The metal ligand affinity of the proximal His in myoglobin for a Cu(II) N-salicylideneaminoacido compound has been used for noncovalent attachment of this complex (50) demonstrating that noncovalent attachment to a protein is possible even if the new metal cofactor does not resemble heme. Although the metal Schiff base complexes Mn(III)salen and Cr(III)salophen are roughly planar and similar in dimension to heme, a structural-based design to modify both the metal complex (through substitution of the 5 and 5′ positions) and protein (mutation of Ala71 with Gly) was required (Fig. 4) (51) to obtain cofactor incorporation. Crystal structures with an Fe(III)salophen derivative reveal disorder of the non-native cofactor induced by steric repulsion from Ala71 (52). In catalytic sulfoxidation, the modification of His64 to Asp allowed the Mn(III) derivative to produce enantioselectivity up to ∼30% (53). Such detailed analysis of an artificial cofactor in a protein has allowed these authors to propose substrate-binding locations and to delineate substrate and cofactor interactions that may be responsible for the catalytic activity. Application of similar techniques allowed the heme oxygenase incorporation of Fe(III)salen (54). This non-native cofactor composite demonstrated the importance of a hydrogen bond to Arg177 for rapid electron transfer in heme oxygenase. Furthermore, the direct participation of the non-native cofactor in electron transfer reactions via the conserved interactions of the native system demonstrates the potential for regulation of non-native cofactors by the native protein environment.

A more general noncovalent attachment method is the use of biotin for attaching cofactors to avidin or streptavidin. This technique was first demonstrated by Wilson and Whitesides (55) who generated a biocatalyst capable of asymmetric hydrogenation of α-acetamidoacrylic acid with up to 44% ee using a biotinylated achiral diphosphinerhodium(I) complex and avidin. Lin et al. expanded this concept with a chiral Pyrphos-Rh(I) complex and hydrogenated itaconic acid with up to 48% ee (56). Recently, Letondor et al. (57) have demonstrated the use of this system by the noncovalent attachment of various diphosphine rhodium, ruthenium and iridium complexes to avidin and streptavidin (Fig. 5). The subsequent tuning of the linker and
Design and engineering of metalloproteins containing non-native cofactors through covalent attachment

The covalent attachment of non-native cofactors to a protein host has the advantage of site-specific incorporation and high yield and is usually achievable with minimal structural modification to the complex or protein host, even if the protein affinity for the cofactor is minimal. A Cu(I)-I. 130 phenanthroline, an efficient DNA cleavage agent, was covalently attached via a cysteine to several DNA-binding proteins (Fig. 6a). The resulting combination of efficient DNA cleavage by the cofactor and selective DNA positioning by the protein makes an excellent artificial nuclease. The covalent attachment of this same complex to an active site Cys in the adipocyte lipid-binding protein cavity has provided high enantiomeric selectivity for several reactions and good conversion. Examples include hydrolysis of acetamidocarbamic acid with 96% ee (58), transfer hydrogenation of p-methyl acetoephone with 94% ee (59), and oxidation of aromatic alcohols (60). A similar system has also been subjected to directed evolution for hydrolysis of acetamidocarbamic acid (61). The stepwise improvement of selectivity to 65% ee demonstrates that the noncovalent attachment of the metal cofactor can be coupled to biological techniques for improvement of the artificial metalloprotein.

**Conclusions**

Great progress has been made in the design and engineering of artificial metalloproteins. The introduction of unnatural amino acids has created new probes of physiologic activity and provided methods for fine-tuning protein properties not available with conventional biochemical techniques. Such techniques have also been used to elucidate the subtle role of key residues in protein metal binding sites as was never possible before. The incorporation of non-native cofactors has enhanced our understanding of protein design by revealing factors, both covalent and noncovalent, that govern cofactor binding and enzyme enantio- and chemoselectivity. Last, novel function has been introduced in metalloprotein constructs, with directed evolutionary, rational design, and combinatorial techniques for the design of non-native metalloproteins has a bright future in biotechnological and pharmaceutical applications.

A "click peptide" is a chemically modified peptide analog used to understand the biologic function of peptides. A click peptide does not exhibit the inherent biologic activity of the original peptide because of a simple chemical modification of the peptide backbone and, by adding an exogenous action ("click") such as pH-change or photo-irradiation, easily affords the native peptide in situ with a quick and easy one-way conversion via a native amide bond-forming reaction. For example, the designed click peptides of Alzheimer's amyloid β peptide (Aβ) 1–42, which did not exhibit a self-assembling nature because of a backbone isomerization from a native Gly25-Ser26 bond to a β-ester bond, could migrate to the intact Aβ1–42 under physiologic conditions by pH- or photo-triggered "click" via an O→N intramolecular acyl migration reaction. This click peptide overcomes the difficulties in handling Aβ1–42 in syntheses and biologic experiments, which clarifies the currently unexplained processes of Alzheimer's disease.

The use of intact peptides in an in vitro experiment sometimes causes considerable discrepancies in the biologic data because of the difficulties in handling and controlling the properties of peptides such as low water-solubility and highly aggregative nature. A "click peptide" is a chemically modified peptide analog used to understand the biologic function of peptides while overcoming the problems associated with the peptide properties (Fig. 1) (1–3).

A click peptide has the ability to:

- Control the following natures of the original peptide.
  - Physicochemical property (e.g., water-solubility, self-assembly, aggregation, or folding)
  - Biologic activity (e.g., ligand-receptor binding affinity, or enzyme-substrate binding affinity)
- Convert to the native peptide in situ by an exogenous action ("click").
- Examples of such an action include pH-change and photo-irradiation.
- Because a rapid amide bond formation is required, an intramolecular reaction is desired.
- A n atom-economical reaction should be selected as the conversion reaction to avoid a side effect derived from coreleased products in biologic experimental conditions.

Additionally, in the design of the click peptide, a simple modification of the peptide backbone is desired to minimize difficulties in chemical synthesis of the click peptide and the conversion process to the native peptide.

Biologic Background

The highly aggregative feature of peptides is a significant obstacle against establishing a reliable in vitro biologic experimental system to investigate the major causative agents of diseases. Recent amyloid β peptide (Aβ)-related studies have encountered such problems because of their highly aggregative nature. A more clear understanding of the pathologic mechanism of Aβ would be of great value to discover novel drug targets against Alzheimer's disease (AD). Aβ is the main proteinaceous component of amyloid plaques found in the brain as a pathognomonic feature of AD (4), and it has been found to be neurotoxic in vitro and in vivo (5). Several studies have supported the hypothesis that neurotoxicity and the kinetics of Aβ1–42 aggregation are related directly to the assembly state in solution. However, the pathologic self-assembly of Aβ1–42 in amyloid plaque formation, a process currently unexplained, is very difficult to demonstrate in vitro because of its uncontrolled self-assembly. The synthesized Aβ1–42 in
Itself contains various oligomeric forms (6), and Aβ1–42 undergoes time- and concentration-dependent aggregation in aqueous TFA (trifluoroacetic acid)-acetonitrile solution used in high performance liquid chromatography (HPLC) purification (7). Moreover, the Aβ1–42 monomer forms aggregates easily even in a standard storage solution such as dimethylsulfoxide (8). This uncontrolled self-assembly in an in vitro experiment causes considerable discrepancies in the biologic data. As a result of its highly aggregative nature, difficulties in handling Aβ1–42 have hampered the progress of Aβ1–42-related AD research such that constructs have been used instead of the native peptide.

Recently, it has been ascertained that the pathologic self-assembly nature of inherent peptides or proteins is one major event that leads to the development of many diseases such as prion protein in prion disease, α-synuclein in Parkinson’s disease, and islet amyloid polypeptide in type 2 diabetes, as well as Aβ1–42 in AD (9).

**Chemistry**

We designed and synthesized the click peptide based on the O-acyl isopeptide (Fig. 21–3). The click peptide has an O-acyl isopeptide structure of the corresponding native peptide. Hydrogen bond interactions between peptide chains often play a crucial role in the onset of physicochemical and biologic actions through their contributions to the conformational stability of the higher order structure. In the click peptide, a newly formed ester bond results in the inhibition of the ordered hydrogen bond interactions, which lead to conformational changes, and mask the activity of the native peptide. Additionally, the target peptide was generated via an O→N intramolecular acyl migration reaction. The O→N intramolecular acyl migration is a very attractive chemical reaction for the click peptide. The O→N intramolecular acyl migration is capable of rapid amide bond formation under physiologic conditions (pH 7.4) because of the energetically favorable intramolecular five-membered ring intermediate. It is an atom-economical reaction; thus, no byproduct is released during conversion to the parent peptide, which is a great advantage in toxicology in biologic experimental systems.

**O-Acyl isopeptide method**

In 2003, we discovered that the presence of an O-acyl instead of N-acyl residue within the peptide backbone changed the secondary structure of the native peptide significantly (10). The coupling and protection efficiencies improved during solid-phase peptide synthesis of peptide derivatives that possess “difficult sequences,” most likely because the O-acyl isopeptide prevented the formation of secondary structures that disfavor coupling. Generally, the difficult sequences are hydrophobic and are prone to aggregate in solvents during synthesis and purification. This aggregation is attributed to inter/intra-molecular hydrophobic interactions and the hydrogen bond network among resin-bound peptide chains, which results in the formation of extended secondary structures such as β-sheets (11). In addition, the target peptide was generated subsequently by an O→N intramolecular acyl migration reaction. This finding marked the beginning of the development of the “O-acyl isopeptide method” for peptide synthesis. The method has begun to be used by several other groups, especially Mimna et al. (12), Coin et al. (13) and Börner et al. (14), which indicates that the O-acyl isopeptide method is widely advantageous for peptide preparation.

**Synthesis of O-acyl isopeptide**

The synthetic procedure of O-acyl isopeptides has been well established (10). O-acyl isopeptides can be prepared easily using Fmoc-based solid-phase peptide synthesis. After Boc-Ser(Thr)-OH is coupled to a peptide-resin to obtain Boc-Ser(Thr-peptide-resin), Fmoc-Xaa-OH is esterified to the β-hydroxy group of Ser(Thr) residue using a DIC (1,3-diisopropylcarbodiimide–DMAP (4-dimethylaminopyridine) method. A thorough esterification on the resin might induce epimerization at the esterified amino acid residue, the use of an O-acyl isopeptide unit, which can be synthesized easily in solution, could avoid this problem (15). The protected O-acyl isopeptide-resin is obtained through coupling of additional amino acid residues using conventional techniques. During Fmoc removal of the second amino acid residue at the N-terminal side next to the ester bond, caution should be used to prevent the formation of diketopiperazines. Finally, the desired O-acyl isopeptide is obtained by
An application of the method to Alzheimer’s Aβ1–42 revealed that the O-acyl isopeptide of Aβ1–42 (in which the Gly10-Ser18 sequence of Aβ1–42 was isomerized to a β-ester bond) could be synthesized effectively and stored without spontaneous self-assembly (1-3). Intact monomer Aβ1–42 could then be obtained from the isopeptide under physiologic experimental conditions. The water solubility of the TFA salt of the isopeptide was 100-fold higher than that of Aβ1–42 (0.14 mg mL⁻¹). Purified isopeptides could be converted quantitatively to Aβ1–42 via O–N intramolecular acyl migration in phosphate buffered saline (pH 7.4) at 37°C with a half-life of 1 minute (Fig. 3), whereas the TFA salt of the isopeptide was stable at 4°C in both solid state and dimethylsulfoxide solution. The Aβ1–42 isopeptide proved to be easier to synthesize and purify than Aβ1–42; moreover, it provided an opportunity to prepare Aβ1–42 in situ rapidly under physiologic conditions. The spontaneous self-assembly of Aβ1–42 could thus be more studied effectively to elucidate the inherent pathologic functions of the aggregative Aβ1–42 in AD. Moreover, slower migration (t1/2 = 3 hours) was observed at pH 4.9, and no migration at pH 3.5 after incubating for 3 hours. These results suggest that this pH-dependent O–N intramolecular acyl migration enables pH-triggered click for controlled in situ production of an intact Aβ1–42 from the click peptide.

Photo-triggered click peptide of Aβ1–42

Furthermore, we have synthesized a photo-triggered click peptide of Aβ1–42, in which a photocleavable 6-nitroveratryloxy-carbonyl group (16) was introduced at the ε-amino group of Ser14 in the Aβ1–42 isopeptide (Fig. 4, 2, 3). The photo-triggered system had been employed to provide well-defined, time-controllable, and position-selective activation by light irradiation when studying biologic systems, because light is the fastest medium and can be focused to a restricted area. In size-exclusion chromatography, oligomers of Aβ1–42 increased in quantity with incubation time (pH 7.4, 37°C) at the expense of the monomer. On the other hand, the photo-triggered click peptide remained in the monomeric form after 24 hours of incubation. Similarly, thioflavin-T fluorescence intensity (17), which corresponds to the extent of fibril formation, increased with incubation time in the case of Aβ1–42, yet unchanged in the case of the photo-triggered click peptide after 24 hours of incubation. Our results indicated that the click peptide was nonaggregative. The isopeptide structure resulted in complete inhibition of the aggregative nature of Aβ1–42. Photo-irradiation of the click peptide and subsequent O–N intramolecular acyl migration afforded intact Aβ1–42 rapidly in situ. In the absence of light, the click peptide was stable during storage. This method may provide a useful system to investigate the biologic dynamics of Aβ1–42 in AD with high spatial and temporal resolution by photochemically inducible activation of peptide self-assembly.

Chemical Tools and Techniques

An experimental system that can prepare a bioactive peptide in situ is advantageous to investigate biologic functions. The click peptide would be a useful tool to establish such an experimental system. As a tool with a similar concept, a “caged” compound is a synthetic molecule whose biologic activity is masked by a covalently attached photocleavable protecting group, and affords the bioactive molecule by photo-irradiation. Generally, such a photo-triggered system is considered to be advantageous for studying the dynamic processes of peptides and proteins, because upon photoactivation, only a short duration of time is required to control the spatiotemporal dynamics.
of the native compounds (18, 19). A fundamental drawback of the caged strategy on large peptides and proteins is that a small photocleavable group does not always mask biologic activity, because high potency may be attributed to large sections of the peptide structure (19, 20). This drawback can be overcome by the “click peptide” strategy because the native properties are masked in the isopeptide and released by O-acyl to N-acyl migration. This advantage should open new doors for the development of novel and useful photo-triggered tools to probe systems in chemical biology and medical science.

Because difficulties in handling Aβ1–42 in syntheses and bio-
logic experiments would hamper the progress of Aβ1–42-related AD research, we expect that the “click peptide” method will help to clarify the currently unexplained processes of AD. Moreover, many amyloidogenic diseases, as well as Aβ1–42 in AD, have recently attracted much attention and are being studied to discover novel drug targets (9). Thus, we hope that the “click peptide” strategy would be applied widely to these amyloid-related peptides or proteins. Click peptide can serve as a tool to study peptide folding and aggregation in chemical biology-oriented research, because acyl migration can be induced chemically or photochemically to release the native peptide.

Peptide-bond formation requires activation of a carboxyl group followed by aminolysis of the activated carbonyl. The reagents and methods employed for activation, the intermediates and activated forms generated and their aminolysis are described. Rationalization of the strategy employed to avoid isomerization during coupling is presented. Approaches for minimizing aggregation that interferes with coupling are also given.

Peptides are employed for therapeutic purposes and for research in the development of new drugs, vaccines, biomarkers, diagnostic agents, and so on. The demand for these peptides has experienced double-digit annual growth over recent years (1). Most peptides are obtained by chemical synthesis. Chain assembly is effected by successive addition of single residues always starting from the carboxy-terminus, which eliminates the danger that isomerization might occur during coupling. If the peptide is long enough, then two or more segments may be combined to produce the final product. Moreover, the chain may be assembled in solution or on a solid phase. Many methods are available for linking two amino acids together. Each has its own peculiarities as well as favorable and unattractive features. Some methods of coupling are of general use, some are not applicable to solid-phase synthesis, and some are employed only for specific purposes. The choice of method depends on circumstances that vary considerably; every method seems to find its place among the armaments employed for synthesis. An intriguing observation is that five different coupling methods are involved in the synthesis in kilogram amounts of the nine-residue drug Atisoban (2).

**Peptide-Bond Formation**

A peptide bond is formed by reaction of the carboxyl group of one amino acid with the amino group of a second amino acid (Fig. 1A). A combination of the two occurs when the carboxyl group is activated, which means it has been rendered deficient in electrons or electrophilic, and the amino group is electron rich or nucleophilic. The amino group is nucleophilic if it is not protonated; the carboxyl group is activated by an electron-withdrawing moiety to it. The latter is achieved by use of compounds called coupling reagents or by one or more chemical reactions. Peptide-bond formation is slower when the activated residue is valine, isoleucine, or threonine protected on the side chain; these are known as hindered residues. During the process of aminolysis, a competing reaction may occur (Fig. 1B) because the carbonyl on the amino group of the activated residue is also nucleophilic. The result is the formation of a five-membered cyclic structure, which is referred to as a 5(4H)-oxazolone that contains nitrogen and oxygen atoms and a carbonyl group, with substituents on carbons 2 and 4. The substituent at C-4 is the side chain of the amino acid; the substituent at C-2 originates from the acyl group of the activated residue. When the acyl group is another amino-acid residue, that is, if the activated component is a peptide, then the structure is a 2-alkyl-5(4H)-oxazolone that is chirally unstable. It readily tautomerizes (Fig. 1F) to give a mixture of the two enantiomers of the oxazolone. When the acyl group is that of the protector of an amino acid, the oxazolone that is formed is a 2-alkoxy-5(4H)-oxazolone, which is chirally stable and does not isomerize (3). These alkoxy-carbonyl protectors (ROCO, often referred to as “urethane” protectors, which is incorrect; urethane = ROCONH₂), namely benzoyloxycarbonyl (Cbz or Z; benzyl carbonyl), tert-butyloxycarbonyl (Boc) cleaved by aci-dolysis, and 9-fluorenylmethoxycarbonyl (Fmoc) cleaved by beta-elimination have been designed, in that order, so that the activated residue does not isomerize during couplings. The effect of the tautomerization of the 2-alkyl-5(4H)-oxazolone is the production (Fig. 1E) of some other isomer of the peptide product because the oxazolone also undergoes aminolysis. Hence, coupling of an N-alkoxycarbonylamino acid occurs without enantiomerization of the residue because even if the 2-alkoxy-5(4H)-oxazolone is formed, it does not isomerize. However, there is a danger to produce epimeric peptides during the coupling of an N-protected peptide because of the severe tendency of the activated peptide to form the 2-alkyl-5(4H)-oxazolone that isomerizes readily and is also a precursor of the product. In all cases, the product of isomerization is a mixture of epimeric peptides. When the activated residue is isoleucine or threonine that have two stereogenic centers and when the activated component is a peptide, which does
Coupling Methods for Peptide Synthesis

Activated Forms

A multitude of activated forms of amino acids and peptides is available (Fig. 2), which have varying stabilities. Some are shelf-stable reagents; some can be prepared and manipulated, but they are not stable enough to be stored; and others are intermediates that have been postulated to explain the results. In fact, the most popular coupling reagents generate activated intermediates that have been postulated to explain the results. When the activated component bears an N-alkoxycarbonyl group and the amino acid is other than glycine, isoleucine, or threonine, the process is an enantiomerization (4), but it is also referred to as racemization. The process of isomerization of an activated peptide is also often referred to as racemization, but it is careless usage of the term and an unwarranted extension of the meaning of the word.

Auxiliary Nucleophiles

Peptide-bond formation involves reaction of the nucleophilic amino group of one residue with the activated carboxyl group of a second residue (Fig. 3). In many cases, the activated residue reacts first with another molecule to produce a compound that is activated by another moiety; the latter then undergoes aminolysis to give the peptide. These molecules are referred to as auxiliary nucleophiles. The original ones were incorporated into coupling reactions when it was realized that their presence had beneficial effects. The common auxiliary nucleophiles (Fig. 3) (6-9), which are also known as additives, appear in Fig. 4. Each possesses a hydroxyl group; all except the HOSu are slightly acidic with pKs in the 3.4-4.6 range. They participate in coupling reactions in one of two forms. Either they are added in their original form HOWN, or they are present by virtue of the fact that the coupling reagent employed is composed of the deprotonated moiety -OW attached to a positively charged atom that is a strong electrophile (Fig. 5). HOSu serves primarily as a nucleophile for the preparation of activated esters (10); that is, it is added to an activated amino acid without the simultaneous presence or subsequent addition of an amino-bearing residue. The other auxiliary nucleophiles are added to carboximide-mediated reactions to suppress the side reactions of isomerization (7) (Fig. 1) and N-acylurea formation (Fig. 4). They protonate the intermediates that are formed, namely the O-acylisoureas (Fig. 4) and the oxazolone (Fig. 1), which prevents their rearrangement and tautomerization, respectively, that lead to undesired consequences. The protonated intermediates are strong nucleophiles that readily yield the peptide product. Hence, the additives trap activated intermediates that prevent the side reactions. When the additives are incorporated into coupling reagents, they are released as the anion -OW as soon as the reaction is initiated. The anion is a strong nucleophile that can react with or trap any activated intermediates that are formed. The compounds generated are activated esters that undergo aminolysis to give the peptide. The traditional additive has been HOBt (7); HOAt (HOABt) (9) is of more recent development. HOObt (8) was not employed in the past because of the known side reaction of aminolysis at the carbonyl of the additive. However, this reaction occurs in negligible amount, and the additive has received renewed interest. Although it was dormant for many years, HOBt (7) has surfaced with a vengeance as it is being employed in multikilogram amounts in the synthesis of cephalosporin and the fusion inhibitor Fuzeon. It and HOAt

Coupling Methods for Peptide Synthesis

Activated forms of N-alkoxycarbonylamino acids (RCO = R1OCONHCHR2CO) and Nα-protected peptides. Some are aminolyzed (A) to give the peptide, and some may generate (B), a second activated form that is also a source of the product. Experience indicates that acyl halides and symmetrical anhydrides of peptides do not exist.

Figure 3 Auxiliary nucleophiles (additives) that suppress side reactions by reacting with activated intermediates, and the two acylated forms of benzotriazole that are produced.

are often superior to HOBt as additives; their hydroxyl groups are slightly more acidic, which provides better leaving groups in the esters. HOcbt is less expensive. The addition of HOBt to a carbodiimide-mediated reaction minimizes the dehydration of side-chain amides that occurs in its absence.

Coupling Methods

Peptide-bond formation is achieved in two ways. In the first approach, a reagent is added to a mixture that contains a component with a free carboxyl group and one with a free amino group. Such coupling reagents include carbodiimides, EEDQ (Fig. 4), andonium-salt based reagents (Fig. 5). The other approach involves preparing the activated component after which the amino-bearing component is added. Here, one can distinguish two separate cases. In one case, the activated form is a shelf-stable compound such as an activated ester or an N-carboxyanhydride (NCA). In the other case, the activated form is employed as soon as it is prepared. Examples include MxAn as well as SyAn and azides.

Dialkylcarbodiimides

The compounds implicated in carbodiimide-mediated reactions (11, 12) appear in Fig. 4A. The reaction is postulated to be initiated by protonation of one of the slightly basic nitrogen atoms by the acid followed by attack at the central carbon atom by the acid anion that generates the 0-acylisourea (OAU). Aminolysis the OAU gives the peptide with liberation of N,N′-dialkylurea. A side reaction of N-acyl-N,N′-dialkylurea (NAU) formation by 0- to N-acyl shift of the OAU can occur. The latter is avoided by adding an auxiliary nucleophile that protonates intermediates. The acyl shift is promoted by heat and tertiary amine that assures a deprotonated nitrogen atom, and delay in the aminolysis caused by bulkiness in the reacting residues. The three common carbodiimides are dicyclohexylcarbodiimide (R4 = R5 = C6H11, DCC) (11) giving urea DCU, disopropylcarbodiimide (R4 = R5 = C(CH3)2, Dic) giving urea
DIU, and ethyl(dimethylamino)propyl)carbodiimide hydrochloride \( R^2 = C_2H_5, R^3 = (HCl) (CH_3)_2NCH_2CH_2CH_2, EDC \) giving urea EDU (12). All carbodiimides are allergic, which cause skin irritation after contact with DCC. The acid displaces the ethoxy group after which spontaneous rearrangement to the MxaN occurs with expulsion of quinoline. Aminolysis of the MxaN is the source of the peptide. Unavoidable aminolysis at the other carbonyl gives a small amount of irreversibly substituted amino component as impurity.

Symmetrical anhydrides (Fig. 2)

In a variant (15) of the carbodiimide method, two moles of an N-alkoxycarbonylamine acid are reacted with one mole of DCC in dichloromethane (DCM). After 30 minutes, the DCU is removed by filtration and the solution is mixed with the aminolysing component. The DCM is sometimes replaced with dimethylformamide (DMF) for the aminolysis step. SyA/N are less reactive and hence more selective but gives clean reactions. Some SyA/N have been isolated and stored (16, 17), but the practice is no longer recommended for synthesis in solution because EDU and the NAU are sol-uble in water. It is available as crystals that are expensive. Re- actions are usually effected by adding the reagent to a mixture of the reacting components and the auxiliary nucleophile if desired. In a variant, the acid is allowed to react with itself and possibly an additive after which the amino-containing component is added. In this case, the N-alkoxycarbonylamine acid is converted into the SyA/N and the activated ester, respectively, prior to the aminolysis. The efficiency of a carbodiimide-mediated coupling of a peptide that is effected in the presence of an aux-iliary nucleophile is enhanced by the presence of cupric ion (13). Cupric ion prevents a 2,4-dialkyl-5-OH l-oxazalone from isomerizing (13).

1-Ethoxycarbonyl–2-ethoxy-1,2-dihydroquinoline (EDEQ)

This variant (14) (Fig. 3B) is employed in the same way as carbodiimides and occasionally by operators who have devel-oped a skin irritation after contact with DCC. The acid displaces the ethoxy group after which spontaneous rearrangement to the MxaN occurs with expulsion of quinoline. Aminolysis of the MxaN is the source of the peptide. Unavoidable aminolysis at the other carbonyl gives a small amount of irreversibly substituted amino component as impurity.

Mixed anhydrides (Fig. 2)

The MxaN method is popular for synthesis in solution; it is inexpensive and simple to effect. Chloroformate \( R^2OCOCl \) \( R^2 = \text{ethyl, } C_2H_5 \text{, or isobutyl, } \text{CH}(CH_3)_2 \) is added to a small excess of the acid at \(-5^\circ C\) in the presence of tertiary amine and after 30–60 seconds, the aminolysing component is added (38). The reaction is complete within 30–60 minutes. Traditional solvents have been tetrahydrofuran and DMF; the favored ter-tiary amine is N-methylmorpholine (NMM). NMM is believed to act as an acceptor of the acyl group that forms the acylmor-pholinium ion (RCO-N'N'MM), which is the acylating reagent. It was thought for many years that halo-containing solvents were unsuitable; however, DCMM is a good solvent provided the ter-tiary amine is not triethylamine as this combination retards the formation of the MxaN (19). Strictly anhydrous conditions are also not essential because a MxaN can be purified by washing it with aqueous solutions (19). MxaN have not been employed in solid-phase synthesis because a side reaction of aminolysis occurs at the wrong carbonyl (Fig. 4B) in the range of 1–10% that is unavoidable. The larger amounts develop when the acti-vated residue is hindered. The urethane produced is stable to all conditions used for deprotection; hence, the impurity can be readily eliminated. Isospropyl chloroformate seems to be a super-ior reagent for MxaN reactions (20). MxaN can be employed for acylation of an amino acid or peptide with an unprotected carboxyl group in polar or partially aqueous solvent.
Coupling Methods for Peptide Synthesis

Figure 4  (A) Compounds implicated in carbodiimide-mediated reactions. The acid is postulated to add to the carbodiimide generating the O-acylisourea. Aminolysis occurs at the point indicated by the dashed arrow. (B) Compounds implicated in EEDQ-mediated reactions. The acid is postulated to displace the ethoxy of the reagent generating \( \text{MxAn} \) which rearranges to the \( \text{MxAn} \). Aminolysis (a) gives the desired peptide and (b) the ethoxycarbonylated nucleophile as impurity.

Figure 5  Structures and examples of nomenclature for phosphonium and carbonium salt-based reagents. Rules of nomenclature dictate that the latter be named as modified ureas; see text for revised structures; “ino” indicates a ring linked at the nitrogen atom.

reagents are more attractive for solid-phase synthesis. The chemistry of the uronium-based reagents is complex. In fact, the BTU of HBTU and TBTU does not have the structure given in Fig. 5, but it is \( 1-(\text{bis}(\text{dimethylamino})\text{methylene}-1-H\text{-benzotriazolylinium} \, 3\text{-oxide, that is, the tetramethylcarbenium moiety} \, \text{is linked to the other nitrogen atom of the ring, analogous to structure 5 (Fig 3) (26). Acylated HOBt had originally been shown to exist in solution as two forms in equilibrium, the ester (RCO}_2\text{Bt}) \, \text{and the N-acyl N'-oxide (RCO}_2\text{Bt} \to \text{O}) (6). In model experiments, the uronium forms of HBTU and HATU reacted more quickly and led to less epimerization than the guanidinium forms (27). Other reagents are continuously being developed, typical examples being Bsc-\, or Bsc-1 (28) and PyCOP (Fig. 5) (29). Reagents based on HODhbt have also been described. All have their unique properties. The azabenzotriazolyl-containing reagents seem to be particularly effective for performing difficult couplings (30). Acyl halides (Fig. 2)

A straightforward method of coupling involves conversion of an Fmoc-amino acid (Fmoc-Xaa-OH) to the chloride Fmoc-Xaa-Cl, using thionyl chloride \((\text{SO}_2\text{Cl})\) in DCM (31, 32) or triphosgene \((\text{O}=\text{C(OCCl}_3)\), which is a source of phosgene \((\text{COCl}_2\)) (33). Only the latter allows preparation of derivatives with acid-sensitive side-chain protectors \( \text{Bzl} \) but not \( \text{Boc} \). Also available are \( \text{Bzl} \), \( \text{Boc} \), and Fmoc-amino-acid fluorides obtained from the acids using cyanuric fluoride \((\text{C}_3\text{N}_3\text{F}_3)\), diethylaminosulfur trifluoride \((\text{DAST, Et}_2\text{NSF}_3)\), or tetramethylfluoroformamidium hexafluorophosphate \((\text{TFHH, Me}_4\text{N}_2\text{C}+\text{HF}_6^-\text{which is activated in DMF by tertiary amine. The amino-containing component is added after removal of excess reagent and side products. TFFH is employed for generating the fluoride in the presence of the incoming nucleophile. The Fmoc-Xaa-Cl are highly activated reagents that generate the strong acid HCl on aminolysis. Neutralization by tertiary amines causes formation of the 5(4H)-oxazolone that is aminalized more slowly, so it is best to avoid this structure by use of KOBt for neutralization or by destruction (reduction) of the acid with powdered zinc (34). For this and other reasons, Fmoc-Xaa-Cl are not used routinely, but they are particularly suited for couplings between hindered residues, and for esterifying a hydroxymethyl-linker-resin. Acyl fluorides are less reactive, hence, are more stable to oxygen nucleophiles such as water or methanol; they have a lower tendency to cyclize to the 5(4H)-oxazolone and can be employed in the absence of base. Their properties resemble those of activated esters. They are also suited for coupling hindered residues, but the possible deleterious effects of prolonged exposure to base because of their lesser reactivity must not be disregarded. Acyl azides (Fig. 2)

The preparation of acyl azides involves conversion of acid \( \text{RCO}_2\text{H} \) to ester \( \text{RCO}_2\text{Me} \) and subsequent aminolysis with
performed with chains. For coupling peptides, activation of the hydrazide is necessary to create products that are enantiomerically pure. Caution: Azides are highly reactive species because of the phenomenon of anion-p binding of two chains because of the tendency of functional groups to form hydrogen bonds (41). Succinimido esters (10) are unique because of the reaction of aqueous AcOH that contains NaNO₂ or tert-butyl nitrite. The acyl azide (RCON ₃) that is formed is extracted into an organic solvent, which is dried and added to the aminalizing component. An acyl azide can be produced directly from the amino acid in the presence of the aminalizing component by use of diphenyl phosphorazidate [(PhO)₂PON₃] (36), which is a reagent that is especially good for converting a linear peptide to a cyclic peptide. The acyl azide reaction is generally applicable to Boc- or Z-Xaa-OH, which includes instances when Xaa = Ser, Thr, or His with unprotected side chains. For coupling peptides, activation of the hydrazide is performed with tert-butyl nitrite (tBuONO₂) and nitrosyl chloride (NO₂Cl) (37). Because hydrazine destroys protectors such as trifluoroacetyl (CF₃CO₂H) and nitrilotriaceticacid (NTA) by converting the hydrazide to an activated ester that allows aminalization to occur in 4 hours instead of 2-3 days (38). Acyl azides are sensitive to tertiary amines; however, they do not form oxazolones, hence, proper manipulation of the coupling species just about guarantees products that are enantiomerically pure. Caution: Azides tend to explode under certain conditions.

Activated esters (Fig. 2)

Two types of activated esters exist, those in which the activating moiety is a substituted phenol and those in which the activating moiety is a substituted hydroxylamine (Fig. 2). Common examples of the former are p-nitrophenyl, pentachlorophenyl, and pentafluorophenyl; common examples of the latter are succinimido, benzotriazolyl, 7-azabenzotriazolyl, and 4-oxo-1,4-dicyclohexylbenzotriazolyl (Fig. 3). All (RCO₂W) react with an amino group (NH₂R) to produce tetrahedral intermediate R¹'O(C=O)W-N⁺H₂R⁻ that collapses to the product R¹-C(ONSu) which is a superactive triazine ester from acids (43). A unique form of activation of an amino acid but not of a peptide is the N-carboxyaminohydride (NCA) (Fig. 2), which is the cyclic anhydride formed between the carboxyl group and a carbonyl group bound to the amino group. These anhydrides are obtained by reacting the amino acid with phosgene in tetrahydrofuran (44). An addition of Xbb-NCA to H-Xaa– gives peptide H-Xbb-Xaa– after acidification to release CO₂ from the amino-terminus (45). It is possible that the NCA oligomerizes, so the reaction must be effected under very controlled conditions of pH and temperature. For this reason, NCAs are not employed routinely. An option that eliminates the dimerization is use of the N-alkoxycarbonyl- or "urethane-" protected amino-acid NCA, Boc, Cbz or Fmoc serving as useful substituents (46). These structures also are not employed routinely but have proved advantageous in certain cases. They decompose in the presence of tertiary amine.

Tactics for Avoiding Aggregation

The coupling of a protected residue to a peptide chain is inefficient or occasionally fails once the chain has been extended to five or more residues (47). Based on the observation that replacement of the part that would normally be hindered by the binding of two chains because of the tendency of functional groups to form hydrogen bonds (41), it has been postulated that the problem occurs because of the chain folding on itself or the binding of two chains because of the tendency of functional groups to form hydrogen bonds (41). The resulting aggregation interferes with the merging of the reacting groups. Tactics to prevent the formation of hydrogen bonds and hence aggregation have been developed. These tactics involve elimination of the hydrogen atom on a peptide bond at the fifth or sixth residue of a chain and the use of microwave energy. Peptides that contain serine and are insoluble in aqueous medium can be administered to an organism in the soluble O-acyl form H-Ser(peptide ₁)-peptide ₂-OH that immediately undergoes O-to-N acyl shift to H-peptide ₁-Ser-peptide ₂-OH at above neutral pH (49).
N-Alkylation of the Peptide Bond

Elimination of the hydrogen atom at a peptide residue to prevent hydrogen bond formation involves replacing it with a functional group that can be removed at the end of the synthesis. The protector must be stable to all the conditions employed during assembly of the chain, be easy enough to introduce onto the amino group, and must allow efficient coupling of the residue bearing the two N-protectors as well as the subsequent aminolysis reaction by the N-alkylamino-acid derivative. Producing such a protector has not been an easy task. The protector of choice for Fmoc/tBu chemistry is 2-hydroxy-4-methoxybenzyl (Hmb) (50) (see Figure 6). Coupling is achieved by HOBt-assisted aminolysis by H-Xaa- of the pentafluorophenyl ester of the N,O-disubstituted-derivative 8 giving 9. The two protectors are removed, the next residue is introduced as the SyAn [(Fmoc-Xcc)2O], which acylates the 2-hydroxy group of the Hmb giving 10. The residue then migrates spontaneously to the amino group via the O-to-N acyl shift giving N-substituted peptide 11. The protector of choice for Boc/Bzl chemistry is 2-hydroxybenzyl.

A different approach that involves N-alkylated residues to prevent hydrogen bonding is the use of cyclic structures called pseudo-prolines (51). These structures are compounds formed by reaction of serine, threonine, or cysteine residues with formaldehyde, acetaldehyde, or an acetone equivalent. The products are oxazolidines or thiazolidines that bear a carboxyl group and one or more methyl groups on the other carbon atoms of the rings (Figure 7). The pseudo-prolines are employed in synthesis as the Fmoc-dipeptides, with the cyclic structure at the carboxy-terminus. The Fmoc-amino acid is combined with the terminal residue either before or after formation of the ring. The pseudo-proline-containing dipeptide is coupled to the amino group of the peptide that is being assembled. At the end of the synthesis, the pseudo-proline is converted back to its precursor amino acid by acidolysis (Figure 7). The strength of acid necessary is dictated by the nature of substituents R1, R2 that originate from the carbonyl compound and the hetero atom O or S of the ring. Methyl groups render the cyclic structures more sensitive to acid; the thiazolidine ring is much more stable to acid than the oxazolidine ring.

Microwave-assisted couplings

The new technology of facilitating chemical reactions by use of microwave energy has been applied to the synthesis of peptides (52, 53). The theory is that the energy excites the growing peptide chain, which prevents aggregation during chain extension. Coupling times are substantially reduced, and products of enhanced purity have been obtained.

In this review, an overview is given for the synthesis of lipidated peptides such as those belonging to the Rab, Ras, eNOS, and hedgehog proteins. The different approaches for the synthesis of specific lipidated peptides (palmitoylated, prenylated, and myristoylated) are discussed with special emphasis on solid-phase synthesis methods, because these methods have turned out to be the preferred synthesis method for most required peptides. Different solid-phase methods are described that are individually suited for different types of lipidated peptides, differing, for example, in lipidation pattern or amino acid side-chain functionality and in their protein ligation functionality. For the described solution approaches, the block coupling strategies followed for the different lipidated peptides are highlighted. A special section in this review discusses the different synthetic tools for the incorporation of the lipid functionalities in the peptides. Although a generally validated strategy for the synthesis of lipidated peptides does not exist, because of the large number of different functionalities, this review aids in the conceptual design of synthetic protocols for lipidated peptides. Finally, the methods for the ligation of lipidated peptides to proteins are shortly discussed, as these methods also significantly influence the design and synthesis of lipidated peptides.

The continued existence of cells crucially depends on their ability to receive signals from the environment and to respond to them in a suitable way. This process of signal transduction, i.e., the forwarding of signals from the extracellular matrix via the cytoplasm into the nucleus, involves, among others, proteins that are modified with structural hydrophobic features attached to the peptide backbone. Posttranslational lipidation by acylation with fatty acids, alkylation with prenyl moieties, and conjunction of more complex lipid components, for instance, the glycosylphosphatidylinositol (GPI) moiety, occurs on a wide variety of intracellular and extracellular signaling proteins. An example of proteins containing lipid moieties are membrane-attached proteins. This review provides a concise overview of the synthesis of lipidated peptides from these membrane proteins and discusses possible methods for generating intact proteins with these peptides. The family of Ras proteins is one of the most relevant examples of lipidated membrane proteins from both their abundance and their biological and pharmaceutical importance and is therefore used as a general motif in this review [1].

General Considerations For Lipidated Peptide Synthesis

Five predominant lipidation motifs can be found on proteins, resulting in increased complexity from the stable and simple myristoyl group that can be found on N-terminal glycines to the GPI anchor featuring, apart from the lipid group, a complex sugar motif and phosphate groups (Fig. 1). The three most common types of posttranslational lipid modifications! encoun-
tered in the Ras superfamily, for example, are N-myristoylation, S-palmitoylation, and S-isoprenylation (2–4), of which palmitoylation is the only reversible one (5). These lipid modifications are important for the correct biological function of Ras proteins, as they require the localization to the inner leaflet of the plasma membrane and are generally found at the C-terminus of the protein. As for other lipidated proteins, until recently, most ex-
periments with these proteins, such as structure determination by X-ray diffraction, nuclear magnetic resonance (NMR), and bio-
chemical characterization, were performed on the soluble part of the proteins, i.e., the protein without the C-terminus. The results obtained via these approaches can, however, at best only give
an approximation of the real situation, especially because diversity between the individual members is often encountered in the lipidated part of the protein. The biochemical generation of fully functionalized and modified lipidated proteins is, however, difficult and time-consuming. In the case of S-palmitoylation, it leads to heterogeneous mixtures and is, therefore, in most cases, not practical or applicable. Therefore, in recent years, chemical biological approaches have been developed that give access to fully functional lipidated peptides and proteins, together with additional non-natural modifications, which was achieved via two techniques that were developed more or less in parallel: 1) the progress in the field of protein ligation and chemical synthesis of proteins (6) and 2) the progress in the field of lipidated peptide synthesis, both in solution and on solid support. The development of these synthetic methods with special attention to the solid-phase methods are the focus of this review. Synthetic strategies giving access to lipidated peptides have been developed during the last 10 years and have been reviewed both for solution and for solid support approaches (7, 8). This review is therefore not an all-inclusive review, but it highlights how different types of lipidated peptides can be most effectively synthesized.

The synthesis of lipidated peptides can follow different strategies such as the use of solid-phase versus solution-phase techniques, the use of lipidated building blocks versus peptide lipidation, and the application of the Boc versus Fmoc strategy as well as enzymatic (9-12) and noble metal (13) sensitive methods. The decision regarding which strategy to follow will generally depend on the types and positions of the lipid groups in the peptides, the length of the peptide, the C-terminal functionality, the presence of additional functional groups such as fluorescent markers or spin labels, and the purification strategy. Particularly regarding the lipids and functional groups, the synthetic strategy has to be fully adapted to the reactivities of these modifications. For solid-phase chemistry, the choice of the linker to the resin is an additional criterion to consider in the synthetic planning (Fig. 2).

For lipidated peptides, some general guidelines have emerged: 1) (strong) Acid-labile protecting groups or linkers cannot be used in combination with prenyl groups. 2) Prenyl groups are not compatible with protecting groups that have to be removed under hydrogenolytic conditions. 3) Thiuesters such as palmitoyl groups attached to cysteines are liable toward nucleophilies. 4) Non-natural functional groups such as fluorophores, photoactivatable groups, and tags for ligation to proteins generally impose synthetic limitations. 5) Prenylated dipeptide esters undergo rapid diketopiperazine formation upon N-terminal deprotection. 6) The palmitoyl group on an N-terminally unmasked cysteine rapidly undergoes an undesired S,N-acyl shift.

An additional issue that requires attention during the synthetic process is the purification of the lipidated peptides. Both final products and intermediates are often badly soluble in both water and organic solvent or feature detergent-like characteristics, which limits purification via both silica gel chromatography and reversed-phase high-performance liquid chromatography (HPLC). Purification can therefore be time-consuming and can result in low yields. However, the strongly dissimilar nature of the coupling partners, for instance, with respect to hydrophobicity, can also be used to facilitate the separation of product and starting compounds or the separation of double-lipidated from single-lipidated peptide.
Considering these features and limitations, it is not surprising that a general strategy for the synthesis of lipidated peptides, such as the Fmoc- or Boc-strategy for normal peptides, does not exist. However, several tools have been developed such as protecting groups, resin linkers, and synthetic approaches that have allowed some general strategies to emerge with which most lipidated peptides can be synthesized. This review tries to guide the reader to some generally validated approaches that meet the restraining demands imposed by the peptides. In our experience, solid-phase approaches offer fast and flexible entries to multiply lipidated peptides; therefore, the main focus will be on these solid-phase approaches.

### Introduction of Lipids Into Peptides

Introduction of lipid functionalities into peptides can follow two general strategies, independent of solid-phase or solution-phase chemistry. Either the lipid groups are introduced via coupling of prelipidated amino acids to the peptide (Fig. 3a), or they are introduced via selective lipidation of a peptide (Fig. 3b-e). Both the use of prelipidated building blocks (14–16) and of resin lipidation (17–25) have been investigated for the synthesis of lipidated peptides on solid support.

#### On-bead lipidation

Lipidation on the solid support requires an orthogonal protecting group strategy that allows the stepwise introduction of different lipid groups on the same peptide such as a farnesyl group and a palmitoyl group (Fig. 3c) (20, 21). This approach generally uses a large excess of the lipid groups, which becomes problematic if the lipid groups need to be synthesized (e.g., in modified form) and requires an extensive protecting group strategy. A possible solution to overcome these problems might be the application of the recently developed reversed approach of S-farnesylation and S-palmitoylation to solid-phase chemistry (26). In this approach, lipid groups are introduced via the S\textsubscript{2} displacement of a bromide by reaction of a thiol containing lipid as nucleophile with bromoalaine-containing peptides as electrophile in solution (Fig. 3a). Another elegant approach to introduce a prenyl thioether into peptides could be the use of a chemoselective conjugate addition of an thiolate nucleophile (e.g., farnesylthiolate) to a dehydroalanine (Fig. 3b,27). The absence of stereoselective control in this conjugate addition can be solved using aziridine-2-carboxylic acid-containing peptides (Fig. 3e) (28).

These newly developed methods for the incorporation of lipidated amino acids might prove beneficial in future solid-phase lipidated peptide synthesis.

#### Prelipidated amino acid building blocks

An approach to overcome the issues associated with on-resin prenylation for the synthesis of lipidated peptides relies on the use of prelipidated cysteine building blocks. These prelipidated building blocks can be handled as normal amino acids in the coupling sequence and can be inserted anywhere in a sequence without the need to modify the protecting group strategy (Fig. 3e). This approach thus provides a highly flexible and generic entry to lipidated peptides (15).

### Synthesis of Lipidated Peptides

Lipidated peptides can be synthesized both in solution and on solid support. The recent focus on lipidated peptide synthesis has shifted to the preparation of lipidated peptides on solid supports as it intrinsically offers faster and more flexible entries to the target peptides (25). Issues that should be considered for solid-phase lipidated peptides synthesis are, for example, the screening of different linkers and cleavage conditions as well as evaluation of synthesis routes for the introduction of the lipid groups with a suitable orthogonal protecting group strategy. By analogy to the solution-phase approaches, protecting groups must be orthogonal to the lipids and eventually other functional groups in the peptides. Additionally, the linker to the resin should be cleavable under conditions not interfering with the peptide functionalities. In an ideal setup, the cleavage of the linker would also allow for the introduction of different types of functional groups at the C-terminal carboxyl function.

Here, both solution-phase approaches and solid-phase approaches undertaken for the synthesis of specific lipidated peptides are reviewed (Fig. 4). For the solution-phase approaches, the focus is on the coupling strategy applied, i.e., which block couplings were pursued. The solid-phase approaches are reviewed with the focus on the type of linker to be used for specific types of lipidated peptides.

#### Small lipidated model peptides for biophysical investigations

Small cysteine-containing peptides similar to sequences of S-acylated proteins were generally synthesized in solution. The
Lipidated Peptide Synthesis

tetrapeptide model Bimane-SC(S^tBu)RC(Far)OMe representative for the carboxy terminus of H-Ras and featuring the Bimane fluorophore was prepared in solution using Fmoc-chemistry, introducing the farnesyl group at the stage of the Fmoc-protected dipeptide (29). The acylated peptides (Myr)GCX-Bimane (X = G, L, R, T, V), which are found in certain nonreceptor tyrosine kinases and \( \alpha \)-subunits of several heterotrimeric G-proteins, were synthesized in solution using common solution-phase peptide synthesis with \( N \)-myristoylglycine as the building block (29). These model peptides were acylated with Palmitoyl-CoA in phospholipid vesicles at physiological pH. For such uncatalyzed spontaneous reactions, only a modest molar excess of acyl donor species (2.5:1) was necessary. Unprotected side chains of threonine or serine do not interfere with this \( S \)-acylation.

Lipidated peptides incorporating the C(GerGer)XC(GerGer)-OMe motif found in several Rab and homologous proteins were also synthesized in solution via Fmoc-chemistry following cysteine deprotection and geranylgeranylation (30).

C-terminal lipidated peptide of the influenza virus hemagglutinin A

The influenza virus hemagglutinin A contains a lipidated peptide fragment at the C-terminus featuring two palmitoylated cysteines and two amino acids with a polar side chain. This peptide has been synthesized in solution and the strategy for this synthesis was based on the fragment condensation of the lipidated tetrapeptide TIC(Pal)I that was coupled N-terminal to the palmitoylated dipeptide RC(Pal) and, after deprotection, elongated with NBD-aca-labeled methionine (31). For this block coupling strategy, a set of three orthogonal protecting groups was required, whereby the use of base/nucleophile-labile and hydrogenolytically removable protecting groups was not permitted. The use of the acid labile Boc group for the N-terminus, the enzymatically removable PAOB ester for the C-terminus, and the Pd0-sensitive Alloc group for the arginine side-chain function turned out to be a successful combination.

C-terminal lipidated peptides of H-/N-Ras

A large body of work has been devoted to the synthesis of the C-terminal lipidated peptides of the small GTPTases H-/N-Ras. As such, these peptides have been synthesized in solution, via combined solution and solid support approaches and completely on solid phase.

For the synthesis of a small library of palmitoylated and isoprenylated N-Ras peptides in solution, a modular strategy was adopted, with the tetrapeptide MGLP as the key intermediate. This tetrapeptide intermediate allowed for further elongation at its C-terminus with lipidated or nonlipidated cysteine methyl esters, as well as the addition of various \( N \)-terminal maleimidoacryloyl (MICA)-labeled dipeptides, consisting of different GC lipidated units (32, 33). The synthesis was performed under common conditions using the Fmoc, Boc, and Alloc protecting group strategy. Using this methodology, a number of N-Ras derivatives containing natural and nonnatural lipid residues were...
Lipidated Peptide Synthesis

Figure 4

Abbreviations: BioAcA: N-(+)-Biotinyl-6-aminocaproyl; MantAca: N-methylanthranyl-6-aminocaproyl; MIC: 6-Maleimidocaproyl; NBDAca: N-(4-nitrobenz-2-oxa-1,3-diazol-7-yl)-6-aminocaproyl.

produced, and the technique was extended to also include a number of fluorescent derivatives.

In a reversed approach, N-Ras lipidated peptides were synthesized in solution via an $\text{SN}_2$ displacement of bromoalanine containing hexapeptides with thiopalmitic acid and farnesylierane as nucleophiles (26). The synthetic route started with the dipeptides and tetrapeptides A(Br)M and GLPA(Br), both incorporating bromoalanine. A farnesylation of the C-terminal tetrapeptide, it was coupled to the N-Alloc protected dipeptide. This farnesylated hexapeptide was then treated with thiopalmitic acid for final palmitoylation.

The key feature of the solution synthesis of the C-terminal octapeptide of H-Ras containing one farnesyl thioether and two palmitoyl thioester moieties is the orchestration of the acid-labile tert-butyl ester as carboxy protecting group, the Pd0-sensitive Alloc function as amino-blocking group, and the reduction-labile tert-butyl disulfide as masking of thiol groups (13). In addition, a serine hydroxyl and, in particular, a lysine $\varepsilon$-amino group are located in the vicinity of the thioester groups, increasing the danger of $\text{S-O}$ and $\text{S-N}$ acyl migrations in the course of the synthesis. The assembly in solution was achieved by dividing the triply lipidated peptide into the two selectively C- and N-terminal unmasked palmitoylated tripeptide building blocks PG(C-Pal) and M SC(Pal), the N-terminally unmasked lysine derivative, and an S-farnesylated cysteine methyl ester. In a combined solution-phase and solid-phase approach the N-Ras lipidated peptide was synthesized by coupling the C-terminal farnesylated cysteine methyl ester to the rest of the peptide that had been assembled on solid support (34). The second cysteine was protected as a tert-butyl disulfide, thus allowing reductive cleavage under physiological conditions, and the N-terminal amine of the peptide was connected to a maleimido group for protein ligation purposes. The use of these protecting and functional groups made the final segment condensation a relatively straightforward task. An important issue that has to be kept under scrutiny when performing such segment condensations is the possibility of racemization, the selection of validated coupling techniques that avoid the use of basic conditions and polar solvents, however, has usually proved sufficient to avoid or minimize this racemization. Typically, the amino acid (4 equiv) is treated with DIC (4 equiv) and an excess of HOBt (6 equiv) in DMF/CH$_2$Cl$_2$ mixtures.

For the complete solid-phase synthesis of H- and N-Ras peptides, the hydrazide linker turned out to be the linker of choice (14). This linker is cleaved by oxidation to an acyldiazene that is then attacked by an acylazide that is then attacked by a suitable nucleophile. The linker is orthogonal to classic amide protecting groups such as Boc, Fmoc, and...
Important precaution was taken, however, to avoid an
solid-phase peptide synthesis (SPPS) with other linkers. One
Coupling conditions of the amino acids were similar to normal
palmitoylated cysteine. It was found that the
shift of the palmitoyl group after the Fmoc deprotection of the
performed using a solution of 1% DBU in DMF for 2
peptides remained stable when the Fmoc deprotection was
vide supra (50 eq.), methanol (215 eq.) CH2Cl2,O2.

Alicoc, and racemization do not occur on cleavage. Typical nu-
clerophiles that can be used for the cleavage are amines, water,
and alcohols (35). The oxidation sensitivity of the linker does
require the coupling reactions, and especially Fmoc deprotecting
reactions, to be performed under exclusion of oxygen.
The hydrazide linker allowed, for example, the synthesis of
a completely lipidated N-Ras peptide sequence, including
an additional fluorophore attached to a lysine side chain or
N-terminal glycine and a C-terminal methyl ester (Fig. 5 (14).
Coupling conditions of the amino acids were similar to normal
do phase peptide synthesis (SPPS) with other linkers. One
important precaution was taken, however, to avoid an S-N acyl/
shift of the palmitoyl group after the Fmoc deprotection of the
palmitoylated cysteine. It was found that the S-palmitoylated
peptides remained stable when the Fmoc deprotection was
performed using a solution of 1% DBU in DMF for 2 × 30
seconds. The next coupling was then performed immediately
with preactivated amino acid and HATU as a coupling reagent.
Using similar approaches, many different peptides of the Ras
family were synthesized on the hydrazide linker, including
those containing farnesyl, geranylgeranyl, fluorescent labeled
geranyl, and palmitoyl lipids. Fluorescent markers such as NBD
and photoactivatable groups like the benzophenone group have
been introduced and Ras superfamily peptides with C-terminal
acid, ester, or amide functionalities have been cleaved from
the peptide, leading to cyclic peptides or oligomers. The more
stERICally demanding and less nuclophilic alcohol functions of,
for example, the serine side-chains feature these problems to a
much lesser extent and can generally be deprotected on the resin.
Having the amine functionalities protected after cleavage thus
requires an additional deprotection step in solution. In general,
the synthesis of lipidated peptides on the hydrazide linker is
successful for peptides with up to 30 amino acids. As such, the
hydrazide linker is one of the preferable systems for a broad
range of solid-phase lipidated peptide synthesis.

Polybasic prenylated C-terminal lipidated peptides

The synthesis of polybasic isoprenylated lipidated peptides, such as the C-termini of K-Ras4B, D-Ral, and Rho A, have been
most successful on the solid support. The solution strategies
to the peptides, generally through fragment condensation, were
difficult because of, for example, different polarities and solu-
bilities of the fragments.
The solution synthesis of the polybasic C-terminus of Rho
A required coupling of a polybasic KKK tripeptide with the
SGC(GeGor) tripeptide containing the geranylgeranylated cy-
sine methyl ester and an N-terminal coupling with a fluorescent
labeled glycine (37). For this approach, the orthogonality of the
Fmoc, Alicoc, and OBlu protecting group was applied. The same
methodology for the synthesis of the polybasic K-Ras4B peptide
failed, however, because of the low coupling yields resulting
from the different solubility properties of the fragments.
The methods of choice for the synthesis of polybasic lipi-
dated peptides such as those corresponding to the C-termini of
RhoA, K-Ras4B, and D-Ral are solid-phase approaches using
the triyl linker or the chlorotriyl linker (37, 38). The mildly
acidic cleavage conditions of these resins are still orthogonal to
the farnesyl moiety and often also to the geranylgeranyl moiety.
Attachment of the peptide via the C-terminus would limit the
C-terminal functionality to a free carboxylic acid. Therefore, the peptide can generally be attached via a lysine side chain near the C-terminus (37, 38), which avoids troublesome block condensations on the solid support with concomitant risk of racemization. The C-terminal prenylated cysteine of the pep-
tide is introduced by coupling a prelipitated cysteine to the selectively deprotected carboxylic function of the anchored lysine. After obtaining such a dipeptide on the resin, the additional steps of the synthesis can be performed in the N-terminal direc-
tion, using standard protocols and, for example, an Fmoc/Aloc strategy. The Aloc protected side chains of lysine and argi-
nine can be liberated on the solid support via cleavage with palladium(0) and an appropriate nucleophile. Treatment of the
resin with only 1% TFA and a scavenger subsequently releases the peptide while leaving the prenyl/geranylated geranyl group intact (38). A critical requirement for the use of the trityl linker in the above-described method is the presence of an anchor group in the C-terminal part of the peptide sequence that allows cleavage from the resin with 1% TFA only. Another current lim-
itation to the method is the incompatibility with thioesters, for example, palmitoylated cysteines. The deprotection of the A-
loc groups with piperidine as scavenger is not compatible with the nucleophile-labile thioester. Optimization of the type of nu-
cleophile might provide a solution, but deprotection of a large number of Aloc groups on solid support is not always a trivial matter. Finally, the Aloc deprotection is incompatible with the maleimide functionality as phosphines, used as ligands for the palladium catalyst, undergo nucleophilic addition to this func-
tionality. Nevertheless, for polybasic prenylated peptides, the use of the trityl linker is a reliable solid-phase approach.

C-terminal lipidated rab peptides

The synthesis of double geranylated peptides representing the Rab C-termini, for example the Rab7 C-terminus, has also been performed both in solution and on solid support. In general, the bivalent character of these peptides, featuring both highly hydrophobic lipid groups and polar amino acids, makes them difficult to handle. The synthesis in solution does not allow assembly of the hexapeptide by N-terminal linear elongation, for example, because of undesired diketopiperazine formation at the dipeptide stage (16). Therefore, a block-coupling method was chosen, with the dipeptide Fmoc-SC(GerGer) as a general building block (15). The dipeptide was elongated by C-terminal coupling with serine allyl ester. After deprotection of the allyl ester, the tripeptide was coupled to a geranylated cysteine methyl ester. N-Terminal elongation of the tetrapeptide to the desired hexapeptide was performed again via a block coupling, this time with the dipeptide Fmoc-CC(SBu)(E/Fm), to introduce a non-native cysteine that allows for ligation of the peptide to the protein. By employment of the Fmoc protecting group for the N-terminal amino function and the Fm protecting group for the side-chain carboxylic acid functionality of glutamic acid, a system was generated that allowed simultaneous cleavage of both protecting groups under basic conditions in a final step. The solid-phase synthesis of lipidated Rab peptides has re-
lied on the hydrazide linker, similar to the lipidated Ras pep-
tides (15). By employing geranylated/geranyl or fluorescent la-
bolated lipidated cysteines as building blocks, a highly flexible straightforward strategy with no extravagant expenses or com-
plex protecting group chemistry was developed. For the peptide assembly standard Fmoc chemistry was used. The side-chain protecting groups O-Trt and COOAll were subsequently re-
moved on the resin to leave only the N-terminal amine and thiol functionalities masked. The usage of different nucleophiles for the cleavage of the peptide from the hydrazide linker al-
lowed the introduction of a variety of functional groups at the C-terminus.

Lipidated peptides of endothelial
NO-synthase

The double palmitoylated and N-terminal myristoylated 29-mer lipidated peptide of eNOS has been synthesized both via a com-
bined solution/solid-phase approach and via a solid-phase peptide chemistry alone. For the combined technique, a combina-
tion of enzyme-labile, acid sensitive, and noble metal sensitive protect-
ing groups was chosen for the solid-phase synthesis, combined with fragment condensation in solution (39). The eNOS pep-
tide was divided into the N-myristoylated decapeptide MYRG-
LKSVGQP, the S-palmitoylated pentapeptide GPPC(Pal)IG, the octapeptide (LG)4L, and the S-palmitoylated hexapeptide
LC(Pal)IGKOG. For the synthesis and selective deprotection of the S-palmitoylated building blocks, the enzyme labile para phenyl-acetoxybenzyloxycarbonyl urethane group and the Pd(0)/ligand allyl ester were chosen as temporary N-terminal and C-terminal protecting functions. The side chains of Aas, Lys, Ser, Gin, and Glu were masked with acid-labile protecting groups to be cleaved off simultaneously in the final step of the synthesis. The entire 29-mer was finally assembled in solution by appropriate fragment condensation. The eNOS lipidated peptide was also assembled on solid sup-
port, for which the Ellman sulfonamide linker was used, which also showed good results for lipidated Ras peptides (36). The linker is stable toward acid and base, activated on alkylation, but orthogonal to the methionine thioether. The target compound is released after attack of a nucleophile (40). These cleavage con-
ditions make it orthogonal to the lipid functionalities and a good tool for the synthesis of lipidated peptides. In some cases, the Ellman sulfonamide linker seems to give even better results than the hydrazide linker, especially for long peptides with multiple lipid motifs. The double palmitoylated and N-terminal myris-
toylated 29-mer eNOS peptide is such a case. Using the prelipitated building blocks the peptide could be easily assembled and ob-
tained after cleavage. The example of the eNOS peptide shows that with good design, both the combined solution/solid-phase approach and the solid-phase approach enable excess to difficult lipidated peptides. The solid-phase approach, however, has the advantage of being significantly faster and easier.

Lipidated peptides of hedgehog proteins

The C-terminal steroid modified heptapeptides, corresponding to the C-terminus of Hedgehog proteins, were synthesized in a combined solid-phase/solution approach (41). The synthesis was built on the dipeptide Fmoc-SG-OA II that was connected to the trityl resin via the free hydroxyl functionality of the serine. The C-terminal allyl ester was cleaved by metal-mediated
Lipidated Peptide Synthesis

Model transmembrane peptides

A palmitoylated model transmembrane peptide consisting of a tryptophane-flanked poly-Leu-Ala peptide sequence similar to gramicidin A has been synthesized on solid support (22). It is an interesting example displaying the possible optimization protocol that has to be undertaken with lipidated peptide synthesis. According to the experience of reported lipidated peptide synthesis, a building block strategy was chosen. The peptide was synthesized on a Rink amide linker. In the final step of the solid-phase peptide synthesis, the coupling of the palmitoylated N-acetyl cysteine building block was not feasible. Aminolysis of the thioester was much faster than the carbodiimide-mediated peptide coupling. Introduction of the palmitoyl group via on-bead lipiddation of the cysteine required deprotection of the N-t-butylsulfanyl protected side chain. The standard deprotection reagents P(But)3 in NMP/H2O, however, led to desulfurization of the cysteine, resulting in an alanine-containing peptide instead of a palmitoylated N-acetyl cysteine. The explanation for this nearly quantitative reaction might reside in the hydrophobicity of the peptide. The phosphoneum-s-cysteine moiety is thus not able to react with H2O and p-elimination mediated by the t-butyl thiolate is the favored step. The S-(4-methoxythiophenyl)cysteine derivative proved to be the building block of choice, as it could be deprotected under mild acidic conditions, orthogonal to the other protecting groups in the peptide, which allowed for the lipiddation of the cysteine and the synthesis of palmitoylated transmembrane model peptide.

Synthesis of Lipidated Proteins Using Lipidated Peptides

Production of recombinant proteins is a key technology in the life sciences. However, progress in generation of authentic or engineered polypeptides has been more difficult for proteins that undergo posttranslational modifications, such as lipiddation. This imbalance is primarily a result of the intricacy of protein modification pathways as well as the lack of methodologies for their manipulation (42). Studies of lipidated proteins require methods that provide quantitative amounts of protein, both with natural and with new functionalities such as fluorescence, photoreactivity, spin-labeled groups, or lipid groups at non-native positions. The recently developed protein ligation methods provide the necessary platform for combining large recombinant protein scaffolds with peptides generated by organic synthesis (43–46).

Progress in the area of protein ligation methods has given access to a broad spectrum of methods for the semisynthetic production of posttranslationally modified proteins. These methods yield either native bonds (e.g., prior thiol capture, native chemical ligation, or expressed protein ligation) or non-native bonds (e.g., imine capture ligation, oxime ligation, or maleimido-diacrylic acid ligation). A variety of methods have been developed for the introduction of modified lipids and lipidated peptides into proteins. Most work in this field has been performed on Ras GTPases, for which two important approaches have been developed (Fig. 6). The first approach that incorporates synthetic lipidated peptides is based on the use of the MIC-controlled ligation (Fig. 6a) (8, 33, 34, 47, 48). This ligation requires an accessible, for example, C-terminal free thiol group on the protein, usually of a cysteine, to connect the N-terminally MIC-modified peptide. The reaction yields a non-native connection, which is, for example, in the case of Ras not problematic, because it occurs in a flexible unstructured region. Care has to be taken with this reaction that there are no other free cysteine side chains available for ligation. The second approach, Expressed Protein Ligation (EPL), connects a lipidated peptide with an N-terminal cysteine to the C-terminus of a thioester-tagged protein via a native peptide bond (Fig. 6b) (15, 16, 38, 49, 50). This reaction is in general highly selective and yields at most a cysteine mutation in the protein as non-native element. An orthogonal approach to introduce specifically prenyl moieties into proteins not relying on lipidated peptide is via an in vitro attachment of the prenyl lipids using the corresponding prenyltransferases (51). A recently explored reaction for the incorporation of lipid motifs in peptides and proteins is the copper(I)-catalyzed Huisgen’s 1,3-dipolarcycloaddition. A GPI anchor could be attached to a peptide successfully, resulting in fast uptake of the peptide into cells (52).

The protein ligation methods have been applied for the synthesis of a library of lipidated Ras GTPases with both natural modifications and non-natural modifications (Fig. 6). The first approach that incorporates synthetic lipidated peptides is based on the use of the MIC-controlled ligation (Fig. 6a) (8, 33, 34, 47, 48). This ligation requires an accessible, for example, C-terminal free thiol group on the protein, usually of a cysteine, to connect the N-terminally MIC-modified peptide. The reaction yields a non-native connection, which is, for example, in the case of Ras not problematic, because it occurs in a flexible unstructured region. Care has to be taken with this reaction that there are no other free cysteine side chains available for ligation. The second approach, Expressed Protein Ligation (EPL), connects a lipidated peptide with an N-terminal cysteine to the C-terminus of a thioester-tagged protein via a native peptide bond (Fig. 6b) (15, 16, 38, 49, 50). This reaction is in general highly selective and yields at most a cysteine mutation in the protein as non-native element. An orthogonal approach to introduce specifically prenyl moieties into proteins not relying on lipidated peptide is via an in vitro attachment of the prenyl lipids using the corresponding prenyltransferases (51). A recently explored reaction for the incorporation of lipid motifs in peptides and proteins is the copper(I)-catalyzed Huisgen’s 1,3-dipolarcycloaddition. A GPI anchor could be attached to a peptide successfully, resulting in fast uptake of the peptide into cells (52).

The protein ligation methods have been applied for the synthesis of a library of lipidated Ras GTPases with both natural modifications and non-natural modifications (Fig. 6). These lipidated Ras GTPases have served to elucidate a variety of biological questions concerning these proteins. The specific localization of Ras protein on membranes was investigated using a fluorescently labeled N-Ras protein, for example, and found to have a preference for the liquid-disordered phase over the liquid-ordered and solid-ordered phase of membranes using fluorescence studies (53). Via AFM studies, it was additionally shown that this protein is actually located in the boundary region of the domains in mixed-phase liquid-ordered/liquid-disordered bilayers. These results suggest that for N-Ras, the membrane localization is probably completely governed by the lipidated C-terminus. As such, the conformation of the C-terminus of Ras proteins bound to the membrane was investigated using NMR (54). The membrane binding of the polybasic K-Ras4B protein was also studied after protein semisynthesis (38). A photoactivatable Ras construct has been made that can be activated to selectively react with protein interaction partners (34). The functionality of these semisynthetic Ras proteins in living cells was also shown (33), enabling advanced cellular characterization of, for example, the prenylation and the palmitoylation process of the protein, using selectively functionalized proteins (55-57).
Figure 6  Schematic representation of protein ligation methods applied for the introduction of a lipidated peptide on proteins and an overview of the synthesized libraries of lipidated proteins as exemplified via Ras GTPases. (A) expressed protein ligation (EPL); (B) Maleimidocaproyl (MIC).

Enzymatic studies using selectively addressable fluorescent Rab proteins have elucidated the geranylgeranylation process (16). Structural studies on selectively prenylated Rab proteins have elucidated the exact interaction mechanism of Ras proteins with their transporter protein GDP dissociation inhibitor (GDI) and have led to a membrane extraction model for Rab proteins (58, 59).

Conclusions

Chemical biology is the application of approaches originating from chemistry and the subsequent combination of chemistry and biology to study biological phenomena previously not accessible via chemical or biological approaches alone. Lipidated peptides alone or ligated to proteins offer such entries for lipi-
Lipidated Peptide Synthesis

dated proteins. For such an integrated research activity, differently modified peptides and proteins with a variety of modifications whose structure can be changed at will through synthesis are invaluable tools. They enable experiments yielding answers in precisely molecular detail hardly accessible with biological techniques alone. Therefore, the synthesis of the lipidated peptides is an important theme and is reviewed here. The reviewed examples are used to present the synthesis of new lipidated peptides and their purification cannot always be generalized. However, with the tools currently developed and appropriate design, most types of lipidated peptides can be synthesized and obtained pure. Recently developed solid-phase synthesis methods delineate the preferred strategy to access the majority of these required lipidated peptides. With the development of these solid-phase lipidated peptide synthesis techniques, the chemical tools to obtain the majority of the required proteins are now accessible.

Further Reading
Peptide libraries, which consist of a few thousands to tens of millions of distinct peptides, can be generated combinatorially through biologic or synthetic approaches. The phage-display peptide library method is simple and economical, and peptides with various natural protein folds can be generated by this approach; but this biologic method generally is limited to peptides that contain only L-amino acids. Synthetic combinatorial libraries, however, can accommodate D-amino acids, unnatural amino acids, and even organic moieties, which makes these approaches highly versatile.

These synthetic methods include the spatially addressable parallel library method, the combinatorial library method that requires deconvolution, the one-bead one-compound (OBOC) combinatorial library method, the self-assembled peptide nucleic acid (PNA) encoded chemical microarrays, and the synthetic library method that requires chromatography selection. Various methods to screen these combinatorial libraries have been developed. For example, phage-display peptide libraries can be screened for the ability of phages to bind to unique immobilized target proteins or whole cells, peptide microarrays can be screened for their ability to interact with fluorescent proteins, combinatorial library methods that require deconvolution can be screened by standard solution-phase assays, and OBOC libraries can be screened by on-bead binding or functional assays or several solution-phase cell-based or biochemical assays. Combinatorial peptide library methods are enabling technologies that have proven to be very useful in basic research and drug discovery.

A combinatorial peptide library is a collection of a few thousands to hundreds of millions of different peptides. Geysen et al. (1) opened the door of the combinatorial library when they reported the first combinatorial peptide library (96 peptides) that was generated with the multipin technology in 1984. Since then, several different combinatorial approaches have been developed to generate libraries that contain many peptides with discrete sequences from which bioactive peptides can be isolated and/or identified. In the early reports in this field, synthetic peptide libraries were generated and screened against antibody molecules or streptavidin (1–4). A bout the same time, the phage-display peptide library method was created (5–7). Since 1990, several totally different combinatorial library methods have been introduced. These methods enable one to generate and screen easily and rapidly libraries with millions to billions of random peptides. The screening of combinatorial peptide libraries allows for the rapid discovery of peptide ligands or substrates against a variety of biologic targets. The principle for selecting new ligands by means of combinatorial peptide libraries exploits the natural diversity of protein-protein and protein-ligand interactions. It has emerged as a powerful tool in the study of many biologic systems. The amino acid sequence of an “active” peptide then is determined. Biologic peptide libraries, such as those that involve filamentous phage-display peptides, typically can accommodate only the 20 natural amino acids. In contrast, synthetic peptide libraries have the potential to incorporate D-amino acids and other unnatural amino acids, as well as specific secondary structures or scaffolding structures that may enhance biologic activity. In addition to amino acids, biologic building blocks such as monosaccharides, nucleotides, lipids, or even small organic moieties can be used. The advent of these peptide library methods not only facilitates the...
Peptide Combinatorial Libraries

Peptide libraries are increasingly being utilized in drug discovery processes. They are also important for the fundamental understanding of molecular recognition. In this mini-review, we will focus on the preparation, screening, structure elucidation, and application of various peptide library methods.

**Peptide Library Methods**

In essence, only two approaches exist to generate combinatorial peptide libraries: biologic and synthetic library approaches. According to the different techniques used, the synthetic library approach can be divided additionally into five methods: 1) the spatially addressable parallel library method (1, 4, 8), 2) the combinatorial library method that requires deconvolution (3, 9), 3) the one-bead one-compound (OBOC) combinatorial library method (2, 10), 4) the self-assembled peptide nucleic acid (PNA) encoded chemical microarrays (11), and 5) the synthetic library method that requires chromatography selection (12). Although the focus of this review is on peptide libraries, it is important to point out that the above synthetic methods can be applied readily to the generation of small molecule, peptidomimetic, and macrocyclic libraries.

Each peptide library method has its own advantages and disadvantages. A comparison of these methods with respect to cost, resources, and uses is shown in **Table 1**.

### Biologic Library Method

The first biologic peptide library was reported by Parmley and Smith in 1988 [13]. They developed the "fusion phage" by inserting foreign DNA fragments into the encoding gene of the pil protein. This development led to the expression of an L-amino acid-containing peptide on the virion surface that did not affect virus infectivity. Each phage particle has five copies of the peptide on one end. The M13 phage is the most widely used phage-display system because of its high capacity for replication and its ability to receive large DNA inserts into its genome. Trinucleotide sequences that encode specific amino acids can be constructed and inserted into the phage genome either to increase diversity or to introduce a bias into the clone population. This very powerful method enables the researcher to routinely generate $10^8$–$10^9$ different phages. Such
Peptide Combinatorial Libraries

Peptide libraries can be panned against a target molecule by standard protocols. Other biologic peptide libraries include plasmid libraries, polynucleotide libraries, fimbria libraries, yeast-display libraries, ribosome-display libraries, and other more recently developed in vitro selection methods. For a review on biologic libraries please see Reference 14.

Biologic library methods enjoy the following advantages over synthetic peptide library methods: 1) Many peptide entities can be generated easily and economically, 2) the biologic library method can take advantage of known protein folds (e.g., immunoglobulin fold, zinc-finger fold, or conotoxin fold) by grafting random oligopeptides onto such tertiary folds, and 3) less restriction exists on the size of the peptide (e.g., 30 amino acids) one can generate. However, the biologic approaches suffer from three major disadvantages: 1) With the current systems, only the natural L-amino acids (20 eukaryotic amino acids) can be incorporated into these libraries, and incorporation of unnatural amino acids or other organic subunits into these libraries generally is not feasible, 2) although simple disulfide cyclization is feasible and longer peptides with specific protein folds (such as immunoglobulin folds) may be used, complicated bicyclic, compact scaffolding, branched structures, or molecules with a special chemistry of cyclization are impossible, and 3) the screening assays of the biologic libraries generally are limited to the binding assays (e.g., panning) and some functional assays such as protease substrate determination (see below). These methods generally are not applicable to most standard drug screens that use solution-phase assays. Synthetic peptide libraries, however, can overcome many of these limitations.

Synthetic Library Methods

Spatially addressable parallel library method

Peptide libraries can be synthesized on solid-phase support by using spatially addressable high-throughput synthetic methods (manual or automated). The amino acid sequence of each of these peptides is predetermined. The reported techniques based on this strategy include multipin technology, SPOT synthesis, NanoKan, peptide microarray, multisyringe system, and the 96 deep-well plate system. These methods are labor-intensive but can be facilitated by robotics. Depending on the library method used, the peptide library is screened either by a direct solid-phase binding assay or by a solution-phase assay. The chemical structure of the positive peptide then is decoded by location. The major drawback of this method is that only limited number of peptides can be synthesized and therefore the library generally is rather small.

Multipin technology

As mentioned earlier, the first peptide library with a limited number of peptides was generated by using multipin technology in 1984 (1). In this method, acrylic acid is irradiation-grafted onto the tip of polyethylene pins. Each pin is inserted into an adapter that fits over a 96-well polypropylene plate with a standard microtiter plate footprint. Each well of the microtiter plate then serves as a separate reaction vessel for the amino acid-coupling steps. In the original experiments, ∼50 nmol (ideally) of a single peptide was linked covalently to the spherical head of each pin. Today, the multipin system is available commercially from Mimotopes (San Diego, CA) as Pepsets. The peptide loading of each pin has been increased significantly by introducing the so-called "SynPhase™ Lantern" (e.g., 75 µmol for the SynPhase PS A-Series Lanterns) or "SynPhase™ Crown" (e.g., 8.3 µmol for the I-Series Crown) to fit into the tip of each pin.

Tea bag and nanokan technique

In 1985, Houghten (15) introduced the "tea bag" method for simultaneous multiple peptide synthesis. In this method, peptide synthesis occurs on resin beads that are sealed inside labeled, porous polypropylene packets. At the end of the synthesis, the individual peptides are liberated from the resin. In 1995, this method was improved by using minibaskets (e.g., Nanokan) to encapsulate radio-frequency microchips (RF tagging) and a sample of resin beads for peptide synthesis (16, 17). Each of these minibaskets can be scanned with an electronic reader before or right after each coupling cycle during the "split-mix" synthesis (see Fig. 1a) (2, 3, 18). Therefore, the synthetic history of each minibasket can be traced. At the end of the synthesis, compounds can be cleaved off the resin beads inside each minibasket and placed in a 96-well plate to form a spatially addressable compound library. The main advantage of this method is that it offers considerable synthetic flexibility as one may use any resin bead in the synthesis. A few thousand to ten thousand individual peptides can be generated easily. Furthermore, peptides can be produced in sufficient quantity (500 µmol) for purification and complete characterization if desired. The IRORI Nanokan® system is available commercially from Discovery Partners International (San Diego, CA). However, the IRORI system is very expensive. A less expensive encoding system, called En-core (Torviq Inc., Granger, IN), uses "necklace" color tags and multicolor reaction vessels to encode the synthetic history. This system also uses the "split-mix" synthesis strategy to generate compound libraries with a limited number of compounds.

SPOT synthesis technique

A peptide library can be synthesized using the SPOT synthesis technique to form a low-density peptide spot array (e.g., 25 spots/cm²). In this method, different peptides are synthesized in situ as low-density arrays on cellulose membrane or paper (B). The volume of 20–25 nmol of Boc-amino acids and coupling reagents dispensed creates a specific SPOT size that determines both the scale of reaction and the absolute number of peptides that can be arranged on an area of a membrane. Cotton (another form of cellulose) and polysyntene-grafted polyethylene film segments also have been used as solid supports. Recently, polymeric membranes that are chemically, mechanically, and thermally more stable have been developed, which include hydroxy-functionalized PEG acrylate polypropylene membranes and an amino-functionalized ester-free PEG...

(b)

Peptide microarrays

Peptide microarrays are prepared by immobilizing many peptide molecules on the surface of a solid support in a small area in an addressable fashion. The immobilization can be achieved via in situ synthesis or chemical ligation through a covalent bond. A hydrophilic linker between the solid surface and the peptide usually is added to minimize steric hinderance caused by the solid support. The most commonly used solid support for microarray printing is a standard microscope glass slide. Other solid supports also have been used such as polystyrene, nitrocellulose membranes, PVDF membranes, Hybond ECL membranes, gold surfaces, and chemical vapor deposited diamond films.

Peptide arrays on paper or cellulose membranes generated by SPOT synthesis generally are low density, even with the commercially available automatic SPOT synthesizer. Such a low-density peptide chip (several thousand peptides) now is available commercially, for example, PepChip™ microarray from Mimotopes. Foder et al. (4) first described the high-density peptide microarray using the photolithographic light-directed parallel synthesis method. The disadvantage of this method is that it requires building blocks (in this case, amino acids) protected with photolabile protecting groups (e.g., 6-nitroveratryloxycarbonyl) that are not available yet commercially. To address this problem, Gao et al. (19, 20) developed digital photochemistry for parallel synthesis of peptides to prepare a peptide microarray. In this method, they combined light-directed synthesis (controlled by computer) with microfluidics so that photo-generated acid (e.g., H+·SbF6−) can be generated in situ (with light) to remove the protecting groups of standard commercially available building blocks such as Boc-protected amino acids. More recently, the same group has developed a novel photogenerated base (PGB) applicable to Fmoc-chemistry for the parallel synthesis of a peptide on a microarray. When fully optimized, this versatile in situ, high-throughput parallel synthesis of peptide microarrays would offer unprecedented opportunities for creating various high-throughput detecting and sensing devices, which would enable a broad range of biochemical and biomedical applications (21).

We reported site-specific ligation of peptides to a carrier protein or polymer before printing onto the glass slide with an automatic arrayer to form a peptide microarray (22). Recently, Dikmans et al. (23) reported a novel process for manufacturing
multifunctional high-density peptide microarrays termed “Spotting compound-support conjugates” (SSC). In this method, a trifluoroacetic acid (TFA) cocktail containing > 80% TFA plus scavengers is used to solubilize the peptide-cellulose of each SPOT. The peptide-support conjugates then are precipitated, redissolved in dimethyl sulfoxide (DMSO), and then printed on glass slides.

Synthetic Library Methods that Require Deconvolution

The term “deconvolution” has been used to describe the process whereby the active molecule or molecules in a library are identified, usually by the iterative testing of mixtures of compounds for a specific biologic property. Using the results from biologic assays, the identity of the active component may be deduced without the need to determine directly or indirectly its chemical structure. The two main deconvolution approaches are the iterative process (24) and the positional scanning (25). In the iterative approach first reported by Geysen et al. (24) in the multipin system, a progressive selection is performed by choosing one amino acid at a time for each position. Sublibraries are generated based on the result of the previous one; therefore, the sequence is obtained step by step. In the positional scanning method reported by Pinilla et al., sublibraries of peptides with an amino acid fixed at one designated position but randomized in other positions are prepared and tested for biologic activities. Based on the biologic assay results, the amino acid sequence of the active peptide can be deduced at the end of the process. This method assumes that the contribution of each amino acid residue to the biologic activity is independent of each other. It works very well only if one predominant motif exists for the target protein. An interpretation of results from targets with multiple binding motifs likely will be difficult.

OBOC Library Method

In 1991, we first reported the OBOC concept to synthesize peptide libraries using a “split-mix synthesis” method (Fig. 1a and 2). The peptide is synthesized on resin beads such as a 90 µm diameter TentaGel resin (Rapp Polymere, Tubingen, Germany). Because each bead is in contact with only one amino acid at a time during each coupling cycle and the reaction is driven to completion, each bead expresses a single peptide entity (Fig. 1d) and carries about 100 pmol peptide. Because the peptide beads in an OBOC combinatorial library are spatially separate, an OBOC library can be considered as a huge chemical microarray that is not addressable.

The main advantages of the OBOC method include: 1) A large number (e.g., 109 – 1010) of peptides can be synthesized (Fig. 1a) and screened rapidly and simultaneously by using either one or a combination of both on-bead and solution-phase assays, and 2) multiple peptide ligands with completely different motifs often can be identified in a single screening. This occurrence is the opposite of the (convergent) iterative approach (see above) in which multistep synthesis and screening result in the emergence of only one, but not necessarily the best, solution motif.

One major disadvantage of the OBOC method using the on-bead screening method is that each library compound is tethered to the solid support via a linker such as polyethylene glycol and may result in steric hindrance between the cellular receptor and the library compound. However, in some instances the linker may be beneficial, for example, the linker can be used as a convenient handle to link the cancer-targeting ligand to the therapeutic payload.

Self-Assembled PNA-Encoded Chemical Microarrays

In this method, peptides or small molecules are prepared by the “split-mix synthesis” method and cleaved from the resin to form an encoded solution-phase library such that each library compound is tethered to a PNA code via a hydrophilic linker (11). The library then is mixed with the target protein and later exposed to planar oligonucleotide microarrays of predetermined sequences. Alternatively, the encoded soluble library can be hybridized to the oligonucleotide microarrays before incubation with the target protein.

Synthetic Library Method that Requires Chromatography Selection

In this method, the peptide library is an equimolar mixture of random peptides in solution phase from which ligands can be isolated with affinity chromatography (12). It usually is synthesized on solid support with a “split-mix synthesis” method. The peptides then are cleaved from the resins, and the solution-phase peptide library is loaded onto an affinity column with an immobilized receptor. After thorough washing, the bound peptides are eluted and microsequenced. Major concerns about this method include nonspecific binding and uninterpretable results if more than one predominant motif is present in the mixture. Additionally, enough purified peptide must be retrieved for accurate microsequencing or mass spectrometry analysis. In general, because of the high background from nonspecific binding, the affinity selection method, with rare exceptions, can be applied only to a relatively small peptide library (e.g., <10,000 peptides).

Peptide Library Screening

Peptide library screening can be divided into two categories: solid-phase screening, in which peptides still are tethered to the solid-phase support, and solution-phase screening in which the peptides are released from the solid support and tested in solution. Solid-phase screening is generally easier with higher
throughout than in solution-phase assay. However, the linker that tethers the peptide to the solid support may interfere with the interaction between the peptide and its receptor. In addition, the multivalent binding between the immobilized synthetic and phage-display peptide gives little information about the real binding affinity between the receptor and an univalent soluble peptide. Different assays such as ELISA, cell-based cytotoxicity assay, antimicrobial assay, affinity chromatography, and radiometric and fluorescence-based assays can be used to screen peptide libraries. Surface plasmon resonance spectroscopy (e.g., BLACore) is a powerful technique to screen soluble and unlabeled peptides, which allows the real-time measurement of soluble peptide binding to different targets of interest immobilized on a chip such as proteins, sugars, fatty acids, nucleic acids, cell membranes, and even whole cells. However, commercially available equipment (e.g., BLACore) that uses label-free detection equipment is generally low throughput. In the last few years, several reports have applied label-free optical detection methods to screen peptide or chemical microarrays (26, 27).

To screen large libraries optimally, carefully selected high-throughput assays should be employed. The choice of the assay system largely depends on the combinatorial library method used to construct the library, the availability of reagents such as enzymes, antibodies, and radiolabeled ligands, and of course the biologic target itself. To isolate the few active peptides from the library successfully, it is essential to have a robust and accurate screening method that can screen large libraries rapidly. One may use several assay systems serially first to narrow down the potential ligands and then retest them for biologic effect and crossreaction with other unwanted targets.

**Phage-Display Library Screening**

The phage-display peptide library can be screened easily by panning (e.g., binding to an acceptor-coated petri dish). The phages that bind specifically to an acceptor molecule will be isolated and enriched via several cycles of panning and amplification in E. coli (E. coli). By the end of the panning, the bound phagemids are eluted, cloned, and processed for subsequent identification via DNA sequencing. The phage-display peptide library also has been screened with intact cells in cell culture to identify ligands that bind cell surface receptors. Peptides with a propensity to bind and then enter intact cells can be selected by eluting the phagemids off the cell surface before lysing the cell for phage recovery. Ligands identified through in vitro protein or cell panning need to be validated and evaluated for in vivo targeting. Phage-display peptide libraries also have been screened in vivo in animal models and humans. For example, different libraries have been screened for binding to the vasculature of various organs and tumors by injecting the phage library intravenously into live animals. Organ- or tumor-bound phage then are amplified in E. coli and screened a second and third time before sequence analysis. In a recent study by Krag et al. (28), patients with late-stage melanoma, breast, and pancreatic cancer were infused with random phage-display peptide libraries or phage-display short chain Fv antibodies in either single or multiple panning experiments. For more information about using the phage-display peptide library approach to identify cancer-targeting ligands, please see our recent review (29).

In some cases, functional assays have been used to screen phage-display peptide libraries. For example, a phage-display hexapeptide library was constructed with an epitope tag distal (N-terminal) to screen for peptide substrates of a specific protease. All the phages were captured by an immobilized anti-epitope antibody. After incubation with a tissue plasminogen activator (tPA), phages that expressed a peptide substrate for tPA were released for subsequent rounds of selection. A similar approach was applied to discover peptide substrates for HIV-1 protease.

**Spatially Addressable Parallel Library Screening**

The spatially addressable parallel libraries can be screened using either a solid- or a solution-phase assay depending on the method used to generate the library. In solid-phase assays, the peptide still is linked covalently to the solid support, such as a pin, SPOT-membrane, or glass surface. The molecular target can be a purified protein, a protein mixture, an enzyme, an intact cell, or a whole organism such as bacteria or virus. For example, enzyme-linked immunosorbant assay (ELISA) assay has been used for a multipin or spot-synthesis peptide library. Binding assays can be used to determine binding specificities, such as for the identification of cell-specific surface markers. One unique feature of chemical microarrays for cell adhesion analysis is that in addition to obtaining binding profiles of different cells to many ligands, one also can examine the signaling response of each binding event. Such signaling profiles can be determined with many fluorescent-labeled antibodies in conjunction with confocal microscopy. Functional properties also could be examined by using other assays to measure specific biologic effects that the ligands have on the target. In the solution-phase assay, the peptides are cleaved from the solid support, which enables the soluble ligands to interact freely with the target molecule or cell. The peptides are put into 96-, 384-, or 1536-well plates for high-throughput biologic analysis with the aid of robotics. Many conventional assays can be applied to the screening including cell-based cytotoxic assays such as MTT and XTT assays, antimicrobial assays, competitive ELISA assays, radioactive assays, radioactive binding assays, fluorescent polarization assays, time-resolved fluorescence assays, fluorescent protein-based recombinant cell bioassays, scintillation proximity assays, and cell-based calcium flux assays.

**OBOC Peptide Library Screening**

OBOC peptide library can be screened on bead or in solution phase if the bound peptides are released via a cleavable linker. The on-bead assays include binding and functional assays. In the binding assays, the target of interest could be a...
purified protein, a protein complex, cell lysates, live cells, or
a whole microorganism. In the case of protein screening, pro-
tein first is incubated with a library of immobilized ligands.
Protein-ligand interaction can be visualized with an appropri-
ate reporting group such as a biotin, an enzyme, a fluorescent
probe, a color dye, or a nucleic acid. The biotinylated pro-
tein can be detected with a colorimetric assay by using a
streptavidin-alkaline phosphatase conjugate followed by color
development with a 5-bromo-4-chloro-3-indoxyl phosphate. Flu-
orescence microscopy has been used successfully to screen bead
libraries with fluorescent probes. An organic fluorescent dye or
quantum dots have been used as a fluorophor to label the target
protein. Radio-labeled probe is useful but more tedious than the
colorimetric method.

The use of intact live cells or whole microorganisms to screen
OBOC peptide libraries is very attractive because purified target
proteins are not needed in such a screening. For microorganisms
such as a virus or a bacteria, a reporter antibody or a specific
dye that stains such microorganisms may be useful. For intact
cells, reporter probes are not needed because cells that bind to
a bead can be visualized easily under a dissecting microscope.
The positive beads can be washed off the cells and sent for
sequencing. To enhance the quality of the results more, the posi-
tive beads can be retested against either the same cells or
different cells lines before being sequenced to ensure that they
are true positives. Alternatively, one may label one cell type
with calcein and leave the negative control cell line unlabeled.

Beads that bind only to fluorescent green cells but not to
colorless cells can be considered true positive beads. After
sequencing, they can be retested against fluorescent green cells
for other assays such as the functional assay described below.

Latipoo et al. (30) recently reported a new method called the
"Bead blot" for identifying ligand-protein and protein-protein
interactions using OBOC combinatorial peptide libraries. In this
method, a peptide library was synthesized on chromatography resin
beads is incubated with a starting material that contains a target
protein for which a ligand is sought. Then the protein-loaded
beads are immobilized in a porous matrix, and the proteins are eluted
directly from the beads and captured on a membrane
that is superimposed on the beads. The location of the target
protein on the membrane is determined by probing the bead
blot with various antibodies, and the beads that originally bound
the protein are identified and sequenced. The advantages of the
"Bead blot" include the ability to select ligands of unpurified
protein, including trace proteins present in complex materials,
and ligands of multiple proteins under a variety of conditions
in a single experiment.

Aggarwal et al. (31) synthesized a random one-bead one-
dimer peptide library on a polyethylene glycol acrylamide
(PEGA) resin by modifying the one-bead one-compound method
and screened the library with a prostate cancer cell line LNCaP.
One peptide (OMAAPKLRELH), was found to bind as a dimer
to LNCaP cells that had been spiked into the blood, but it did
not bind to normal hemapoietic cells.

In addition to the binding assay, functional assays have been
developed for the screening of OBOC libraries to identify
specific substrates for protein kinases and proteases. Highly
porous PEGA resin is used for the peptide library construction
because it allows the enzyme to gain access to the bead interior.

To identify peptide substrates for protein kinases, the bead
library is incubated with [γ-32P]ATP and the protein kinase.
The phosphorylated peptide bead library is washed thoroughly
and immobilized on a glass plate with agar. The 32P-labeled
beads then are detected by autoradiography, and individual
radio-labeled ("active") beads are isolated for microsequencing.

For protease substrate screening, OBOC peptide libraries with
fluorescent dye incorporated at the C-terminus and a quencher
at the N-terminus have been used. Peptide-beads susceptible
to protease cleavage will fluoresce. These fluorescent-labeled
beads were isolated for microsequencing under a fluorescent
microscope or isolated by a fluorescent-activated bead sorter
(e.g., COVA™ BIOBEAD, Union Biometrica, Inc, Somerville,
MA). Information about the substrate sequence, the cleavage
point, and the degree of cleavage can be obtained in a single
screening. Redal (32) extended the OBOC concept to gen-
erate one-bead two-compound (OBTC) peptide libraries. For
example, an OBTC library can be generated on a PEGA resin
that contains both a library of inhibitors of proteolytic enzymes
and a fluorescence-quenched substrate that competes with the
inhibitor for binding to the active site of the enzyme.

Thus far, only a few groups have reported on the release of
compounds from OBOC libraries for solution-phase assays. An
elegant and powerful approach to screen the OBOC libraries is
the in situ solution-phase releasable assay, in which the
compound-bead libraries are immobilized in a thin layer of agar
(33). Compounds from each bead then are released to the vicin-
ity of each bead for a solution-phase assay in the semi-solid.

This method works particularly well for identifying antimi-
icrobial and anticancer agents because a zone of growth inhibition
around the positive beads can be detected easily. Jayawickreme
et al. (34) reported a "cell-based lawn format" that uses an in
situ photolysis/cleavage method to release the compound. These in
situ releasable solution-phase assays have great potential but
will require more development before they can be used reliably
for drug screening. For example, special solid supports need to
be developed so that all compounds will diffuse freely out of all
beads into the surrounding media. We recently have developed
novel bilayer shell core beads for such purpose (unpublished
work). These beads consist of a polystyrene core in which the
coding tags reside and a hydrogel shell on which releasable
library compounds are attached.

An alternative approach to using solution-phase assays to
screen an OBOC library is to release compounds from an
individual or small collection of compound beads in a microtiter
plate. The released compounds then are subjected to standard
solution-phase assays or are used to print multiple replicates of
chemical microarrays. To have enough material from one single
bead for biologic assays, one may use macrobeads (250-500 µm
diameter) or bead aggregates that are prepared by cross-linking
the TentaGel resin beads with glutaraldehyde.

Peptide Combinatorial Libraries

Synthetic Libraries that Require Deconvolution

Many existing solution assays can be applied to the peptide libraries made by this approach. As mentioned above, multistep synthesis and screening that identify only one, not necessarily the best, solution motif are performed.

Self-Assembled PNA-Encoded Chemical Microarrays

In the original report, it was used for the screening of protein binding. Like the OBOC method, a whole-cell binding assay also can be applied to the encoded planar chemical microarrays, although this has not been reported.

Synthetic Libraries that use Affinity Chromatography Selection

For the affinity column selection library, a solution-phase peptide library (a mixture) is loaded onto a column with an immobilized target protein. This method has been applied successfully to retrieve an antibody-specific binding peptide from a mixture of peptides. It also was reported to identify peptide motifs for SH2 domains and kinase domains of protein tyrosine kinases.

Elucidation of the Chemical Structure of Active Peptides

A n important goal in screening combinatorial libraries is the identification of novel structures that interact with receptor targets of biologic interest. Depending on the methods used to generate the library, the procedures for the structure determination of active peptides identified from screening vary.

Phage-display peptide library

Standard DNA sequencing is used to elucidate the structure of an active peptide. From the DNA sequence, one then can determine the amino acid sequence of the displayed peptide.

Spatially addressable library

The structure of each peptide in the library is known already; therefore, structure determination of the positive lead is not needed.

OBOC combinatorial library

In peptide libraries composed of α-amino acids (including many unnatural α-amino acids), automatic microsequencing by Edman degradation is the method of choice. However, the Edman sequencing method is expensive, is relatively slow, and requires that the N-terminus of the peptide be free; plus, the peptide consists of α-amino acids only. For peptides without a free N-terminus (e.g., cyclic peptides that use the N-terminal amino group for cyclization), branched peptides, and peptides with one or more nonsequenceable building blocks (e.g., β and γ-amino acids), the OBOC library synthesis requires different synthetic and chemical encoding strategies. Based on the chemistry used, decoding can be achieved by either Edman microsequencing, mass spectrometry (MS), or gas chromatography. To eliminate the interference of coding tags with the screening, the coding tags should be in the bead interior (Fig. 2a). We recently have developed two simple, yet highly robust, methods to prepare topologically segregated bilayer beads (Fig. 2b) (35, 36). We recently reported a new "ladder-synthesis" approach that combines both "ladder-synthesis" and bilayer bead concepts to encode OBOC nonsequenceable peptide and pep- tidomimetic libraries (36). An add-in benefit of the new "ladder-synthesis" is that the library beads generated by this method are amenable to both MS and Edman microsequencing if the compound is a sequenceable peptide (Fig. 2c). More recently, Joo et al. (37) used a similar approach for a high-throughput sequence determination of OBOC cyclic peptide library members using partial Edman degradation/MS.

Synthetic library methods that require deconvolution

Structure determination by physico-chemical methods for deconvolution libraries is not necessary because the chemical

Figure 2. (a) Spatial separation of a testing peptide and coding tag. A, B, and C are sequenceable or nonsequenceable amino acids; X, Y, and Z are sequenceable coding units; and X encodes A, Y encodes B, and Z encodes C. (b) Photomicrograph of topographically segregated bilayer beads. Free amines at the inner core of each bead (which is the site for a coding tag) were reacted with bromophenol blue to show blue color. (c) MS decoding of an OBOC library generated by the new "ladder-synthesis" approach.
Peptide Combinatorial Libraries

structure of the active compound can be deduced from the synthetic history and analysis results of the compound mixtures.

Self-assembled PNA-encoded chemical microarrays

The identity of the positive library compound that interacts with the target protein can be determined by knowing the nucleic acid sequences of the oligonucleotide microarrays.

Affinity column selection

For the synthetic library method that uses the affinity chromatography selection approach, the bound peptides can be eluted and microsequenced by Edman degradation. Concurrent microsequencing of the retrieved peptide mixture can be performed rather than sequencing individual peptides. Sequence motifs then can be defined in a fast and efficient way. However, the amino acid sequence obtained will be the result of the summation of the peptide mixture. Unless a predominant, distinct motif and an alignment of one or more of the critical residues exists within the peptide sequence of the library, with a fixed residue at a specific position, the result could be very difficult if not impossible to interpret.

Practical Applications of Combinatorial Peptide Libraries

Combinatorial library technology can be employed to study almost any biologic target, and results from these studies can increase our fundamental understanding of cellular function and signaling pathways. It also can be used for the discovery and optimization of drug leads. Random peptide libraries displayed on phages have been used successfully for a variety of biologic applications. These applications include the discovery of peptide ligands to target receptors, specific ligands for DNA sequences, enzyme inhibitors, peptides that mimic carbohydrate structures, protein-protein interfaces, and receptor binding sites. Others include peptide ligands for cancer cells and cancer-associated proteins. In vivo screening of phage-displayed peptide libraries has resulted in the discovery of peptide ligands that bind to the endothelium of tumor blood vessel and lymphatic vessels of specific organs, tissues, or cancers.

Over the last decade, the synthetic combinatorial library approach has been applied successfully to various biologic systems. These systems include the identification of ligands against antibodies (both continuous and discontinuous epitopes), streptavidin, avirin, opioid receptors, melanin-diminulating hormone (MSH) receptors, signal transduction adapter molecules such as SH2 and SH3 domains, adhesion molecules such as gplllbIlla, specific metal ions, double-stranded DNA, and organic dye molecules. In addition, peptides with antiprotease (including HIV protease), anti-inflammatory, antibacterial, and catalytic activities have been discovered. Furthermore, substrate motifs for various protein kinases, proteases, deacetylases, and other posttranslational modification enzymes have been elucidated. Peptide-based enzyme mimics (artificial enzymes) have been identified through screening combinatorial peptide libraries. We reported the use of a $^{32}$P or $^{33}$P phosphorylation assay and an autoradiographic method to identify specific and efficient peptide substrates for protein kinases. We also have described the use of whole-cell binding assays in which bead libraries are mixed with live cells to identify cell surface-binding peptide ligands specific for prostate cancer, nonsmall cell lung cancer, and lymphoma cells. Table 2 summarizes some published applications of combinatorial library methods.

Combinatorial chemistry also has been applied successfully to the field of material science (38, 39). This application includes the discovery of polymeric structures with specific physical, chemical, electrochemical, photochemical, or photoelectric properties.

Future Directions

Combinatorial chemistry has been playing a central role in the field of chemical biology. Huge libraries of peptides, peptidomimetics, small molecules, natural product-like molecules, and macrocycles can be generated on solid support or in solution phase. Many methods have been developed to screen such libraries. Numerous reports detail the successful application of these technologies to basic research and to the development of pharmacetics, diagnostics, imaging agents, new materials, catalysts, and biosensors. Biologic libraries such as phage-display peptide libraries, although very powerful and useful, are limited primarily to the standard 20 L-amino acids. With existing technology, the incorporation of a few selected unnatural amino acids into such libraries is, in principle, feasible but far from a routine (40). A need exists to develop highly robust biologic combinatorial chemistry systems that enable one to incorporate many unnatural amino acids, including some that can be modified subsequently through site-specific ligation or derivatization. Peptide and chemical microarrays (planar or bead-based), with or without microfluidics, have been evolving rapidly in the last decade. Many new technologies to generate and screen such microarrays have been developed. One major challenge is to develop a robust label-free optical detector that can measure the real-time binding kinetics of a pure target protein or complex protein mixtures against high-density microarrays (e.g., 10,000-20,000 discrete peptide or chemical spots per three square inches, a size of a microscope glass slide). A further challenge is to develop an efficient in situ light-directed synthesis of chemical molecules other than peptides and nucleic acids in a high-density microarray format.

The OBOC combinatorial library method is highly versatile and economical. It also is a form of chemical microarrays. Many investigators successfully have applied the on-bead screening methods in their research. The solution-phase and cell-based assays for OBOC libraries, however, are much less developed and have been applied successfully in only a few laboratories. A need exists to develop robust methods that allow investigators to screen routinely huge OBOC releasable peptide or chemical libraries (e.g., 200,000 compounds) with multiparametric...

solution-phase cell-based assays for compounds that affect specific cell signaling pathways or target proteins in one single 10 cm Petri dish. In the areas of catalysis and material sciences, one would expect that new materials would continue to be developed combinatorially. We will not be surprised if one day novel chlorophyll mimics that consist of peptides and organic chromophores and are developed through combinatorial chemistry become a major component of future photocells. The future of combinatorial chemistry is bright, and it will continue to serve as an indispensable research tool for many investigators to solve difficult problems across many different scientific disciplines.

This review article provides an introduction to folded and extended conformational motifs of synthetic peptidomimetics as templates for chemical biology applications. Several variants of these 3-dimensional structures have been assessed, which comprise versatile scaffolds for presentation of side-chain and main-chain peptide groups for molecular recognition. Specifically, relevant parameters and stereochemical consequences are discussed for helices of peptidomimetics based on: 1) \( \alpha \)-amino acids alkylated (e.g., methylated or ethylated) at the \( \text{C}^\text{\lambda} \)-atom; 2) \( \omega \)-didehydroamino acids, in particular \( \omega \)-didehydrophenylalanine, with a carbon–carbon double bond between the \( \alpha \)- and \( \beta \)-positions; 3) N-alkylated \( \alpha \)-amino acids, whereby the side chains typical of coded residues are transferred from the \( \text{C}^\text{\lambda} \)-atom; 4) \( \beta \)-amino acids, the subclass of residues investigated most extensively in which the amino and carboxyl functionalities are separated by more than one carbon atom; and 5) short-range, backbone-to-backbone cyclizations that generate small-ring, monolactam or dilactam building blocks.

Introduction

Peptidomimetic is a molecule that bears identifiable resemblance to a peptide that, as a ligand of a biologic receptor, can imitate or inhibit the effect of a natural peptide. Numerous peptidomimetics have been developed over the past 25 years by bioorganic and medicinal chemists. Some molecules (i.e., those with modifications in the backbone amide group) also have been termed pseudopeptides or peptide bond surrogates (1). These synthetic analogs of peptides have a variety of applications, but most expanded interest in this area focuses on their potential for developing metabolically stabilized and/or more potent and selective bioactive compounds. The complex synthetic aspects (2) and relevant biological data (1, 3, 4) of peptidomimetics have been summarized extensively in review articles and in book chapters. In this introductory review, we focus on the 3-dimensional (3-D) structural properties of peptidomimetics characterized heavily by a few, well-studied amino acids with modifications in the main chain and/or in the side chain. An effort was made through appropriate citations to expose the nonexpert and the beginning graduate students to the remarkable advances made in this area of research. The field of peptidomimetic chemistry is entering new decades of exploding activity. This time is exciting as new techniques and methodologies have now made it possible to answer questions that were not possible to address even few years ago. Many developments ushered in the new era of peptidomimetic chemistry, which include advancements in solution and in solid-phase peptide synthesis, organic synthesis, nuclear magnetic resonance and related biophysical techniques, and mass spectrometry. These advancements take advantage of an increasing understanding of protein folding. Numerous examples now exist of low molecular weight peptides and peptidomimetics that adopt folded or extended structures, and in some cases they serve as exceptional substitutes for their much larger protein counterparts in life processes. Chemists in both academia and industry are making important strides to push the frontiers in these areas. With the ability to incorporate unnatural amino acids that have strong conformational or nucleating bias, it will be possible to force much smaller peptides and peptidomimetics to adopt appropriate 3-D structures and functions. The future for the young scientists who ultimately want to pursue this line of research is indeed very promising. Rather than looking at peptidomimetics as a mature field, it should be argued that we are only in our infancy in terms of sophistication. Every reason exists to believe that a combination of approaches, which include biophysical and functional characterizations, will propel this area forward in the next years. It is especially important for those who are considering future research areas to analyze seriously the potential of such studies.

Among the various types of known ordered secondary structures adopted by peptides formed exclusively by \( \omega \)-amino acid building blocks, in this review article we shall discuss the classic...
Peptides Based on Cα-Alkylated α-Amino Acids

Peptides rich in the uncoded Cα-methylated α-amino acids (1) are biased strongly to fold tightly into the intramolecularly H-bonded, α-helical, or the strictly related 310-helical conformation (5–9), the latter generated by sequences of helical p-turns (10,11). The same 3-D structural propensities are shared by the α-helix coiled coil (14–16) (Fig. 1a), which has an integer number of amino acids per turn (n = 3.3) and consequently its smallest repeat (i.e., the shortest main-chain length that brings two side chains exactly one on top of the other) is a heptad (7 residues); and 2) in the 310-helix (Fig. 1b), which has an integer number of amino acids per turn (n = 3.0), a triplet of residues selected carefully will produce the expected amphiphilicity.

The amphiphilic helical structure of most antibacterial peptides is a prerequisite for their propensity to form channels across the double-layered biological membranes [12]. In aqueous solution, positions a and d of the α-helical heptad repeat (a, b, c, d, e, f, g) (13) require hydrophobic residues for the onset of the widespread antiparallel dimer (or multimer) superstructure (α-helix coiled coil) (14–16) (Fig. 2). The hydrophilic positions e and g, immediately on the back, reinforce the dimer stability via ionic interactions. Deep knowledge of the factors operative in helix dimer formation may help our understanding greatly of protein-protein interactions in chemical biology.

The preferred conformation of peptides based heavily on Cα-ethylated α-amino acids (3) is different. In the resulting 2.05-helical conformation, intramolecular H-bonding takes place between the N-H and C=O groups of the same amino acid building block (17, 18). To achieve the pentagonal disposition, the H-bonding parameters are distorted remarkably and the sp2 N-C=C-C= bond angle is compressed severely (by ∼6.5°). An example of this fully extended (all-trans) conformation, based on Cα-Cα-diethylglycine (3, R = CH₂CH₃) (17), is illustrated in Fig. 3. This twofold structure is extremely rare in globular proteins and is known only for a Gly-rich sequence (18).

Only few Cα-alkylated α-amino acids occur naturally (in peptide antibiotics) (20, 21), which include Aib (α-aminoisobutyric acid or Cα-amino-α-methyl glycine) (1, R = CH₂CH₃), Iva (isovaline or Cα-ethyl, Cα-methylglycine) (1, R = CH₂CH₃), and (αε)Val (Cα-ethyl norvaline) (3, R = CH₂CH₃). (αε)Val

1 In the poly(Pro)ₙ helix, all α-Cα-Cα- (N₁-O₁-C₁₁) torsion angles are in the unusual cis conformation (0°).
2 The (Cα–Cα)=C–C– bond angle.
3 The (N=C–C=N)=C–C bond angle.
4 Number of amino acids per helical turn (positive values refer to right-handed helices, whereas negative values refer to left-handed helices).
5 A axial translation (per residue).
6 Pitch or axial translation per helical turn.

Peptides Based on Cα,β-Didehydro α-Amino Acids

Cα,β-Didehydro α-amino acids (∆AA-α) are found in a variety of naturally occurring microbial and fungal metabolites, in a limited number of globular proteins, and in polycyclic peptide antibiotics (22). Bioactive peptide molecules that contain these residues are less prone to enzymatic degradation.

The double bond between the sp2 Cα and Cβ atoms of ∆AA-α induces higher lipophilicity and geometric alterations in the bond distances and angles and restricts the conformational

The flexibilities of the peptide backbone and the side chain as compared with those of protein residues. Most 3-D structural studies in this subclass of peptidomimetics have exploited ΔPhe mainly because of its convenient chemical synthesis and interesting conformational properties. ΔPhe exists in two diastereomeric forms: the Z-configurational isomer (ΔZPhe, 4), where the N–H group is in the cis disposition with respect to the benzyl moiety, and the E-isomer (ΔEPhe, 5), where it is in the trans disposition. Almost all conformational studies described so far have been performed on the Z-isomer (22–24) essentially because a large part of the synthetic routes results in this stereoisomer.

From the investigations on ΔPhe-based peptides, it is clear that the 3-D disposition largely preferred by this residue is the helical conformation (23, 24). Therefore, most corner positions of the various types of β-turns and all positions of 310/α-helices are accessible easily to this residue. Fig. (4) shows the right-handed 310-helix generated by a double repetition of the model triplet -ΔZPhe-ΔZPhe-L-Ala (a). Aromatic amino acid residues, which include ΔZPhe (25), are known to...
Peptidomimetics

(a)

(b)

Figure 4 Right-handed 310-helical conformation formed by a double repetition of the \(\Delta\text{ZPhe-}\Delta\text{ZPhe-L-Ala}\) model peptide: views orthogonal to (a) and down (b) the helix axis.

Another useful property of \(\Delta\text{Phe}\) is its strong absorption in the near-UV region (\(\sim 280\) nm). This characteristic has been exploited in several studies to probe peptide conformational transitions and helix screw sense changes of chiral switches (26-28).

Interestingly, a series of homo-peptides derived from the \(\text{C}^{\alpha,\beta}\)-didehydro \(\alpha\)-amino acid with the shortest side chain (\(\text{C}^{\alpha,\beta}\)-didehydroalanine or \(\Delta\text{Ala,}6\) was shown unambiguously to overwhelmingly adopt a multiple, consecutive, fully extended conformation (29). These peptide molecules are essentially flat, including the amino acid side chains, and form completely planar sheets (Fig. 5). This uncommon peptide 3-D structure is stabilized by two types of intramolecular H-bonds, \(\text{N-H} \cdots \text{O} = \text{C}\) (typical of the 2.05-helix) and \(\text{C}^{\beta}{i+1} \cdots \text{H} \cdots \text{O} = \text{C}\) (characteristic of \(\Delta\text{Ala}\) peptides). The molecules are isolated and pack in layers without any significant contribution from intermolecular \(\text{N-H} \cdots \text{O}\) H-bonds. For this exceptionally flat ("sole-like") peptide structure, it is reasonable to foresee a bright future as a potentially active bridge in charge transfer systems.

Peptides Based on N-Substituted \(\alpha\)-Amino Acids (Peptoids)

In 1992, Simon et al. (30) introduced a new concept in the search for potentially biactive peptide molecules: The side chain of the \(\alpha\)-amino acid \(\alpha\)-carbon is shifted by one atom along the backbone to the next nitrogen to generate a peptoid (i.e., an N-substituted oligoglycine). Peptoids have been shown to be protease resistant (only tertiary amide groups are present in the main chain), oral bioavailable, and easy to synthesize in oligomeric forms with complex sequences (31). Peptoids have been also exploited for the construction of many biologically active compounds in many different fields of pharmaceutical research.

Because of this principal structural divergence from coded peptides, peptoids lack amide protons. This property precludes the formation of the intramolecular H-bonds that contribute largely to the stabilization of the most common helical structures of \(\alpha\)-peptides. Unlike that of \(\alpha\)-peptides, the peptoid backbone is inherently achiral (as it is based on Gly residues). However, it has been reported that sufficient bias to form stable helices of a specific screw sense can be provided by side chains with an \(\alpha\)-chiral carbon atom (that is linked directly to nitrogen) (32, 33). The extraordinary resistance of these helices to loss of their ordered secondary structure is another intriguing property of peptoid molecules.

The only published X-ray diffraction structure for any peptoid oligomer, the \(\text{N-rich}\) homo-pentamer, shows clearly that the molecule is folded in a left-handed helical conformation with...
Peptides Based on β-Amino Acids

ω-Amino acids (that have more than one carbon atom intervening between the amino and carboxyl functions) possess a larger degree of conformational variability than α-amino acids. Initial conformational investigations of oligomers of ω-amino acids were driven by the extensive interest in the various forms of nylon. More recently, a large body of 3-D structural investigations on β-amino acid oligomers have been discovered, but the conformational preferences of peptides based on ω- and l-amino acids and of “hybrid” peptides (e.g., those formed by ω- and β- or ω- and γ-amino acids) are also the subject of numerous spectroscopic and X-ray diffraction analyses (37-39). In this section, we summarize the most relevant conformational results extracted from the studies of peptides rich in the β-amino acids listed below.

In p-Ala [30], the simplest amino acid of this class, the central, characteristic C2=C3 bond is unconstrained and can adopt values for the related n (also called µ in some publications) torsion angle of approximately ±60° (gauche) and 180° (trans). Detailed analyses of the rotational flexibility about this bond in linear p-Ala peptides revealed that it is mostly trans oriented (40, 41). Also, these studies provided almost exclusive evidence for the formation of extended peptide chains, which usually self-aggregate into sheet-like structures.

More recently, introduction of (one or multiple) substituents and chiralities on the C2 and C3 atoms (32-32, 15, 16) and incorporation of C2=C3 (14, N=C2 (17), and N=C3 (18) cyclized motifs seemed to facilitate folding of β-peptides into a new type of helices (42-47). A variety of these ordered structures has been authenticated. If the nomenclature is used that terms peptide helices according to the number of atoms involved in the pseudocyclic structure generated by the intramolecular C=O···H-N H-bond, those found most frequently are the 14-, 12-, and 12/10-helices. Interestingly, although the direction of the H-bond for the 12-helix is the same as that typical of α-peptides (i.e., from a C-terminal N-H group to an N-terminal C=O group; in this specific case i → i + 1), the direction is reversed (i → i + 1 and i → i + 2, respectively) for the 10- and 14-helical, β-amino acids in the extended conformation may also produce parallel or antiparallel pleated-sheet structures.

The 14-helix emerged as the best documented structure among the β-peptide folded structures. The ω, ω torsion angles are extended (±130° - 140°). The n value is constrained (e.g., by the cyclohexyl ring of the cyclic β13AA (34) (n = 2), close to ±60°. Both the pitch and the diameter of this termary helix are ±5.0A.

When the substituents on the C2 and C3 atoms of the β-amino acid are part of a five-membered ring (as in the trans cyclic β13AA, 34, with n = 1), the accessible n torsion angle is restricted to about ±95°. The resulting 12-helix has a set of ω, ω torsion angles near ±90°. The helix repeats approximately every 2.5 residues, with a pitch of ±5.5A, and a diameter slightly less than 4.0A.

The 12/10-helix was found in alternating β12 (33) and β11 (12) monosubstituted residues. The dipeptide unit that contains a CONH-bond with no adjacent R-NH2 substituents generates the 12-membered ring, whereas that with the two adjacent substituents is part of the 10-membered ring. This ordered structure consists of consecutive narrower 10-membered and wider 12-membered H-bonded rings. Consequently, the two successive H-bonded rings exhibit opposite directionality. In this conformationally mixed helix, the peptide planes of the 10-atom rings are approximately perpendicular to the helix axis, whereas the peptide planes of the 12-atom rings are aligned nearly with the helix axis. As in the 14-helix, the n value is close to ±60°. The number of amino acids per turn is 2.7. The
overall helix macrodipole is much smaller compared with those of the other helical structures. The $\text{C}=\text{O}$ (and the $\text{N}$–$\text{H}$) bonds show an alternating up/down direction with respect to the helix axis.

Two (parallel and perpendicular to the helix axis) views for each of the three β-peptide helices discussed in this section are presented in Fig. 7. Recent applications of β-peptide helices to relevant biological issues (antibacterial activity, transport across cell membranes) (48–51) will certainly stimulate additional work in this promising area.

Lactam-Based Peptides

Several review articles and books have dealt extensively with the synthetic problems encountered and have discussed in detail the biological data of lactam-based peptides. However, insufficient attention has been paid to the conformational implications induced in the resulting constrained analogs (52–56). Here, we will mention briefly only those lactam-based conformational restrictions in peptides that are achieved by short-range cyclizations that involve the backbone $\text{N}$ and $\text{C}^\alpha$ atoms (from residue $i$ to residue $i$ or $i+1$). Therefore, conformational restrictions that involve the $\text{C}^\gamma$ (carbonyl) atom and those obtained by medium- and long-range cyclizations, although of great theoretic and practical interest, have not been considered. In addition, in all peptides discussed in this section, the repeating $\text{N}$–$\text{C}^\alpha$–$\text{C}^\gamma$ sequence is maintained.

As a part of a program that evaluates N-acylated γ-lactams as conformationally constrained building blocks of pseudopeptide foldamers, homo-oligomers of L-pyroglutamic acid (L-pGlu) (19) to the tetramer level were synthesized (57). The preferred conformation of this pseudopeptide series with $\text{N}_i \leftrightarrow \text{C}_{i+1}$ ring restriction in structure-supporting solvents was assessed by various spectroscopic techniques. In addition, the crystal-state structure of the $\text{N}^\alpha$-protected dimer was established by X-ray diffraction. A high-level DFT computational modeling was also performed based on the crystallographic parameters. In this analysis, it was demonstrated that an $\alpha\text{C}^\gamma$-$\text{H} \cdots \text{O}$=C intramolecular H-bond is responsible for the stabilization of the s-trans-L-pGlu-L-pGlu conformation by 1.4 kcal mol$^{-1}$. This effect can be detected easily by $^1\text{H}$ NMR because of the anomalous chemical shifts of the $\alpha\text{CH}$ protons present in all oligomers. In summary, a new polyimide-based, foldameric structure (Fig. 8) was developed that, if functionalized appropriately, holds promise as a rigid scaffold for novel functions and applications.
Figure 7: Two orthogonal representations for each of the β-peptide 14-, 12-, and 12/10-helices (a, b, and c, respectively) formed by a β^2 AA or/and a β^3 AA, where R^2/R^3 are methyl groups. The H-atoms, except the -CONH- H-atoms, are omitted for clarity.
Peptidomimetics

Figure 8
Computer model of the ternary helical structure of the pseudopeptide \(- (L-pGlu)_{4} - \) segment generated by the repeating \( \psi_{1}, \omega_{1}, \) and \( \psi_{2} \) backbone torsion angles obtained from the X-ray diffraction structure of Boc-(L-pGlu)_{2}-OH (Boc, tert-butyloxycarbonyl) (57).

Figure 9
Computer models of: (a) the cyclic correlate based on 12 monomeric units of \( (2S, 4R)-4\text{-amino-5-oxopyrrolidine-2-carboxylic acid} \). The idealized backbone \( \phi, \psi \) torsion angles are \( 120^\circ, 120^\circ \), respectively. (b) The nanotubular structure resulting from vertical self-assembling of the cyclic correlate through intermolecular N-H···O = C=H-bonds that involve the trans amides (62). The black and white atoms are oxygens and hydrogens, respectively.

Energy calculations for \( (S)-3\text{-amino-2-pyrrolidone (\( \gamma \)-lactam) and (S)-3-amino-2-piperidone (\( \delta \)-lactam) derivatives indicate that the most stable conformations have \( \psi \) values restricted to the range \(-125 \pm 10^\circ\). As a consequence, these chiral mono-lactams can be accommodated readily at the left corner of a type II' \( \beta \)-turn \( (\psi = -60^\circ, \phi = -120^\circ) \) (10, 11), a position occupied typically by \( \alpha \)-amino acids of \( \alpha \) (D) chirality, but obviously not at the same position of a type-II \( \beta \)-turn \( (\phi = -60^\circ, \psi = 120^\circ) \). X-ray diffraction, \( ^{1}H \) NMR, CD, and computer graphics analyses on a variety of analogs of bioactive peptides are in excellent agreement with the theoretic findings, in particular that underlie the strict requirement of reversing the chirality of the residue at the left corner of the \( \beta \)-turn to keep the same type (II or II') of chain folding when a 5(or 6)-membered ring lactam replacement is involved (59). Despite the gross conformational similarities between the 5- and 6-membered ring lactams, distinct biological properties usually are noted for peptides that contain such rings. More subtle differences in conformation and/or in bulkiness between the two lactams might be responsible for the observed diverging biological activities.

The effect of the incorporation of a succinimide \( (22) \) moiety into a peptide chain (another type of \( C_{\alpha} \leftrightarrow C_{\alpha}^{+1} \) ring restriction) has been examined carefully (60, 61). The five-membered succinimide annular system is an intermediate in the repair of selective degradations of side-chain deamidated proteins. It has been shown both theoretically and experimentally that L-Asu-Xxx- (Asu, \( \alpha \)-aminosuccinyl) dipeptide sequences strongly favor the type-II' \( \beta \)-turn, a behavior similar to that of the \( \gamma \)-lactam modification discussed above.

The conformational preference of the terminally blocked homo-trimer from \( (2S, 4R)-4\text{-amino-5-oxopyrrolidine-2-carboxylic acid (22a), characterized by C}_{2}^{n} \leftrightarrow C_{2}^{n+1} \) ring restriction} and an unique, alternating cis-trans secondaryamide sequence was analyzed by X-ray diffraction (62). Using computer modeling, it was also shown that the rigid 3D structure of the
trimer can be exploited as a template to construct novel linear oligopeptide foldamers and large ring cyclic correlates with self-recognizing properties (for the latter, see Fig. 9).

The most stable conformation of peptides that contain 3-amino-2-piperidone-6-carboxylic acid (22b, also an amino acid with a C^α ↔ C^α+1 ring restriction, has been determined by ^1H NMR (63). A chair conformation is a feature that characterizes the piperidone ring. Also, an intramolecularly H-bonded β-turn form is the most plausible explanation for the experimental finding on these peptides.

The synthesis of a novel macrocyclic (10-membered ring) dilactam (23, n = 2), an additional template with a C^α ↔ C^α+1 ring restriction that may promote formation of type-II β-turns, has been reported (64). By analysis of the ^1H NMR spectrum, it was established that a chair-like conformation is preferred for this ring structure and that the two amide groups are trans with roughly parallel planes. It seems, however, that the presence of the two macrocyclic secondary amide functions perpendicular to the plane of the turn would facilitate intermolecular association that leads to poor solubility and gel formation. A similar (11-membered) ring structure has been synthesized to generate a relatively rigid model of the bioactive peptide thymopentin. Peptides that contain two consecutive macrocyclic dilactams, separated by a C^α-C′-N-C^α region that retains flexibility about the ψ_i+2 and ω_i+2 torsion angles, have been prepared (65). This swivel-like effect can allow the peptides to adopt low-energy folded conformations. From potential energy calculations, it was established that the best candidates for β-turn models are the 12-membered ring structures that have the configurational sequence L,L,D,D (in these compounds all amide groups are nearly trans planar). The 10- and 11-membered dilactams were shown to be higher in energy. The results of a CO-H NMR study are consistent with the presence of a β-turn in the -L-Lys-L-Glu-D-Lys-D-Glu-bis-dilactam-bridged tetrapeptide.

In search for enkephalinamides with improved analgesic activity, conformationally restricted analogs, where the Tyr, Gly, Phe, and Leu/Met residues are cyclized to form a piperazin-2-one (24, an n = 2, → N_i+1 ring restriction), have been prepared. Analogs with either D-Tyr¹ or L-Leu⁵(L-Met⁵) are active. The absolute configuration of the piperazin-2-one derived from the intermediate dipeptide amide H-L-Phe-L-Leu-NH₂ has been assessed by X-ray diffraction. The enantioface-differentiating abilities of cyclic peptides that contain N,N'-ethylene-bridged dipeptides have been examined. The X-ray diffraction structure of an L-Ala-L-Ala piperazin-2-one derivative has been described (66). The ψ_i torsion angle is fixed at about −35°, whereas ϕ_i and ω_i, in part external to the ring structure, are trans.
Summary

In this introductory review we have presented the most relevant 3-D structural characteristics of a selected set of peptidomimetics that, hopefully, will be of help to the nonspecialized scientists for potential use in the currently expanding field of chemical biology. More specifically, we have discussed examples of peptide surrogates with main-chain and side-chain modifications either at the α-carbons, or at the β-carbons, or with different types of cyclizations (N=N, N=C, and C=C). For journal issues or books devoted to these and other types of peptidomimetics, the reader is referred to References 67–73.

Synthetic Peptides to Define Structure-Function Relationships
Amide bonds are found ubiquitously in natural or synthetic molecules of biologic interest. Since the early days of synthetic organic chemistry, methods for the formation of amides have been described. More recently, with the development of solid-phase chemistry and automated peptide synthesis, new strategies and reagents have been devised to overcome typical problems such as low conversion and racemization. This article provides an overview of the methodology that is available today. Depending on the nature of the synthetic target and the associated synthetic challenges, different approaches can be envisaged. Methods range from the rather straightforward use of acyl halides, anhydrides, and carbodiimides, to the more elaborate, low-racemization inducing methods that use phosphonium/uronium-based reagents. New amide bond-mediated ligation methodologies now offer new convergent strategies for the synthesis of highly functionalized molecules of biologic interest.

Amide bonds are found commonly in small or complex synthetic or natural molecules of biologic interest. Amide bonds are, for example, the structural backbone of proteins that play a crucial role in almost every biologic process. In nature, amides are formed via complex enzymatic pathways that ensure selectivity and specificity of the formed molecule. An analysis of the Comprehensive Medicinal Chemistry database revealed that more than 25% of known drugs bear amide functionality (1). For example, Taxol (paclitaxel; Bristol-Myers Squibb, New York) is a highly functionalized diterpenoid, which is extracted originally from the bark of the pacific yew tree. It is used to treat ovarian and breast cancers (2). Fuzeon (enfuvirtide; Roche Pharmaceuticals, Nutley, NJ) is a synthetic biomimetic peptide and is the first of a novel class of fusion inhibitor antiretroviral drugs used to treat HIV-1 infection (3). Lipitor (atorvastatin hemicalcium salt; Pfizer, Inc., New York) is the best-selling drug in the world, and it is used to treat high cholesterol (4). Sprycel (dasatinib; Bristol-Myers Squibb) is an oral dual BCR/ABL and Src family tyrosine kinase inhibitor, which is approved for use in patients with chronic myelogenous leukemia (5) (See Fig. 1).

Since the early 1840s (6), amide bond formation has been a very active field of research in organic chemistry. A multitude of synthetic methods have been elaborated and optimized (7). Relevant examples of these methods available to the bioorganic, organic, medicinal, or combinatorial chemist are reported in this article.

Amide Bond Formation: Overview

Amide bond formation by direct condensation between an acid and an amine is not obvious and must overcome adverse thermodynamics (8). This dehydrative process can be achieved under forcing conditions such as high temperatures (160–180 °C), which are usually incompatible with the presence of other functionalities. Contrary to the ester formation between an acid and an alcohol, which is an equilibrium, the acid and the amine undergo first an acido–basic reaction that yields the stable salt. Therefore, the acid must be activated by the attachment of a leaving group before being reacted with the amine (see Fig. 2). These two steps can be carried out separately with intermediate isolation of the activated species or by a one-pot synthesis with late introduction of the amine. More recent conditions allow coupling to occur with both the acid and the amine present in the reaction mixture. Often, the choice of the methodology for one specific amide formation is not only governed by the yield. Avoiding racemization at neighboring chiral centers, improving difficult isolation...
from reaction by-products or reducing the costs of the reagents, might be the key elements for decision.

Amide Bond Formations: Methods and Strategies

Acyl halides

Acyl or acid chlorides are used frequently in amide formation as activated forms of the corresponding carboxylic acid. A wide selection of acyl chlorides is available commercially. Otherwise, they can be prepared readily from the corresponding carboxylic acid in the presence of reagents such as thionyl chloride (9), oxalyl chloride (10), phosphorus trichloride (11), and phosphorus pentachloride (12). Reactions that use oxalyl chloride or thionyl chloride are promoted by the addition of a catalytic amount of DMF (13) (see Fig. 3).

Despite the high reactivity and low cost, these chlorinating reagents generate hydrogen chloride in situ and are not suitable for amide formation in the presence of acid labile groups. Hence, alternative basic conditions have been studied. For example, cyanuric chloride is used commonly to generate acyl chloride in nonacidic conditions (14). The presence of an organic or inorganic base maintains the basic pH conditions throughout the reaction. The cyanuric chloride method is also used in large-scale synthesis (15).

Neutral conditions (i.e., non-acid generating) that use triphenylphosphine and a source of chloride as carbon tetrachloride (16), hexachloroacetone (17), trichloroacetimide (18), or trichloroisocyanuric acid (19) have been developed. Alternatively, 1-chloro-N,N,2-trimethylpropenylamine (20) converts acids into acyl chlorides readily without HCl formation.

The coupling reaction with the amine usually requires an additional acid scavenger (often a base like triethylamine, DIEA, or NMM) to trap the formed HCl. The reaction can also be accelerated in the presence of a catalytic amount of DMAP (21), pyridine, or metallic zinc (22).

Nevertheless, acyl chlorides have some limitations. Acyl chlorides that bear α-hydrogens can undergo ketene formation under basic conditions (23). The subsequent amine addition occurs with potential loss of chirality and side reactions (24). Oxazolone-mediated racemization is encountered in peptide chemistry. N-protected peptidoyl chlorides yield the corresponding oxazolones spontaneously. These transient species react readily with nucleophiles; but, under the standard aminolysis conditions, the α-proton is acidic enough to enable acido–basic equilibrium, which compromises the chirality of the α-center. Peptides are, therefore, grown usually at their N-terminus, thus avoiding the oxazoline formation. Furthermore, the acyl chloride activation of N-urethane-protected amino acid (e.g., Boc, Fmoc, or Cbz) is unadvisable, as they react with the carbonyl of the neighboring urethane to yield the corresponding NCA (25). NCA functionalities are notoriously reactive and promote many side reactions (see Fig. 4). Similar problems can also be observed with other activation methods.

Alternatively, acid fluorides are used to activate the acid. Acyl fluorides are less sensitive to moisture and are more reactive toward primary and secondary amines than the corresponding acyl chloride. Furthermore, they are compatible with basic (Fmoc and Cbz) or even acid- (Boc) labile amine protecting groups and less prone to promote racemization than their chlorinated homologs (26). Thus, the acid fluoride method is often used in peptide synthesis (27). Cyanuric fluoride (28), TFFH (29), DAST (30), and deoxofluor (31) are used commonly as fluorinating reagents (see Fig. 4).
Acyl chloride formation using oxalyl chloride and DMF as catalyst:

\[
\text{Cl}_2\text{C}=\text{Cl} + \text{H}_2\text{N} \rightarrow \text{Cl}_2\text{CO} + \text{HCl}
\]

Racemisation via ketene formation:

\[
\text{R}^-\text{CH} = \text{O} \rightarrow \text{R}^-\text{C} = \text{O} \quad \text{addition}
\]

Racemisation via oxazolone formation:

\[
\text{R}^-\text{CH} = \text{O} \rightarrow \text{R}^-\text{N} = \text{C} = \text{O} \quad \text{amination}
\]

NCA mediated side reactions:

\[
\text{RCOOH} + \text{Nu} \rightarrow \text{R}^-\text{N} = \text{C} = \text{O} + \text{CO}_2
\]

Figure 4  Acyl chloride–mediated amide coupling and potential side reactions.

Acyl azides

The acyl azide strategy was developed for peptide synthesis in the early 1900s. The original preparation of the acyl azide from the corresponding methyl ester is a two-step synthesis. Displacement of the methyl ester with hydrazine, which generates the acyl hydrazide, is followed by the nitrosation reaction to yield the acyl azide. Isocyanate formation, also called the Curtius rearrangement, is a possible side reaction, and ureas are often observed as side products. An improvement of this method is the one-pot synthesis of the acyl azide from the carboxylic acid using DPPA. Acyl azides are, however, potential explosives and the leaving group (free azide) is toxic, which provides some limitation to this method.

Acyl imidazoles

CDI allows one-pot amide bond formation and is also used for large-scale peptide chemistry. Initially, the mechanism may involve the formation of acyl carboxy imidazole and imidazole. Both intermediates react together to lead to the activated species as the acyl imidazole. Then the amine is added to undergo aminolysis. As imidazole is generated in situ, the reaction does not need an additional base and it is usually compatible with amine HCl salts. Incidentally, the acyl imidazole intermediate can also be isolated and stored. Some simple acyl imidazoles are even available commercially. Similarly, carbonylimidazolium salts have been introduced. For example, CBMIT is described as an efficient amino acylating reagent for peptide synthesis with sterically hindered amino acids.

Anhydrides and mixed anhydrides

Anhydrides react readily with diverse nucleophiles such as amines. For example, the use of acetic anhydride was reported in the 1850s to produce acetamides. Symmetric anhydrides can be prepared by dehydrating the corresponding acid under strong acidic conditions or at high temperatures. A more practical approach, however, consists of treating the carboxylic acid with DCC. The anhydride is then subjected to aminolysis with the desired amine. Under some specific conditions, hydroxyl carboxamides can be prepared directly from the corresponding hydroxyl acid without protection of the alcohol.

\end{align*}
\]

Figure 4  Acyl fluorides, acyl azides, and acyl midazoles.

Figure 5  Symmetric anhydride preparation and coupling reaction.

process, which practically limits the application of this method to cheap and commercially available symmetric anhydrides. Several mixed anhydride methods have, therefore, been developed. The acid is coupled to a second acid moiety that is considered to be disposable. This strategy relies fully on the regioselectivity of the aminolysis where the reactive center a is more reactive than b (see Fig. 6). The concept of mixed anhydrides has been extended to carbonic, boric, iso-ureas, phosphoric, and phosphinic acid-derived species. Iso-ureas and phosphorous-containing reagents will be discussed in separate articles.

Mixed pivalic anhydride 18 (42) is an example of selective mixed carboxylic anhydride. Selective aminolysis could be caused by the steric hindrance of the tert-butyl group. A mixed carboxylic anhydride strategy has also been studied to overcome the aminolysis selectivity problem. This method exhibited excellent selectivity when ethoxycarbonyl 19 (43) or tert-butyloxycarbonyl 20 (44) anhydrides were used. The selectivity is mainly caused by the higher electrophilicity of one of the carboxylic centers toward the amine. Ethoxycarbonyl anhydrides can be prepared conveniently using ethyl chloroformate or EDDQ 21 (45).

Acyl aryl boron species also react with amines to yield amides with mixed results. For example, catecholborane was used to generate lactams successfully (46). Aryl boronic acids with electron-withdrawing groups, such as 3,4,5-trifluorobenzoic boronic acid and 3,5-bis-(trifluoromethyl)benzenboronic acid, can act efficiently as an amidation catalyst when added to a mixture of acid and amine (47).
Synthetic Chemistry: Formation of the Amide Bond

O-acyl iso-ureas

O-acylisourea species 22 are generated easily by reacting carbodiimides with a mixture of the desired carboxylic acid and amine. Then, they undergo aminolysis readily to form the amide and the urea by-product (48). Often, formation of unreactive N-acylureas 23 by acetyl transfer and racemization are observed (see Fig. 7). This side reaction can be minimized substantially by reacting the acid with the carbodiimides at 0° C before adding the amine or by using DMAP or HOBt 24 as adjuvants (49).

DCC 17, DIC 25, EDC 26, and polymer supported PS-CC 27 are available commercially. Elimination of the resulting ureas can be achieved easily by filtration or solvent wash depending on their solubility. In the case of PS-CC, the urea by product is formed advantageously on the solid support while the amide is released in solution.

Esters

Alkyl esters

Alkyl esters (e.g., methyl, ethyl, benzyl esters) are usually stable toward amines and, thus, are used as protecting groups. Some anecdotic examples of amide bond formation with alkyl esters, however, are reported in the literature. High reaction temperature, addition of a Lewis acid (52), or use of organoaluminium species generated from DIBAL-H-H2NR (53) can enable these reactions. Saturated ammonia in methanol can also react with

Figure 7 Carbodiimides.
methyl esters at room temperature to form the primary amides (54).

Recently, amidation of methyl esters with unprotected amino alcohols in the presence of a catalytic amount of IMes, a readily available carbene, was achieved in good yields (see Fig. 8). Initially, the carbene was proposed to react with the methyl ester to generate the activated C2-acylimidazolium intermediate (55). X-ray evidence, however, suggests a more complex mechanism (56).

Figure 8  Heterocyclic carbene catalyzed amidation.

Activated esters
Usually, esters of phenols are easier to hydrolyze than alkyl esters and they also react with a wide range of nucleophiles such as amines. The reactivity is increased when electron withdrawing groups are present on the phenyl ring. Activated esters can be obtained from the acid using DCC 37 mediating coupling or via the acid chloride. They can be used immediately without additional purification or they can be stored. For example, PNP 28 esters are purified easily by recrystallization in alcoholic solvents with which they do not react. Then, amidolysis is performed at room temperature (37). Other examples of alcohols used to activate acids are represented in Fig. 9.

PFP esters have been recommended for the synthesis of heterocyclic amides, when DCC 17 mediated coupling or via the acid chloride. They can be used immediately without additional purification or they can be stored. For example, PNP 28 esters are purified easily by recrystallization in alcoholic solvents with which they do not react. Then, amidolysis is performed at room temperature (37). Other examples of alcohols used to activate acids are represented in Fig. 9.

Phosphonium-based coupling reagents
80F 38 also known as Castro’s reagent, was the first of the HOtB-based oxonium reagents (73). (see Fig. 13). The deprotonated acid reacts first with BOP 39 to produce both the highly reactive (acyloxy)phosphonium 40 species and the OBt anion. The initial mechanism postulates the direct attack of the OBt anion on the (acyloxy)phosphonium 40, which generates the aminolysable activated O-Bt ester 41. This process is driven by the formation of the stable phosphoric triamide 42 (74). More recent studies suggested the existence of an additional step. The (acyloxy)phosphonium intermediate 43 reacts with the carboxylate to form the symmetric anhydride 44. The subsequent activation with HOtB 45 is relatively slow and yields the anticipated O-Bt ester while regenerating the carboxylate. The additional step can be accelerated by the addition of HOtB 45 to the reaction mixture (75). Whether it is really necessary to use HOtB 42 in conjunction with HOtB-based oxonium or phosphonium reagents is still debatable and it must be investigated on a case-by-case basis. PyBop (G.L. Biochem (Shanghai) Ltd., Shanghai, China) and PyAOP 45 (76) where the dimethyl moieties were replaced were introduced to avoid the generation of toxic HMFA (42,77). Other examples of phosphonium-coupling reagents are shown in Fig. 32.

A new field of application for active esters is solid-phase synthesis. Some polymer-supported reagents are available commercially (see Fig. 9). The acid is first immobilized on a polymer support as an active ester and the excess reagents are washed away conveniently. Finally, the amine is released by amine treatment. During the cleavage, a limited amount of amine can be used to avoid the presence of excess amine in the final mixture. The acid is loaded onto the resin using classic ester condensation methods for TFP resin 35 (66), HOtB resin 36 (67), and oxime resin 37 (68). In the case of the triazine resin 38, the acid is loaded via an aromatic nucleophile substitution in the presence of a base (69).
N-methylated amino acids. The Bt ester is believed to be too stable to react with these hindered amines, which enables degradation or racemization to occur. Some effective reagents that eliminate the need for HOBt have therefore been developed (see Fig. 12). For example, PyBrop is an efficient peptide-coupling reagent for N-methylated amino esters. It is interesting to notice that reagents such as CloP and BroP had been considered initially as poor peptide-coupling reagents as they lead to noticeable racemization with primary amino acids.

Other organo-phosphorous reagents are based on the mixed carboxylic-phosphoric or phosphinic anhydrides. Initially used to convert carboxylic acids into acyl azides, DPPA has been introduced as a one-pot coupling reagent for peptide chemistry, and it was adapted later to solid-phase chemistry. The driving force of these reactions is the formation of the phosphoric or phosphinic acids and their salts. Later DPP-Cl and FDPP were introduced. FDPP has been used successfully in macrocyclizations. Examples of phosphoric- and phosphinic-based coupling reagents are shown in Fig. 12 [DEPBT, BDP, BOP-Cl].

Uronium/guanidium-based coupling reagents

Another popular family of reagents is based on uronium species such as HBTU and TBTU. These species are the hexafluorophosphate and tetrafluoroborate salts of the same molecule, respectively. The coupling is performed the same as the phosphonium reagents, and the nature of the non-nucleophilic counter ion has no influence on the outcome. The driving force is, in this case, the formation of the stable tetra-methylurea (see Fig. 13). In some cases, the amine can react directly with the coupling reagent to form the undesired guanidine. This side reaction can be suppressed by adding HOBt to the reaction. Usually, these reagents are found in their more stable guanidinium form (N-form) (89, 90). The uronium species of HBTU and HATU, however, have been isolated and are more active than the guanidinium species. Unfortunately, under standard coupling conditions, the O-form is converted quickly to the N-form (91) (see Fig. 14).

Some examples of uronium-based coupling reagents are represented in Fig. 15 (e.g., BCC, TDBTU, TNTU, TPTU, TSTU, HAPyU, TAPipU, CIP, BTFFH, HOTT / TOTT). As for phosphonium-based coupling reagents, poor results are observed with sterically hindered amines when HOBt is present. Therefore, some alternative reagents have been designed.

**Iminium-based coupling reagents**

Example, HATU 58 has proved to be very efficient in some sterically hindered couplings (64, 98). The superior reactivity of the At-activated ester toward amines is discussed in the Activated Esters section. TOTU 70 enables the formation of an activated acyl oxide intermediate, and low racemization in peptide couplings has been reported (99).

Inimium reagents are inspired directly from the uronium family. They differ structurally by the replacement of the amino groups with a hydrogen, an alkyl, or an aryl group. For example, BOMI 71 was reported to be more reactive than the correspondent uronium reagents (100). The increased reactivity could stem from...

**Quaternized nitrogen-based coupling reagents**

**Triazinyl esters**

Recently, DMTMM 75 has been described as an efficient, one-pot coupling reagent for ester and amide bond formation (102). This reagent first undergoes an SNAr reaction as in the case of cyanuric fluoride 9. The activated ester then undergoes amidolysis. The in situ liberation of N-methyl morpholine avoids the use of an additional base conveniently. The triazine 76 by-product is eliminated easily by an aqueous wash (see Fig. 16).

An inexpensive substitute to DMTMM is 2-chloro-4,6-dimethoxy-1,3,5-triazine in the presence of an additional organic base (103).

**Mukaiyama’s reagent**

2-Chloro-1-methylpyridinium iodide 77, also called Mukaiyama’s reagent, in the presence of a carboxylic acid and a tertiary amine yields an activated 2-acyloxy-pyridinium species 78. This intermediate reacts with a range of nucleophiles. The driving force for this reaction is the generation of a stable tautomeric pyridone. Mukaiyama’s reagent has been reported in the preparation of activated esters, the formation of amides, and the conversion of β-amino acids to the corresponding β-lactams (104, 105). The poor solubility of pyridinium iodides in conventional solvents indicates that the reaction requires refluxing in methylene chloride. To alleviate this limitation, novel reagents have been suggested: BEMT 79 (106), BEP 80, FEP 81, BEPH 82, and FEPI 83 (107) (see Fig. 16). Tetrafluoroborate and hexachloroantimonate have been adopted as counter ions. These reagents were used successfully in the synthesis of oligopeptides and in solid-phase peptide synthesis.

**Isoxazolinium Salts**

Woodward’s reagent K or NEPIS 84 is a zwitterionic isoxazolinium that reacts with N-protected amino acids in presence of triethylamine to form the activated enol ester 85 (108) (see Fig. 16). This intermediate can be reacted without additional purification with an amine to yield the desired amide and the sulfonate by-product that can be easily removed by aqueous extraction.

**Amide bonds by chemical ligation**

New ligation strategies allow the selective formation of an amide bond between two highly functionalized fragments such as unprotected peptides, glycopeptides, or other molecules of biologic interest. The convergent assembling of complex, pre-formed peptidic sequences overcomes the inevitable contamination issues observed during extended linear peptide synthesis (109).

**Native thioligation**

This original methodology (110) requires the presence of a cysteine at the N-terminal position of fragment B and the...

introduction of a thioester at the C-terminal position of fragment A. Regiospecific coupling of the two unprotected fragments can be achieved in a two-step process described in Fig. 17. The first step is a chemoselective trans-thioesterification between the thiol functionality of the terminal cysteine and the terminal thioester to form the thioester linked intermediate. This step is called the "capture reaction." The second step is the rapid, intramolecular acyl transfer from the thio- to the amino-position of the cysteine to yield the desired amide bond. Usually, no racemization is observed (111).

Different Boc (112) or Fmoc (113) compatible solid-phase strategies have been devised to allow the preparation of peptides bearing a C-terminal thioester. Recently the introduction of a 2-(ethyldisulfanyl)phenol ester at the C-terminal position of fragment A has been used in an elegant solution phase approach (114) (see Fig. 18). The first amino acid of fragment A is coupled to 2-(ethyldisulfanyl)phenol. The resulting phenol ester is sufficiently stable to be used as a protecting group and to allow the growing fragment A to use standard Boc strategy peptide synthesis. After final deprotection, fragment A can undergo native thioligation. First, the disulfide bond is cleaved under reductive conditions or in the presence of an excess of thiol reagent. The resulting 2-mercaptophenyl ester might be in an unfavorable, yet dynamic, equilibrium with the corresponding S-2-hydroxyphenyl thioester via intramolecular O- to S-acyl transfer, which generates in situ the appropriate setup for native thioligation.

A similar type of native chemical ligation has been extended to B fragments that contain homocysteine (115), selenocysteine (116), and histidine (117) at their N-terminal positions.

**Staudinger ligation**

The Staudinger ligation (118) is a less restrictive approach that can be applied to couple unprotected peptides. First, a C-terminal phosphinomethylthioester is introduced on Fragment A, and the N-terminal amine of fragment B is converted to the corresponding azide (88). The two fragments are then reacted together via a Staudinger reaction (see Fig. 19), which yields the iminophosphorane (89). This intermediate undergoes intramolecular S- to N-acyl transfer readily to produce the corresponding hydrolysable amidophosphonium salt (90).

In principle, this methodology is independent of the nature of amino acids present at the ligation point and can be even extended to all types of acids and amines. For example, N-glycosylated amides (119) and peptides have been prepared via stereoselective Staudinger ligation (120). Challenging, medium-sized (7- to 10-membered) lactams have been ring-closed in good yield using the Staudinger ligation sequence described in Fig. 19 (121). In this example, the phosphine reagent has been protected judiciously as a borane complex. The Staudinger ligation is then triggered by the deprotection of the phosphine under basic conditions.

**Enzymatic catalysis**

Enzymes such as proteases (122), subtilisin (123), acylases, peptidases, amidases, and lipases (124) are reported to catalyze amide bond formation with, in some cases, enantiospecificity of over 99%. Despite limited enzyme-substrate compatibility, specific conditions have been developed to reverse their natural reactivity, which is in favor of the hydrolysis. For example, Kyotorphin (Tyr-Arg) (125), a potent analgesic, was produced on an industrial scale using \( \alpha \)-chymotrypsin, a peptidase isolated from bovine pancreas.

**Conclusions**

This article presents an overview of the different amide bond formation methodologies that are available to the organic and biochemist. For nearly two centuries, the methods have evolved from the original symmetric anhydrides and acyl chlorides. When Fischer started to study peptidic couplings in the early 1900s, it became obvious that poor yields and racemization would present a major challenge. During the last three decades, the design and synthesis of new coupling reagents have been an area of intense investigation. The predominance of carbodiimide and active ester procedures have been replaced gradually...
by onium salts approaches. The introduction of racemization suppressants combined with the development of solid-phase chemistry and urethane-based protecting group have allowed high-throughput chemistry and automated peptide synthesis to be a reality. Emerging technologies such as ligation allow convergent synthesis by amide coupling between two highly functionalized molecules.

Synthetic Peptides and Proteins to Elucidate Biological Function

Christian F. W. Becker and Roger S. Goody
Max-Planck Institut für Molekulare Physiologie, Dortmund, Germany

doi: 10.1002/9780470048672.wecb583

The enormous progress made in the use of gene technological techniques over the past several decades has been the main driving force in the accumulation of our knowledge of biology at the molecular level. This progress has at times tended to push more classic approaches, such as those stemming from synthetic chemistry, into the background, and there has even been a tendency to regard contributions from this area as being superfluous. This attitude has begun to change recently, with the emergence of the field now referred to as chemical biology, and it is now appreciated that synthetic chemistry can make a unique contribution to the outstanding problems in fundamental biological and medically oriented research. The full potential of these methods is beginning to be realized in the area of peptide and protein synthesis, and this will be the topic of this article.

Synthesis of Biological Macromolecules

One of the early dreams of synthetic chemists was to achieve the total synthesis of important complex biological molecules (1). At the level of polymeric molecules, this includes proteins, nucleic acids, and polysaccharides. In all cases, early work initially involved synthesis of small fragments of the polymeric molecules (peptides, oligonucleotides, oligosaccharides) and addressed, and partially solved, the initially formidable synthetic obstacles, in particular those concerning protection and deprotection to prevent reactions occurring at unwanted positions of the molecules involved. The seminal breakthrough that led to extension of these methods to longer polymers in reasonably short periods of time was made by Merrifield (2), who was the first to show that synthesis of polymeric biological molecules could be achieved on a solid support, thus removing or at least dramatically simplifying the need for time-consuming purification and isolation of intermediates after the addition of each monomer. Merrifield introduced this principle for peptide synthesis, but in fact polynucleotide synthesis, in particular DNA synthesis, proved to work at least as well, and in terms of reaching the long-term aim of total synthesis of biological macromolecules was the first to be accomplished successfully and in relatively routine fashion (3). This is largely due to the fact that oligonucleotide synthesis of fragments of a length of ca. 50 nucleotides is relatively facile on a solid support, and that enzymes can be used to ligate such fragments in a directed fashion to achieve the goal of total gene synthesis. Although this is not the most routinely used method for generation of complete coding regions for specific proteins, there are often situations where this is the method of choice, because it allows complete control of codon usage to optimize protein expression in the organism to be used. Gene synthesis is now offered on a commercial basis and plays a significant role in modern biological research.

Progress toward total synthesis of proteins has been slower, mainly due to the lack of easy availability of an enzymatic procedure equivalent to DNA ligation that would allow coupling of peptides of a length that can be conveniently prepared by solid-phase synthesis (depending on sequence, the largest fragments that can be produced are between 50 and 100 residues long). This situation has changed significantly over the past 10–15 years with the introduction and widespread use of methods for the ligation of protein fragments together with the combination of the methods of synthetic chemistry with techniques originating in biology.

In the following, we initially discuss the advances that have been made at the technical level, and then introduce some of the many applications that exploit the new methods for the study of biologically important processes.
Chemical Methods for the Generation of Large Polypeptides

The principles of solid-state peptide synthesis have been reviewed extensively and will not be repeated here, except to remind the reader that this usually involves attachment of a suitably protected amino acid, which will become the C-terminal residue in the finished sequence, via its carboxyl group to a polymeric support. After exposing the N-terminus of this residue, this is allowed to react with the next protected and activated amino acid to form a peptide bond between the last and the penultimate amino acids in the target sequence. Repetition of this cycle allows the stepwise construction of the desired polypeptide from the direction of the C-terminus toward the N-terminus. Removal of protecting groups and cleavage from the solid support leads to the free polypeptide.

The procedure outlined here is limited to oligopeptides and polypeptides of up to ca. 50 amino acids, and thus, it limits the availability of fully synthetic proteins, because most proteins or functional domains are at least ca. 100 residues long. A solution to this problem would be to generate polypeptides with a length of several tens of amino acids and then to couple (or ligate) them to produce significantly larger proteins. In earlier work, this principle was used in a block condensation approach using fully protected polypeptides, but this did not prove to be a viable procedure in most cases. Another approach is to connect fragments of the protein using non-peptide linkers with chemistry, which obviates the need for side-chain protection. An example of this approach is given below, and it can be put to good use in certain cases. A major breakthrough was the introduction of the method known as native chemical ligation in 1994 (4). In this procedure, a peptide or polypeptide bearing an N-terminal cysteine residue (Fig. 1) The ligation reaction involves a thioester exchange reaction followed by an S→N acyl transfer to generate a native peptide bond, a reaction that had been reported much earlier (5) but that had not been considered as a ligation method.

Chemical ligation has been used for the total synthesis of a large number of proteins in recent years, as described in several reviews (6–9), and recent examples extend the size range to the order of 200 amino acids, in this case using multiple ligation steps (10, 11). Despite this progress, an attractive approach that is being used increasingly is that of a combination of synthetic and molecular biological methods in the technique referred to as expressed protein ligation, as discussed in a later section.

First Access to HIV1-PR

HIV-1 PR is a homodimer made up of 99 amino acids (per monomer) that was made accessible for the first time in 1988 by Schneider and Kent, who synthesized this protein using solid-phase peptide synthesis (SPPS) (13). An automated, rapid, and highly efficient procedure in combination with purification by size exclusion chromatography was used to generate a partially purified HIV-1 PR (14), which then also became available later on in 1988 by recombinant expression in Escherichia coli (15). Proteins generated by these two procedures had the same enzymatic properties. After the initial synthesis of HIV-1 PR, one advantage of this methodology, namely, the possibility to incorporate unnatural amino acids during chemical synthesis, was demonstrated by replacing all cysteine residues in HIV-1 PR by α-amino-n-butyric acid. The resulting enzyme was fully active and was crystallized to obtain one of the first three-dimensional structures of HIV-1 PR that formed the basis for structure-assisted design of HIV-1 PR inhibitors (16, 17). At the same time this structure confirmed that chemically synthesized proteins can fold and crystallize identically with proteins from natural sources. Three different crystal forms of chemically synthesized HIV-1 PR with bound peptide inhibitors were subsequently published and contributed to the further development of HIV-1 protease inhibitors (18–20).

Backbone Engineering of HIV-1 PR

The flexibility of chemical protein synthesis was used to introduce changes into the protein backbone that could not be incorporated by other means. This paved the way for a general protein engineering approach and at the same time introduced the possibility of joining two fully unprotected peptide segments by a chemoselective reaction that generated an unnatural thioester bond between Gly51 and Gly52 of each HIV-1 PR subunit (Fig. 2a). The thioester linkage was generated by reacting an N-terminal HIV-1 PR peptide segment (aa 1–51) carrying a C-terminal thioester with a C-terminal segment (aa 52–99) having the N-terminal glycine replaced by bromoacetic acid and all additional cysteine residues replaced by α-amino-n-butyric acid (Fig. 2a) (21). This constitutes an early example of a chemoselective ligation reaction that provided access to a medium-sized protein by linking two smaller unprotected polypeptides (easily accessible by SPPS) without the need for elaborate protection schemes as used in fragment condensation reactions.

The resulting enzyme exhibited full activity, even though the thioester bond was placed inside a flexible β-hairpin loop (flap region) of HIV-1 PR, a region that undergoes drastic conformational changes during substrate and inhibitor binding. This

HIV-1 Protease as a Paradigm for Elucidating Biological Function by Chemical Protein Synthesis

Chemical protein synthesis and semisynthesis have been used to study the molecular basis of protein function in numerous cases. One of the very early and most impressive applications of chemical synthesis to the production of functional as well as site-specifically modified enzymes concerns the protease from human immunodeficiency virus 1 (HIV-1 PR). This enzyme cleaves the gag-pol polypeptide into functional proteins during virion budding from host cells and is essential for replication of the virus (12). Inhibitors of HIV-1 PR are an important class of anti-HIV drugs, and their development is at least partially based on the availability of structural and molecular information obtained with chemically synthesized HIV-1 PR.
Native chemical ligation (NCL) between two unprotected peptide segments. The initial trans-thioesterification reaction leads to an intermediate that undergoes an S to N-acyl shift via a five-membered cyclic transition state and generates a native amide bond at the ligation site.

is due to the positioning of the two glycine residues on the outside of the flaps, away from the substrate. However, the synthesis of another HIV-1 PR analog by Kent and Baca placed the thioester bond between Gly49 and Ile50, leading to a reduction in catalytic activity by a factor of 3000 (Fig. 2b) (22). This constituted the first experimental evidence that hydrogen bonds between the backbone of the flap region and the substrate are important for catalytic activity. However, substrate specificity and affinity were not affected. These particular hydrogen bonds are “transmitted” from the protease backbone to the substrate via an internal water molecule and are believed to contribute to the distortion of the scissile bond of the substrate (23).

The applicability of the thioester-forming chemoselective ligation approach was broadened by the fact that this chemistry can be carried out under acidic conditions in the presence of sulfhydryl groups. By taking advantage of this selectivity of the alkylation reaction, two different HIV-1 PR monomers were prepared. These monomers carried a free sulfhydryl group at their N- or C-terminus, respectively, and were, subsequent to the thioester-forming ligation step, joined together by a disulfide linkage to generate tethered dimers of two distinct HIV-1 subunits (24). This tethering of the two subunits produced one of the largest functional proteins prepared by chemical synthesis at that time and allowed the preparation of HIV-1 PR molecules with asymmetrical subunits. One example of such asymmetrical HIV-1 PR analogs was constructed with one subunit having a thioester bond between Gly51 and Gly52, which did not interfere with the biological activity of the protease, and a subunit that had a thioester bond between Gly51 and Gly52 and an additional ester bond instead of an amide bond between Gly49 and Ile50 (23). By replacing an amide with an oxygen atom in a unique position, no backbone hydrogen...
Synthetic Peptides and Proteins to Elucidate Biological Function

Figure 2. Chemical synthesis of backbone engineered HIV-1 protease. The peptide segments were synthesized by SPPS and harbored a C-terminal thioacid (HIV-1 PR, aa 1-49, shown in blue) or an N-terminal bromoacetic acid modification (HIV-1 PR 51-99, shown in red). These unique functional groups led to an unnatural thioester bond either between Gly51 and 52 (Strategy A; the ligation site is shown in yellow in the cartoon representation of the HIV-1 PR dimer) or between Gly49 and Ile50 (Strategy B; the ligation site is located at the end of the N-terminal peptide segment depicted in blue). The chemoselective ligation reaction is followed by purification steps and folding of the protein into its functional conformation. Strategy A led to a fully functional HIV-1 PR, whereas strategy B led to a severe reduction in catalytic affinity. The functional dimer of the HIV-1 PR is drawn as a cartoon with only one subunit showing the modifications introduced during synthesis. The second subunit (in green) is shown unmodified for clarity. Aspartic acid 25, site-specifically labeled with $^{13}$C for NMR spectroscopy studies, is shown in magenta in one HIV-1 PR subunit.

Site-Specific Side Chain Labeling of HIV-1 PR

The incorporation of an aspartic acid residue with a $^{13}$C atom at the side-chain carboxyl function at position 25 into aspartyl protease has made this catalytically essential group visible for nuclear magnetic resonance (NMR) spectroscopy (Fig. 2 (25)). The chemical shifts of this $^{13}$C atom were observed as a function of the pH and the presence and absence of substrate or inhibitor molecules. These titration experiments provided additional evidence for the suggested working model of aspartyl proteases and confirmed that HIV-1 PR is a member of this class of enzymes (26). The two aspartyl side-chain carboxyl groups (one from each subunit) act as general base and acid, respectively, thereby leading to the breakdown of the enzyme-substrate intermediate.

The work on HIV protease demonstrates how chemical protein synthesis allowed isotope labeling of a 22-kDa protein with atomic precision and provided further insights into the chemical basis of the proteolytic cleavage reaction. Isotope labeling with atomic precision has since then been used to reveal structural features of other either chemically synthesized or semisynthetic proteins (27-28).
A Mirror Image HIV-1 PR

A characteristic feature of many biomolecules is their chirality and the stereochemical specificity that is conferred to proteins and especially enzymes by being constructed from monomers with uniform stereochromical configuration. This fact has inspired chemists and biochemists to generate mirror images of proteins (as well as other biomolecules) to test the properties and especially enzymes by being constructed from monomers 

Although the total synthesis of a protein allows complete control over the structure, including posttranslational modifications and regard their biophysical behavior, enzymatic activity, and specificity. Currently, it is still not possible to modify ribosomal protein synthesis so that all-D-polypeptides can be produced, and this would in fact be a daunting undertak

ing. However, chemical protein synthesis and its ability to link peptides produced by solid-phase peptide synthesis via chemoselective reactions to form medium-sized proteins allows the synthesis of peptides from D-amino acids. M. Ilton et al. demonstrated this capability of chemical protein synthesis by producing a mirror image HIV-1 PR using their already described thioester-forming ligation approach (30). When compared with the L-form of this enzyme (also produced by chemical protein synthesis), both proteins exhibited full catalytic activity but inverse chirality, meaning that the D-form only cleaves L-substrates and the L-form only D-substrates. A crystal structure of the D-HIV-1 PR revealed that it was the mirror image of the L-form, and in the presence of a substrate-based D-inhibitor (D-MVT101), all major interactions between enzyme and substrate were clearly visible (31). In addition, all secondary structure elements clearly exhibited mirrored relationships such as the inverse handedness of alpha-helices and twists of anti-parallel beta-sheets (6). The synthesis of D-HIV-1 PR impressively demonstrates the basic determinants of protein structure and emphasizes the freedom and power of chemical protein synthesis. So far only a few D-proteins have been prepared, but potential applications are mirror image-based screenings where one screens a large library of L-peptides (generated by phage display) against a D-protein for high affinity binders (32). Any hits out of such a screen could be translated into D-peptides that would bind to naturally occurring L-proteins and possess highly interesting properties such as high stability against proteolytic cleavage and possibly low immunogenicity.

Semisynthetic Proteins of the Ras-Superfamily

A thorough total synthesis of a protein allows complete control over the structure, including posttranslational modifications and introduction of labels at desired sites in the sequence, it is still a major undertaking for which most laboratories whose main interest is in the biology of their target proteins are not equipped. In certain cases, for example when the site of introduction of a specific chemical modification is near the C-terminus, a combination of molecular biological and chemical methods has proved to be very powerful.

With the Ras-family of guanine nucleotide binding proteins, where the C-terminus plays a critical role in location to specific membranes, two approaches have been used to solve the problem of generating a C-terminus that is either naturally or unnaturally modified. In one of these, C-terminall peptide and the reaction product (prenylated Ypt1) are insoluble

In the example described, which uses chemistry to create an unnatural linkage between the C-terminal region of Ras and the rest of the prote

Figure 3  (a) Preparation of prenylated Ypt1 (a yeast Rab-protein) by expressed protein ligation. A C-terminal thioester of the truncated Rab protein was allowed to react with a doubly geranygeranylated tricysteine peptide, leading to transesterification and an S→N acyl shift to generate a native peptide bond. (b) Interaction of the C-terminus of semisynthetic doubly geranygeranylated Ypt1 with the lower domain of yeast GDI. GDI is shown in green as a ribbon structure, the C-terminus of YPT1 in magenta, and the geranygeranyl groups in red and blue CPK representation. Several residues of the C-terminus of YPT1 were not visible in the electron density map, so that the connection to the prenyl groups is not observed directly. One prenyl group (in red) is buried deeply into the hydrophobic core of GDI, whereas the other (in blue) is more superficially bound and shows interaction with the other prenyl group. The lipid binding site is generated by an opening movement of two α-helices.

In an aqueous environment, the ligation reaction was performed in detergent solution. Using the expressed protein ligation approach, both singly and doubly prenylated Ypt1 molecules could be produced. The complexes of these proteins with their solubilizing protein, GDI (GDP-dissociation inhibitor), could be crystallized, and their three-dimensional structures were determined (46-48). This revealed for the first time the nature of the lipid interaction with a binding site in an unexpected part of the GDI molecule (Fig. 3b). In the previously determined structure of GDI without a bound Rab molecule, this binding site was not detected, because a movement of one of the α-helices of...
the lower domain of GDI has to occur to create space for lipid binding, and this seems only to occur when the lipid residues, or possibly the whole prenylated Rab molecule binds. The position of binding was essentially the same for single or double geranyl groups, and this seems only to occur when the lipid residues, or possibly the whole prenylated Rab molecule binds. The position of binding was essentially the same for single or double geranyl groups, and the structure depicted in Fig. 3b shows that the corresponding residue in yeast GDI (I100) is not in the lipid binding site but makes an important hydrophobic interaction with a conserved hydrophobic motif in the Rab C-terminal hypervariable domain.

The same technology was used to create Rab proteins bearing a variety of fluorescent groups at the C-terminus. This approach allowed introduction of such reporter groups near to the reactive SH groups, which are the site of prenylation while leaving these groups free for the prenylation reaction, a process that results in large fluorescence signal changes in certain cases. Experiments on the prenylation of such selectively modified Rab proteins allowed insights into the molecular basis of another hereditary disease, namely x-linked choroideremia, a disease caused by underprenylation of certain Rab proteins [50]. The structural determination of the complex between GDI and the Rab protein GDIα, which is highly expressed in brain, and which thus sediments to a high degree in the lipid binding site, has provided considerable information on the mechanism of action of GDI in the recycling of Rab proteins between target and donor membranes (48, 49). It also sheds light on the molecular basis of a form of x-linked non-syndromic mental retardation, in which there is an L92P mutation in GDIα, which is highly expressed in brain, and which results in a reduced ability to extract Rab proteins from membranes. It was previously thought that this residue would be in the lipid binding site, but the structure depicted in Fig. 3b shows that the corresponding residue in yeast GDI (I100) is not in the lipid binding site but makes an important hydrophobic interaction with a conserved hydrophobic motif in the Rab C-terminal hypervariable domain.

Split-Inteins for Protein Semisynthesis in vitro and in vivo

The technique of expressed protein ligation has been exploited extensively during the last couple of years to produce semisynthetic proteins with tailor-made properties [4, 38]. Examples are described above, and the method has been reviewed in detail recently [41, 51–53]. The discovery that naturally occurring inteins, protein splicing domains that can excise themselves from a given polypeptide and join the flanking domains via a peptide bond, can be split into two pieces that possess the ability to spontaneously associate and form a functional intein has further extended the utility of intein technology [54–56]. In particular, the DnaE intein system has enabled the first semisynthesis of a GFP–FLAG fusion protein in vivo [59]. To achieve this goal, the N-terminal DnaE segment was fused to GFP and expressed in CHO cells. These cells were complemented with a chemically synthesized C-terminal part of the intein together with a FLAG tag and a protein transduction domain (PTD) for efficient uptake into the cells. The GFP–FLAG fusion protein that was generated upon successful trans-splicing was unambiguously identified by GFP- and FLAG-specific antibodies. Such a system allows the in vivo incorporation of biophysical probes, as long as the chemically synthesized part can be brought into the cells of interest. Detailed insights into the mechanism of the trans-splicing reaction of the DnaE intein were provided by crystal structures of this protein after excision and of a splicing-deficient precursor protein [60].

Further applications of the DnaE split intein include the development of a tandem trans-splicing system that is based on a combination of the DnaE split intein and the engineered, inducible VMA split intein [61]. Such a system allows the segmental labeling of proteins with specific isotopes [as demonstrated by Otomo et al. with the artificial PiP-Pul and PiP-Full split inteins (62)] and fluorophores. The DnaE split intein was also used by Camarero et al. to achieve the site-specific, oriented immobilization of proteins such as maltose binding protein (MBP) and enhanced green fluorescent protein (EGFP) onto glass surfaces [63]. A covalent bond to the glass surface was established by thiol-ene formation between a maleimide group on the surface and a thiol group bearing PEG linker that also carried four amino acids, including a cysteine residue, which could act as a nucleophile in trans-splicing reactions, and the C-terminal segment of the DnaE intein (36 aa). Upon addition of a MBP- or EGFP-N-intein fusion construct that was either produced by recombinant or cell-free expression the intein evolves associated and trans-splicing occurred, leading to the immobilization of MBP or EGFP on the surface. The associated DnaE intein halves were washed away, and the proteins remained, covalently bound via a PEG spacer, on the surface. The advantage of this approach is that no purification of the expressed proteins is necessary because only intein fusion constructs undergo the highly specific immobilization reaction. Furthermore, only low concentrations are needed to achieve efficient trans-splicing reaction (dissociation constant of the DnaE split intein halves is 43 nM, and trans-splicing occurs at a rate of ca. 7 × 10^7 s^-1) [61, 64], which constitutes an advantage over immobilization techniques that rely on chemoselective reactions and strongly depend on reaction concentrations [65–68]. Thus, this approach points to a new route to produce protein chips without the need for large amounts of purified protein.

The DnaA Intein

The DnaA intein from Synechocystis spp. consists of 429 amino acids, including a formin endonuclease domain, in its native form. The removal of 275 amino acids leads to the formation of a C-terminal segment consisting of only 36 aa and is easily accessible by chemical synthesis and therefore allows the addition of specifically modified peptides to its C-terminus that are, upon trans-splicing, transferred onto the N-terminal protein that was expressed as a fusion protein with the N-terminal intein segment. This split intein system has enabled the first semisynthesis of a GFP–FLAG fusion protein in vivo [59]. To achieve this goal, the N-terminal DnaA segment was fused to GFP and expressed in CHO cells. These cells were complemented with a chemically synthesized C-terminal part of the intein together with a FLAG tag and a protein transduction domain (PTD) for efficient uptake into the cells. The GFP–FLAG fusion protein that was generated upon successful trans-splicing was unambiguously identified by GFP- and FLAG-specific antibodies. Such a system allows the in vivo incorporation of biophysical probes, as long as the chemically synthesized part can be brought into the cells of interest. Detailed insights into the mechanism of the trans-splicing reaction of the DnaA intein were provided by crystal structures of this protein after excision and of a splicing-deficient precursor protein [60].
Synthetic Peptides and Proteins to Elucidate Biological Function

Figure 4  Mechanism of trans-protein splicing. (a) Initial association of the intein halves to form a functional intein. (b) Activation of the N-terminal splice-junction via an N-S acyl shift. (c) Formation of a branched intermediate upon transthioesterification. (d) Branch resolution and intein release by succinimide formation. Spontaneous S–N acyl rearrangement yields the processed product with a native peptide backbone.

To test whether trans-splicing also occurs in vitro, Mootz et al. expressed a fusion protein consisting of MBP and the N-terminal half of the DnaB intein (104 aa) and a fusion construct of the C-terminal half (47 aa) and a hexa-histidine tag (69). Upon mixing in stoichiometric amounts, successful trans-splicing produced the MBP-His-tag fusion protein. This constituted the first case of an artificial split intein that spontaneously assembled to form the active intein and underwent trans-splicing without the need for a denaturation-renaturation step. The only other artificial split intein that does not require such a renaturation-denaturation step was the VMA intein from Saccharomyces cerevisiae. However, the N- and C-terminal segments of this intein do not assemble spontaneously to form a functional intein. They require a dimerization domain that brings both halves in close proximity to each other, which induces trans-splicing (70–72). This renders the DnaB split intein highly interesting for protein engineering approaches, and in combination with the DnaE split intein or with an inducible split intein such as the VMA intein, it provides a valuable tool to combine three protein segments with each other by two concomitant or subsequent trans-splicing reactions. An additional advantage of the DnaB split intein is the occurrence of a serine residue as the C-terminal nucleophile for the splicing reaction instead of cysteine residues. Cysteine residues might not be desirable in some cases because they can interfere with folding or labeling of the newly generated protein. Nevertheless a cysteine can replace the serine as a nucleophile at this position as demonstrated by the fact that the DnaB intein has been used to generate protein segments with N-terminal
cysteine residues. This was achieved by expressing the desired DnaB intein as a fusion construct with the target protein in inclusion bodies and by taking advantage of the pH sensitivity of the DnaB intein to prevent premature cleavage during work up (73).

To extend the utility of the DnaB split intein, Liu et al. have tested 13 different sites to split this intein into two segments of different length (58). Until this series of experiments, all known artificial split inteins had been split at the endonuclease domain. Out of 13 tested sites, 3 gave functional split inteins that would undergo trans-splicing, including 1 that consisted of only 11N-terminal amino acids. Such a short N-terminal split intein half is accessible by chemical synthesis, and the introduction of chemically modified peptides at the N-terminus via trans-splicing was recently demonstrated. Such a system nicely complements the already established C-terminal modification approach via the DnaB split intein (74).

Prospects

The work reviewed here illustrates that, in the century since Fischer formulated his vision that the synthesis of proteins should be achievable using the methods of organic chemistry (1) this prediction has been largely fulfilled. While he could not possibly have predicted was the role that molecular biological techniques would play in combination with chemical methods, although he was realistic enough to imply that chemistry would not be the method of choice if biotechnological methods were available. Future developments in the area of synthetic and semisynthetic proteins are likely to include extension of ligation methods to amino acids other than cysteine and the increased use of strategies for generating proteins with precisely engineered properties in cells, including such approaches as conditional splicing, a technique in which a specific protein activity is generated intracellularly by exposure to a small membrane-permeable molecule (70–72).

Synthetic Peptides and Proteins to Elucidate Biological Function

To circumvent the constraint imposed by the 20 canonical amino acids on the study of protein structure and function, various chemical and biosynthetic methods have been developed to incorporate unnatural amino acids into proteins. Unnatural amino acids now can be genetically encoded in living cells in a manner similar to that of common amino acids, which expands site-directed mutagenesis to diverse novel amino acids. The use of unnatural amino acids grants researchers a multitude of chemical and physical properties that cannot be found in the normal genetic repertoire, which significantly improves their ability to manipulate proteins and protein-involved biologic processes. Changes have been tailored into proteins to accurately dissect the contribution of hydrogen bonding, hydrophobic packing, cation-π interaction, and entropy to protein stability, as well as to precisely examine the structural and functional role of crucial residues. Unnatural amino acids also enable the introduction of new chemical reactivities, biophysical probes, mock posttranslational modifications, photoactive groups, and numerous other functionalities for the modification and regulation of protein activities. These studies not only reveal fundamental information of protein structure and function but also explore new means for generating novel protein properties and controlling biologic events.

Conventional site-directed mutagenesis of specific amino acids currently is the preferred method for investigating various structural and functional characteristics of proteins. A serious limitation to this methodology is the constraint of using the 20 canonical amino acids fixed by the universal genetic code. This constraint lies in the limited chemical and physical properties of these amino acids, which hinder the ability to make precise alterations. For instance, modification of an amino acid such as glutamine is limited because only asparagine has similar characteristics. For amino acids such as proline, no analogous amino acid exists in the genetic repertoire, which makes it difficult to investigate the role of this amino acid in specific processes without abolishing it completely. Breaking this limitation would enable in-depth investigation of the principles underlying protein structure and function as well as the engineering of novel protein properties and cellular functions. In the past decade, great progress has been made in incorporating unnatural amino acids into proteins to harness their extensive and powerful capabilities. Here, we will introduce unnatural amino acids with a brief overview of various methods for incorporating them into proteins and we will present examples that illustrate how unnatural amino acids have impacted a wide array of research that investigates biologic systems.

Unnatural Amino Acids

Common amino acids consist of an amino group, a carboxyl group, a hydrogen atom, and a side chain all attached to the Cα in the L configuration. Analogs with altered side chains, or those that deviate from other features, are generally called unnatural amino acids (Fig. 1). The most widely used group of unnatural amino acids is the group in which the Cα side chain is charged.

Unnatural Amino Acids to Investigate Biologic Processes

Figure 1  Different forms of unnatural amino acids.

Variation of unnatural side chains is diverse and can range from structural analogs of canonical amino acids to those with specific chemical moieties, such as reactive functionalities and reporter groups for biophysical characterization. Modification of the amino group results in changes in the peptide backbone. For example, changing the amino group into a hydroxy or sulfhydryl group converts the endogenous amide bond between two residues into an ester and thioester link, respectively. Such changes make the resultant analog no longer an “amino” acid but an α-hydroxy acid and a thio acid. An analog with aminooxy replacing the amino group also has been incorporated into protein biosynthetically (1). The amino group also can be alkylated with different moieties to form amino acids that contain secondary amines (2). Another category of unnatural amino acids is α,α-disubstituted amino acids, whose α-hydrogen is replaced by an additional side chain. Moving the amino group away from the α-carbon leads to extended β- or γ-amino acids, which can be compatible with protein biosynthetic machinery as well (3). Finally, D-amino acids, which are mirror images of the L counterparts, have been introduced selectively into functional proteins to study structural characteristics (4).

Methodology

Although this review is mainly focused on the use of unnatural amino acids in the investigation of biologic systems, a brief background of the methodology of incorporation is useful in understanding the power and application of this technology. A more comprehensive coverage of various methods can be found in Reference 5 and the references contained therein.

Chemical approaches

Global alterations to certain amino acids can be done in vitro through chemical modification of their exposed reactive side chains (6). The selectivity of chemical modification relies on the differences in chemical reactivity of amino acid functional groups. Judiciously selected chemicals will react with specific amino acids only, which allows chemical changes to be applied to that amino acid alone. Typical modification involves the thiol group of Cys, the ε-amino group of Lys, the carboxylate group of Asp and Glu, and the N-terminal amino group. The hydroxy group of Ser and Thr can be oxidized selectively when Ser and Thr are at the N-terminus of the protein (7). Side chains of Tyr and Trp can be modified selectively with transition metal catalysts (8, 9). Initial applications of this method focused on determining the functional roles of certain amino acid species for biologic activity, but they have expanded to other applications, including biophysical probe tagging, chemical cross-linking, and the conjugation of various synthetic functionalities. However, site-specific alterations are difficult using this approach because the chemical will react with all accessible target amino acids if more than one such amino acid exists in the protein.
In addition, chemical modification must be done in vitro, and affects only those side chains that are solvent-accessible. A further method to introduce unnatural amino acids into a polypeptide chain is through complete chemical synthesis (10). The predominantly used method, stepwise solid-phase peptide synthesis (SPPS), attaches the C-terminal amino acid to a solid support, and amino acids are added one at a time to the N-terminus. A clear advantage of chemical synthesis is that it enables the accurate introduction of unnatural amino acids at any site in a protein. The number of unnatural amino acids that can be introduced is limited only to the size of the chain, and chains of entirely unnatural amino acids can be produced using this method. Chemical synthesis is useful particularly for the incorporation of isotopic labels and unnatural amino acids that are toxic to cells or incompatible with the translational machinery. However, construction of a polypeptide chain using even the most advanced chemical synthesis techniques is daunting when confronted with the construction of an entire protein, as these methods currently are limited to approximately 100 amino acids (10).

Semisynthetic protein ligation methods, in which two or more protein fragments of recombinant or synthetic origin are chemically ligated to make the full-length protein (11), overcome the size limitation of SPPS. Among these methods, the native chemical ligation strategy couples peptide fragments to form a native peptide linkage, which leaves no chemical artifacts behind (12, 13). The desired unnatural amino acid is introduced in the synthetic fragment by using chemical synthesis and is then incorporated into proteins after ligation. Once this unnatural protein is folded, biochemical characterization of kinetic parameters and function can be performed. Peptide ligation in living cells is also possible. A synthetic fragment can be injected into cells to react with an endogenously produced protein. This method, like SPPS, has the power to form a native peptide linkage, which leaves no chemical artifacts behind (14). This method, like SPPS, has the power to form a native peptide linkage, which leaves no chemical artifacts behind (12, 13).

Biochemical approaches

Methods that use the endogenous cellular machinery to introduce unnatural amino acids into proteins are not limited by protein size and will facilitate the investigation of biologic processes in vivo. A general in vitro biosynthetic method allows for the site-specific incorporation of unnatural amino acids into proteins (15). In this method, a suppressor tRNA is chemically acylated with an unnatural amino acid, and the codon of interest in the target gene is mutated to the amber stop codon, TAG. When added to cell extracts that support transcription and translation, the suppressor tRNA recognizes and selectively incorporates the attached unnatural amino acid in response to the UAG in the transcribed mRNA. Using this method, a variety of unnatural amino acids have been incorporated into proteins, regardless of position or protein size, and have been applied to a large number of problems in protein chemistry (16). Besides the amber stop codon, rare codons and extended codons also have been used to specify the unnatural amino acid (17). An extension of this method involves the microinjection of the chemically acylated tRNA and UAG-containing mutant mRNA into Xenopus oocytes (18). The endogenous oocyte protein synthesis machinery supports translation and incorporation of the unnatural amino acid. This method enables the structure-function studies of integral membrane proteins, which are generally not amenable to in vitro expression systems (19). A purified in vitro translation system that consisted of only ribosomes, initiation factors, elongation factors, mRNA, and tRNAs preloaded with desired amino acids was used to incorporate simultaneously several unnatural amino acids into peptides in response to sense codons (20). By reassigning the meaning of codons, this system ultimately may allow the synthesis of peptides and proteins that contain multiple unnatural amino acids. The drawback to these methods lies in the chemical acylation of the suppressor tRNA, which is technically demanding and can exclude certain unnatural amino acids from attachment. In addition, acylated tRNA is consumed stoichiometrically and cannot be regenerated in cells or cell extracts, which leads to low expression of the target protein.

Multiple incorporation of unnatural amino acids by using cellular machinery has been achieved in auxotrophic bacterial strains (21) and in mammalian cells (22). This method relies on the idea that aminoacyl-tRNA synthetases, although with very high substrate specificity can mischarge unnatural amino acids that are close structural analogs of the cognate amino acids. An unnatural amino acid analogous to a canonical counterpart is introduced into a bacterial strain that is incapable of producing the natural amino acid or into mammalian cells that are deprived of the natural amino acid. The translational machinery then replaces the natural amino acid with its analog in all proteins. The incorporation efficiency of unnatural amino acids can be improved by increasing the expression level of the synthetase (23) and by introducing mutations that relax the substrate specificity of the aminoacylation domain (24) or attenuate the proofreading function of the editing domain of certain synthetases (25). However, this strategy is limited because it is restricted to global replacement of one amino acid with an analog and does not allow specific single alterations with a specific protein.

It would be ideal to genetically encode an unnatural amino acid in a manner similar to that of common amino acids, enabling site-directed mutagenesis in living cells with unnatural amino acids. A general method to expand the genetic code to include unnatural amino acids was developed. It involves the generation of a new tRNA-codon-synthetase set that is specific for the unnatural amino acid and does not crosstalk with other sets for common amino acids (26). The new synthetase is evolved to charge specifically an unnatural amino acid onto the new tRNA. This tRNA recognizes a codon that does not encode any common amino acids (e.g., a stop codon or an extended codon). When expressed in cells, the new tRNA-synthetase pair enables the unnatural amino acid to be site-specifically incorporated into proteins at the unique codon with high fidelity and efficiency. This method allows the use of unnatural amino acids in the investigation of biologic systems in an in vivo setting. It may be possible to generate stable cell lines or...
transgenic animals capable of inheriting such alterations for long-term studies. However, toxic unnatural amino acids and those incompatible with the protein biosynthesis machinery cannot be incorporated using this approach.

Application of Unnatural Amino Acids

Unnatural amino acids enable the structural, chemical, and physical properties of the building blocks of proteins to be customized according to needs. Such tailored changes have contributed to our understanding of the fundamental questions of protein chemistry on the molecular and atomic level, have been used to modify and enhance protein properties, and are being exploited to control protein activities to investigate various biologic processes and to create novel biologic functions.

Protein stability

There are many factors contributing to protein stability, including hydrogen bonding, hydrophobicity, packing, and conformational entropy, among others. It is difficult to access individual contributions by using conventional mutagenesis because changing one common amino acid to another often alters several properties at a time. For example, mutagenesis to disrupt hydrogen bonds, usually by deleting one member of a hydrogen-bonded pair, will leave an unpaired hydrogen donor or acceptor and/or alter local solvation and packing interactions, all of which may lead to protein destabilization.

To determine the effect of side-chain hydrogen bonding on protein folding, Tyr27 in staphylococcal nuclease (SNase) was replaced with several isosteric, fluorinated tyrosine analogs (unnatural amino acids 1 to 3) (Fig. 2) (27). These unnatural amino acids were designed to gradually increase the strength of the Tyr27-Glu10 hydrogen bond while minimizing the steric and electronic perturbations associated with deleting one hydrogen-bonding member. The stability constants \( K \) of the corresponding mutants were found to be in the range of the hydroxyl group in the tyrosine analogs. This result provides strong evidence that intramolecular side-chain hydrogen bonds preferably stabilize the folded state of a protein relative to the unfolded state in water.

\( \alpha\)-Hydroxy acids have been used to study the contribution of the backbone hydrogen bonds to protein stability (Fig. 3). The replacement of a common amino acid with an \( \alpha\)-hydroxy acid that contains the same side-chain effectively substitutes a good hydrogen-bond acceptor (the amide carbonyl group) with a considerably weaker one (the ester carbonyl group) in a conservative manner and disrupts a potential backbone hydrogen bond because the ester linkage cannot serve as a hydrogen-bond donor as does the N-H. \( \alpha\)-Hydroxy acids were incorporated at the N-terminus, the middle, and the C-terminus of the \( \alpha\)-helix 39-50 of T4 lysozyme (28). At the N-terminus and the C-terminus, where only one hydrogen-bonding interaction is perturbed, the ester substitution destabilizes the protein by 0.9 kcal mol\(^{-1}\) and 0.7 kcal mol\(^{-1}\), respectively. In the middle of the helix, where such substitution perturbs two hydrogen bonds, the protein is destabilized by 1.7 kcal mol\(^{-1}\). In another study, Leu 14 in an antiparallel \( \beta \)-sheet of SNase was replaced with leucic acid (29). This amide-to-ester change decreases the stability by 1.5-2.5 kcal mol\(^{-1}\). Altogether, these results convincingly show that both side-chain hydrogen bonds and main-chain hydrogen bonds significantly contribute to protein stability.

To examine the importance of the packing interaction in the core of a protein, Leu133 in T4 lysozyme was replaced with a series of analogs with extended or shortened alkyl side chains (unnatural amino acids 4 to 7) (30). Leu133 lies along the edge of the largest cavity in the interior of T4 lysozyme, which makes it possible to change the bulk of the side chain with minimal conformational strain. Incorporation of (S,5)-2-amino-4-methylethanoic acid (unnatural amino acid 4) and (S)-2-amino-4-cyclopropanoic acid (unnatural amino acid 5) stabilizes T4 lysozyme by 0.6 kcal mol\(^{-1}\) and 1.24 kcal mol\(^{-1}\), respectively, which indicates that the increased bulk of buried hydrophobic residues can enhance protein stability. During protein folding, the cyclic amino acid 5 will lose less conformational entropy than does 4. That the 5-containing mutant is more stable than the 4-containing mutant suggests that there is a packing role of a residue that is misinterpreted by or remains ambiguous to conventional mutagenesis and other methods. For example, Glu43 is important for the catalytic activity of SNase.

Protein structure and function

Structural and Functional Role of Specific Residues

Unnatural amino acids can be designed to elucidate the functional role of a residue that is misinterpreted by or remains ambiguous to conventional mutagenesis and other methods. For example, Glu43 is important for the catalytic activity of SNase.
because its replacement by Asp and Gln significantly decreases the catalytic efficiency. Previous structural and mutagenesis studies suggested that Glu43 functions as a general base to activate a water molecule for hydrolyzing the phosphodiester bond of DNA. However, substitution of Glu43 with either homoglutamate (unnatural amino acid 9) or (S)-4-nitro-2-aminobutyric acid (unnatural amino acid 10) yielded mutant enzymes with kinetic constants similar to those of wide-type SNase (33). Because these two unnatural amino acids are isoelectronic and isosteric to glutamate but a much poorer base, such substitution would decrease SNase activity if Glu43 were a general base during catalysis. In addition, the X-ray crystal structure of the...
homologumate mutant showed that the carboxylate side chain of this residue occupies a position and orientation similar to that of Glu43 in the wild-type enzyme. Therefore, Glu43 may play a structural role instead and serve as a bidentate hydrogen-bond acceptor to fix the conformation of the neighboring loop.

Proline is unique among the natural amino acids in that its α-nitrogen is part of a pyrrolidine ring. The proline residue disrupts main-chain hydrogen bonding; it cannot serve as a hydrogen-bond donor because of the lack of a backbone NH moiety. Also, proline forms cis-peptide bonds at a frequency (5%) much higher than any other natural amino acids (22). In ion channels, Pro is often conserved at critical sites, such as Pro221 in the nicotinic acetylcholine receptor (nAChR) and Pro256 in the 5-hydroxytryptamine-3A receptor (5-HT3AR). To probe which feature of Pro is functionally significant, α-hydroxy acid anologs (analogs of Gly, Val, and Leu) were incorporated at these sites, which all produced mutant receptors with properties similar to the wild-type receptor (34, 35). In contrast, incorporation of canonical amino acids Gly, Ala, or Leu yielded nonfunctional receptors. Because α-hydroxy acids similarly lack the NH moiety for backbone hydrogen bonding and the nature of side chains does not affect receptor activity, these results suggest that the functional importance of the conserved Pro in both receptors is to remove backbone hydrogen bonding. A further conserved proline residue of the 5-HT3AR, Pro308, has been shown to be indispensable for channel gating using conventional mutagenesis. However, substitution of this Pro with α-hydroxy acids produced nonfunctional receptors, which suggests that the lack of backbone hydrogen bonding is not the key to the proper function of this Pro. Interestingly, proline analogs that strongly favor the cis conformer (unnatural amino acids 11 and 12) produced no gating response, but those that favor the cis conformer (unnatural amino acids 13 and 14) yielded highly sensitive channels. Moreover, a linear energy correlation was observed between the cis-trans energy gap of the proline analogs and the receptor activation (36). This study strongly suggests that the critical role of Pro308 is to provide the switch that interconverts the open and closed states of the channel through cis-trans isomerization.

Cation-π Interaction

Cation-π interaction is a noncovalent electrostatic interaction between a cation and the electrons in π orbitals, which plays an important role in protein structure, binding, and catalytic function. The energetic contribution of this interaction to proteins cannot be measured accurately with conventional mutagenesis because no positively charged natural isoctepe exist for common amino acids. To engineer a cation-π interaction in SLase, Val74, which occupies a hydrophobic pocket composed of one tyrosine side chain and two phenylalanine side chains, was replaced with the positively charged 5-methylmethionine (an unnatural amino acid) to yield SLase with homologumate mutant. Because fluorine is an electron-withdrawing group, substitution of H with F in the aromatic ring weakens the cation-π interaction. Ab initio quantum mechanics was used to predict the cation-π-binding abilities of the fluorinated tryptophanes, and the calculated binding energy has a linear relationship with receptor activation by the agonist (38). Such correlations were not observed for other aromatic residues, which suggests that the cation-π interaction indeed exists for agonist binding and pinpoints it to Trp149. This interaction was shown later as a general binding pattern between the Cys-loop superfamily of neurotransmitter receptors, such as the 5-HT3AR receptors and γ-aminobutyric acid receptors, and their cationic ligands or substrates (39).

Biophysical Probes

The site-specific introduction of biophysical probes into proteins has proven extremely powerful in revealing subtle changes of proteins with high spatial resolution. The carbon-deuterium (C-D) bond absorbs at ~2300 cm⁻¹, which is within the transparent IR window (~1800-2700 cm⁻¹) of proteins and, therefore, makes it easily observable by IR spectroscopy. The inherent fast timescale of IR spectroscopy also provides high temporal resolution. Therefore, unnatural amino acids with C-D bonds are excellent probes of protein folding and dynamics. Absorptions at different frequencies indicate the existence of multiple intermediates, and an increased line width of the absorption shows increased flexibility of the local environment. Amino acids containing C-D bonds were incorporated at different positions throughout cytochrome c (cyt c) by using semisynthetic approaches (40). By characterizing the absorption frequencies and line widths of the C-D bonds of these residues, it was found that no significant difference exists in the flexibilities of the oxidized and reduced states of cyt c. The data also show that parts of the protein exist in dynamic equilibrium with locally unfolded states and that cyt c is less stable than previous studies suggest.

A another infrared probe, p-cyano-L-phenylalanine (pCNPh), has been genetically encoded in E. coli and used to examine different ligand-bound states of the heme group in myoglobin (41). The stretching vibration of the nitrile group of pCNPh is strongly absorption and a frequency (νCN) at ~2200 cm⁻¹, which falls in the transparent window of protein IR spectra. A substitution of pCNPh was made for His64, which is at the distal face and close to the iron center of the heme group in myoglobin. In the ferric myoglobin, the Fe(III) ligand was changed from water to cyanide, νCN shifted from 2248 cm⁻¹ to 2236 cm⁻¹, which indicates a less polar active site. In the ferrous myoglobin, a νCN absorption at 2239 cm⁻¹ was observed for the linear Fe(III)CO complex, and the bent Fe(III)NO and Fe(III)O2 complexes showed a νCN absorption at 2230 cm⁻¹. These results demonstrate that the nitrile group is a sensitive probe for ligand binding and for local electronic environment. Small fluorescent probes sensitive to various environmental changes have the great potential for monitoring many biologic processes.

Unnatural Amino Acids to Investigate Biologic Processes
Unnatural Amino Acids to Investigate Biologic Processes

events as a complementary reporter for the widely used fluorescent proteins. For example, L-(7-hydroxycoumarin-4-yl)ethylglycine (CmrGly, 28) has been incorporated into holomyoglobin to study its local unfolding (42). CmrGly was incorporated at position Ser4 in helix A and at position His37 in helix C, respectively. The coumarin fluorescence intensity increases with solvent polarity. When the Ser4CmrGly mutant was unfolded with 2 M urea, its fluorescence increased 30%, which indicates that helix A is disordered. In contrast, the fluorescence intensity of the His37CmrGly mutant did not change significantly until the urea concentration was raised to 3 M. These results suggest helix C and helix A unfold at different times and concentrations of the denaturing agent.

Modification and regulation of protein activity

Green fluorescent protein (GFP), whose chromophore is autocatalytically formed by the tripeptide Ser65-Tyr66-Gly67, has become one of the most important in vivo markers for biologic studies. An aromatic amino acid at position 66 is necessary for fluorescence generation. To determine how the spectral properties of GFP could be altered by this residue, tyrosine analogs bearing different substituents at the para position of the phenyl ring (unnatural amino acids 21 to 24) were used to replace Tyr66 (43). The absorbance and fluorescence emission maxima of mutant GFPs are all blue-shifted, spanning the range from 375 to 435 nm and 428 to 498 nm, respectively. The wavelengths of the maxima increase in the order of bromo, iodo, methoxy, hydroxyl, amino, and deprotonated hydroxyl group. This shifting trend is consistent with the electron-donating ability of the substituents. In another experiment, Trp66 of the enhanced cyan fluorescent protein was replaced with \( L - 4 \)-aminotryptophan (unnatural amino acid 25) (44). The electron-donating amino group significantly red-shifts the fluorescence emission by 69 nm, which changes the color from cyan to gold.

Comparison of the \( p \)-methoxy-Phe (unnatural amino acid 22) mutant GFP with wild-type GFP also provides direct evidence for the peak assignment of GFP. Wild-type GFP has two absorbance maxima at 397 nm and 475 nm, which are believed to correspond to a neutral chromophore (phenol of Tyr66) and an anionic chromophore (phenolate anion of Tyr66), respectively. Excitation at either absorbance peak leads to a single fluorescence emission centered at 506 nm, which corresponds to the anionic chromophore in the excited state (45). Picosecond spectroscopy revealed that the excited neutral chromophore should emit at 460 nm (46). The absence of 460 nm emission in wild-type GFP suggests that an excited state proton transfer process is involved. Substitution of the hydroxyl group of Tyr with a methoxy group removes the possibility of deprotonation and proton transfer. Indeed, when Tyr66 is replaced with \( p \)-methoxy-Phe, only one absorbance maximum at 394 nm is observed, which is close to the absorbance maximum of the neutral chromophore of wild-type GFP. Moreover, only one emission maximum at 460 nm is detected for this mutant, which corroborates the ultrafast spectroscopic results (43).

The specificity of nucleic acid-binding proteins relies greatly on the hydrogen bonding between protein polar atoms and nucleic acid bases. Unnatural amino acids that can change isosterically the hydrogen-bonding pattern have been exploited to alter the substrate specificity. The \( \lambda \)-repressor recognizes the C:G pair at position 6 in the operator site OL1, and Lys4 of the \( \lambda \)-repressor is crucial for this recognition. The \( \epsilon - \text{NH}_2 \) group of Lys4 forms hydrogen bonds with the carbonyl group of Asn55 and the 6-oxo group of the guanine, functioning as two hydrogen bond donors. Substitution of Lys4 with isosteric \( S -(2 \)-hydroxyethyl)-cysteine changes the \( \epsilon - \text{NH}_2 \) to the \( \text{–OH} \) group, which now should accept hydrogen bonding from the amino group of adenine while preserving the hydroxyl group of Lys4 with Asn55 as a donor (Fig. 4). In fact, after the unnatural amino acid was introduced into the \( \lambda \)-repressor through site-directed mutagenesis and chemical modification, the binding specificity was switched from the C:G to T:A base pair (47).

The chirality of \( D \)-amino acids has been harnessed for pharmaceutical purposes. \( D \)-peptide ligands should be resistant to proteolytic degradation and thus are more desirable as...
Unnatural Amino Acids to Investigate Biologic Processes

Drugs. However, large libraries of D conformers cannot be encoded genetically and expressed for selection. A method termed mirror-image display solved this problem in an intriguing way (48). An L-peptide library is encoded genetically and displayed on the phage surface, and peptides of this library are selected by the target protein that is synthesized using all D-amino acids. The identified L-peptide then is resynthesized using D-amino acids, which should interact with the target protein of the natural handedness for reasons of symmetry. This approach has been used successfully to identify D-peptides that bind the Src homology 3 domain of c-Src and the HIV-1 gp41 protein (48, 49).

Unnatural amino acids that mimic posttranslational modifications can be used to control protein functions. For example, protein phosphorylation regulates many signal transduction pathways and is a reversible process catalyzed by various phosphatases and kinases. The dynamic change of the phosphorylation status of a protein makes it difficult to study the effect of this modification in detail. The generation of metabolically stable phosphoproteins would be useful to dissect the function and to direct signal transduction. Unnatural amino acid p-carboxymethyl-L-phenylalanine (pCMF, 26) is a non-hydrolyzable analog of phosphotyrosine and was found capable of mimicking the phosphorylated state of Tyr. This capability was demonstrated in a model phosphoprotein, the human signal transducer and activator of transcription-1 (STAT1). STAT1 has only a weak affinity for DNA, but during phosphorylation of Tyr701, STAT1 forms a homodimer and strongly binds a DNA duplex that contains M67 sites. The mutant STAT1 with Tyr701 substituted with pCMF also bound the M67-containing DNA duplex tightly, which suggests that pCMF could replace phosphotyrosine in the generation of constitutively active phosphoproteins (50).

The development of photoactive amino acids provides researchers with an extremely useful tool not only to probe biologic function but also to control spatially and temporally a variety of biologic processes. One strategy is to attach a suitable photoremovable protecting group to the amino acid, which renders the amino acid inactive. Photolysis releases the caging group and converts the amino acid to an active form, which generates abrupt or localized changes to the target protein. The 2-nitrobenzyl derivative is the most prevalent form for caged compounds. For example, the conserved Ser1802 at the upstream splice junction of the self-splicing DNA polymerase of Thermococcosis litoralis was substituted with o-(2-nitrobenzyl)serine (Fig. 5a). The full-length precursor protein underwent photolysis only when the unnatural residue was reverted back to wild-type Ser during photolysis (51). In other examples, o-nitrobenzyltyrosine (Fig. 5b) was used to replace Tyr93 or Tyr198 in the α subunit of the nAChR. These two Tyr residues are highly conserved for agonist binding. Millisecond flashes of light at 300–350 nm decaged the protected tyrosines and produced abrupt increments of currents that were conducted by the ion channel (52). Also, o-nitrobenzyltyrosine has been incorporated at the essential Tyr93 site of β-galactosidase to activate its enzymatic activity by using light both in vitro and in E. coli (53). Mutation of the active-site cysteine residue in the proapoptotic protease caspase 3 to o-nitrobenzylcysteine led to a catalytically inactive enzyme, whose activity could be restored by photocleavage (54). In addition to caging the active side chains, the 2-nitrobenzyl group

Figure 5 Photolysis of 2-nitrobenzyl caged serine (a) and tyrosine (b) restores the wild-type residues. Photolysis of 2-nitrophenyl glycine (c) cleaves the protein backbone.
Unnatural Amino Acids to Investigate Biologic Processes

Figure 6 (a) The geometrical change resultant from the cis-trans isomerization of azobenzene moves an ion channel blocker in and out of the ion channel to close and open the ion channel, respectively. Such activity was used to modulate the spontaneously firing hippocampal neurons. The firing frequency is significantly decreased when the azobenzene is in the cis-form after irradiation at 390 nm. Normal firing behavior is restored during irradiation at 500 nm (reprinted from (57), Copyright 2005, with permission from Elsevier). (b) Structure of phenylalanine-4′-azobenzene (AzoPhe) in trans-form and gel mobility shift assay to determine the binding affinity of the catabolite activator protein (CAP) to the lactose promoter DNA fragment (reprinted with permission from (56), Copyright 2006, American Chemical Society). Lane 1, DNA only. Lane 2, DNA+ wild-type CAP. Lane 3, DNA+ CAP with AzoPhe incorporated at residue 71 (after irradiation at 334 nm). Lane 4, DNA+ CAP with AzoPhe incorporated at residue 71 (before irradiation at 334 nm). Substitution of Ile71 with trans AzoPhe in CAP results in a fourfold decrease of the binding constant $K_b$ of the CAP for its promoter sequence. Photoirradiation at 334 nm partially converts the trans AzoPhe to the cis-form and decreases the $K_b$ by another fourfold. The latter affinity loss can be completely recovered after irradiation at $>420$ nm, which switches the cis-form back to the predominant trans-state.

Photolysis of a caged amino acid residue is an irreversible process. Reversible modulation can be achieved with the photocromic azobenzene compounds. Azobenzene undergoes a reversible cis-trans isomerization: The more stable trans isomer can be converted to the cis isomer upon illumination at 320–340 nm, and the cis-form can revert to trans-form either thermally or by irradiation at $>420$ nm. The resultant change in geometry and/or dipole of the compound can be used for regulating protein activity. For example, a known K$^+$ channel blocker, tetra-ethyl ammonium, was linked via an azobenzene group to a cysteine that was introduced at specific sites of a K$^+$ ion channel (Fig. 6a). When the azobenzene group isomerizes between the extended trans-form and the shorter cis-form in response to specific wavelengths of light, the structural change moves the blocker into or out of channel-blocking position and, thus, opens and closes the ion channel, respectively (58). Such photomodulation can be used to control neuronal activity non-invasively. The azobenzene group has been genetically encoded in the form of phenylalanine-4-azobenzene (AzoPhe). AzoPhe was incorporated at the Ile71 site of the E. coli catabolite activator protein (CAP), a transcriptional activator. Its binding affinity for the promoter sequence decreased fourfold after irradiation at 334 nm (Fig 6b), which converts the predominant trans AzoPhe to the cis-form. The isomerized cis AzoPhe then was switched back to the trans-state by irradiation at $>420$ nm, after which the affinity of the protein for the promoter was completely recovered (56).

Future Directions

The examples summarized here are only representative and by no means comprehensive. Many unnatural amino acids now can be incorporated, but simply have yet to be used in the investigation of biologic function. Unnatural amino acids that contain photocross-linkers, biophysical probes, chemical moieties with unique reactivities, and posttranslational modifications, among many others, have much promise in their capabilities. The use of these amino acids will expand the capabilities of probing protein structure and function as well as protein-involved biologic processes. The methodology of incorporation is advancing as well. It may be possible to genetically encode unnatural amino acids in many other cell types and organisms. The incorporation of multiple unnatural amino acids simultaneously by using

WILEY ENCYCLOPEDIA OF CHEMICAL BIOLOGY © 2008, John Wiley & Sons, Inc.
extended codons may enable more complex investigations to be performed. A different work using unnatural amino acids can lead to the design and synthesis of novel and diverse biologic functions. By incorporating specific chemical moieties and physical characteristics into proteins, new protein properties may be discovered and used. Such exploration can be attempted either rationally or combinatorially. Diversities of protein libraries would be increased greatly by the addition of only a few unnatural amino acids, which may enhance the probability of discovering proteins that contain novel properties and functions. It is easy to see how unnatural amino acids can be extended into the pharmaceutical industry to create more efficient therapeutics. Finally, the creation of a sustainable organism that is capable of using unnatural amino acids will enable the investigation of the evolution of the genetic code on this planet.

doi: 10.1002/9780470048672.wecb310

Membrane potentials are a ubiquitous feature of all living cells and play different roles in manifold cellular processes. Three different membrane potentials are known to exist that include the transmembrane potential difference, the surface electrostatic potential and the membrane dipole potential. Each of these are discussed in terms of their different physical origins and characteristics together with representative examples of how they feature in cell biology as well as some examples in physiology. Techniques for the quantitative measurement of each of these potentials are described in both model systems as well as with living systems. As many of these practices involve the use of spectroscopic technologies (particularly fluorescence) they lend themselves to spatial (single cell) imaging applications and examples of the biological roles that spatial variation or localisation of each of these potentials are also outlined.

Biological Background

Membranes act as one of the major macromolecular assemblies of living cells (both prokaryotic and eukaryotic) but also feature as physical envelopes in viruses such as influenza and HIV. Typically cell membranes act as semi-permeable structures that compartmentalise cellular processes and behave as 2D fluids, rapidly annealing any fractures by 2D molecular flow. Membranes, however, undertake many more biological roles than these simple generalizations imply as they also act as platforms for many important biochemical processes. Similarly, it has recently been appreciated that membranes exhibit localised structures in the form of microdomains (i.e. so called rafts) as shown in Fig. 1. These act as structures upon and within which, additional physico-chemical mechanisms may operate. The following sections outline the biological features of the trinity of membrane potentials (1) and their physico-chemical origins. Practical methodologies for their respective measurements are then described that exploit these different molecular origins.

The transmembrane potential difference: roles in signaling and energy transduction

The first membrane potential to be considered resides in a membrane’s ability to act as a permeability barrier or resistance to solute (particularly electrolyte) movement. Thus ions that are actively transported across the membrane by membrane proteins are not easily able to return to their former compartment. This leads to a thermodynamic gradient that is utilised by cells in two ways. The first, takes advantage of the ionic concentration gradient of a specified ion across the membrane. The second due to a small electrical capacity of the membrane (ca. 1 µF cm⁻²) may lead to an electrical gradient across the membrane. Thus chemical or light energy that is ‘spent’ transporting the ions across the membrane is partially ‘conserved’ as the ionic gradient across the membrane (e.g. as illustrated in Fig. 2). Two enormously important biological examples featuring these processes are worth emphasising, the first example is that the conservation of light or chemical (oxidation-reduction)
energy as an ionic/electric gradient is an essential part of the process of oxidative or photosynthetic phosphorylation. The ionic gradient in these latter cases resides in a proton gradient across the mitochondrial or chloroplast membranes respectively (2). Interestingly, in the case of the mitochondria, the proton gradient manifests mostly as an electrical gradient (3) due as mentioned above, to the relatively small electrical capacity of the mitochondrial membrane with only a small pH gradient. Whereas due to the relatively easy movement of Mg\(^{2+}\) ions across the chloroplast membrane, the electrical capacity is effectively much increased and the proton gradient then manifests mostly as a pH gradient with a small electrical gradient. Both these manifestations of the electrochemical potential difference of the proton across the membrane however, are equivalent and are utilised to manufacture ATP directed through the membrane ATPases. In fact, this electrochemical gradient is utilized essentially as a power source for many additional utilities such as coupled solute transport, to drive the flagellum movement of some bacteria as well as for protein import across prokaryotic and eukaryotic membranes (4).

The second general biological example is that the electrical gradient so generated can be utilised as a signalling mechanism such as in nervous transmission in neural cells or as a driving force for ionic currents that mediate cell signaling. These signaling mechanisms are both complex and ubiquitous with ion channels activated through soluble or membrane-bound ‘ligands’ or 2nd messengers that upon opening permit e.g. calcium ion movements driven by the membrane potential that then elicits further cell signaling cascades for neurotransduction, muscle contraction and nuclear translocation of molecular switches to turn genes on or off. Typically there are spatial elements in these signaling elements and thus there are also many measurement strategies that include imaging modalities as part of the experimental goals.

Finally, in the case of the role of membrane potential in nervous conduction, a travelling wave of an electrical potential gradient (voltage) is used to relay signals over relatively long distances along the cell membrane i.e. as in axonal linkages between cells (see e.g. 5). This latter manifestation of a “membrane potential” as part of the nerve impulse is perhaps the most commonly understood membrane potential and is described very fully in Reference 6.

The membrane surface potential: roles in modulating ion channels and cell–cell interactions

The surface potential is now understood to play important roles in many physiological processes. These range from the simplest involving coulombic repulsion between adjacent membranes that prevent cells sticking to each other. Thus sialic acid as a sugar moiety to the membrane protein glycoporphin present on the cell surface of many cells and particularly red blood cells appears to prevents cell–cell aggregation. Under circumstances of uncontrolled-diabetes, however, the nature of the sugars on the erythrocyte cell surface may change with sialic acid replaced by uncharged sugars. This reduces the coulombic repulsion between the red cells allowing thrombosis to occur (7, 8).

The contribution to the cell membrane surface potential by sialic acid is also implicated in gating the voltage dependence of Na\(^{+}\) Channels (9). This kind of electrostatic effect on ion pump/channel loading/unloading (with other contributors to the surface potential such as phosphatidylserine), however, has been considered for many years. McLaughlin as long ago as 1971, for example, suggested that surface potential changes were responsible for negative or positive shifts of the current-voltage relationships of neural tissue as embodied in the Hodgkin-Huxley equations (5). This kind of process is the result of the effect of the surface potential on the activity of ions on a membrane surface and leads to changes of e.g. the pK of membrane surface-located acid-base groups (10, 11). We have exploited this latter phenomenon to develop a panel of fluorescent phospholipids as real-time measures of the membrane surface potential (12). By measuring small changes of the membrane surface potential in this manner due to the interaction of charged molecules, it proved possible to study the kinetics and thermodynamics of intermolecular interactions with membranes (13).

The membrane dipole potential: role in modulating microdomain-located membrane proteins

The presence and biological roles of cell membrane microdomains (often referred to as membrane rafts) are discussed elsewhere in the WECB although it must be conceded that presently, this subject remains slightly contentious. Nevertheless in our hands we have clearly observed these structures in both artificial model systems (14) and the membranes of living cells (1). We published the first theoretical model of the possible mechanisms of assembly and disassembly of these structures (14) and firmly believe they are a feature of living cell membranes. The accepted functions of microdomains appear to revolve around their ability to act as local platforms for endocytosis/ectocytosis or to localise reactants whether they be small ligands or proteins. In this way rafts are localised in the raft aiding their interaction or they are sequestered from the more fluid membrane preventing their interaction with potential...
partners resident in the fluid membrane. Both these processes, however, are conceptually analogous. We considered that membrane microdomains may exhibit a vastly different membrane dipole potential to that of the fluid phase membrane due to their different lipid packing and complement of sterols and lipids (etc). We later demonstrated this was indeed a fact of the various lipids present (15) and also showed that this parameter had a significant effect on membrane protein conformation (16).

This work demonstrated with representative ligand-receptor systems that this behaviour may alter the function of such receptor systems depending on whether they were resident in the rafts or in the fluid phase regions of the membrane (15, 17). Following this a number of other laboratories also observed modulation of membrane behaviour via the agency of the dipole potential (18). Thus the membrane dipole potential appears to be an additional tool for which membrane protein function can be controlled in particular localities. The explicit molecular mechanism by which this may take place is discussed in the next section.

Physical Chemistry Background of Membrane Potentials

It is axiomatic that biological systems must adhere to the physico-chemical laws of nature. Sometimes, biology when appearing to contradict such laws (eg organisms and cells representing low entropy structures, historically brought it into conflict with the 2nd law of thermodynamics), however, merely serves to illustrate the ingenuity of nature in working within the laws. Electrostatics and electrolydynamics together represent one such cornerstone of nature that biology exhibits great expertise in making use of to derive exquisite control of biological function, as briefly outlined above.

Membrane potentials manifest in a number of different ways as part of the process of biology and relate to their physical origins and will be described in this section. Taking each type of the three potentials in turn, the transmembrane potential difference is considered first as this is the most well known and features prominently in undergraduate text books dealing with biochemistry and physiology. Historically this membrane potential is also known simply as the membrane potential, unfortunately has lead to some confusion as it shares nomenclature with the 'other' membrane potentials. In this article the same nomenclature is adopted as that described in a comprehensive treatise on biological membrane potentials (1) that is consistent with the 'other' discipline of electrochemistry, so unifying the chemistry and biology communities' versions of the nomenclature.

The transmembrane potential difference (\(\Delta \phi_m\))

Membranes represent permeability barriers to the movement of ions (and electrons) and this phenomenon is utilised in a number of ways in biological systems as mentioned in the previous section. In terms of generalising and for the sake of briefness, this gradient of ions has two principal uses, the first as an energy store albeit labile and secondly a means of shuttling ions across the membrane. In terms of an analogy with the charging of a capacitor, this well known latter phenomenon is described by the following expressions:

\[
V = \frac{q}{C} = \Delta \phi = \text{Em} \text{ or } Vm = \Delta \phi_m \tag{1}
\]

where, \(V\) is the electrical potential difference across the membrane ie. \(Vm\) or \(Em\) and \(\Delta \phi\) is the capacitance of the membrane (dielectric) and \(q\) is the number of charges transported across the membrane. The term, \(\Delta \phi_m\) is included as this represents a more consistent nomenclature, and would be better recognised by disciplines outside biology (e.g. Electrochemists, \(\Delta \phi\) is the form utilised by biochemists (2) and \(Vm\) or \(Em\) is the form utilised by Physiologists (6).

The transport of electrical charge across a membrane may take the form of cation, anion (both inorganic and organic) or electron transport all requiring an energetic input. It can be passive due to membrane leaks or mediated by ionophores such as valinomycin. All other things being equal it is possible to utilise equation 1 to calculate a trans-membrane (ie trans-dielectric) potential difference (19). Thus, under these circumstances there is a simple and direct equivalence of the voltage across the membrane (ie \(\Delta \phi_m\)) to the Gibbs Free energy (ie. \(\Delta G\)). In biological membranes, however, the transport is frequently coupled either to the movements of other ions due to co- or anti-porting enzymes, or to chemical reactions as in the case of oxidative phosphorylation or hydrolysis of ATP. The value of \(\Delta \phi_m\) established in such complex systems is governed by the relation \(\Sigma Z_i \phi_i = 0\), where the sum has to include all flows \(j\) of charged species \(Z_i\) across the membrane (1). When this relation is satisfied, charging of the membrane capacity has ceased, and a (pseudo) steady state with a (approximately) constant \(\Delta \phi_m\) is then attained. Its value depends on the difference in chemical potential (\(\Delta \mu\)) of all transported species and on the affinities of coupled chemical reactions. The pertinent relations are usually transcendental and cannot be solved explicitly except for some special cases. In particular, if only one species permeates through the membrane, a true equilibrium state is reached and the resulting transmembrane electrical potential difference is described by what is known as the Nernst equation (below). This equivalence, however, becomes more complicated because biological membranes are not totally impermeable to ions (i.e. there is leakage back across the membrane - e.g. Reference 20), the concentration gradients must also be included in the Gibbs free energy of the expression and finally there is usually a coupling of the transport mechanisms to the movements of other ions as well as to the energy input (as in oxidative phosphorylation or the hydrolysis of ATP – see Reference 2). Nevertheless, ion gradients are established across many membranes whereby the ion leakage is balanced by further energy-linked ion transport. Biological membranes, therefore, exhibit quasi-equilibrium transmembrane concentration gradients of charge based on selective transport of the ions found in physiological electrolytes. This is described by the well known Nernst equation which incorporates the transmembrane concentration gradient of electric...
charge as follows:

$$\Delta \phi_{i} = \left( e Z_i \right) \log \left( C_{\text{inside}} / C_{\text{outside}} \right)$$  \hspace{1cm} (2)$$

In which $\phi$ is an abbreviation of $\text{K}T/e \approx RT/F$; with $F$ = fara-
day constant, $R$ gas constant and $C_i$ indicate the concentration of
the respective ionic species in the aqueous phases separated
by the membrane.

Thus, the Gibbs Free energy expression for such an ionic gra-
dient across the membrane consisting of $n$ positively charged
species $C_i$ would be of the form of the following expression:

$$\Delta G = - nF \Delta \phi + 2.3RT \log \left( C_i^{\text{inside}} / C_i^{\text{outside}} \right)$$

The electrical component ($\Delta \phi_{el}$) and the chemical component
($\Delta \phi_{ch}$) are combined to indicate the thermody-
namic potential difference due to the ionic gradient.

Finally, its also worth emphasizing that related to the trans-
membrane potential difference, a transmembrane gradient of
electric charge known as the Donnan potential is also known to ex-
ist. The Donnan potential arises from the inability of larger
charged macromolecules or other fixed charges to move across
a membrane and for counterions to compensate this gradient.

The membrane surface potential ($\phi_s$)

Many of the electrical phenomena that feature on membrane
surfaces are similar to those found in electrochemistry. Thus
derivation of formalisms describing interactions of ions with
charged membrane surfaces have evolved from and are in many
ways similar to those that have been developed to describe the
ion relations of electrodes in electrochemistry. It's worth empha-
sizing, however that care must be taken when simply reworking
concepts that originate from electrochemistry, as there are im-
portant differences between membranes and electrodes that may
complicate formal descriptions. Electrodes are essentially ho-
mogeneous hard solid metal surfaces, whereas membranes are
soft, fluid, highly heterogeneous interfaces that interact and actu-
ally require their aqueous environment to exist (i.e. through the
hydrophobic effect).

Ions are attracted towards the charged membrane surface but
the hydrated radius of the ions in the layers adjacent to the
surface prevents them from moving to the membrane surface
without becoming actually adsorbed. The initial treatments of
this phenomena by Gouy and Chapman in terms of the interac-
tions of ions with electrodes involved treatment of the ions as
point charges but a modification of this model was presented by
Stern who developed the much earlier Helmoltz-Perrin model
with that of Gouy-Chapman (21). The Helmoltz-Perrin model
described the double-layer concept that counterions formed an
ionic “sheet” upon a charged surface, the ions being at least
partially dehydrated in the direction of the surface. Much of the
history of the development of these ideas as directed towards
metal surfaces in aqueous media (i.e. electrodes) may be found
in comprehensive electrochemistry texts (21).

The forces involved in the specific ionic-interactions with
membranes were initially thought predominantly to be electro-
static and van der Waals in nature, and large enough to counter
the thermal motion/diffusion of the ions away from the interface
to the bulk medium. Later, it was suggested that water molecules
may adopt a specific orientation upon the charged surface due
to their permanent dipoles (this latter feature has some bearing
on an understanding of the dipole potential described below).

A number of diffuse phases or layers as illustrated in Fig. 3a,
have been identified which are thought to exist adjacent to the
surfaces of membranes. These include the so-called Stern layer
(Fig. 3a) which represents contact adsorbed counter-ions (either
totally or partially dehydrated) and oriented water molecules.
The plane running through the centre of the contact adsorbed
ions is referred to as the Inner-Helmholtz plane. The first layer
of hydrated ions is then referred to as the Outer-Helmholtz
plane. The Gouy-Chapman-Stern model was formalised by con-
sidering the adsorption of counter-ions only, the process being
approximated by a Langmuir-type adsorption isotherm (1, 21).

Surface potentials at the electrode-solution interface have
been described by a number of formalisms. The most successful
of these was offered originally by Gouy and Chapman with sub-
sequent elaborations from Chapman, Stern, Bockris etc.,
(outlined in ref 1 & 21). M-L aughlin (22) and others (inlined in
1) suggested that a combination of the Poisson and Boltzmann
equations best describes the state of affairs in the space between
the membrane surface and the bulk phase aqueous solution i.e.
the electrode-water interface. The Poisson-Boltzmann equation,
with defined boundary conditions can be solved analytically
(1, 22) to yield an expression for the surface potential as follows:

$$\phi_s = \left( 2e o \right) / \left( 2A \ln \left( 2e o / (2e o) \right) \right)$$

where $\phi_s$ as in Eqn. 4 and the abbreviation $\phi_s = \phi_{G,C}$
whereby $\phi$ represents the surface charge density, and $\lambda_s$ is known
as the Debye length. At 25 $^\circ$C ($e o = k T/2e N_A)^{1/2} = 0.304$ nm
$M^{-1/2}$ for an aqueous phase with $o = 80$.

Thus the potential profile in the diffuse layer shown in Fig. 3a
is given by:

$$\phi(x) = \phi_s \ln \left( \left( 1 + \tan h (x / \lambda) \right) / \left( 1 - \tan h (x / \lambda) \right) \right)$$

for $x \geq 0$  \hspace{1cm} (5)

The membrane dipole potential ($\phi_d$)

Many membrane components such as phospholipid include moi-
eties such as the $\text{C}^\text{ii} = \text{O}^\text{ii}$ and $\text{C}^\text{ii} = \text{P}^\text{ii}$ exhibit polarisation.

The membrane dipole potential $\phi_d$ has its origins in the dipole
moments of polar groups from the lipidic components of the
bi-layer, it seems likely that the water molecules at the molec-
ular surface of membrane also make a contribution (1). The
organisation of the membrane components that contribute to this
potential have been verified from neutron diffraction studies and
NMR spectroscopy (23) and quite recently using cryo-EM tech-
niques has also added quantitative estimations of the potential
(24). These dipolar groups seem to be oriented in a way such
that the potential located towards the hydrophobic interior of the
membrane is positive with respect to the pole located towards
the external aqueous phases, and $\phi_d$ has a magnitude of several hundred millivolts (typically about 300 mV see Fig. 4).

Symbolically formalising the measured molecular arrangements in order to undertake modelling of the membrane dipole potential is also not as straightforward as it may seem. It is possible to begin by identifying a vector drawn from the point of the negative charge $-Q$ to the positive charge $+Q$ of any dipole which is the familiar electric dipole moment $\mathbf{p}$. The magnitude is $Qa$, with $a$ defining the distance between the centres of the charge density. The potential at a given point with a position vector $\mathbf{r}$ with respect to the centre of the dipole can be expressed as:

$$\phi = \frac{\mathbf{p} \cdot \mathbf{r}}{(4\pi \varepsilon_0 \varepsilon_r r^3)} = \frac{\mathbf{p} \cdot \cos \theta}{(4\pi \varepsilon_0 \varepsilon_r r^2)}$$

for $r \gg a$, where $\theta$ is the angle between $\mathbf{r}$ and $\mathbf{p}$. Higher order terms become influential if $r \gg a$ is not fulfilled.

This expression, however, only deals with a single molecular dipole and as many such dipoles would be required to describe the overall membrane dipole potential but as a mean-field expression, this term is practical and cumulatively offers the approximation of the estimated dipolar organisation shown in Fig. 4. A further complication, however, involves the solvent environment and this too is also often dealt with as a mean field or in a continuum manner. But the relative permittivity (or dielectric constant) $\varepsilon_r$ cannot be considered to possess the same value throughout the multiphase system represented by a membrane in an aqueous medium. The permittivity profile has been measured to vary from about 78.5 in the bulk aqueous.
There are many techniques available for the measurement of membrane surface potential (φs) to around 2 in the membrane interior. Measurements of transmembrane potential differences in living cells are well established with the methods fairly reliable and robust. Many of these membrane potential measurement strategies are generic and hold for plasma membranes of neurons and other excitable tissues.

Chemical Tools & Techniques

Measurements of the transmembrane potential difference (Δφm)

There are many techniques available for the measurement of Δφm (e.g., 1, 2, 5) historically these involved the use of electrodes in which the voltage in one compartment would be compared to that in another separated by the membrane. And whilst this is not a major problem with larger structures such as eukaryotic cells, with bacteria penetration by an electrode would represent a major invasive procedure. Electrodes are still utilized routinely (6, 28) but the use of spectroscopic probes has evolved as perhaps the most commonly utilized current technology (26). Experimental strategies involve measurement of the redistribution of membrane-permeant indicators that migrate according to the Nernst equation, upon rearranging yields:

\[ \Delta \phi_m = \frac{RT \ln 10}{Z_i F} \left( \frac{c_i,s}{c_i,b} \exp(-Z_i F \phi_s/(RT)) \right) \]  

that when introduced into the logarithmic form of the Henderson-Hasselbalch equation, upon rearranging yields:

\[ \log(c_H,b)/c_{HB}) = pH - (pK_a - F \phi_s/(RT \ln 10)) \]  

Measurements of the membrane surface potential (φs)

In our laboratory we have developed novel fluorescence technologies that illuminate the respective membrane potentials. For measurements of φs this involved the synthesis of fluorophores attached to a phospholipid molecule that have the advantage of being virtually non-invasive as they are used at very low concentrations and do not perturb the membrane. One such probe molecule, FluoresceinPhosphatidylEthanolamine (FPE), has proved to be a versatile indicator of the electrostatic nature of the membrane surface in both artificial and cellular membrane systems (12, 17, 25). FPE is sensitive to changes in the surface potential φs at the membrane-solution interface because the fluorescent moiety of the FPE lies precisely at the membrane solution interface (see Fig. 3a). Any changes in the number of surface charges at the membrane, such as the binding of an inorganic ion or a charged oligopeptide, will cause an alteration in φs. These probe molecules operate in the following manner: thus according to the Boltzmann equation the concentration of a charged species at the membrane surface is

\[ c_{i,s} = c_{i,b} \exp(-Z_i F \phi_s/(RT)) \]  

Figure 4  Profile of dipole potential in the membrane.
Measurements of the dipolar membrane potential ($\phi_D$)

The dipole potential $\phi_D$ may be measured using a series of potentiometric fluorescent indicators that operate by electrochromic mechanisms. $1-(3$-sulfonatopropyl)$-4-(p$-$2$(di-n-octylamino)-6-naphthyl) vinyl) pyridinium betaine (known as di-8-ANEPPS) in particular has been successfully applied to the measurement of $\phi_D$ using dual-wavelength ratiometric fluorescence methods (15, 16, 30). This method forestalled problems arising from small differences in dye concentration between different samples, dye bleaching or the influence of light scattering on the fluorescence measurements.

The excitation spectrum of di-8-ANEPPS is altered when it lines up (symmetrically or asymmetrically) with the membrane dipoles causing electronic redistributions within the probe molecule (see e.g. Fig. 5a). This promotes red or blue shifts in the excitation spectrum depending on the magnitude and direction of the dipole moment of the ambient environment that the probe finds itself in as shown in Fig. 5b. Preparation of membranes with sterols etc (ie that possess quite different dipole-moments to PC) promote changes in the membrane dipole potential, and significant variations of the intensity and position of the excitation maximum are observed. The excitation spectrum of di-8-ANEPPS in phosphatidylcholine (PC) membranes for example is significantly altered when 15 mol% of either 6-ketocholesterol (KC) or phloretin are added to such membranes. In the case of phloretin the difference spectrum has a minimum at 450 nm and a maximum at 520 nm (Fig. 5b). In the case of KC however, the difference spectrum has a maximum at 450 nm and a minimum at 520 nm, which is the opposite effect to that of phloretin.

Comprehensive studies of the dependence of the relative magnitude of the dipole potential on the membrane lipidic composition have been reported previously and a summary is reported in ref. 15. Of quite some interest, however, is the possibility that di-8-ANEPPS may be used to indicate the interactions of some macromolecules with membranes as shown in the equation above, the number of molecules that become bound. If $\phi_D$ is measurably influenced by peptides/proteins that insert (at least partially) into the membrane and just as importantly vice versa.

Spatial Imaging of Membrane Potentials

The dominant technologies (outlined above) utilised to determine biological membrane potentials are optically based and particularly involve fluorescence. Thus spatial imaging is a logical extension of these spectroscopic applications. The use of a modified electrode technology has also been utilized to acquire imaging data in which the electrode is rastered over a cell surface to identify localization of ion transport behaviour and by implication spatial variations of the transmembrane potential (28). Measurements that include a spatial element have become extremely important in addressing biological problems as living cells exhibit enormous heterogeneity in the spatial disposition of these potentials. Lateral gradients of each of the membrane potentials, therefore, are implicated in manifold biological processes. In our laboratories for example we have developed the concepts (outlined above) relating to the interesting possibility that elevated dipole fields within membrane microdomains (15) modulate protein structure and that this modulates signaling activity (1, 17) or the activity of ion channels (18). We developed the use of di-8-ANEPPS to determine how the membrane dipole potential may be utilised to reveal macro-molecular interactions with membranes (15, 16). By illuminating spatial variations of this parameter and particularly how it varies in membrane rafts it led us to propose that the value of $\phi_D$ is quite different in membrane rafts as compared to fluid mosaic membranes (1, 17). Figure 6 illustrates this striking heterogeneity of the $\phi_D$ about the cell surface with measures currently being taken to correlate this or co-locate such signals that are emanating from the raft microdomains within membranes. The latter is a significant issue as there remains much confusion as to the in vivo existence of membrane rafts (33).

Similar approaches utilising such indicators as FPE to visualise the membrane surface potential $\phi_D$ are also routinely employed in our laboratories (17). By correlating the change of the fluorescence and hence surface potential with the addition of net electric charges from the macromolecule that becomes bound, it is possible to quantitate on the basis of the poisson-boltzmann equation above, the number of molecules that become bound. This allows us for example to determine localised molecular interactions on the membrane surface (17, 34).

Future Studies of Biological Roles and of Technologies for Measurement

Future aims and understanding of the biological roles of membrane potentials

Each of the membrane potentials described above are fundamental properties of living cells and as such there will be a growing appreciation of their roles in cell biology. In particular the development of an understanding of their roles in complex signaling pathways in which the coupling between the electrical and chemical signaling networks are clarified. Ci-VSP, for example (37) is a recently described protein with sequence similarity to both the voltage-sensing domain of a voltage-gated potassium channel and the phosphate PTEN, and functions as a transmembrane phosphoinositide phosphatase that is regulated by changes in voltage across the plasma membrane (37). More extensive and integrated conceptual developments of the cellular role of all aspects of membrane potentials will undoubtedly emerge as the new biological sub-discipline known as ‘systems biology’ matures (38).
Figure 5. Spectroscopic tools for identifying the membrane dipole potential. Fig. 5a indicates the excitation spectrum of different membranes labeled with di-8-anepps with the emission collected at 580nm. Spectra are shown for membranes made up of 100% phosphatidylcholine (−), membranes made up of phosphatidylcholine and 15mol% 8-Ketocholestanol (⋯⋯) and membranes made up of 15 mol% phloretin (····). These excitation spectra are better visualized as the difference spectra shown in 5b in which membrane made up of different lipid mixtures are compared to a reference spectrum, typically these are normalized and compared to phosphatidylcholine and shown as LHS upper (phloretin) and lower (8-ketocholestanol) spectra. The spectra upper RHS indicates the spectral shift of a membrane following interaction with a peptide and the lower plot illustrates the time course of the interactions in which the upper and lower limbs of the spectra are ratioed and plotted against time.
Future technologies for measuring membrane potentials

With the introduction of the green fluorescent protein (GFP) initially as a fluorescent label to track proteins, subsequent development of the technology to manufacture other colours (X-FP) has been used to visualize protein-protein interactions through confocal microscopy. Di-8-anepps labels all the intracellular membranes as well as the plasma membrane and thus indicates these membranes also possess very localized regions of elevated dipole potentials indicative of intracellular membrane microdomains. The LHS image indicates a bright field image of the same cell.

The methods and applications of NMR-based metabolomics are introduced in this article. As important tools for systems biology research, metabolomics, metabonomics, and metabolite profiling have been applied successfully for biomarker exploration at the molecular level. In addition to the detection and identification of putative disease biomarkers, NMR-based metabolomics also can be performed in many areas including nutritional science, disease monitoring, and drug toxicology studies. In the following sections, basic and advanced NMR technologies associated with metabolomics are summarized. Also, to process the complex spectral data and obtain useful information, pattern recognition techniques or multivariate statistical methods are necessary. These methods successfully simplify the multivariable data set, and their improvement may enhance the development of metabolomics. Finally, several important applications of NMR-based metabolomics are summarized, and examples are described.

Introduction

Metabolomics and the closely related metabonomics and metabolite profiling represent a growing field in the study of complex biologic systems (1-5). The aim of metabolomics is the study of concentrations and fluxes of low molecular weight metabolites present in the biofluids, tissues, or tissue extracts of living systems to retrieve information on biologic systems. As an emerging tool, metabolomics may be integrated with genomics, transcriptomics, and proteomics to achieve a comprehensive understanding about the physical condition of the system (6-8). Metabolomics improves that understanding by evaluating the metabolic changes that reflect the integrated responses of the system to internal or external perturbations. Also, compared with the numbers of modified proteins (>100,000) and genes (>30,000), measuring metabolites in biofluids or tissues is a much more direct and in principle simpler analytical problem to collect the useful information. The availability of detailed metabolic maps (9) can make interpretation of the results more straightforward.

Metabolomics is related closely to metabonomics, defined by Nicholson (10, 11), who pioneered several advances that combine NMR with pattern recognition techniques. Metabonomics emphasizes “the determination of systemic biochemical profiles and regulation of function in whole organisms by analyzing biofluids and tissues” (10). For clarification, definitions of common terms used in metabolomics research are summarized in Table 1 (10, 12-15). In this article, metabolomics is used as a general term.

The field of metabolomics has been developing very rapidly in part because of advances in the analytical methods of high-resolution nuclear magnetic resonance (NMR) spectroscopy and mass spectrometry (MS) and their combination with multivariate statistical analyses (16-22). Additional methods, such as infrared spectroscopy (23) and electrochemical methods (24), also have been used in metabolomics studies to a lesser extent. Because of the excellent quantitative capabilities and high measurement reproducibility of NMR, 1H-NMR spectroscopy has proven to be highly useful and reliable in metabolomics studies. The positive identification of interesting metabolites has been extremely useful in several studies.
The application of metabolomics has been widespread in areas ranging from systems biology studies to drug discovery, pharmaceutical research, early disease detection, toxicology, food and nutrition science, and others (25-28). Recent clinical examples of this approach include promising studies of ovarian cancer and insulin resistance (29, 30), the latter having been detected by NMR for over 20 years (31, 32). NMR spectroscopy plays an especially important role in metabolomics by providing highly reliable and reproducible measurements of the biologic samples that include a variety of biofluids and tissue samples. In this review, we highlight recent developments in NMR-based metabolomics methods for biomarker discovery and describe the main methods of statistical analysis currently used. Finally, we describe applications of the technology in several areas including nutritional studies, toxicology, and early disease detection.

### Current NMR Technologies in Metabolomics

In a sense, high-resolution NMR has been used for metabolic profiling of biofluids and tissue extracts for many decades (12, 33, 34). It is well known that the complexity of biofluids or tissue extracts often contains hundreds of detectable metabolites and thus thousands of spectral lines gives rise to complicated NMR spectra. However, the high reproducibility and quantitative characteristics of NMR data are well matched to the requirements for multivariate statistical analysis (12), which can provide a method to reduce the spectral complexity. Progress also has been made to reduce the congestion of regular one-dimensional (1-D) 1H-NMR spectroscopy by means of the J-resolved experiment (35) and other two-dimensional (2-D) methods. In addition, the NMR sensitivity and resonant frequency do not depend on the pKa value or hydrophobicity of the sample, which makes it an excellent choice for broad-based analyses especially suitable for biological samples in different conditions, whereas the required sample preparation for standard NMR measurements is limited. With advanced high-throughput NMR methodology, 100-200 samples per day can be measured routinely with the assistance of flow-injection probes and automated liquid handlers. The detection limit is decreased to tens of nanograms by the use of microcoil probes (36). Nevertheless, the complexity inherent in biologic samples generates many peaks within a small chemical shift range (3-10 ppm) in the 1H-NMR spectrum, and therefore spectral overlap is still a problem, especially in the aliphatic region (1-5 ppm). Therefore, potentially important compounds present at smaller concentrations often are overshadowed by larger peaks and thus are less likely to be detected.

Typically in metabolomics, NMR measurements are carried out on biofluid samples such as urine, blood serum, or plasma, although the analysis of intact tissue samples also is gaining in popularity. Unless the amount of sample is limited, approximately 200-400 µL of the biofluid typically is used for a standard measurement. If some samples, buffer solution is added to stabilize the pH, followed by centrifugation to remove insoluble species. In addition, 10% deuterium oxide is mixed with the sample and used for frequency locking. Also, a compound that serves as the standard chemical shift reference (0 ppm) is added to allow the alignment of the spectra. An added benefit is that the peak area of the standard compound may be used.
1-D Water Saturation Pulse Sequences

In NMR-based metabolomics studies, especially when biofluid samples are used, the overwhelming signal of the water resonance must be suppressed by using special NMR pulse sequences to measure the useful metabolites. The simplest water saturation pulse sequence consists of a continuous low-power irradiation over the period of an acquisition delay, which is usually 1–2 s long. The irradiation is applied at the water frequency (~4.8 ppm) that is to be suppressed. This simple pulse sequence usually is referred to as presaturation or PRE-SAT, as shown in Figure 1a where presaturation occurs during the relaxation and mixing times. Other water suppression pulse sequences include WATERGATE (WATER suppression by gradient tailored excitation), the PURGE sequence, and excitation sculpting (39–42). For example, the new PRESAT with 1-D NOESY (nuclear Overhauser effect spectroscopy), as shown in Figure 1b where presaturation occurs during the relaxation and mixing times. Other water suppression pulse sequences include WATERGATE (WATER suppression by gradient tailored excitation), the PURGE sequence, and excitation sculpting (39–42). For example, the new PRESAT with 1-D NOESY (nuclear Overhauser effect spectroscopy), as shown in Figure 1b where presaturation occurs during the relaxation and mixing times. Other water suppression pulse sequences include WATERGATE (WATER suppression by gradient tailored excitation), the PURGE sequence, and excitation sculpting (39–42). For example, the new PRESAT with 1-D NOESY (nuclear Overhauser effect spectroscopy), as shown in Figure 1b where presaturation occurs during the relaxation and mixing times. Other water suppression pulse sequences include WATERGATE (WATER suppression by gradient tailored excitation), the PURGE sequence, and excitation sculpting (39–42). For example, the new PRESAT with 1-D NOESY (nuclear Overhauser effect spectroscopy), as shown in Figure 1b where presaturation occurs during the relaxation and mixing times. Other water suppression pulse sequences include WATERGATE (WATER suppression by gradient tailored excitation), the PURGE sequence, and excitation sculpting (39–42). For example, the new PRESAT with 1-D NOESY (nuclear Overhauser effect spectroscopy), as shown in Figure 1b where presaturation occurs during the relaxation and mixing times. Other water suppression pulse sequences include WATERGATE (WATER suppression by gradient tailored excitation), the PURGE sequence, and excitation sculpting (39–42). For example, the new PRESAT with 1-D NOESY (nuclear Overhauser effect spectroscopy), as shown in Figure 1b where presaturation occurs during the relaxation and mixing times.

CPMG experiment

When large molecular weight species such as lipoproteins are present in the biofluid sample, a profile that contains broad peaks will be detected. The broad lines result from a combination of fast relaxation, multiple and unresolved couplings, and the overlap of similar but distinct molecular subtypes. In such cases, the CPMG (Carr-Purcell-Meiboom-Gill) spin echo pulse sequence is used to attenuate the broad signals that result from macromolecules according to their molecular and relaxation time, as shown in Figure 2. In particular, the number of spin echoes, n, and the delay time, τ, which determine the mixing time of the experiment, are critical for the suppression of broad protein signals. Ideally, these parameters should be properly optimized for each sample type (44). 1-D PRESAT and CPMG pulse sequences of the same human serum sample are shown in Figure 2. The effect of CPMG is evident when comparing the panels a and b, in which the broad signal has been suppressed effectively, especially in the aliphatic region (0.4–5.5 ppm). However, the suppression of broad signals by CPMG also may result in a loss of useful information. It is necessary, sometimes, to perform multiple experiments with and without CPMG when measuring blood serum or plasma samples.

2-D experiments

2-D NMR experiments improve the ability to interpret spectra because the peaks are dispersed extensively, which increases the resolution and information content. Several commonly used homonuclear 2-D experiments include correlation spectroscopy (COSY) and total correlation spectroscopy (TOCSY). A typical 1H–1H correlation spectrum provides information on spin–spin couplings between protons that are linked by covalent bonds. When hundreds of peaks appear in the 1-D 1H–1H NMR spectrum, 2-D spectroscopy provides a means to assist the identification of key metabolites.

Homonuclear experiments take advantage of the high sensitivity of the 100% natural isotopic abundance of 1H. Although heteronuclear (1H–13C) 2-D experiments are less common in metabolomics because of their lower sensitivity (caused by the 1% 13C nature abundance), several are useful in helping identify
unknown metabolites. In particular, HSQC (heteronuclear single quantum coherence) (45) is used in metabolomics to assist in metabolite identification (46). HSQC experiments, especially $^{13}C$–$^1H$ and $^{15}N$–$^1H$ HSQC, in which isotopic $^{13}C$ and $^{15}N$ labels are introduced biochemically are used frequently in protein NMR spectroscopy. In metabolomics research, when homonuclear spectroscopy is not adequate for structure elucidation, a $^1H$–$^{13}C$ HSQC spectrum often is acquired. A cross peak indicates the presence of an H–C bond. A typical HSQC spectrum of human urine sample is presented in Fig. 3. Another similar pulse sequence HMBC (heteronuclear multiple bond coherence) is used to detect longer-range couplings through two or three bonds.

An improvement in the resolution and sensitivity of 2-D experiments of complex samples will increase the ability to identify more metabolites of interest. A recent approach developed by Shanaiah et al. enhanced the sensitivity of $^1H$–$^{13}C$ HSQC for metabolomics studies (47). A certain class of metabolites, amino acids in this case, was derivatized with labeled 1,1$'$-$^{13}C_2$ acetic anhydride, which produced N-acylated products and increased the sensitivity by 100-fold. Cross peaks of these metabolites could be resolved in the HSQC spectra.

Pattern Recognition Techniques

Statistical pattern recognition methods (48–50), such as principal component analysis (PCA) and partial least squares (PLS), when combined with NMR measurements, create enormously powerful opportunities for metabolomics research. In particular, they provide important data reduction and simplification methods, as well as extensive capabilities for distinguishing very similar spectra. Most multivariate analyses used in the field of metabolomics are based on the projections of the original data set onto a new coordinate system. If a certain degree of similarity exists between rows (spectroscopic measurements) in the data matrix $X$, such projections in principle can predict the outcome of a new data set. The advantages of projection methods are:

1. The multivariate model is based on the complete data set.
2. It can tolerate a certain amount of missing data.
3. It provides visual representation of the classification within the data matrix $X$ (the score plot).
4. It assumes the existence of noise in the data.
5. In the case of PLS, it can interlink different data sets X and Y and generate results that easily can be interpreted (51).

Preprocessing
Before multivariate analysis, certain preprocessing steps have to be carried out for several reasons. The overall goal of preprocessing is to achieve a better discrimination and obtain the results with better interpretability. First, spectra are aligned using the chemical shift reference. Next, unwanted peaks are removed. In the case of 1H-NMR spectra, unwanted peaks include the residual water signal after suppression and the chemical shift reference peak. In the case of urine samples, the urea signal is broad and partially attenuated because of its fast isotopic exchange with the (saturated) protons in water and, thus, also is removed.

Normalization
For biofluid samples such as human urine, the concentrations of different metabolites are highly dependent on the amount of consumed water. Therefore, it is necessary to normalize the whole spectral region to the same level to eliminate the effect of the unwanted overall concentration variations. The most common way to normalize the data sets is to use total integrated intensity normalization, which simply sets the total intensity of the whole spectral region to a constant value. An alternative method is vector length normalization, which sums the square of each variable and sets it to a constant. In the view of multidimensional space, each spectrum can be represented by a vector. After normalization, the length of each vector has the same value. Another common method is to divide the whole spectrum by the peak intensity of a concentrated metabolite. For example, in the case of an 1H-NMR spectrum of urine, creatinine often is used by the medical community as an intensity reference. This use is because of the underlying assumption of constant excretion of creatinine into urine. Thus, creatinine can be used as an indicator of urine concentration.

Mean-Centering
Mean-centering is carried out by subtracting the mean value from each variable. In other words, an average spectrum is calculated from the whole data set and then subtracted from each spectrum. By the use of mean-centering, the center of the data distribution in the multidimensional space is set to the origin.

Scaling
Scaling is used to change the emphasis from metabolites with high concentrations to those with moderate or small concentrations. Mean-centering must be applied before performing any scaling process. Variance scaling, in which each variable is divided by its standard deviation (square root of variance) is the most commonly used. In this way, all variables are scaled to unit variance. The purpose of this operation is to decrease the dominant effect of large and variable NMR signals on statistical models and to allow the contribution of small peaks to be included. A combination of mean-centering and variance scaling is termed autoscaling. Variance scaling is recommended when the variables have different units. However, this situation is not the case for NMR measurements. Variance scaling may cause an undesired emphasis on noise. Another popular scaling method is Pareto scaling, which uses the square root of the standard deviation as the scaling parameter. If metabolites with moderate or small concentrations are important, then Pareto scaling tends to be useful as it is less dominated by noise.

Principal component analysis (PCA)
The goal of principal component analysis (PCA) is to eliminate the noise-associated variance and reduce the dimensionality.
of complex spectral data sets. In metabolomics research, the unsupervised method of PCA usually is the first multivariate analysis applied to the data to detect possible clusters and outliers in the sample set. PCA refers to a method that builds linear multivariate models of complex data sets. The PCA model is built on the basis of orthogonal vectors, in other words, eigenvectors. The central step of PCA is to solve for the eigenvectors and eigenvalues of the covariance or related correlation matrix. The covariance matrix X' calculated from the original data set X usually is computed using the following expression:

\[ \mathbf{X'} = \mathbf{X} \mathbf{X'} \]

The eigenvectors of X', or principal components, are calculated and then arranged in decreasing order according to their corresponding eigenvalues. Usually the first several principal components will explain most of the variance generated in the whole data set X. The rest of the PCL, which mostly contain noise, will form the residue matrix E. Thus, PCA acts as a powerful data reduction method.

The results of PCA can be written in the following matrix equation:

\[ \mathbf{X} = \mathbf{TP} + \mathbf{E} = \mathbf{t}_1 \mathbf{p}_1 + \mathbf{t}_2 \mathbf{p}_2 + \ldots + \mathbf{t}_k \mathbf{p}_k + \mathbf{E} \]

where the score matrix T contains all the projection scores of spectra in the data matrix X on the chosen PCs, and the loading matrix P is the ranked eigenvectors according to their corresponding eigenvalues. The scores \( t_1 \), \( t_2 \), which correspond to the first two PCs (\( p_1 \) and \( p_2 \)), usually are used to provide an overview of all data in the form of a scatter plot. The original data set is projected onto the PCA model for consistency and is performed by dividing the samples into subsets, generating a statistical model based on one subset, and testing or validating the model on the other subset. Next, new observations are projected into each PCA model and the residual distances are calculated to assign the class membership of each observation. The SIMCA model is constructed on a training set. Once the model is defined, a separate data set is used for testing its accuracy.

**Partial least squares (PLS)**

Another popular method of projection is partial least squares (PLS), which uses two data matrices X and Y. The two data matrices can be, for example, different spectroscopic measurements or different omics data from the same sample set. As a bilinear model, PLS fits data matrices X and Y and recasts these data as score plots, loading plots, and weight plots. Similar to PCA, the PLS score plot is generated by projection onto the new coordinate system. The only difference is that the selection of the axis is based on the regression of X against Y. Compared to PCA, the PLS model seeks to maximize the variances from both X and Y matrices.

In particular, when Y has only one variable that contains the group assignment of each sample or measurement, PLS always is referred to as PLS-DA (partial least squares-discriminant analysis). In this case, Y is called the “dummy matrix.” As a supervised method, PLS-DA modeling establishes the difference between preassigned sample groups. PLS-DA is performed to maximize the separation among classes and to identify distinguishing features or potential biomarkers.

For example, when building a PLS-DA model of male and female biofluid samples, the class membership of each sample is input into the Y matrix as a dummy variable (i.e., 0 = male; 1 = female). Corresponding loading plots (of LVs) largely reflect the effects that result from gender (52). Typically, models based on supervised methods such as PLS-DA require validation that uses an additional sample set because of the ease and danger of overfitting the initial trial sample data. Careful and rigorous validation is necessary to avoid the common problems related to overfitting that seem to be too prevalent in supervised statistical studies in metabolomics.

**Soft independent modeling of class analogy (SIMCA)**

Introduced by Wold (53), soft independent modeling of class analogy (SIMCA) first uses PCA, which is performed individually on each class. The PCA scores and loadings thus are used to define each class, with the number of principal components usually being preselected or decided by a cross-validation process (54). Cross validation involves the testing of a data set for consistency and is performed by dividing the samples into subsets, generating a statistical model based on one subset, and testing or validating the model on the other subset. Next, new observations are projected into each PCA model and the residual distances are calculated to assign the class membership of each observation. The SIMCA model is constructed on a training set. Once the model is defined, a separate data set is used for testing its accuracy.

**kth nearest-neighbor analysis (KNN)**

kth nearest-neighbor analysis (KNN) is a method of classification based on the similarity within classes. Each spectrum can be treated as a point in a multidimensional space. In KNN, the Euclidean distance between every pair of spectra is calculated first. The class assignment of one sample is based on the majority vote of its nearest neighbors. K is a set of integers starting from one. The best choice of K also can be chosen by cross validation.

Beckonert et al. (55) performed a toxicologic metabolomics study in which they applied KNN for classification and prediction. All the urine samples collected from the subjects were measured using 1-D NMR spectroscopy and subjected to KNN analysis. Leave-one-out cross validation was used, and the same number of samples were chosen in the training and test sets. As the results show, KNN analysis resulted in a good predictability of liver and kidney toxicity (55).

**Orthogonal signal correction (OSC)**

The orthogonal signal correction (OSC) filter was developed to remove variations in the data matrix X that are uncorrelated to their corresponding eigenvalues. Usually the first several principal components will explain most of the variance generated in the whole data set X. The rest of the PCL, which mostly contain noise, will form the residue matrix E. Thus, PCA acts as a powerful data reduction method.

The eigenvectors of X', or principal components, are calculated and then arranged in decreasing order according to their corresponding eigenvalues. The scores \( t_1 \), \( t_2 \), which correspond to the first two PCs (\( p_1 \) and \( p_2 \)), usually are used to provide an overview of all data in the form of a scatter plot. The original data set is projected onto the PCA model for consistency and is performed by dividing the samples into subsets, generating a statistical model based on one subset, and testing or validating the model on the other subset. Next, new observations are projected into each PCA model and the residual distances are calculated to assign the class membership of each observation. The SIMCA model is constructed on a training set. Once the model is defined, a separate data set is used for testing its accuracy.
NMR-Based Metabolomics Technology in Biomarker Research

The Y data matrix (56). Especially when Y is a dummy matrix, the OSC filter is extremely useful for removing X variations that are orthogonal to class membership. Combined with PCA or PLS-DA, unwanted variation thus can be separated from signals of interest. For example, by applying OSC-coupled PCA and PLS-DA, circadian-related metabolic variation can be removed from the spectral data in the study of strain-related metabolic differences between two phenotypically different mouse strains (57). As with PLS, the use of OSC needs to be rigorously cross-validated, preferably with a new data set to avoid problems associated with overfitting.

**Statistics-assisted NMR spectroscopy**

In addition to the differentiation of sample subgroups, statistics also may assist in the improvement of the ability to detect a biomarker in NMR spectroscopy. Statistical total correlation spectroscopy (STOCSY) (58) takes advantage of the inherent colinearity of multiple peaks from a compound in a set of NMR spectra. Based on correlation alone, the identity of a metabolite with multiple correlated peaks can be determined. Statistical heterospectroscopy (SHY) (59) uses the Pearson correlation to combine spectroscopic measurements from NMR and MS on the same sample set and, thus, additionally improves the efficiency of the molecular biomarker identification. It also is possible to identify compounds metabolically related to known biomarkers using SHY, and this works across spectroscopic platforms (60).

**Advanced NMR Technologies**

New NMR methods have focused on simplifying and improving the interpretability of complex spectra for metabolomics studies. For example, a relatively simple approach such as liquid-liquid extraction to separate biologic samples into hydrophilic and hydrophobic fractions can improve the resolution (61). As an alternative approach, the selective-TOCSY experiment can focus the analysis on certain target molecules with much improved resolution and sensitivity compared with the normal 1-D NMR. A rather important technique, projected j-resolved spectroscopy, can be used to simplify the 1-D NMR spectrum by removing j-coupling effects (35). These two techniques are summarized in the following sections.

---

**Figure 4** PCA results of human urine samples from 20 healthy controls and 6 patients with IEMs: (a) the score plot and (b) the loading plot. When analyzed individually, well-known biomarkers for the IEMs are more apparent in the loading plots.
2-D J-resolved spectroscopy

J-resolved spectroscopy (J-Res) separates the chemical shifts and spin–spin couplings (J-couplings) along two (nontopolog- nal) frequency axes. Compared with a normal 1H-NMR mea- surement, the acquisition of J-Res spectra is time-consuming because of the 2-D data set, and typically requires 20-minute acquisition times or more (62). The projection of the J-Res spec- trum onto the chemical shift axis yields a proton-decoupled 1H-NMR spectrum. This projection can simplify greatly the spectrum of biofluid samples, especially in the region where peaks are highly overlapped, because J-coupling causes a high degree of additional peaks in the 1-D 1H spectrum. J-Res spec- troscopy therefore improves the spectral dispersion and thus is potentially useful when measuring complex biofluid samples in metabolomics (35). Figure 5 clearly shows the difference be- tween regular 1-D NMR and the projection of the J-Res (P-Jres) spectrum. For both types of measurements, PCA score plots show a distinct classification. However, the corresponding load- ing of the P-Jres data is much easier to interpret because of its simplicity. The only drawbacks of this approach are the long acquisition times and a loss in direct quantification compared with the 1-D spectrum.

Selective-TOCSY

Another promising NMR technique for metabolomics is selective-TOCSY (total correlation spectroscopy) (63). Selective-TOCSY is a 1-D pulse sequence that uses homonu- clear Hartmann-Hahn matching to transfer magnetization between protons through J-coupling (covalent bonds). In a typical 2-D TOCSY experiment, cross peaks can be observed among all J-coupled members within a molecule. Magnetization is transferred successively over up to seven bonds, as long as successive protons are coupled. The number of transfer steps can be adjusted by changing the mixing time and can be tuned from 1-2 bonds up to 5-7 bonds. A one-step transfer would give a spectrum very similar to a COSY spectrum. In the 1-D selective-TOCSY, an isolated proton usually is irradiated by using a selective pulse (shaped soft pulse) and magnetization is transferred through J-coupling from that 1H spin to the others in the molecule during the mixing time. All resonances from the same coupling system then may be observed after the detection period. The selective-TOCSY technique is highly useful in isolating certain components in the NMR spectrum of a complex mixture (63). Sandusky (64, 65) applied selective-TOCSY in a metabo- lomics study and showed that the classification of samples could be improved significantly. When differen- tiating sample groups using unsupervised PCA, species that have larger concentrations usually dominate the statistics. However, low concentration species also may be important. Selective-TOCSY may be used to emphasize such com- pounds by selectively irradiating their peaks without being overwhelmed by more concentrated, overlapping species. The effectiveness of selective-TOCSY is demonstrated in Fig. 6. It should be emphasized that the intensities of the selective-TOCSY peaks are affected greatly by the mixing time. However, if calibrated, the results can be quantitative, and the selective-TOCSY signals are proportional to the concentration. In summary, selective-TOCSY can be used to emphasize important metabolites, which may appear as low-concentration species, to achieve a better discrimination in metabolomics (64).

Applications in Metabolomics

A growing number of exciting applications for NMR-based metabolomics exists. A few areas of interest chosen from many are presented below to indicate the breadth of opportunities developing in the field.

Nutrition

The integration of metabolomics and nutritional science is one of the most natural applications of metabolomics. It is clear that metabolic variations in biofluids can result largely from dietary effects. By measuring the varying chemical compositions of biofluid samples, dietary factors that may contribute to the metabolic changes thus can be understood and controlled. For example, the metabolomics study of the effects of dietary supplements can provide useful information on the metabolic changes involved. A recent study compared the effects of black and green tea consumption on human metabolism as detected by NMR-based metabolomics. Urinary excretion of hippuric acid and 1,3-dihydroxyphenyl-2-O-sulfate was studied (66), and the presence of various amines in individuals who ate fish was observed also.

Dietary changes can be observed rapidly by using NMR-based metabolomics, as shown in a recent paper by Gu et al. (67) that focused on the study of rats by both NMR and MS approaches. Moreover, when developing models for disease detection, biomarkers must be distinguished from metabolic variations because of diet. For this objective, one approach is to identify certain metabolic pathways that are connected to dietary changes and use this information to distinguish these effects (67). Given the large changes observed, NMR-based metabolomics can play an important role in evaluating dietary effects in biofluid samples. To explore this issue, a human study was carried out by obtaining urine, plasma, and saliva samples from 30 healthy volunteers whose food intake was controlled and recorded during the study (68). Samples were analyzed us- ing 1H-NMR spectroscopy followed by PCA and PLSDA. It was found by PCA that interindividual variation in urine may be reduced by restricting dietary intake. However, this finding was not observed when measuring plasma or saliva. Moreover, the PLSDA score plot highlighted the metabolic changes over time, which indicates that the changes were largely because of creatinine in urine and acetate in saliva. Several possible nutri- tional studies can be contemplated, especially given the current and growing importance of studies that link nutrition with health and disease. However, to date, NMR-based metabolomics stud- ies have yet to exploit this rich research area fully.

Toxicology

NMR-based metabolomics has been applied very successfully to the study of toxicology (4, 11–13, 16, 50, 55, 69, 70), and many early metabolomics methods were developed for applications in this area (4, 71–73). The goal of toxicological studies is to find the organs that are affected by the toxin, the magnitude of the effect, and the mechanism by which the toxin alters the living system or its biochemical processes. When a living system is perturbed by certain toxic compounds, the altered concentrations of endogenous metabolites in biofluids can be measured by NMR spectroscopy and emphasized by multivariate analysis.

Typically, NMR-based metabolomics studies of toxicology are carried out on biofluids, especially urine, acquired typically from rodents. In a prototypical preclinical toxicity study, Han–Wistar (HW) and Sprague–Dawley (SD) rats were dosed with either hydrazine or HgCl₂ (74). Urine samples from control and dosed rats were collected and prepared for NMR measurements under the same protocol. PCA and SIMCA were used to evaluate the ¹H–NMR spectral data. Clear classifications in the PCA score plots were achieved between the dosed and control groups, as shown in Fig. 7. Biomarkers corresponding to each toxin were elucidated from the PCA loadings. It was found that several organic acids, amino acids, and sugars were altered in the case of mercury dosing, whereas taurine, β-alanine, creatine,
L-proline and 10 mM L-arginine with selective excitation on the proline (1.98 ppm). (c) Selective-TOCSY spectrum for a mixture of 10 mM defined: control, clear toxicologic lesion, and marginal lesion; as research subjects. For each study, three subclasses were pre-
responses to 147 toxins and treatments. Rats and mice were used
a database that would contain the NMR spectra of rodent re-
nitional collaboration between research institutes and pharmaceu-
tical companies (75). The objective of this study was to generate
the purpose of prediction. Using the model from the first three
doses, respectively. Several multivariate analyses were applied
to construct chemometric models. Although it was not possible
to define the toxic response for each of the toxins uniquely,
this database provides a comprehensive approach for the ex-
ploration of biomarkers in toxicologic screening and provides a
wealth of data on the metabolic toxic responses. More studies in
the area of toxicogenomics also were suggested by the project
coordinators.
As a result of the early metabolomics toxicology studies,
several methods were developed that now are used widely by
researchers in the field, including normalization (76), trajec-
tories, correlation methods, and so forth. (59, 77) NMR-based
metabolomics study of toxicology remains a vibrant area of
research.

Disease detection
NMR-based metabolomics also shows promise for detecting
molecular biomarkers of disease and for understanding the
biochemical disease processes. Although several studies have
identified interesting molecules, these putative biomarkers need
to be validated on a large sample size (many hundreds to
thousands of samples) before they can be used for clinical
diagnosis.
One promising application is the detection of metabolic dis-
eases such as a variety of inborn errors of metabolism (IEM).
Current standards of care include the routine screening of
newborn infants for 20–40 of the most common IEMs, typ-
ically using gas-chromatography with mass spectrometry de-
tection. However, borderline and undiagnosed cases require
the development of alternative approaches. It is hoped that
metabolomics-based approaches may improve the detection of
such difficult cases. NMR has been used to diagnose IEMs for
many years (31, 32), but the application of metabolomics-based
approaches may provide additional diagnostic power. Recently,
such a study has been carried out by using blood spot sam-
pies for the detection of phenylketonuria (PKU) and maple
syrup urine disease (MSUD) (44). Samples from patients and
healthy controls were measured by 1-D CPMG NMR. PCA
was performed to discriminate healthy and disease samples.
A similar study involved the diagnosis of phenylketonuria (PKU)
and maple syrup urine disease (MSUD) (44). Samples from patients and
healthy controls were measured by 1-D CPMG NMR. PCA
was performed to discriminate healthy and disease samples.

4.5 4.0 3.5 3.0 2.5 2.0 1.5 ppm

PROLINE
Serum samples were used for the 1-D 1H-NMR measurements. The PCA score plot could classify all serum specimens from the 38 patients with EOC from all of the normal samples and from all the sera from patients with benign ovarian disease. Also, it was possible to separate 37 of 38 (97.4%) cancer specimens from 31 of 32 (97%) postmenopausal control sera. SIMCA was used to provide a validation for the classification. Particularly, by applying ROC (receiver operating characteristic) analysis, it was found that the lipid signals at 2.77 and 2.04 ppm and 3-hydroxybutyrate were altered in the EOC samples, although the two lipid signals were not associated with particular metabolites.

Disease detection using NMR-based metabolomics currently is extremely promising and potentially very useful. Many diseases such as cancers, type II diabetes, and heart diseases cannot be detected easily in their earliest stages. Many validated biomarkers such as CA125, a protein that is found to be elevated in some cancers, are not very sensitive or specific. Along with the development of better protein-based tests, metabolomics provides promising, noninvasive, and cost-effective approach with competitive accuracies. However, metabolomics seems to provide a validation for the classification. Particularly, by applying ROC (receiver operating characteristic) analysis, it was found that the lipid signals at 2.77 and 2.04 ppm and 3-hydroxybutyrate were altered in the EOC samples, although the two lipid signals were not associated with particular metabolites.

For the future, more advanced NMR and statistical methods are likely to appear. In addition, the combination of highly sensitive mass spectrometry with NMR spectroscopy in various ways provides several new avenues for development (59, 60, 78). Both NMR and MS provide unique metabolic profiles and can be combined to explore novel biomarkers that may not be identified easily with a single method. In the longer run, this combination of methods may show more potential to correlate metabolomics extensively with proteomics and genomics, although this problem has been an overwhelmingly challenging problem to date. In summary, NMR-based metabolomics likely will provide an extremely useful approach for the investigation of key problems in systems biology.

Summary

The field of metabolomics is growing rapidly and attracting increasing interest. NMR-based metabolomics, sometimes coupled with other analytical methods, has broad appeal and a promising future for many applications. The common objective in metabolomics is the selection of a set of reliable, key metabolites that can be used to identify and follow changes in biologic systems. In particular, NMR spectroscopy provides quantitative and reproducible measurements of the metabolic profile, whereas multivariate analyses are used to select important metabolites. For these purposes, more sensitive, reliable, and high-throughput analytical tools to perform metabolomics studies are highly desirable. New statistical tools, such as advanced multivariate analyses, will likely be developed and applied to different types of sample sets.

For the future, more advanced NMR and statistical methods are likely to appear. In addition, the combination of highly sensitive mass spectrometry with NMR spectroscopy in various ways provides several new avenues for development (59, 60, 78). Both NMR and MS provide unique metabolic profiles and can be combined to explore novel biomarkers that may not be identified easily with a single method. In the longer run, this combination of methods may show more potential to correlate metabolomics extensively with proteomics and genomics, although this problem has been an overwhelmingly challenging problem to date. In summary, NMR-based metabolomics likely will provide an extremely useful approach for the investigation of key problems in systems biology.

Combinatorial Libraries: Overview of Applications in Chemical Biology

H. Peter Nestler, Combinatorial Technologies Center, Tucson, Arizona
doi: 10.1002/9780470048672.wecb405

The sequencing of genomes gave access to the complete set of building blocks for organisms of various species. A plethora of "-omics" technologies has been developed to investigate the dynamic interactions of the building blocks to understand the functioning of living organisms. Synthetic molecules have proven to be powerful tools to modulate that states of biological systems, but the challenges to find suitable probes are tremendous. Combinatorial libraries allow preparing and testing diverse sets of molecules with high efficiency. In this article, we will discuss how combinatorial chemistry enables to investigate and modulate biochemical function in the quest to chart chemical and biological spaces.

The scholar disciplines of chemistry and biology have for a long time lived in separate academic universes, although they heavily depend on each other. Combinatorial chemistry started to bridge this intellectual gap by introducing the concept of diversity and selection into synthesis, which mimics biological evolution. It was triggered by the frustration of chemists trying to study biological systems with insufficient chemical matter. The recognition that chemical structures cannot be tailor-made to interact with biological space stimulated the development of methods for fast synthesis and screening of small molecules. Albeit combinatorial chemistry was recognized in its infancy as one basic pillar of the proteome into target families, assuming that members of the same protein family share structural features. This assumption holds true especially for enzymes and GPCRs but less though for proteases and ion channels, which are the four most common target families in drug discovery. Other protein families such as nuclear hormone receptors and transcription factors display even higher structural variations. However, chemical biology is also founded on the understanding of the biological function of the protein families, information about assaying as well as privileged ligand motifs that can be transferred from one target family member to another. Although combinatorial chemistry and chemical biology may seem to be opposite concepts, in reality they are highly complementary and interacting. Using the insights gained from chemical biology to bias the design of combinatorial libraries will help to assess a chemical space suitable to probe biological systems. In this article, we will discuss the roots of combinatorial chemistry, the technologies for generating and assaying compound collections, and studies performed on biochemical systems.

Chemical Biology—One Short Definition

Chemical biology covers many aspects of the influence of chemical molecules on biological function. In a broad definition, the understanding and investigation of toxicological effects, modulation of gene and protein expression, transformation and transport of the molecules in cell and whole organisms, and the change of the metabolic pathways and patterns are topics of chemical biology. With the definition below, we put a focus on one subtopic of chemical biology pertinent to the discussions in this article.

The sequencing of the human genome (1) marked the apex in the transition of biology from an observational and descriptive activity to a hypothesis-driven science. With the information about complete sets of building blocks for cells available, methods could be devised to group proteins on a structural level and to investigate the phenomenology of organisms on a molecular and structural level. Similarities in protein structures have been investigated for a long time, which cover all levels from primary (sequence) via secondary (domain folds) to tertiary (overall three-dimensional) structures. Investigations of tertiary structures help to predict functional sites and roles for uninvestigated proteins from their primary sequence. Especially through bioinformatic analysis, it has been possible to...
identify homologous reaction mechanisms even within proteins with lower sequence similarity and different biochemical functionality (2, 3), as highlighted by the cases of Leukotriene A4 hydrolase and angiotensin-converting enzyme (a zinc metalloprotease), which are both inhibited by bestatin but have distinct biological roles (4). Primary structure investigations have been preferentially of interest for evolutionary analyses. These phylogenetic analyses have been crucial in defining target families, which are groups of proteins that have a similar gene and therefore protein sequence, which lays the foundation for "chemical biology." Kinases are the prototypic target family as their active sites are structurally highly homogenous and bind the same co-substrate, adenosine triphosphate (ATP). Other gene families include G-protein coupled receptors (GPCR), ion channels and transporters, and proteases, although the structural diversity in these families is higher and they therefore group in structurally and mechanistically diverse sub-families, such as cysteine or metalloproteases.

Soon after the sequences became available, researchers discussed how many of the approximately 27,000 genes that had been assigned (1) would be "druggable" (i.e., their associated protein products could be modulated with small molecules in a directed fashion to achieve a desired physiological effect (5). For a small molecule to exert its biological action, it is crucial that the molecular shape of the molecule complements the cast offered by the target protein. This fact has been recognized first by Emil Fischer who phrased it as a "Key-Lock" principle (6), being unaware of the dynamic and flexible nature of protein structures. Today, we examine the interactions of two molecules more in a "Hand-Glove" fashion with strong elelements of induced fit (7). We term the ensemble of available interaction shapes in the proteome the "biological space," whereas the "chemical space" is considered the ensemble of shapes offered by small molecules. With our structural understanding constantly evolving through molecular biology and crystallography, the efforts to design matching chemical structures rationally have increased and led to successes in drug development; the HIV-protease inhibitors are one prime example. Rational design depends on structure-activity relationship to bias the contribution of various molecular motifs to the intermolecular interactions properly; therefore, it is powerful for the optimization and understanding of activity and selectivity on the protein target level. Rational design suffers shortcomings when we attempt to address the challenges of finding novel starting structures from scratch. High-throughput screening efforts try to tackle this challenge through engaging in a high-numbers trial-and-error game. As the screening collections reflect the target history of the respective company, they often cover narrow aspects of chemical space. This challenge is addressed by combinatorial chemistry.

Considering that most novel therapies would rely on oral administration of drugs, such molecules have to fulfill requirements to achieve suitable pharmacokinetic behavior. The most quoted and commonly used guidelines are Lipinski’s “Rule-of-5” (8) and Veber’s “rotational bonds” (9) that have been based on a statistical analysis of marketed oral drugs. Considering such boundaries, it has been estimated that about 10–15% of the human genome would be "druggable" (10). Although this number may seem low, it should be considered that only one third of these mechanisms are currently targeted, and a significant fraction of drugs, even those in development, still act through undefined molecular pathways. Furthermore, the hype around the sequencing of the genome and the assumed impact on drug discovery meanwhile has vanished, as it was recognized that biological networks are too complex and redundant to allow control through one molecular dial. Systems biology tries to address this challenge by exploring the interactions of proteins and the resulting pathways of transferring biological signals and actions. Chemical biology is the matching component in drug discovery that tries to synergize on structural relationships of proteins to address the druggable genome efficiently (11). Furthermore, the concepts of chemical biology are transferred towards the understanding of pharmacokinetics by identifying and investigating proteins that are involved in transport through the organism and the metabolic transformation of the molecules. Models to predict unwanted effects (commonly referred to as "toxicity" or "side effects") are developed based on our increased understanding of biological pathways and the proteins involved therein that may offer interaction sites for the molecules. As those investigations do not involve combinatorial chemistry approaches, they will not be topic of this article.

Chemical biology has reshaped all stages of the drug discovery and today is a widely used discovery paradigm in pharmaceutical industry. The focus as well as the impact of using targeted family knowledge has been on the early stages from target identification via structural understanding through lead finding efforts. The later stage of the drug-discovery process, which included the optimization of lead compounds into drug candidates, is not as amenable to technological solutions that can be provided through target family concepts as the challenges become very specific for each lead series. Still, transferring insights and understanding compound interactions with targets and other proteins help to avoid entering dead-end alloys of modification. However, the focus of this article will be on the biochemical level of chemical biology. Most chemical examples will be of peptidic nature, as most reports around the topic of this article are based on libraries derived from peptides, although this may change in the near future. The main theme of this article will be more on the general concepts and approaches than on specific molecules, but the interested reader can find a bounty of literature on specific molecules that modulate biological systems especially from a viewpoint of drug discovery.

**Combinatorial Libraries—A Brief Overview**

Historically, the art of chemical synthesis demanded that individual molecules are prepared efficiently with high yield and are extensively characterized. Over decades, more and more complex molecules were prepared by dissecting the target molecule at key reactive bonds, devising strategic options for the assembly, and developing novel reactions to address the synthetic needs. Although this "logic of synthesis" laid the foundation for
Combinatorial Libraries: Overview of Applications in Chemical Biology

Today’s capabilities to prepare a wide variety of conceivable target structures, it did not provide the numbers of molecules necessary for and efficient investigation of the “biological space.” The resolution of this conundrum required a conceptual rethinking by chemists. Assuming that our hypotheses about evolution are correct, the natural evolution of complex organisms occurred through generation of molecular diversity and selection and amplification of suitable structures. Today, we observe this process at a level of high structural complexity; genetic selection of alleles and somatic selection of antibodies are among the most prominent aspects. Thus, it was not too surprising that the concept of combinatorial chemistry was devised based on immunological challenges (12). To be successful in the game of evolution and life, four aspects have to be addressed: 1) generation of diversity, 2) compartmentalization of the individual members, 3) selection for desired properties, and 4) reproduction of selected members. The third aspect will be the topic of other articles, whereas the other aspects will be discussed here. We will not review the variety of chemistry possible for the preparation of libraries, which has tremendously developed over the last decade and has been comprehensively reviewed on a regular basis by Dröffe et al. (13).

**Synthesis of combinatorial libraries**

Biology handles diverse gene and protein populations by compartmentalizing the members in cells. The selected library members are amplified by growing clones of the cells that survive the selection step, which allows ultimately for the reporting of the structures for selected members through gene sequencing. The “yeast-two-hybrid” (14) or the “phage display” technique (15) are used to study protein/protein and protein/peptide interactions in vivo, and the “SELEX” technology allows for the in vitro evolution of short oligonucleotides, which are called aptamers, that interact with small molecules and proteins (16). Such biological libraries will not be topic of this contribution.

Synthetic molecules by amplified by growing clones, and chemists who handle libraries face two major problems: the compartmentalization of the individual library members and the determination of the molecular structure of the selected species (17). Three approaches have been devised to tackle these challenges:

1. **Spatial arraying of compounds during synthesis and assay**
2. **Synthesis of mixture libraries and deconvolution of active sublibraries**
3. **Encoding of particles carrying individual compounds to be tested**

Spatial arraying has been used traditionally for the assaying of historic compound collections. As the identity of the molecule is correlated to position in the array, this approach carries the least challenge for structural assignment for active array positions. As an additional aspect to ease the implementation of arrayed libraries, arrayed libraries are commonly handled as solutions. A most biological assays are based on homogeneous test systems, providing the libraries in solution is the obvious choice. Today the preparation of arrayed libraries in solution is mostly addressed through robotic means (which basically provides high-throughput parallel syntheses), but significant approaches are available to provide arrayed libraries by synthesis at predetermined locations of solid supports. The earliest experiments used functionalized polystyrene mounted on plastic rods, which were arranged in a 96-well microtiter plate format and were used for the synthesis of the libraries and the compounds were released into the wells for their biological testing (18). Various implementations of this strategy have been developed, such as spot synthesis on cellulose membranes (19, 20) or photolithographic wafer techniques (21). However, these techniques impose limitations on the numbers of compounds that can be prepared and usually the 96-well format is used to test sublibraries and mixtures of compounds. Instead, DNA and RNA libraries prepared through photolithographic technology are used more widely used in genomic diagnostics.) To ameliorate the restrictions caused by the spatial addressing, Berk and Chapman (22) devised a strategy for the generation of two-dimensional spatial arrays of compounds that allow for determination of synergistic effects of residues in the same molecules, which combines the advantages of solution-based biological assays with an efficient testing of large numbers of compounds.

Several groups have reported the generation of combinatorial libraries in solution (23–26) as well as the fractionation of complex libraries by HPLC (27). Although the handling of compounds and libraries in solution makes them more amenable to the formats used for biological tests, the task of elucidating the structures of the active compounds requires complex deconvolution through sublibraries. This task can be performed by simultaneous preparation of the required sublibraries that control residues in one or two variable positions, which is called “positional scanning,” or by subsequential narrowing of the options by repeated testing and resynthesis of the most active sublibraries with additional defined positions. Both approaches are based on the hypothesis that the most active compound in a library is defined by the combination of the most active moieties in the various positions. In that respect, the deconvolution approach is conceptually related to fragment-based approaches, that will be discussed later. Despite all doubts about the reliability of results that stem from the testing of complex mixtures, there have been successes to the deconvolution strategy, which have been reviewed by Houghton et al. (28). Most recently, the mixture screening and deconvolution was applied in vivo (29).

To avoid this caveat of screening mixtures and the identification of active compounds through deconvolution, approaches to compartmentalize the library on moieties of solid supports have been devised. Houghton (30) suggested the use of labeled “teabags” that contain peptide synthesis resin for the compartmentalization and tracking of the library members (30). This approach was modified by using radio chips for the labeling of the “tea bags” (31, 32), which allow the robotic sorting of the containers for synthesis and spatial arraying. Yet, the size of the bags still puts limits on the diversity of such combinatorial libraries. "Split synthesis" (33, 34) lifts the restrictions for the complexity of libraries by creating “one-bead-one-structure libraries” that display the individual library members separated on beads of a solid support. Successive cycles of distributing and
mixing portions of the support lead to a combinatorial increase of the diversity of structures contained in the library. As each bead of the resin reacts with only one set of reagents per synthesis cycle, each bead carries one individual structure, which is determined by the sequence of reactions that occurred during the synthesis. Library members that interact with the targets can be isolated by selecting beads detected in assays performed on the beads. However, the application was limited to peptides and oligonucleotides because of the analytical means of determining the structure of the molecules on the beads. Molecular encoding was the breakthrough that opened the way for the application of the whole repertoire of synthetic chemistry for generating combinatorial libraries by solving the problem of structure determination from a single bead: Easily detectable molecular tags are attached to the resin beads as they proceed through the split synthesis during the library construction, which thereby records and reports the reaction history of each individual bead (35) (corresponding to the genetic coding of proteins in cells). After screening the library, these molecular tags are cleaved from each selected bead and then analyzed to report the structures of the library members on these beads. Several encoding methods are currently in use, which include microsequencable oligonucleotide (36) or oligopeptide strands (37, 38), as well as nonoligomeric schemes that employ small molecules that can be analyzed by gas chromatography (35, 39), HPLC (40), or mass spectrometry (41).

Fragment screenings and dynamic combinatorial libraries

In recent years, two variations of combinatorial chemistry approaches have been explored that do not present preassembled molecules to the biological target (42). Both variations make use of the detection of interactions instead of using biochemical inhibition as a readout. One approach, "fragment screening," uses fragments/building blocks of the molecules and relies on the detection of low-affinity interactions. Several detection approaches have been described, based on NMR (43), cocrystallization (44), or surface plasmon resonance (45, 46). The second approach, which is called "dynamic combinatorial chemistry," relies on forming the complete molecules from fragment in presence of the target molecule and enriching molecules with high affinity in the equilibrium reaction (47). This approach has been applied to generate artificial receptors for peptides (48, 49) as well as inhibitors for enzymes with detection by cocrystallization (50).

Mapping Enzymatic Activities

One key aspect of applications of combinatorial libraries in chemical biology is the mapping of substrate specificities for enzymes. Although the early studies that use peptide libraries were focused on studying antibody epitopes (12), the substrate mapping for enzymes that transform peptides and the development of molecular probes found widespread interest.

Proteases

The earliest applications focused on proteases. The major challenge that had to be tackled was the generation of a read-out signal. Although most protease assays rely on generating a chromophoric or fluorophoric molecule on cleavage from the carboxy-terminal amino acid (e.g., nitrophenyl, coumarins), this method was not applicable to the screening of peptide libraries as the cleavage does not necessarily occur at the carboxy-terminus of the sequence. The problem was resolved through the introduction of fluorophor-quencher pairs at the ends of the peptide sequence. As long as the peptide is intact, the quencher at the distal end of the peptide suppresses the fluorescence. After cleavage, the quencher diffuses away from the support, and the support becomes fluorescent because of the fluorophor at the proximal end of the peptide (51, 52).

Another challenge that had to be addressed for the screening of proteases was the penetration of the supports and its handling in aqueous environment during the assays. The classic supports used in peptide synthesis show a limited amount of swelling and penetration by proteins in aqueous environment, which makes only peptides on the surface accessible for study (this behavior was used to develop a molecular encoding approach by discriminating surface and interior positions of the bead (53)). Grafting of hydrophilic chains of polyethylene-glycol and preparation of supports based on cross-linked acrylamide yielded supports that could be handled in organic solvents for synthesis and water for assaying (54). With all these different approaches in hand, substrates for all protease subfamilies have been identified from combinatorial libraries (55–59), but the application of the data has been extended the most for cathepsins (60). Based on the sequence information obtained, Greenbaum et al. (61) designed inhibitors by incorporating the epoxide motif from E-64, which is a well-known unspecific and irreversible cysteine protease inhibitor. These inhibitors allowed pulling down various cathepsins from cell extracts or labeling them with some selectively using fluorescently labeled inhibitors, which thus fingerprinted cathepsin activity in cells. The surprising observation in these studies was that specificity could be instilled into the inhibitors starting from the unspecific E-64 by attaching it to the various substrate sequences. The latest step forward was the demonstration that these substrate based inhibitors can be used to monitor cathepsin activity in living mice. The inhibitors were generated using an acyloxymethyl ketone-inhibitor motif, which acts as a suicide substrate. The two sides of the substrate were labeled with infrared fluorescent dyes and a quencher and were injected into the tail veins of mice xenografted with tumors that express high levels of cathepsins B and L. The inhibitor became fluorescent on cleavage, and the labeled cathepsins allowed a distinct imaging of the tumors (62). The use of covalent inhibitors offers the advantage of localizing the fluorescent signal to the locus of generation as the diffusion of the signal is limited by the slow diffusion of the cathepsins. Recently, a new approach based on substrates was described, which will lead to the ability for fast real-time monitoring of proteases in vivo (63).
The screening of combinatorial libraries for kinases faced another challenge. Whereas kinases allow the straightforward generation of a readout signal on peptides through the transfer of radioactive (32P)-ATP, the association of the radioactive signal to individual members of highly diverse libraries posed a problem. Autoradiography using photographic film was used to visualize groups of beads immobilized in agarose gels, and individual beads were isolated through repetitive steps of isolation of beads from the gels and dilution, which made the process work intensive (64, 65). The process was dramatically simplified by embedding the beads directly into the photographic emulsion, which allowed for the microscopic identification of individual radioactive beads (66, 67). The other approaches for library preparation and screening like positional scanning (68) or arrayed synthesis (69) were successfully applied as well.

For the main purpose of the kinase chemical biology of routine profiling and substrate identification in a high-throughput mode, the array synthesis seems to be established because of the ease of readout. Recently, a novel approach lifted the need of using radioactive ATP for the screening for tyrosine-kinase substrates. The library of fluorescein-labeled peptides is encoded with PNA tags and incubated with a kinase. The peptides are then incubated with a DNA-microarray that complements the PNA strands of the individual peptides in solution. After such attachment of the peptides to the array, the array is treated with a phosphotyrosine-recognizing antibody sandwich, which carries the fluorescent dye Cy3. The microarray is then read out at two wavelengths to allow the detection of fluorescein and Cy3. The quantitative determination allows for a sensitive calibration against PNA/DNA complexation differences and the identification of kinase substrates (70).

Unlike in the protease field, the straightforward translation of kinase substrate information into inhibitors by using non-cleavable phosphate mimics (71) and their use for biological investigation has been limited due to the substrate size and the challenges for biological application. Most kinase inhibitors target the ATP-binding pocket and the associated hinge region, and their use has been found mostly in drug discovery with detailed pharmacophore insights (72). After the sequencing of the human genome (1), the use of substrate sequence information has been successful for the identification of kinase substrates (70). Most kinase inhibitors target the ATP-binding pocket and the associated hinge region, and their use has been found mostly in drug discovery with detailed pharmacophore insights (72).

Phosphatases and other enzymes

Conceptually, the screening for the substrates of proteases and kinases is rather straightforward, as both enzyme classes allow for detection by either fluorescence or radioactivity of their altered substrates. Other enzyme classes are not that amenable and require more elaborate assay designs. Cheung et al. (73) described an elegant scheme to identify substrates for leukocyte antigen receptor (LAR) phosphatase. Although it may be conceptually envisioned to detect the substrates for phosphatases by reduction of radioactivity after hydrolysis of a radiolabeled phosphate, the screening of combinatorial libraries for signal differences proves to be unsuitable, because of the varied concentration of the individual members. Thus, all readouts for the screening of combinatorial libraries should be laid out to yield the appearance of an effect. The screen for phosphatase substrates capitalized on the stability of phospho-tyrosine peptides against proteolysis by chymotrypsin, whereas their dephosphorylated counterparts are very susceptible to cleavage.

A 186-bead combinatorial N-acetyl peptide library that features phosphotyrosine in the center of each peptide sequence was incubated with LAR. Subsequently, the library was treated with chymotrypsin, which led to the cleavage of peptides that had been dephosphorylated. The resulting free amino-terminal were derivatized with amine-reactive chromophores or fluorophores to visualize the individual beads. After sequencing a coding peptide strand on the beads, six substrates were identified. Each of these substrates shows faster dephosphorylation than one native substrate, which is the D_WGbpG_WGpeptide of the EGF receptor (73). Several enzyme classes have been targeted using the positional scanning approach, such as farneyl transferase (74) and β-glucosidase (75), the latter establishes that the screening of peptide libraries is not limited to enzymes that transform peptides.

Studying Protein–Protein Interactions/Whole-Cell Systems

The use of combinatorial libraries for the study of protein–protein interactions is currently focused on the diagnostics and the fingerprinting of interaction surfaces. The starting point for combinatorial libraries was the investigation by Lam et al. (12) of antibody epitopes with a one-bead-one-compound peptidomimetic library. An α β-endorphin antibody recognized only 6 peptide sequences out of 2.5 million possible sequences. The intellectually intriguing aspect of the study was the use of an antibody as a biological probe; antibodies are the prime example for somatic combinatorial chemistry in biological systems.

The same study also demonstrated that combinatorial chemistry can identify ligands to proteins that are unrelated to the natural ligands. The tripeptide IPPN was the privileged binder to streptavidin, and competition experiments clearly showed that it binds at the same site as biotin.

From the screening for antibody epitopes it was a short step to address another larger class of cell-surface molecules, which is called GPCR. Using a 5000-membered dinner and trimer-peptidomimetic
IN-alkylated glycine polymers library, new ligands to adrenergic and opioid receptors were discovered. The peptoids discovered as ligands to the adrenergic receptor carry three aromatic residues and thus mimic an ephedrine polymer; the peptoids discovered for the opioid receptor resemble Met-enkephalin. Sequences for both receptors are very lipophilic, which points to a challenge that affects many library screenings. However, both types of sequences are nanomolar antagonists for their respective receptors (76). In an interesting twist, Spatola et al. (77) designed a cyclic peptoid library in a way that only one round of screening was necessary to deconvolute the most active peptoid sequence. The library contained 82,944 peptides in 48 sublibraries with various defined positions. One round of screening revealed the cyclo-Pro-D-Val-Leu-D-Trp-D-Asp(T) sequence as the most active antagonist of endothelin 1. This sequence already had been established earlier from a microbial peptide (77). Although the concept of self-deconvolution is very intriguing, the effort in design and limitations on diversity prevented further widespread application of this approach. Combinatorial libraries have also allowed to look into the intracellular side of GPCRs. Martin et al. (78) studied the interaction of the G-protein α subunit with Rhodopsin using a 11-mer peptide library displayed on phage. After several rounds of binding to rhodopsin-load membranes and amplification of the phage, several sequences similar to a sequence in the carboxy-terminus of the G-protein α subunit could be identified. After resynthesis, these sequences bound to rhodopsin and helped to stabilize the meta-II rhodopsin state. Yet, phage-display libraries are not crucial to the study of intracellular protein–protein interactions. One of the most common motifs in protein–interaction domains is the Src homology 2 (SH2). This domain is an integral part in kinase-signaling binding to the phosphorylated peptides. Thus, peptides that bind to the SH2-domain could be valuable tools for dissecting the cellular-signaling cascades. Sweeney et al. (79) used a hexapeptide library while carrying a phospho-rylserine in the center. The library beads were incubated with various biotinylated SH2-domains and the SH2-binding beads were visualized using streptavidin conjugated alkaline phosphatase. Sequences binding selectively to the SHP-1, SHP-2, and SHIP-2 SH2-domains could be identified. Furthermore, the resynthesized peptides could be used to pull down the full-length proteins from cellular extracts. The peptide sequence information was used to search for binding partners to the respective SH2-domains in genomic databases, which identified known proteins and a variety of hitherto unknown binding candidates.

For routine diagnostics in which the number of probes to be tested is smaller than in a de novo interaction screen, arrayed libraries show the higher potential because of the simplified handling. Today, these libraries are produced by spotting the libraries on microscope slides that can be read out in fluorescent microscope readers after assaying. Reddy et al. (80) reported a study that fingerprinted three different proteins against an array of 7200 octamer peptides. Each protein showed distinct interaction patterns, although the peptoid library was naïve against the proteins. Using scatter plots of the interaction intensities, clear dependencies of detection approaches (direct labeling of protein vs. antibody detection) in the read outs could be found. However, the quality of the assays and the ease of handling makes the approach using peptoids promising as a complementation of DNA and protein arrays used in diagnostics today.

One of the most recent examples of combinatorial library applications comes back to the theme of in vivo imaging discussed earlier in the protease section. A one-bead-one-compound library of urea-capped octapeptides built around a central LDV-motif was screened against JURKAT cells. Beads were selected based on observed cell adhesion under a microscope, and the compounds on these identified beads was characterized by EDMAN sequencing of encoding peptide tags in the interior of the beads, which yields only to different sequences. Because of the biasing with the central LDV motif, these compounds showed high affinity and specificity to αvβ3-integrin. After complexation with the NIR dye Alexa680-streptavidin conjugate, the peptides were used for the imaging of various tumors in nude mice. Tumors that expressed the αvβ3-integrin became fluorescent, whereas tumors not expressing the integrin did not provide imaging signals (81).

Most recently, the utility of combinatorial libraries in proteomics was demonstrated by enriching platelet proteins. Using columns loaded with a combinatorial peptide library, low abundant proteins from platelet extracts could be enriched through capturing and eluting them. The diversity of the library allowed capturing proteins without knowledge of their identity and binding partners. Using two different libraries, 175 new proteins could be identified and sequenced (82).

**Modulating Biological Systems—Artificial Receptors**

Traditionally, the approach to interrupting biological processes aims to find small molecules that fit into a binding site offered by one binding partner. This approach has been and still is very successful for drug discovery. Combinatorial chemistry opened the way to another approach for the modulation of biological processes. For the first time, it became possible to develop receptor molecules for peptides without detailed knowledge of the peptide conformation and without intricate design for the rigidification of the receptor and fitting of the intermolecular interactions. Using cheno(12-deoxy)cholic acid as a scaffold to orient combinatorial decapeptide chains, Boyce et al. (83) identified receptors that would bind and distinguish Leu- and Met-enkephalin, which are two pentapeptides. Thus, it became conceivable that one could prevent an enzymatic transformation by trapping the substrate instead of blocking the active site of the enzyme. The viability of the approach was shown on the example of the farnesyl transferase inhibitors. Farnesyltransferase inhibitors have been under preclinical and clinical investigation for a long time, but they suffer severe unwanted side effects, as a plethora of other
proteins require the farnesylation of their respective CaXX-box sequences. Although these sequences are similar enough to be transformed by the same enzyme, each protein carries its characteristic CaXX-sequence. Using a library of receptors based on four identical combinatorial tetrapeptides that grew from a trilysine scaffold, receptors that recognize the CVLS-sequence of H-Ras could be identified in an on-bead screening assay. 

After resynthesis, these receptors suppressed the farnesylation of H-Ras, while still permitting the farnesylation of K-Ras (CVM) and Laminin (CAVM) (84). One receptor prevented the localization fluorescent GFP-H-Ras to the cell membrane after microinjection into Xenopus eggs, which demonstrated the use of such receptors and molecular biology tools. In another demonstration of this approach of “epitope protection,” Zhang and Kodake (85) showed that a linear 15-mer peptide identified from phage-display library can bind to the cleavage site of interleukin-1β. This cleavage site is prototyped by Caspase-1, which is a key initiator of intracellular processes. A subset of the key switches for inflammation and apoptosis, Caspase-1 has a broad substrate specificity, which has made the therapeutic development of Caspase-1 inhibitors very challenging. The identified peptide could suppress the cleavage of interleukin-1β, while at the same time having no effect on the catalytic activity of Caspase-1, one of the key factors in Caspase-1 mediated signaling (85). Yet, not only peptide epitopes can be recognized with peptide derived receptors. Using the same combinatorial receptor library as in the H-Ras study (see above, (84)), Fukase et al. discovered receptors for liposaccharides (86). Echerichia coli Lipid A, which is a strong endotoxin, is responsible for inflammatory and lethal septic events during bacterial infections. Thus, molecules that absorb the endotoxin could be of high therapeutic value. In another affinity screening, tritium-labeled Lipid A analogs were equilibrated with the library, and beads that bind the radioactive liposaccharides were visualized by microscography. Decoding of the binding beads and resynthesis of the respective receptors yielded “molecular forceps” that can bind and distinguish the various Lipid A analogs, whereas another E. coli liposaccharide, O111:B4 LPS, was not recognized by the forceps (86). The field of using artificial receptors to camouflage enzyme substrates or to absorb toxic biologicals is still in its infancy, and no biological activity of artificial receptors beyond the cellular level has been reported to date. Yet the ability to generate and identify receptor molecules that show binding properties similar to antibodies opens intriguing avenues to chemical tools for the study of molecular biology. Once we learn how to handle the tools provided by combinatorial libraries, we will have access to a tool chest for the investigation of cells and organisms at the molecular level, the key aspect of chemical biology.

Epilogue

The use of combinatorial libraries in chemical biology is plentiful. This article focused on the plethora of possibilities and challenges in a fast developing field, which highlighted some achievements. With the evolution of synthetic repertoire and analytical technologies, high-throughput screening starts to move from structurally related libraries as discussed here to libraries assembled from historic collections. With the increased diversity of structures, we will observe many more molecular tools for chemical biology. As many efforts are focused on drug discovery, one should also expect novel therapeutic approaches based on our increased understanding of chemical and biological spaces and networks.

Fluorescence spectroscopy in all of its variations can be considered among the most powerful types of analysis available to chemical biology. However, to be useful almost all applications are dependent on optimal labeling of biomolecules with a fluorophore and on the appropriate choice of analytical technique. In this article, we examine the applications and contributions of fluorescent spectroscopy to chemical biology in three inter-related sections. We first examine the properties of the common fluorophores available from many disparate structural and functional classes, which includes a discussion of their individual benefits and liabilities in the context of their application. The available conjugation chemistries used to attach fluorophores to myriad biomolecules are next reviewed. As each class of biomolecule differs in both structure and function, the focus here is on strategies for the specific labeling of different functional groups. Last, some major types of fluorescent spectroscopy and the associated biologic questions and analysis that can be addressed with them are covered briefly.

Fluorescence can be defined as the emission of a photon from an excited singlet state electron returning to the ground state orbital of a molecule where it is paired with, but of opposite spin to, the second ground-state electron (1). Fluorescence, although it typically originates from molecules containing multiple double-bonded aromatic groups, can also be emitted from many structurally diverse substances. The power of fluorescent analysis results from the ability to label myriad biomolecules with fluorophores (or to use their intrinsic fluorescence), discretely excite and visualize them in a heterogeneous sample, and then monitor their function either in vitro or in vivo with a variety of different techniques. For the purpose of this review we define chemical biology as “applying the tools of chemistry to the understanding of biological problems” and focus in this article on the diverse classes of available fluorophores, their labeling chemistries, the predominant fluorescent techniques in use, and some biologic questions that can be answered by their application. As fluorescence is a diverse and complex discipline, an in-depth description of each aspect is beyond the current scope; the focus here is more a generalized overview of fluorophore structure/function, fluorescent applications and important considerations within a chemo-biologic context. The continuing challenge in this field remains in labeling the biologic molecule(s), both in vivo and in vitro, in a specific manner such that useful data can be derived from the configuration. Fortunately, many fluorophores are available commercially along with affordable instrumentation (2). Interestingly, the most popular application of fluorescent labeling is in microscopy, for example, antibody labeling or in situ hybridization, and the many facets of this particular technique are discussed in other related articles. Additionally, myriad other prominent analytical techniques rely on fluorescent detection,
including fluorescence activated cell sorting (FACS), real-time polymerase chain reaction (PCR), and various microarray analyses, all of which are covered to some extent in other articles. For the interested reader, Lakowicz’s Principles of Fluorescence Spectroscopy can be considered the primary go-to reference for almost all questions on fluorescent analysis, including history, theory, basic and advanced concepts, techniques, fluorophores, instrumentation, and applications (1). Although primarily a catalog of fluorophores, Haugland’s The Handbook, A Guide to Fluorescent Probes and Labeling Technologies is another excellent resource (available from Invitrogen, Carlsbad, CA) (2).

Properties of Common Fluorophores

Fluorophores come in a huge diversity of structures based on the materials they are derived from and can be divided into three primary classes: organic, inorganic, and biologically derived materials. Fluorophores manifest many intrinsic physical properties that are exploited in the various experimental formats, which includes their absorption/emission profiles (spanning the UV-to-near-infrared (IR) regions of the electromagnetic spectrum), varying fluorescent lifetimes, stokes shifts and quantum yields, and in some instances their sensitivity to their local environment. The exact choice of fluorescent probe for a particular application obviously depends on several factors, including the nature of the system under investigation, the question to be addressed, the pertinent biolabeling chemistries, and the available analytical instrumentation.

Biologic materials

Amino acid fluorophores

Biologic materials are a class of fluorophores that can range from amino acids and enzymatic cofactors to fluorescent proteins. As their fluorescence originates from their structures, they are sometimes referred to as intrinsic fluorophores (1). The aromatic amino acids, tryptophan (Trp), tyrosine (Tyr), and phenylalanine (Phe) are the simplest structural class of these fluorophores and are ubiquitous in most naturally occurring proteins (see Fig. 1a). The UV absorbance at 280 nm, which is commonly used for protein quantitation, and the resulting emission at 340–360 nm originates mostly from the indole ring of the tryptophan residue (1, 3). Tryptophan emission also reflects the polarity of its local solvent environment and can be sensitive to the binding of substrates/ligands, protein-protein association interactions, protein denaturation, and global conformational changes in structure (1, 4–6). These interactions can be used for protein characterization and sometimes can form the basis of certain types of biosensing (see below). Because of its UV emission, tryptophan has also been used as a donor in various fluorescence resonance energy transfer (FRET) studies examining intraprotein distances and conformational changes (3). Phenylalanine has a low quantum yield, and tyrosine residues are less prevalent in proteins and have been far less used for fluorescence.

The advent of recombinant DNA technology has enabled researchers to introduce these three residues into any desired site(s) within a cloned protein for potential fluorescent usage. It is particularly advantageous for FRET configurations in which optimal placement of a donor fluorophore is desired (2). Although it is an advantage in some cases, the widespread occurrence of these residues in almost all natural protein structures can also be considered a disadvantage, especially in applications in which observing a specific protein in a heterogeneous environment is desired. A further potential disadvantage includes excitation confined to the UV region, which can result in high background signals from scatter and autofluorescence within cells or other biomolecules in a sample matrix.

Fluorescent cofactors

Enzymatic cofactors, such as nicotinamide adenine dinucleotide (NADH), nicotinamide adenine dinucleotide phosphate (NAD(P)H), flavin adenine dinucleotide (FAD), flavin mononucleotide (FMN), and pyridoxal phosphate, are fluorescent and commonly found associated with various proteins where they are responsible for electron transport (see Fig. 1b and Table 1). NADH and NADPH in the oxidized form are nonfluorescent, whereas conversely the flavins, FAD and FMN, are fluorescent only in the oxidized form. Both NADH and FAD fluorescence is quenched by the substrate found within their cofactor structures, whereas NADH-based cofactors generally remain fluorescent when interacting with protein structures. The fluorescence of these cofactors is often used to study the cofactors’ interaction with proteins as well as with related enzymatic kinetics (1, 9-12). However, their complex fluorescent characteristics have not led to widespread applications beyond their own intrinsic function.

Fluorescent proteins

Fluorescent proteins (FPs) are a class of fluorescent probes of which green fluorescent protein (GFP) from the jellyfish Aequorea victoria is probably the best characterized and can be considered the prototype (13-16). Their utility is derived primarily from the ability to append genetically and to coexpress these proteins as a chimeric fusion with a desired target in a wide range of host cells, including bacteria, lower eukaryotes such as yeast, almost all higher eukaryotic cells, and even within transgenic animals (17). This process makes FPs, in general, a very powerful chemical biology tool for many applications, including in vivo labeling of specific proteins in cells as well as monitoring of intercellular signaling and intracellular processes (18-25). Beyond basic research, many FPs are used in a variety of applications related to drug discovery. The field has progressed rapidly to the point where now several GFP variants exist, such as blue, cyan, yellow, and various dimeric (Ds) and monomeric (m) red fluorescent proteins (BFP, CFP, YFP, DsRed, mRFP) (26-28). Continued cloning from many different species, including coral (29), in conjunction with functional optimization has led to a variety of commercially available FPs with emission maxima that range across the spectrum from 470 nm to 630 nm (Fig. 2). Tsien’s monograph on the green fluorescent protein is perhaps the best source in many important photophysical considerations when using all fluorescent
Fluorescent Labeling and Fluorescent Spectroscopy: Overview of Applications in Chemical Biology

Proteins (14). Issues of relevance when using FPs include size, maturation time; absorption and emission shifts; sensitivity to pH, O₂, temperature, and certain ions; obligatory dimerization or oligomerization; optimal placement; and photobleaching (21, 26, 30). Another important consideration, when appending such large fluorescent probes onto a protein of interest, is verifying that the primary function/activity of the endogenous parent protein is not perturbed in any way (20, 21). Rationally designed FRET sensing in live cells to monitor signaling events would not have been possible without the ability to append genetically these FPs to species of interest, with some commonly used FRET FP pairs, including GFP/BFP and CFP/YFP; see below (3, 13–18).

Phycobiliproteins, such as phycocyanin and phycoerythrin, are members of a family of fluorescent accessory, non-chlorophyll-based pigments found in cyanobacteria and eukaryotic algae. The phycobiliproteins have characteristic broad absorption profiles spanning 450–600 nm, emissions ranging 570–660 nm, and small stokes shifts; see Fig. 3. The major structural subunits, phycoerythrobilin (PEB) or phycocyanobilin (PCB), have multiple covalently attached bilin chromophores (open chain tetrapyrol, between 6 and 34) per moiety, which result both in the large molecular weight (∼10 times that of GFP) and a remarkable extinction coefficient (∼100 times that of GFP). The strong brightness and photostability of these fluorophores have led to their wide use as a very sensitive probe (31, 32). Although appearing to succumb to classic photobleaching under constant illumination, the loss of specific fluorescence of some phycobiliproteins, such as B-phycoerythrin (B-PE), may actually be from the exciting of more than one chromophore per protein that can annihilate the excited state and decrease the quantum yield (1, 33). These FPs are currently available from several commercial sources (Martek Biosciences Corporation, Columbia, MD; Invitrogen; Cyanotech Corporation, Kailua-Kona, HI; and Europa Bioproducts Ltd., Brussels, Belgium) and are commonly conjugated to antibodies or streptavidin for use in a variety of immunoassay and other detection formats.

Phytochromes are a family of bilin binding proteins that function as photoreceptors, regulating many physiologic processes.

†Quantum yield added where available; the quantum yield and fluorescent lifetimes can be highly dependent on the local environment. A fluorophore free in solution may have a different quantum yield than the same fluorophore attached to a protein, which in turn also depends on the extent of protein-to-fluorophore labeling (1–3).

‡Sigma-Aldrich Product # 71603 Ru(bpy)2(phen-5-isothiocyanate) (PF6). In plants, cyanobacteria, and other microorganisms (34, 35). Unlike their light harvesting phycobiliprotein counterparts, native phytochromes binding their natural bilins (phytochromobilin or phycocyanobilin) result in a nonfluorescent conjugate caused by deactivation by an efficient double-bond isomerization. If, however, the apophytochrome is allowed to bind phycoerythrobilin (PEB; found naturally in phycobiliproteins), a highly fluorescent protein results, which is referred to as a phyfluor (36). These proteins have large extension coefficients, high quantum yields (0.7), and good photostability and pH stability. Highly fluorescent proteins can also result from site-directed mutagenesis of the apoprotein while maintaining the natural bilin (37). In contrast to phycobiliproteins, phytochrome-based FPs have not found widespread application as fluorescent probes primarily because in their natural form, they are not fluorescent and only become so through either genetic mutation of the bilin binding site or insertion of a non-native bilin.

Enzyme-generated luminescence

Chemiluminescence and bioluminescence are unique processes in the sense that the excited state species is generated enzymatically through a chemical reaction rather than photophysically. Although closely related, chemiluminescence (CL) originates from reactions with synthetic substrates. Both processes result from an enzymatically catalyzed reaction that generates an excited state chemical product that decays to produce light emission, generally between 400 nm and 550 nm (3). Although a variety of BL and CL enzymes/substrates combinations are available from which to choose, the firefly Luciferase/Luciferin pair is the most commonly exploited BL reporter system and Horseradish peroxidase (HRP) is the most popular CL system (3). BL and CL are dark field techniques, which means they do not require an excitation source, therefore, reducing the background fluorescence and greatly improving the sensitivity and potential limits of detection (LODs) when used for detection. BL/CL have been applied widely, including in microarrays and nanoarrays, in vivo imaging ranging from whole animals down to single cells, in numerous biosensors, and as tracers in immunoassays such as enzyme-linked immunosorbent assays (ELISAs) (38–40). The only major disadvantages of using BL and CL are that multiple wash and reagent addition steps are often required in the “development” of the signal, which can make the analysis time longer, and the user typically has a limited time in which to collect the generated signal as the local substrate is consumed rapidly. Therefore, when multiple samples are run

Organic materials

Standard organic fluorophores

Organic dye materials represent the largest and best characterized class of probes used in all manner of fluorescent analysis. As an overall class, these dyes are used in almost all areas of biotechnology, including biosensing, cellular imaging, clinical immunofluorescence, and in DNA/protein microarrays (42–45). Several major structural classes of organic fluorophore span the UV-to-near-IR spectrum; see Fig. 4. UV dyes are typically pyrene-based, naphthalene-based, and coumarin-based structures, whereas the Vis/near-IR dyes include a variety of fluorescein-based, rhodamine-based, and cyanine-based derivatives; see Fig. 5. Fluorescein dyes are extremely popular because they have good quantum yields, are relatively cheap, water soluble and readily bioconjugated, and easily excited using a standard argon-ion laser (488 nm). However, fluorescein has a high rate of photobleaching, is sensitive to pH (sometimes considered an advantage; see below), and can self-quench at high degrees of substitution onto biomolecules. Various alternatives are available such as Oregon Green dyes (Invitrogen, Carlsbad, CA), which are fluorinated fluorescein analogs; AlexaFluor dyes (Invitrogen; (46)); Cy dyes (GE Healthcare, Buckinghamshire, United Kingdom); and BODIPY dyes (Invitrogen), all of which claim to alleviate some of these issues. For some redder dyes, overlabeling can induce protein precipitation because of their low solubility in aqueous environments (47). A fos, several organic-based dyes are used as fluorescent stains for visualizing cell membranes, proteins, and DNA in cells or separation gels (1, 2, 48). These dyes also include fluorescent dyes attached to lipids that allow membrane labeling and intercalating probes like ethidium bromide, which are typically weakly fluorescent until bound to DNA (1, 2, 48). In general, organic dyes have several issues that have to be considered before use; these include broad absorption/emission profiles with small stokes shifts (which can be problematic for FRET-based applications or multiplexing), solubility issues, and susceptibility to environmental influences. Cumulatively their many advantages, which include extensive characterization in the literature, their wide availability from several commercial sources, relative cost, ease of use, and many different available bioconjugation chemistries, often outweigh the above liabilities and mean that they are usually the first choice in most experiments. Haughland’s handbook is an excellent reference on many aspects of most commercial organic fluorophores (2).
Fluorescent Labeling and Fluorescent Spectroscopy: Overview of Applications in Chemical Biology

Environmentally sensitive fluorophores

Environmentally sensitive fluorophores that exhibit some change in their absorption or emission properties as a function of their environment are often referred to as indicator probes (1, 3). Such dyes may be sensitive to changes in pH, ionic strength, ionic type, oxygen, solvation, or polarity. Although many dyes will exhibit some sensitivity to perturbation of their local environment, fluorescein is probably the best known; with sensitivity to pH, see Fig. 6. A gain Haughland’s handbook is an excellent reference for organic dye probes optimized for environmental sensing (2). Many new indicator probes, which are sensitive to neutral and ionic molecules as well as to oxygen reactive species, have been reviewed recently in the literature (49, 50). These indicator dyes have applications for chemical sensing both in vitro and in vivo. Important considerations when loading cells with these indicator probes include whether the probe is as follows: toxic to the cell, and at what concentration, and where the dye will likely be sequestered during loading into the cell, such as within the organelles.
Fluorescent Labeling and Fluorescent Spectroscopy: Overview of Applications in Chemical Biology

Fluorescent polymeric microspheres and nanospheres

One photophysical limitation of organic fluorescent dyes is the tendency toward self-quenching that occurs when attempting high conjugation ratios to improve both sensitivity and LODs. Researchers have overcome this limitation by functionalizing polymeric microspheres and nanoparticles with multiple fluorophores (100s–1000s) that result in highly fluorescent particles. This strategy also allows one to label biomolecules with dyes that would otherwise lack reactive groups for bioconjugation or are inherently insoluble in an aqueous environment (3). Fluorescently functionalized microspheres and nanospheres are available commercially from several sources, spanning the UV-to-IR, in a variety of sizes ranging from 20 nm to 5 µm (3). Fluorescent microspheres are also commonly labeled with primary or secondary antibodies and are used as solid supports in many sandwich immunoassays, where they take full advantage of solution-based kinetics (51–53). Alternatively, microspheres can be obtained with carboxyl, amine or other surface-displayed functional groups for chemical conjugation to biologic molecules (3). The recently developed FloDots, which are functionalized with either antibodies or DNA, have demonstrated applications in several areas, including bioimaging, cell detection, gene detection, and protein arrays (54). Similar sol-gel-derived silica nanoparticles have also been investigated (55). Coded microspheres, which are internally labeled with specific concentrations of two fluorescent dyes, are an integral part of the Luminex flow cytometry technology and have been used in many biomedical research and diagnostic applications (56, 57). Environmentally sensitive dyes have been immobilized in various cross-linked polymers to produce PEBBLE (Probes Encapsulated by Biologically Localized Embedding) nanosensors for several ionic and neutral species. When delivered into cells, these PEBBLE nanosensors are used to image and monitor the presence of intracellular chemical species (58, 59). In general, the liability of working with a microsphere that is far larger than an organic or intrinsic fluorophore can be offset greatly by the increased sensitivity and stability.

Inorganic materials

Metal chelates and long-lifetime fluorophores

Long-lifetime dyes typically consist of either the luminescent lanthanides or the ruthenium-metal chelates. The principle advantage of working with long-lifetime dyes over conventional fluorophores originates from the ability to gate out, through time-resolved measurements, any background fluorescence originating from matrix components in the sample (such as autofluorescence and scattering), thus greatly improving the sensitivity of detection. Of the four lanthanides, terbium (Tb), europium (Eu), samarium (Sm), and dysprosium (Dy), that emit in the visible region, Tb and Eu are the most commonly used probes (60–63). In particular, chelate ligands of the lanthanide ions are typically used for biophysical applications. The chelates are designed to 1) tightly bind the lanthanide ion, imparting high thermodynamic and photochemical stability; 2) position a sensitizing chromophore in close proximity to the ion; and 3) contain a reactive group allowing bioconjugation (see Fig. 7). Because of their relatively low extinction

Figure 6. (a) Normalized absorption and emission (b) changes of fluorescein as a function of its ionization state (c). The monocationic and dicationic species are the more fluorescent. (Modified from Reference 3.)
coefficients (~1 M\(^{-1}\) cm\(^{-1}\)), lanthanide ions are almost impossible to excite directly so the sensitizing chromophore is an essential part of the lanthanide chelate probe as it functions as the initial light-harvesting antenna. Lanthanide probes are characterized by unique, sharp emission profiles (see Fig. 7), which originate from both magnetic and electric dipole transitions, along with large Stokes shifts (excitation 343 nm, emission > 500 nm). The fluorescent lifetimes of these materials range from ms to ms, and this allows lanthanide probes to be used in luminescence resonance energy transfer (LRET) applications along with various clinical bioassays (60, 61, 63-65). Commercial sources for lanthanide probes include CIS-Bio International (Yvette, France) and Packard Instrument Company (Downers Grove, IL; cryptate-based probes), PerkinElmer, Inc. (Waltham, MA; LANCE, a pyridine-based system), Invitrogen (Lanthascreen; polyaminocarboxylate chelates, coupled with a CS124 sensitizer), and GE Healthcare who market a europium (Eu) complex in the iso(thio)cyanate form for biocorjugation to amines. Also, an increasing number of reports appear in the literature of lanthanide-doped nanoparticles being used as bifunctional labels where their benefits can be compounded for exploitation (66-68).

Long-lifetime ruthenium metal–chelate complexes were originally used by Lakowicz as anisotropy labels for measuring the rotational dynamics of proteins (69, 70). These transition metal complexes typically contain one or more bi-dentate or tri-dentate ligands and use metal-to-ligand charge transfer processes; see Fig. 8 (1, 71). Sigma-Aldrich Corporation (St. Louis, MO) offers a series of reactive ruthenium complexes for biolabeling that are derived from Lakowicz’s work. They are characterized by relatively small extinction coefficients (34,500 M\(^{-1}\) cm\(^{-1}\) and low quantum yields (0.05), but they possess long lifetimes, typically >500 ns, coupled with a fairly large Stokes shift. As with the lanthanide probes, several applications have used the ruthenium complex as a donor in LRET-based studies. The major advantage of these transition metal complexes is that they can be activated to give an acceptor dye, which leads to significantly improved sensitivity (72).

Fluorescent metal nanoparticles

Atomic clusters consisting of a few noble-metal atoms have demonstrated intense fluorescence emission as well as some interesting nonlinear optical properties. Gold (73), silver (74, 75), and copper (76) nanoparticles have both size-dependent and shape-dependent absorption and luminescent profiles, with the resulting emission exhibiting strong resistance to photobleaching. The potential benefit here would be the extremely small size; however, these nanoparticles are currently not available commercially and to date have found limited use as fluorescent labels, mostly because of complex synthesis and stabilization along with lack of biocorjugation routes.

Semiconducting nanoparticles: quantum dots

The II-VI group of semiconductor nanocrystal materials or quantum dots (QDs), namely CdSe and CdS, are extremely well characterized in the literature and have proven their applicability as fluorescent probes in a wide range of biologic applications, including FRET-based investigations (3, 77), biosensing (78), drug discovery (23), cancer diagnostics and investigative treatments (79, 81), and many other areas of biomedical research (82, 83). QDs or Qdots have several unique properties that make them ideal fluorescent probes compared with organic dyes: 1) high quantum yields and molar extinction coefficients (>10 to 100 times those of organic dyes that steadily increase toward the UV); 2) high resistance to photobleaching and chemical degradation; 3) broad absorption coupled with narrow emission profiles (see Fig. 9b); 4) large Stokes shifts, >200 nm for the red-emitting QDs; and most importantly, 5) size-tunable photoluminescence; see Fig. 9a (83, 88). Although QDs have been synthesized from many binary and ternary semiconductors, the most commonly used are a CdSe QD core overcoated with a ZnS shell, which acts to passivate and protect the core (83, 89). Critical to the development of QD biotechnology has been the ability to make these inherently insoluble materials biocompatible through the use of bifunctional ligands (83, 87). QDs are available commercially from Invitrogen and Evident Technologies, Inc. (Troy, NY); they are typically overcoated with a protecting layer and then precoated with avidin or other proteins that facilitate biocorjugation. Several detailed discussions have occurred on the synthesis of QD core-shell materials (89, 92). Many applications specifically aim to minimize the large protecting outer layers, which is often desired in FRET-based applications where acceptor distance from the QD donor core can be an issue (77, 93).

Silicon and more recently germanium semiconductor-based nanocrystals have also demonstrated intense fluorescence emission (94-98). Si-based nanoparticles have found some applications as biolabels (98, 99), whereas Si-based and Ge-based nanoparticles are still in the early stages of development. However, all are characterized by immature synthesis and stabilization that has limited their biologic use to date. That said, they still have a promising future as optical probes that potentially may be a nontoxic alternative to semiconductor materials.

Fluorophore Bioconjugation

Chemistries

To exploit analytical fluorescence in biologic assays fully, it is often necessary to label target biomolecules by introducing a fluorophore, usually through a chemical reaction. Ideally, the reaction should take place in aqueous conditions, be fast, high yielding, and nondestructive; target reactive groups already present on the biomolecule; and allow easy purification of product from unreacted dye. Many reactions have been developed that fit some or most of the above criteria, and this section is only intended to give the reader a general outline of the common/practical chemical methods of achieving fluorescent labeling. Several excellent reviews (100) and books (3, 101, 102) cover this extensive topic exhaustively, and the reader is referred to these and to the current literature in the field of biocorjugation for additional insight.

### Synthetic considerations

Labeling biomolecules with fluorophores can be challenging because of the differences in the nature of the two reactants and the small quantities of reagents employed (pmol to µmol). Because of their widespread incorporation in countless assays, many fluorophores are now available commercially in reactive form, targeting chemical groups already present in biomolecules, with amines and thiols being by far the most common targets (2). Although sometimes expensive, reactive fluorophores are the most convenient to use as a stock solution can be prepared and the conjugation reaction can be performed by adding a known concentration of fluorophore to the biomolecule dissolved in the appropriate buffer. Fluorophores are often hydrophobic molecules with limited water solubility, whereas biomolecules are soluble in water at a wide pH range. To facilitate the reaction between these disparate entities, a large excess of dye is usually employed. As a result, a common problem often encountered in fluorescent labeling of biomolecules is the presence of a heterogeneous reaction mixture: soluble biomolecule and solid dye in two immiscible phases. One way to address partially this issue consists of adding small quantities (usually between 20% and 50% of the total reaction volume) of a carrier solvent, such as dimethylsulfoxide (DMSO) or N,N-dimethylformamide (DMF). The carrier solvent facilitates the solubilization of some hydrophobic dye in the water medium and diminishes the problems associated with the formation of aggregates. Labeling reactions usually take place under some moderate-to-vigorous stirring, and if the desired substitution level is not achieved in a reasonable reaction time (usually 1-2 hours), repeating the conjugation is preferred over extended reaction times as many reagents tend to hydrolyze over time. Because of the necessity of...
lowering background fluorescence in the final assay, purification of the fluorescent adduct from the unreacted fluorophore is necessary and sometimes complex. The large excess of fluorophore employed in the labeling reaction can compound purification of the labeled adduct, and several rounds of purification using different techniques may be necessary. Centrifugation and precipitation are the first steps that can help in removing suspended unreacted fluorophore and in facilitating additional purification steps. Gel-permeation, reverse-phase high-performance liquid chromatography, electrophoresis, dialysis, and combinations thereof are the techniques more commonly employed to achieve a high-purity labeled product. Depending on application, site-specific labeling may be a preferred strategy as opposed to nonspecific or generalized labeling of a common functional group, for example, a single-labeled protein-thiol versus multiple lysine-amines. Lysines are abundant on most proteins, there is also the possibility of a distribution of labeled-adducts expressing various degrees of functionalization. Furthermore, lysine residues may be the key to subsequent function, and labeling can interfere with this process.

Polypeptides and nucleic acids as biomolecular targets

Proteins, antibodies, and enzymes consist of long polypeptide sequences folded in ways that favor the positioning of hydrophobic residues at their interior, whereas more hydrophilic or easily ionizable residues are at the periphery. Water-exposed residues are therefore important and available targets for bioconjugation, most notably the carboxyl group of aspartic (103) and glutamic acid (104), the primary amine of lysine and arginine (105, 106), the secondary amine of histidine (107, 108), the thiol of cysteine (109, 110), and the phenolic hydroxyl of tyrosine (111). All behave as nucleophiles under appropriate conditions, such as specific pH ranges, and their reactivity can be exploited for the attachment of several reactive probes (112, 113). Such target-expressing residues can also be introduced recombinantly at well-defined specific sites in proteins (114, 115). Besides the presence of these residues, it is also possible to introduce alternative functional groups, or to interconvert existing ones, through the use of versatile and readily available bifunctional reagents (116). For example, 2-bromoethylamine can be used to transform thiol-containing amino acids (cysteine) into primary amines, whereas N-succinimidyl-s-acetylthioacetate (SATA) reacts with amine containing amino acids to form a protected sulfhydryl group, which can be deprotected readily using hydroxylamine to a free thiol (101). The use of bifunctional reagents provides versatility to the bioconjugation chemist, extending the repertoire of reactions and functional groups available and permitting the fine-tuning of other factors, such as the spacing or the solubility of the fluorophore.

Nucleic acids do not display the same promiscuous chemical reactivity of proteins. Instead, individual synthetic nucleotides can display a unique functional group that can be exploited even more for direct attachment of probes (117). The simplest method of labeling DNA uses high-affinity bis-intercalating dyes such as ethidium bromide, acridine, and thiazole orange monomers...
and dimers (118). These dyes, which have almost no emission in water, display fluorescent enhancements of 30–1000-fold after binding to DNA and remain bound even during electrophoresis, hence, their use as gel stains. Different DNA samples can be prestained with differentially emissive dyes before electrophoresis, then mixed, and finally covalized (119). Perhaps the biggest liability of these dyes is their toxicity, which necessitates careful handling and disposal. The 5′-backbone phosphates can be targets for modification through carboxylimide-mediated formation of a phosphoramidate (120, 121). Such reactions, however, are not easy to control, and the expertise required makes this type of approach not very common. Two other techniques are usually preferred for tagging DNA with a fluorescent probe: 1) direct enzymatic labeling and 2) postsynthetic modification. Direct enzymatic labeling usually uses some type of enzymatic introduction of modified ddNTPs (122, 128), which results in the generation of an oligonucleotide sequence that contains the probe or an appropriate functional moiety such as an amine to which a probe can be attached. Several enzymatic techniques are available, including PCR, nick-translation, random-primed labeling, and 3′ tailing with terminal transferase, which are all methods reviewed in References 129 and 130. Issues of this enzymatic insertion include the limited types of modified nucleotides that can be introduced, as the enzymes employed can be very selective when it comes to incorporating non-natural substrates, cost, and the necessity of long incubations in some cases. Postsynthetic modification of nucleotides usually consists of the automated synthesis of a short DNA fragment incorporating a specific chemical moiety—usually an amine or a thiol—within or at the termini of the sequence (117, 130–132). The functionalized oligo is then tagged with the fluorescent probe, which exploits reactions very similar to those employed for the proteins above or listed in Table 2. These reactions, however, are not easy to control, and the expertise required makes this type of approach not very common. Two other techniques are usually preferred for tagging DNA with a fluorescent probe: 1) direct enzymatic labeling and 2) postsynthetic modification.

**Type of linkages**

Table 2 presents a list of the most common target groups used for fluorescent biodiagnosis along with their cognate reactive partner and the type of product formed. Amines and thiols are by far the most commonly exploited target functional groups as they are both good nucleophiles, readily available and/or easily introduced in biomolecules. Figure 12 shows the most common reactions for targeting amines. Isothiocyanate (ITC) (153–155) and succinimidyl ester (OSu) (151, 152) derivatives are the most common amine-reactive groups readily forming, respectively, stable thioesters and amide linkages (Fig. 1a, 1b). ITCs, however, present long-term storage stability problems, which makes the OSu derivatives more popular. Nonetheless, certain types of reactive ITC probes, such as the fluorescein (FITC) and tebramethylrhodamine (TRITC) derivatives, are still used widely. OSu derivatives are extremely common, and many of them are available commercially (3). OSu derivatives can also be prepared as starting material from a carboxylic derivative and N-Br-Succinimide as reagent. Less common, but still viable, reactive partners for amines are sulfuric chlorides, unstable in aqueous (156), which leads to more stable sulfonamides (Fig. 1c) and aldehydes (157) yielding Schiff bases (imines) (Fig. 1d). Carboxylic acids can also be reactive toward amines, ultimately forming amide bonds, but they require prior activation usually achieved by employing a water-soluble carboximide reagent (Fig. 1e) (158, 164).

Maleimides (133–138), iodoacetamides, and alkyl halide derivatives (133, 139–141) are the most common thiol-reactive groups (Fig. 1a, 1b). All of these reagents readily react when a free thiol is present to give stable thioethers. Disulfide exchange of a free thiol with an activated piriylisulfide is another common and effective reaction (146, 147, 171, 174) (Fig. 1c), but the resulting disulfide containing product may not be stable under reducing conditions or in the presence of other free thios.

Other chemical groups such as aldehydes, ketones, and alcohols are also exploitable targets for bioconjugation. The reactivity of alcohols in water is very low, and usually intermediate steps are involved to transform the hydroxyl into a more reactive or more easily exchangeable group. The resulting multistep scheme, although not an alternative to more readily labeled groups, is an option when other reactive groups, such as carbohydrates, are not present (175). Aldehydes and ketones react with amines to give imines (149, 150). However, both groups are not commonly found and often have to be generated by oxidation of the corresponding alcohol or vicinal diol. Hydrazines are also very good reactive partners for ketones and, to some extent, aldehydes, which yield hydrazones (148). The hydrazones can be stabilized even more by reduction yielding an irreversible product. Interestingly, these same groups are also common targets for modifying sugars and carbohydrates using

*Glen Research (Sterling, VA; www.glenres.com) and Trilink Biotechnologies (San Diego, CA; www.trilink.com) offer a variety of fluorescent phosphoramidates for automated DNA synthesis.*
some of the same chemistry. However, sugar modification is a
less well-developed chemistry in general and thus less prevalent,
although strong research in this area continues (2, 101).

Another commonly exploited labeling method takes advan-
tage of the very strong interaction between the protein Avidin
(or Streptavidin) (176) and its natural ligand biotin, as reviewed
in Reference 2. This labeling scheme usually starts with the bi-
otinylation of the target biomolecule by employing one of many
commercially available biotinylating reagents. The biotinylation
chemistries available are essentially similar to the ones already
mentioned for the fluorescent labels above. After biotinylation, fluo-
rescently labeled Avidin or Streptavidin is added, which results
in strong binding to the biotin and forms a basically irreversible
linkage that has found use in countless biologic applications
(177, 178).

Beyond the above chemical methods for the introduction
of fluorophores, several emerging technologies target in vivo
fluorescent labeling for applications where the probe has to be
located inside a target cell. Fluorescent proteins such as the
GFP can be appended onto the target protein by recombinant
techniques resulting in the coexpression of fluorescent protein
cimers (14, 179). FLASH technology can be used in the specific
in vivo tagging of proteins expressing a Cys–Cys–Pro–Gly–Cys–Cys
sequence by employing a cell-permeable dye that becomes fluores-
cent only during labeling (180–182). The HaloTag method consists of a fusion

Fluorescent Labeling and Fluorescent Spectroscopy: Overview of Applications in Chemical Biology

Figure 10 Schematic representation of the most common reactions for labeling an amine: (a) reaction with isothiocyanate to give a thiourea; (b) reaction with a succinimidyl ester to give an amide; (c) reaction with a sulfonyl chloride to give a sulfonamide; (d) reaction with an aldehyde to give an imine (Schiff's base); and (e) reaction with a carbodiimide-activated carboxylic acid to give an amide.

A recent and growing conjugation methodology worth mentioning is the implementation of click chemistry to bioconjugation. Click chemistry is a fairly generic term referring to a certain class of quick, high-yielding reactions. For bioconjugation, this term usually indicates the Cu(I) catalyzed 1,3-dipolar (Huisgens) cycloaddition between an alkyne and an azide to give a 1,2,3-triazole as the product. This reaction proceeds very rapidly and is compatible with both aqueous chemistry and a variety of functional groups, which makes it an excellent candidate for future development and applications (184, 185). However, the current drawback to this chemistry is the unavailability of widely applicable commercial kits for introducing the necessary alkyne and azide cognate precursors onto both target and probe. However, the Click-iT kit (Invitrogen) targeting glycoproteins probably represents the first of many applications to come that will use this exciting chemistry.

Selected Fluorescent Techniques

Fluorescence anisotropy

The extent of the polarized emission from excited state fluorophores in a solution can be described in terms of their anisotropy (r), and measuring this can provide insight into the angular displacement of the biomolecule(s) to which the fluorophores are attached (1). Within a homogeneous solution, the ground-state fluorophores are all oriented randomly. However, when exposed to a polarized excitation source, the molecules with their absorption transition moments oriented
Fluorescent labeling and fluorescent spectroscopy: Overview of applications in chemical biology

**Figure 11** Schematic representation of the most common reactions for labeling a thiol: (a) reaction with an alkyl halide to give a thioether; (b) reaction with a maleimide to give a thioether; and (c) reaction with an activated pyridyl-disulfide to give a mixed-disulfide through disulfide interchange.

Along the electronic vector component of the light will be excited preferentially (1), which means the excited population is not random in orientation, but their transition moments are all oriented. For chemical biology, the factors that affect the rotational correlation time, or anisotropy, can then be investigated, including biomolecule-biomolecule interactions, modifications, or denaturation. Anisotropy is also a powerful tool for measuring viscosity in select environments such as membranes and lipid composition. Again, the interested reader is referred to Lakowicz’s text for more detailed reading on all facets of this subject (1).

Anisotropy, which is sometimes used interchangeably with polarization, although the former is preferred, is a dimensionless quantity that is independent of sample intensity. A fluorometer and appropriate polarizing filters (parallel and perpendicular) are the simplest instrumental setup that can be applied (1). Measuring the steady-state fluorescence anisotropy provides data on only the average anisotropy decay and the interpretation can be complex. Far more information is gained from measuring the time-resolved anisotropy; however, the equipment and analysis required is more complex. Direct monitoring of fluorescent anisotropy provided insights into the binding modes of the G protein-coupled type A and B cholecystokinin receptors (186). These receptors, which share homology to rhodopsin and β-adrenergic receptors, have important regulatory functions in certain hormonal responses. Monitoring changes in anisotropy of differentially labeled probes while interacting with the receptors confirmed that each type uses a distinct mode of high affinity binding. The structure of UrEc, which is an essential Bacillus pasteurii protein required for the in vivo activation of the enzyme urease, has also been probed with both steady-state and time-resolved anisotropy analysis (187). Although this protein behaves as an intrinsic unstructured dimer, the conformation it assumes is unknown, for example, fully folded, molten globule, or random coil. Direct analysis of steady-state anisotropy and intrinsic tryptophan fluorescence wavelength shift allowed monitoring of transitions between native and unfolded states upon increasing concentrations of a denaturant (see Fig. 12). Furthermore, the hydrodynamic parameters obtained by time-resolved fluorescence anisotropy in the presence of a denaturant confirmed the existence of a stable but disordered dimer formed at a unique cysteine residue. This key bond acts to stabilize the dimer under native conditions.

**DNA and fluorescence**

Fluorescent labeling and spectroscopic analysis have had a profound impact on two areas: research into DNA structure/function and myriad diagnostic and sequencing applications. For the former area, the focus is to understand complex
nucleic acid chemistry and more recently to exploit the inherent self-assembled structures for creating precisely formed nanoscale architectures (188, 189). For the latter arena, the focus has been on all aspects of genomic analysis from clinical/genetic diagnostics to the creation of the genomic databases (190). Although this field is relatively young, with fluorescent DNA sequencing described just ~20 years ago (191), commercial applications have driven progress and the completion of the Human Genome map (192); many focused reviews are available in this area (3, 193-195).

Fluorescent sensing

Fluorescent sensing can provide a powerful tool to the chemical biologist especially for in vivo applications. One version of this analysis originates almost exclusively from the environmental sensitivity of selected fluorophores discussed earlier (1-3). Fluorescein, for example, has been exploited for intracellular pH monitoring (see Fig. 6). Intracellular calcium-sensing techniques are a powerful and widely used technology with many applications in neuroscience and in cardiovascular and signal transduction research. It has also proven useful recently in monitoring receptors associated with odor detection (194). This particular technique is discussed extensively in other articles; see, for example, the article “Calcium Signaling.” The ability of membrane-localized receptors to “sense” and transduce an odorant was monitored by their ability to elicit a coupled-intracellular calcium transient. Invitrogen also offers a variety of commercial probes targeting diverse ions as modified endogenous intracellular analytes. "Fluorescent Dyes and Other Photochemically Active Molecules," in Haughland's handbook is an excellent reference on this subject (2). This type of fluorescent sensing is well developed but may be limited by the lack of multiplexing capability. That is, only one or two of these dyes can be used simultaneously because of their broad absorption/emission profiles.

Fluorescent sensing has been exploited even more by implanting environmentally sensitive fluorophores into select proteins to create a variety of in vitro and in vivo sensors. The proteins provide biologic specificity for target recognition, whereas the fluorophores provide signal transduction. This type of sensing relies on some change in the proteins structure during binding, which in turn causes a change in the local environment of the fluorescent dyes and, thus, its photophysical state. The superfamily of bacterial periplasmic binding proteins has provided an excellent source of sensing proteins for diverse analytes from which to begin designing such sensors (197), but long-term fluorophore instability has remained an issue and may necessitate preparation of fresh sensors for each experiment. The prototype for this sensor design has been the maltose binding protein (198), and many different maltose sensors have been assembled to test a variety of signal transduction modalities, including a variety of surface-tethered versions with complex kinetic functions; see Fig. 13 (198, 199). Hellinga and Frommer (197, 200) have been at the forefront of this field where they have applied computational design to identify critical sensing sites within a variety of natural and de novo rationally designed proteins.

Energy transfer

As FRET is a significant analytical technique for a variety of in vivo and in vitro biosensing configurations, the concepts and applications will be discussed in other articles. However, FRET is heavily dependent on optimal placement of two or more fluorophores either within a single biomolecule or in two separate biologic entities (1, 3, 201). As such, discussion is warranted on some relevant issues. The first is choice of fluorophores with appropriate spectral overlap and their placement such that the proximity exists between the fluorophores for efficient FRET (1, 3, 201). Depending on the structure and the available functional groups, site-specific sequential or orthogonal labeling of a single biomolecule with multiple fluorophores is still challenging. DNA and other oligonucleotides are synthesized readily with both site-specific amine- or thiol-functions for facile labeling with appropriately reactive dyes (2, 101). Single cysteines can be introduced recombintantly into specific protein sites; however, the presence of other cysteines can cause “thiol-scrambling” of the structure and subsequent loss of function (3). Hellinga and colleagues (202) have described recently a method for the sequential labeling of multiple cysteines within a single protein to address this issue specifically. Primary amines are ubiquitous to proteins, and thus, fluorophores targeting these functions tend to be nonspecific. The same considerations for thiois and amines usually apply to labeling synthetic peptides.

Proteins can also be engineered to express a variety of fluorescent proteins appended at different points within the structure. Frommer and colleagues (203, 204) have designed advanced sensors that couple two fluorescent proteins at select sites within sensing proteins and ligand binding is signaled by changes in their FRET efficiency. Figure 14 is an example of a cell-surface expressed version of such a sensor that detects glutamate release from neurons (205). The recently developed FLASH, HaloTag, and SNAP tag techniques offer alternative methods for labeling specific recombinant sequences in vivo with proprietary reactive dyes (3). The use of two disparate fluorophore classes as donors/acceptors in FRET configurations is steadily growing as exemplified by quantum dot—dye or fluorescent protein—dye pairings (3, 7). Interestingly, although not fluorophores per se, fluorescent quenchers and gold nanoparticles have found utility as acceptors in myriad FRET applications (3). In vivo sensing of toxins and second messengers with FRET-based fluorescent protein sensors is an important and related area covered in several other chapters.

Single-molecule analysis

In theory, single-molecule analysis (SMD) represents the ultimate analysis as it can provide the highest sensitivity while providing stochastic sensing. In an ideal experiment, fluorescent signal transduction is suited particularly to this analysis as a lone fluorophore can emit photons against a dark background. Practice has proven far more complex, however, and this remains a technically challenging and still nascent technique (3). The two confounding issues remain sample immobilization coupled with optical detection configuration. Almost all SMD is dependent on microscopy and the 1D immobilization of biomolecules by surface tethering or fixation within a network.
Fluorescent Labeling and Fluorescent Spectroscopy: Overview of Applications in Chemical Biology

Figure 13  (a) Schematic of a surface-tethered maltose biosensor with complex binding kinetics. The modular arm consists of DNA, a dye, and terminates in the maltose analog beta-cyclodextrin (β-CD). The maltose binding protein (MBP) is site-specifically dye labeled, and both it and the β-CD are assembled onto a Neutravidin (NA) functionalized surface using biotin (b). For MBP, this uses a biotin–nickel nitroloacetic acid (Ni-NTA) intermediary to bind the MBP’s 5-histidine sequence, 5-HIS. MBP binding of the β-CD-dye-DNA arm assembles the final sensor by bringing dyes 1 and 2 into proximity, which allows FRET or FRET quenching. Maltose displaces the β-CD-dye-DNA arm in a concentration-dependent manner. The addition of second modulator DNA that hybridizes to the arm can alter and extend the binding kinetics. (b) Representative binding curve and approximate binding constant (Kapp) for titrating the sensor against maltose. (Reprinted from Reference 199 with permission of the ACS.)

or 2) monitoring and averaging of a continuous sample of individual molecules to overcome any photobleaching effects. The required instrumentation is still some combination of confocal imaging, cooled avalanche photodiode (APD) detector, and total internal reflection or similar microscope, although continuous technological innovations have made these simpler and more affordable. SMD has been applied recently to detecting the cystic fibrosis transmembrane conductance regulator (CFTR) localized to the erythrocyte plasma membrane (206). In this case, a novel experimental approach that combined atomic force microscopy with quantum-dot–labeled anti-CFTR antibodies was employed to detect individual CFTR molecules. The results suggested that quantification of CFTR in a blood sample could be useful in the diagnosis of CFTR-related diseases. An important issue for every SMD experiment is whether immobilizing the analyte affects its function, and thus, monitoring in this state may reflect “unrealistic” data. The benefits of SMD include bypassing ensemble averaging completely, taking measurements from fixed “quantities” of analyte, and the ability to monitor intermediary reaction states that can be “masked” in an ensemble. For all pertinent issues, the reader is referred to References 1, 207, and 208 for a comparison of ensemble versus single-molecule FRET studies. The interested reader is referred to other pertinent articles on SMD of various analytes.

Fluorescence correlation spectroscopy

Fluorescence correlation spectroscopy (FCS) is a technique that allows monitoring of single molecules but does not necessitate surface immobilization as above. At its most basic level, this process is a monitoring of fluorescent translational diffusion into/out of a minute volume defined by a focused laser and imaged with a confocal aperture (1). Diffusion continuously replenishes the analyzed molecules and their short transit times through the laser focal point to mitigate any photobleaching issues. The fluorescent bursts are collected and analyzed with the Stokes–Einstein equations to correlate their diffusion coefficients and thus provide insight into their size, rotational properties, concentration, and so on. FCS has found extensive applications in biochemical reaction monitoring and kinetic...

The rapid testing of chemical libraries for biological activity is the primary aim of high throughput screening (HTS). Advances in HTS have paralleled those in molecular biology, instrumentation and automation, and informatics, and the increased availability of arrayed compound libraries. Sophisticated high sensitivity assays and the associated technologies required to implement these assays in HTS have been largely developed within the pharmaceutical industry for the identification of new chemical matter for drug development. However, HTS approaches are now widely applied to the broader questions within biological research. By way of introduction, we will describe the components of HTS and provide examples of strategies used to identify novel chemtypes for specific biological targets using large chemical libraries. We then will illustrate how more narrowly defined compound collections (e.g., targeted libraries or bioactive compounds) have been profiled against related targets or cell types for the purpose of discovering or defining, compound class/gene family selectivity, off-target activity or "hidden phenotypes", toxic fingerprints, or any other relationship between chemical structure and bioactivity. In this way, HTS systems can expand the scope of an experimental hypothesis to address questions of chemical biology, be they at the level of an isolated enzymatic activity or that of a complex cellular phenotype.

High throughput screening (HTS) is a technologically enabled field of applied science that creates an interface between chemical libraries and biological assays for the purpose of rapidly exploring and identifying chemical bioactivity. The technologies that make HTS of large compound collections possible have been supported principally by the pharmaceutical industry because of the needs inherent to drug discovery but are increasingly being used to expand the boundaries of traditional academic disciplines such as enzymology and cell biology. "Chemical biology" that emphasizes the application of synthetic chemistry in the study of biological processes or "chemical genetics" in which compounds are used to recapitulate the effect of genetic mutations are particularly enabled by HTS as it allows the identification and profiling of wide-ranging chemotypes that modulate individual gene products or cellular phenotypes (1, 2). HTS laboratories are now an integral part of many universities, and in 2004 the U.S. National Institutes of Health (NIH) implemented a specific initiative to expand access to HTS for translational research (3–5). Whether the aim is chemical biology or drug discovery, HTS is most effective when biological assay systems are designed and screening results interpreted with the technological capabilities and limitations of the entire process in mind.

As a primer to this area, we outline the basic process of HTS and synergisms between pharmaceutical and chemical biology research endeavors and provide examples of platforms that use HTS technologies to enable chemical biology.
Bridging Chemistry and Biology with HTS

Compound discovery or profiling that uses HTS involves merging diverse types of chemical libraries and biological assays (6) (Fig. 1), and generally involves four major components that include the compound library itself, high-quality assays, process engineering platforms, and informatics procedures to track, analyze, and annotate the results. As a consequence, implementation of HTS requires expertise from multiple disciplines. In this section, we highlight some of the important features for each of these processes and how these technologies currently are being applied to the goals of chemical biology.

Chemical libraries

Multiple categories, including natural products (7) and synthetic bioactives (e.g., metabolites, carcinogens, and approved drugs (8)); privileged scaffold-based libraries (e.g., untested analogs of synthetic drugs or natural products such as benzodiazepines (9), indoloquinolizidine (10), or diketopiperazines (11)); biologically uncharacterized compounds of low diversity but high density (e.g., combinatorial chemistry-derived libraries (12, 13)); and consolidated samples/collections that represent extensive structural diversity (e.g., Molecular Libraries Small Molecular Repository, see PubChem (14)) have been used to describe the general character of library collections in use today (Fig. 1a). These libraries range in size from small focused or diverse sample collections of ∼1000 compounds or less to very large collections that may contain a million or more compounds. The cost can range from between a few dollars per mg for specialty sets of a few hundred compounds to ∼$1500 compounds or less to very large collections that may contain a million or more compounds. The cost can range from between a few dollars per mg for specialty sets of ∼1000 compounds or less to very large collections that may contain a million or more compounds. The cost can range from between a few dollars per mg for specialty sets of ∼1000 compounds or less to very large collections that may contain a million or more compounds.

The nature of the library is dependent on the aim of the experiment. For example, if an inhibitor of a novel protein kinase is desired, then a targeted library derived from the aminoquinazoline scaffold (31) (Fig. 1a, i) might be considered, whereas an enzyme that belongs to a gene family with no precedent of small-molecule modulation may benefit from a more random or diverse collection (32). Aiming for many dissimilar scaffolds (the central rigid part of the molecule capable of positioning key interactions) and analogs could lead rapidly to very large libraries, and, therefore, the complexity and the redundancy of the library needs to be carefully managed. The quality of the compounds should also be determined with respect to the stability, synthetic tractability, resupply, and purity of the samples. Various chemical descriptors can be used to measure library diversity; however, a universal method has not been found (21, 33). General screening compound collections aim to contain many different scaffolds with few analogs and are expanded in size by similarity searches using parameters such as the Tanimoto coefficient (34) to consider how new compounds may complement or add to the novelty of the collection. At the other extreme are combinatorial libraries that contain few scaffolds but potentially thousands of related analogs that systematically explore the activity relationships between two or more structural variables. Several thousand different combinatorial libraries have been described since 1992 (35, 36). Combinatorial libraries are synthesized using a variety of methods and can be very large in size (10^9), and although these libraries are not classically diverse, they provide the advantage of containing many subtle changes in structure that can be enormously important for biological activity (37). Knowledge around compound classes that target specific members of a gene family, as in the case of protein kinases or G-protein-coupled receptors (GPCRs), can form the basis of targeted libraries that can increase the probability of finding useful leads (12, 38). More specialized libraries are often required to address certain target classes, such as protein-protein interactions that have been historically refractory to conventional small-molecule approaches. For example, fragment library approaches in which small scaffolds (MW 150–300) are screened at very high concentration to identify weak interactions using nuclear magnetic resonance (NMR)- or X-ray crystallography-based methods have been successful for these difficult target classes (16). Once active fragments are found, the affinity is improved by merging or growing fragments into nearby sites on the protein through the use of structure-guided techniques.

Chemical library handling

Collection sample preparation, formatting for screening (39), short- and long-term storage, and analytical quality control (QC) (40) comprise important variables in the management of HTS libraries. Generally, libraries are arrayed with a single compound per well, but strategies that employ pooling of compounds have been described to compensate for limited screening capability (41). For the purpose of HTS, compounds are routinely dissolved in DMSO, a so-called "universal solvent" at high (typically 10 mM) concentrations, and stored in polypropylene microtiter plates. Critical to the "stability" of these collections is the control of humidity and temperature. DMSO is highly hygroscopic, and when it absorbs water, because of nonideal behavior, it becomes more structured and viscous and limits compound solubility, which can lead to compound precipitation (42). That precipitation, rather than compound degradation, is the central factor determining library integrity has been supported by studies on modern pharmaceutical screening collections (40, 43, 44). Therefore, refined compound storage units use desiccated inert chambers (e.g., argon saturated environments) and dry conditions. If dry conditions cannot be maintained, then the compound collection can be stored at room temperature (never...

Figure 1  Chemistry and biology. a) Categories of compounds. i, ii) Representative chemical scaffolds that could be present either as part of a diverse set of compounds (i) or as a combinatorial library template, illustrated with the 4-amino-quinazoline scaffold (ii). Here a “split and mix” strategy is used in which the library is synthesized on solid support beads that contain the scaffold. Chemical side chains are added to the scaffold by reacting building blocks (or synthons) in separate batches and then pooling all the batches and dividing the beads equally for the next round of synthesis. In the example shown, 10 unique synthons are added at each of three positions (X, Y, and Z) to create a library of $10 \times 10 = 1000$ different 4-amino-quinazolines in three steps. iii) Compounds that represent known drugs. Shown are anti-inflammatory compounds (aspirin and celecoxib) and the HMG-CoA reductase inhibitor, Atorvastatin. (iv) Natural product libraries represented by trichostatin A, forskolin, or a compound from a natural-product-derived synthetic library (Boston University). b) Categories of different assay methodologies based on purified (i, ii) or partially purified (iii) targets and intact cellular systems (iv). Examples of purified molecular targets (i) or partially purified (ii) targets and intact cellular systems (iv). i) Examples of purified molecular targets (i) or partially purified (ii) targets and intact cellular systems (iv). Examples include, enzyme catalyzes turnover of a profluorescent red emitting substrate (i) or a substrate/product (e.g., ATP) of the target enzymatic reaction catalyzed, for example, by an ATPase (ii) is detected by the “reporter” enzyme firefly luciferase via luminescent (iv).

*must consider the nature of potential assay liabilities (e.g., sensitivity to compound library fluorescence) and match counter or orthogonal assays (e.g., an assay that is insensitive to compound fluorescence) to stringently and accurately verify or eliminate the primary assay findings. Ideally, a counterscreen is integrated into the primary HTS either as multiple measurements from the same assay well or as independent assays run in close proximity. As an example of the latter, a 13536-well robotic screen used fluorescent polarization to measure the interaction between the C-terminus of the tumor suppressor protein BRCA1 and a phosphopeptide derived from an interacting protein pBACH. Here, two assays that differed only in the labeled phosphopeptide ligand, carrying either a green or red fluorescent probe, were interleaved into a single HTS (53). The experiment was designed to discriminate signal changes from fluorescent samples, likely to affect the assay pair differentially, from genuine inhibitors of the protein-phosphopeptide complex that should have an unbiased effect on the assay. For cell-based assays, dual-luciferase reporter systems, for example, where one luciferase is constitutively expressed to track cell number, have been used to segregate compounds that modulate the biology in question from nonspecific effects on the assay format or cytotoxicity (54, 55).

Assay technologies for modern drug discovery have been fueled by achievements in molecular biology and the numerous genome sequencing projects that have lead to the cloning and expression of novel proteins, highly engineered cell lines (54, 56, 57), and model organisms (58, 59) with convenient reporters such as luciferases (55), fluorescent proteins (57), or enzymes that act on fluorescent substrates such as β-lactamase (60). In current drug discovery, HTS involves a variety of assay types (Fig. 1b) based on purified molecular targets, reconstituted enzyme cascades, cell extracts (61), and cellular/organism phenotypes (62). The use of reconstituted systems or extracts is particularly attractive as multiple molecular targets/interactions can be tested without the complication of the test compounds binding to serum, having limited cell penetration, or undergoing rapid cellular efflux. Also, such systems can be used to identify the target through techniques analogous to genetic suppression (63).

Decisions surrounding specific HTS assay technologies will take into consideration factors including pharmacological relevance, HTS compatibility, follow-up strategy, and costs, among others. For example, whether a membrane receptor antagonist is sought using a SPA-based radioligand binding assay with an enriched membrane preparation or through a cell-based reporter gene assay may depend on the availability of a suitable radioligand and ability to prepare sufficient plasma membrane versus developing a stable cell-based assay responsive to receptor activation. Also, in this example, a consideration of the cost of assay implementation including handling/disposal of radioactive versus the counter or orthogonal assays required to sort out the often multiple possible mechanisms of action from reporter gene responses are critical evaluation criteria. In a recent review (64), we provided detailed information and references on technologies used in HTS assays and the considerations in assay protocol design and reporting (65) to aid in evaluating the options for HTS assay development and communication of protocols and results.

Optimizing assays for HTS performance involves several steps including reducing the number of required reagent additions; assessing QC and availability of the reagents; determining
the stability and batch variability testing of the reagents; determining the DMSO tolerance of the assay (particularly important for cell-based assays); minimizing incubation and measurement times; and calibrating and optimizing detector settings. Therefore, an HTS assay can differ greatly from typical laboratory assays, and not all assays that function adequately in bench-top experiments will be adaptable to HTS. Typically, libraries are screened at one concentration in a manner in which every compound is assayed once. This "n = 1" experiment is rapidly performed on as many as 1 million samples, and, therefore, the assay must show excellent precision; but this does not guarantee nor should it be confused with biological fidelity (66). Therefore, during HTS implementation, the entire procedure is validated with test plates to assess the assay precision. The goal is to minimize variation and provide adequate signal:background (S:B) with-out adversely effecting the sensitivity or biological relevance of the assay. A measure of the assay performance or quality is typ-ically made using a parameter, the Z-factor (67, 68) (Table 2) (67-71), that is a measure of both assay variation and S:B in which assays that exhibit Z-factors > 0.5 are generally consid-ered acceptable. The background can be taken from specified control wells (Z') or the median of the sample field (Z).

To obtain statistical significance, these parameters should only be reported from entire microtiter plates (e.g., 96-wells or higher densities) and are best measured by performing the experiment in triplicate on different days. Also, the accuracy of the assay response in reflecting the biology under investi-gation can be measured when control compounds are present. IC50/EC50 can be compared with accepted values typically ob-tained from the literature and should include a consideration of the assay precision. For this purpose, the minimum-significant ratio can be calculated from control titrations across individual assay plates, which provides the smallest potency ratio between two compounds that can be considered real based on the preci-sion of the assay (72).

**Engineering processes in HTS**

To achieve a "high-throughput" process requires that systems are available to test compounds rapidly by processing of 96-well or higher density plates (73). The throughput of HTS can vary from low (10,000-50,000 data points/day) to ultrahigh (uHTS) where > 100,000 data points are collected/day. Efficiency in HTS requires highly engineered systems and components, such as high-density microtiter plates, precision, low-volume liquid handlers for dispensing assay reagents (nl to l) or concen-trated compound solutions (pl to nl) (74-76), microtiter plate readers varying in sophistication from reporting changes in a well's total absorbance to the subcellular distribution of target proteins within a cell (77, 78), and robotic systems to inte-grate these components (Fig. 3). Fully integrated systems that leverage miniaturized parallel assay processing (e.g., 1536-well plates) served by robotic arms having direct access to compound libraries, reagent/compound dispensers, and plate incubators and readers can achieve throughputs as fast as 10 samples/sec (79, 80). Operating within a thin margin for error, automated assays by virtue of their speed and parallelism should be validated carefully on the robotic system, and the entire process of as-say implementation should be managed to minimize costly loss of reagents that can occur quickly if the screen is improperly initiated and monitored (73).

**HTS data analysis and informatics**

Several independent streams of data are tracked and integrated throughout the HTS lifecycle. The library samples' structures, plate locations, and array positions, concentrations, and other parameters and annotations comprise one group; a second group is the detector output readings for the assay responses, and a third group include process information, such as time stamps and trace files that track compound and assay plate histories. For smaller-scale screens (a few 1000 compounds) Excel spreadsheets and an Access database can suffice, but as the scale of the HTS increases, organizing this large amount of chemical and biological assay data requires efficient laboratory informa-tion management systems (LIMS) that cover and provide tools to facilitate the entire experimental process. Flexibility has been cited as one of the primary requirements in LIMS design as both the processes and nature of the information content will change over time (81).

HTS assay data is statistically analyzed to identify genuine outliers from systematic or random assay noise, which allows the level of activity for each compound tested in the assay to be determined. The values used in the final analysis are derived from a normalization procedure that converts the raw data to the percent activity relative to the control values (Table 2). Wells that contain controls can be placed in any number of wells on an assay plate, but a common practice is to use ≤ 10% of the plate for controls, often in columns along the left or right edges (Fig. 4a).

A threshold cut off is the simplest method to select putatively active compounds (Table 2). For example, in Fig. 4, samples to the left of (Fig. 4b) the 3 standard deviation (σ) threshold or below it (Fig. 4c) are considered "active" (red values; often referred to as "hits") and are selected for "confirmation" or prioritized with additional criteria (e.g., clogP < 4 or availability of analogs). However, several problems have been noted with this method (70). For example, the controls may be unstable or, in the case of uncharacterized biology, may be absent entirely, which makes it difficult to derive accurate normalized percent activity values. Therefore, methods such as the z-score (69) have been used where the test samples act as the controls (Table 2).

Several methods have been employed to correct for positional variations within the screening data that can be very common in HTS and include edge effects, dispensing artifacts, and changes in reagent stability during the course of the screen. Correction of systematic errors requires special software and is facilitated by incorporating blank plates (e.g., containing DMEM alone without test compounds) uniformly throughout the screen to capture a sample-independent signature of the plate signal variation (Fig. 4). One method that considers positional effects uses the b-score (for "better" score) that is analogous to...
### Goals of chemical biology

The goals of chemical biology have been stated in various ways. In the “gene-centric” view, the aims are borrowed from classical genetic studies in which genes were mutated to determine their role in phenotypes. In this analogy, small molecules rather than gene mutations are used to affect protein function and perturb the biological system. Terms have been coined such as “forward chemical genomics” to represent phenotypic or response assays that are used to identify compounds that generally affect a cellular or model organism phenotype (Fig. 8). However, no single technology is sufficient to identify a target for a small molecule from such phenotypic assays, and target identification remains a challenging area in chemical genomics. In “reverse chemical genomics,” the starting point is often based on an assay that uses an isolated protein, and with subsequently identified compounds, one backs away from the “gene product” to determine the effect on phenotype. In this respect, classical drug discovery resembled forward chemical genomics in which isolated compound testing was often conducted in physiological model systems (e.g., organ bath), whereas modern drug discovery follows a reverse chemical genomics paradigm in which isolated molecular target-based assays are used for compound discovery, and these then are progressed into disease models and eventually to testing in humans. It is now widely appreciated that the proteome is considerably larger than the sum of its genes, and defining what constitutes a “gene” has become increasingly complex (84). Mechanisms such as alternative splicing result in an average of three protein isoforms/gene leading to a larger and more complex proteome. In this “proteome view,” chemical biology has the goal of annotating every protein with compounds capable of inhibiting, activating, or allosterically regulating their function. Ultimately, both the gene-centric and the proteomic viewpoints converge to create a pharmacological database that relates compound activity to biological effects (85). This “chemical probe directory” will list compounds useful for the interrogation of basic biological questions and initiation points to develop novel therapeutics.

The z-score except positional and plate effects are additionally taken into account and result in a marked reduction in false positives (Table 2) (70). However, such methods can fail in screening-focused collections, such as combinatorial libraries in which many analogs around a common scaffold are present, because the assumption that the majority of the tested wells are inactive may not hold when many genuine actives occur on the same plate. Therefore, for combinatorial libraries, the activity is better addressed using multiple assays to help rank or profile the actives or screening at multiple concentrations where potencies can be resolved (see below, Fig. 4d). More attempts to improve active selection from large HTS data sets include the use of structure-activity relationships (SAR) (82) to help reduce false negatives and advanced population analysis to construct predictive models of activity (83).
High Throughput Screening (HTS) Techniques: Overview of Applications in Chemical Biology

Bottom: Plumbing and valve control of a solenoid-based for nL dispenser. b) Methods for nL dispensing of compound solutions in DMSO (beige wells) to assay plate wells (blue wells) using contact-based dispensing with pin-tools (i) that may contain slots as shown or noncontact-based dispensing as in using a focused acoustic beam (ii). For acoustic dispensing, it is necessary for the destination plate to be inverted over the source plate. c) Reader modalities (i–iii) are depicted for population averaged detection, (i) transmittance using microtiter plates made of clear plastic (e.g., polystyrene or cyclic olefin polymers), (ii) luminescence, typically using opaque white microtiter plates, and (iii) fluorescence where in the example shown epifluorescence is collected by using focusing optics for excitation (green arrow) and emission (red arrow) above the well of an opaque black microtiter plate. d) Detection output (i, ii) for single object enumeration or imaging. (i) Cell cytometry in HTS is possible using either flow or microtiter plate systems (78). Here, the population distribution of green and blue fluorescent cells in a β-lactamase reporter gene assay is analyzed. (ii) High-content screening using automated wide-field or confocal microscopes. High-resolution confocal image of G2/M cell cycle sensor (GE Healthcare) expressed in U2OS cells. Actin and microtubular staining using Texas red- and Alex488-labeled antibodies, respectively, and nuclei stained with DAPI.

Furthermore, as the pharmacological database becomes populated with diverse biological assays and grows in structural scope, it will act to guide the design of higher-quality libraries that will access the darkest recess of the genome.

Chemical probes

To understand the nature of chemical probes, we can evaluate these probes relative to the current drug discovery process. Although the goals of drug discovery have a clear end point, the development of a therapeutic, the goals of chemical biology are broader so that although all drugs are probes because of the special requirements of drugs, not all probes are intended or can be developed into drugs (Fig. 2). Chemical probes can be drawn from the embryonic stages of the drug development pipeline, for example, in the lead optimization stage, once activity has been confirmed and compounds of sufficient potency have been obtained. Early stage absorption, distribution, metabolism, elimination (ADME)-toxicity data such as plasma serum binding, cytochrome P450 inhibition/induction, and cell permeability data can be obtained around chemical probes to determine their usefulness for in vivo testing. Although cell permeability and low serum binding are important, fully optimized ADME-toxicity parameters are not a requirement for many chemical probes. For example, the natural product forskolin (Fig. 1a, iv), an activator of adenylyl cyclase, has been used extensively and primarily in the study of Gi-coupled or "inhibitory" GPCRs in many cellular model systems, with no need to consider ADME-toxicity data around such a tool compound. Furthermore, although selectivity is an important consideration for drug development and many tool compounds, a pan-inhibitor such as staurosporine that is broadly active against the kinase (86) has proven useful in the validation of assays for protein kinases. Also, some pan-inhibitors have been used to develop generic protein kinase assays (87). However, the hydroxamate-containing antifungal antibiotic trichostatin A (TSA; Fig. 1a, iv) has been used as an investigational tool to study histone-deacetylases (88) (more than 2000 publications have resulted from the use of TSA since the initial discovery in 1976) and as a proof-of-principle compound in the validation of novel cancer drug targets. Also, drugs have been used as probes to uncover new targets as in the case of the identification of cyclooxygenase-3 (COX3), a splice isoform of COX-1, through the investigation of the pharmacology associated with analgesic/antipyretic drugs (e.g., acetaminophen and coxibs, Figure 1a, iii) (89).

Academic chemical biology and pharmaceutical drug discovery synergies

Finally, it is worth noting where chemical biology can support the discovery of novel therapeutics. For example, many
High Throughput Screening (HTS) Techniques: Overview of Applications in Chemical Biology

Figure 4  Data processing and Informatics. a) Heat maps depicting 1536-well plate activity for a library of 1408 compounds that was screened from low to high concentrations using qHTS (black bar indicates increasing concentration) in triplicate with each plate containing a different compound concentration. Controls are contained in the left four columns (128 wells) and used to obtain normalized activity from the raw data. Background signatures are derived from plate sample wells containing DMSO/assay buffer alone (not shown) and used to correct for systematic artifacts before scoring and selection of “actives.” The final corrected activity shows actives increasing with concentration (blue: inhibitory activity in well, red: activating activity in well, and white: inactive). The background signature shown (striped pattern) indicates a systematic artifact because of liquid dispenser tip variability. This background signature was subtracted from the normalized data to yield the final corrected activity. b) Traditional HTS is typically conducted at a single concentration (e.g., 10 µM), and treatment of this data is shown. Distribution of activity at one concentration using the highest tested concentration of the qHTS data. A 3σ threshold differentiates the active (red) and inactive (blue) data sets. c) Scatterplot representation of the single concentration-based data set. Example CRC data sets are shown in (d) for a single compound that showed a concentration–response relationship or where (e) multiple CRCs are obtained through the use of qHTS.

rare genetic and infectious diseases are not currently the focus of the pharmaceutical industry but provide fertile ground for public–private partnerships that use chemical biology as the vector to initiate and coordinate programs around these disease areas. The unprecedented open access to screening data enabled by the National Center for Biotechnology Information that manages PubChem (14), where results are found from a diversity of bioassays tested against a growing compound library, will provide new avenues and opportunities for drug discovery and development. Such initiatives have now made a large amount

Figure 5  Reverse and Forward Drug Discovery/Chemical Biology. Reverse chemical genomics starts with a target-small-molecule interaction and progresses to determine the pharmacologic effect on an organism’s phenotype, whereas forward chemical genomics begins with a chemically induced phenotype and aims to identify the target(s) responsible for the phenotypic effect. HTS is enabling to both processes.
of chemical information available on the worldwide web (90). The open access model also brings together laboratories that possess the proper expertise both in the know-how of HTS and the required knowledge of the biology under investigation that is critical to advance compounds in an efficient manner. Recent broad access to HTS and chemical screening data should act to alleviate bottlenecks in our knowledge around new target classes and their potential modulation by small molecules and possibly lower the investment for development by industry.

Example HTS Platforms that Support Research in Chemical Biology

HTS can serve the needs of chemical biology by functioning in the traditional mode of “mining” large chemical libraries with individual assays to identify specific chemical matter for development (91, 92) or “profiling” a specific small ensemble of compounds with bioassay panels (88, 93) or combining both to populate a pharmacological database (94). In this section, we will touch on specific examples from the literature on the profiling of annotated chemical libraries and show the power automation can bring to increase the scope of these experimental designs. Lastly, we discuss several areas of chemical biology that have been beneficiaries of HTS-derived leads, which, with tighter integration to HTS, will enhance the value of new chemical probes.

Profiling assays for understanding mechanism of action

Defining the spectrum of activity for a collection of compounds can be achieved by profiling bioassay panels focused, for example, on gene families (86) or distributed across diverse signaling pathways (95). Bioactivity profiling can be most efficiently performed when the assays share a common format such as a luciferase-reporter system to streamline assay implementation, results quantification, and interpretation. Also, with format homogeneity, nonspecific effects across the profile can be readily identified. As an example, we describe experiments using the cell-based protein complementation assay (PCA) technology (96, 97). In this system, cells are engineered to express two interacting proteins where each protein is fused to complementary fragments of a split yellow fluorescent protein (EYFP). Interaction of the two protein fragments yields a reconstituted EYFP whose signal is at least 10 times brighter than either fragment alone. This system has been used to place cellular “sentinels” along points in signaling pathways where modulation of the sentinel complex reports on a compound’s effect in that pathway. In the work of Macdonald and colleagues (95), a collection of 107 drugs from six therapeutic classes was screened with 49 PCA assays and provided 127 different concentration–response curves (CRCs) against 35 activated protein kinases. Drugs with similar mechanisms of action revealed similar cellular response profiles, for example, PPARγ agonists induced PPARγ/SRC-1 complexes, and differences in profile signatures often attributable to chemical structure. Additionally, the hierarchical clustering of compound activity exposed a supercluster of drugs that did not share any common therapeutic target or mechanism of action but showed a “hidden phenotype” of antiproliferative activity. Therefore, pharmacological profiling enabled with assays such as PCA can be used at an early stage of chemical characterization or optimization to identify such hidden phenotypes, understand off-target activity, or decipher the mechanism of action.

Pharmacologically defined libraries and their uses

Drugs and bioactives from compound collections, such as the Library of Pharmacology Active Compounds (LOPAC, Sigma-Aldrich; Table I), or chemical probe collections available from vendors, such as Tocris, represent libraries that are annotated with biological activity. These types of libraries often show more activity across a broader range of HTS assays compared with nonbiologically biased libraries (e.g., based on synths and scaffolds selected for synthetic tractibility alone) and therefore are useful in identifying controls for assay development and validation. A noted advantage can be used to generate a hypothesis around the mechanism of action for a given response phenotype (98). However, the reliability of the annotation, often derived from multiple databases or fragmented literature sources, can be misleading and should be “triangulated” or corroborated with structurally distinct chemical classes. A group at Amphora, Inc. has approached this problem by employing microfluidic technologies to construct an annotated database in-house by measuring IC₅₀ for 88 protein kinases against a set of 1330 compounds (99). Collecting and improving the annotation of large compound collections against a wide range of biological targets is an active area of research in cheminformatics (100), but ultimately, the activity profile of library molecules will be confirmed experimentally owing to the advances in HTS such as those described below.

Automation of compound profiling

Once an assay platform configurable with highly engineered HTS robotic systems is developed, large-scale compound profiling becomes possible. An example of such an experiment was described by scientists at the Genomics Institute of the Novartis Research Foundation where automated cell culturing through dispensing in either 384- or 1536-well plates was used to test 1400 small-molecule kinase inhibitors to generate concentration–response curves (CRCs) against 35 activated tyrosine-kinase-dependent cellular assays (80). Similar to the PCA system described above, the results of these screens were used to cluster the kinase inhibitors based on the phenotypes observed in the cell-based assays. At the NIH Chemical Genomics Center (NCCG), we have leveraged the advances in HTS technology to determine concentration–response relationships of large chemical libraries routinely across diverse biological systems, a process called quantitative HTS or qHTS (94). To date, >5 million CRCs have been generated in >100 unique assays within 3 years of operation (see PubChem [141] using qHTS at the NCGC. The relatively
short timeframe under which such large-scale experiments can be conducted has enabled the needs of scientists with diverse interests and backgrounds, for example, scientists searching for antiapoptotic agents (79, 101), comparing experimental with in silico screening results (102), and testing hierarchical clustering algorithms for cheminformatics (103). The large data sets achievable from methodologies like HTS will be indispensable to progress in chemical biology and often will serve as the only means by which a foothold at the interface of chemistry and biology can be made.

Chemoproteomic methods: profiling gene families and downstream uses for chemical probes

For investigating the function of enzyme gene families within cells, activity-based probes (ABPs) are particularly useful (104). Requirements for an ABP include sufficient affinity (< 100 nM), pan-selectivity for the enzyme family, an expressed active enzyme to modify covalently, and a reporter tag such as a fluorophore for detection. In a recent exploration of metalloproteases, ABPs were synthesized around two alkyne-tagged hydroxamate-benzophenone libraries, and metalloproteases that bound the probes could be covalently labeled through the benzophenone group (Fig. 2b) (26). The alkyne was placed distal to the metal-binding hydroxamate moiety and readily coupled via click-chemistry with an azido-containing tag (e.g., rhodamine or biotin). The two libraries identified metalloproteases from nearly all branches of this enzyme superfamily, and the authors used the library to detect differences in metalloprotease activity from invasive and noninvasive melanoma cells.

Another method that enables large-scale profiling is the development of generic platforms for entire gene families. Researchers at Aribit have developed a competitive-binding assay that involves the expression of human kinases as fusions to T7 bacteriophage and a set of adenosine triphosphate (ATP) competitive pan-inhibitors tagged with biotin that enable selectivity profiles of kinase inhibitors to be determined on hundreds of protein kinases (more than 250 now available) (86). This format shows exquisite sensitivity with the ability to measure binding affinities as low as 1 pM.

Researchers at Sereis (now part of Pfizer) have turned the compound discovery process on its head using affinity chromatography to "proteome mine" and asking what proteins bind to the compounds rather than searching the library against a single protein (105). In this system, a chemical scaffold such as purine is tethered to a solid support, and a cell, tissue, or organ extract is passed over the surface so that the purine-binding proteins are specifically captured by the affinity resin. Then, library members are added to displace (specifically elute) the targets competitively at single or multiple concentrations, and the proteins that bind to these targets are identified by chromatographic separation and MS analysis. Some considerations in these affinity-based panels are that the affinity of the interaction must be high (Kd < 100 nM), the targets must have relatively good abundance (> 100 copies/cell with 10^6 cells typically harvested), and the identification of specific binding requires optimization of the washing protocols.

Ongoing HTS advancement includes systems that more closely replicate physiological context in the assay format. For example, techniques in which cells are grown under 3-D culture conditions better mimic the biological and pharmacological consequence of the response after compound treatment. An excellent review using 3-D culture of a multicellular tumor spheroid model was recently published (106). The use of 3-D cultures in these tumor models recapitulates the morphological, functional, and mass transport characteristics of the tumor tissue in vivo (107). Such 3-D cultures are also being used in high-throughput toxicity screening and in the analysis of their cytochrome P450-generated metabolites (108). Simple metazoan model organisms (e.g., Caenorhabditis elegans and zebrafish) offer the opportunity to identify substances that modulate complex physiological systems through HTS (58, 59). As these organisms are suitable to both reverse and forward genetics, screens based on target-directed or phenotypic assays are possible. Furthermore, rapid organogenesis (hours to a few days) in these metazoans allows, for example, developmental neurotoxicity and teratogenicity to be studied on the timescales compatible with HTS (6).

Biophysical and analytical measurements adapted to HTS systems have broadened the sophistication of assays formats, as witnessed by the rapid evolution of electrophysiological assays to measure ion channel function (109). The high sensitivity and multiparametric output inherent in flow cytometry (110) has also been applied to HTS and provides a platform for assay multiplexing that uses either beads or intact cells (111). For example, in one study, a three laser flow cytometry system was used to enumerate over 15 different parameters from phosphorylation events within multiple cell types including primary cells to define both pathway and cell-type-specific compounds (112). Such technologies enable the simultaneous correlated measurements of signal transduction networks that provide physiological relevant compound mechanism and selectivity data. Other methods are being developed, based on principles of microcalorimetry, that will enable the mass screening of compounds against targets with unknown function or ligands (113). These advances are but a few of the biological and technological advances that are impacting the future direction and uses of HTS in chemical biology.

Summary and Future Perspective

HTS developed rapidly in the pharmaceutical sector after the molecular biology revolution changed the drug discovery paradigm from a forward to a reverse genetics model (Fig. 3). Technological breakthroughs that allow sensitive in vitro assay designs (64) combined with the explosion in the availability and quality of chemical libraries (Table 1) accelerated the evolution and need for efficient HTS (114). Broad commercialization of HTS platforms and components coupled with an emigration of many "discovery" scientists from industry to academia in recent years has created a unique environment for HTS technology and expertise to enable academic chemical biology. Within a setting less restrained by market pressures, scientists will continue to find novel uses for the experimental power of HTS.
Breaching the ∼90% of the human genome not currently inter-
dicted by small molecules, particularly the “dark matter” of
the genome whose functions remain undefined, is a key challenge
for HTS-assisted chemical biology. The current drug pharma-
copedia targets only ∼330 proteins although as many as 8000
may be involved with disease (115). Aiding to this situation,
polymorphic variations between individuals will demand in-
creased intricacy in chemical genomics research that will fuel
the growing field of pharmacogenomics and ultimately usher
in the era of personalized medicine. Redirecting the fate of
pluripotent stem cells, the holy grail of regenerative medicine,
will likewise find an ally in HTS (116). Understanding the dis-
position and effects of small molecules on biological systems
through research in chemical biology should provide more op-
timal prediction of in vivo efficacy (64) and toxicity (117).
The new HTS approaches are poised to have a transformative
impact on biology and medicine, to remove many historical
limitations to experimental designs, and to bring the promise
of the genomic revolution closer to realization. Finally, the ad-
vent of synthetic biology, which spans from designer receptors
(118, 29) (e.g., Receptor Activated Solely by a Synthetic Lig-
and (RASSL) and Receptor Exclusively Activated by Designer
Drugs (DREADDs)) to genome transplantation (119) to future
man-made life forms, will require novel ligands and designer
drugs to complement and control (or keep in check) this new
biological frontier.

Advances in both genomics and proteomics have provided researchers with access to large collections of biomolecules, including DNA, proteins, and metabolites. High-throughput methods are needed to study the function and regulation of these biomolecules within complex systems. Microarrays have emerged as a common platform to study biomolecular interactions that involve nucleic acids, proteins, and small molecules. DNA microarrays have revolutionized genomic research by allowing researchers to study gene expression, sequence variation, and transcription factor binding sites on a whole-genome scale. Protein microarrays can be used to study interactions with other proteins, DNA, RNA, and small molecules, including lipids, carbohydrates, and drugs. Protein microarrays can also be used as analytical tools to profile complex protein mixtures, such as fractionated cell lysates, in an effort to study antibody specificity, measure changes in protein abundance, or characterize disease states. Small-molecule microarrays are useful tools for ligand discovery, comparing inhibitor specificity across enzyme classes, high-throughput, cell-based phenotypic screens, and as diagnostic tools for pathogen detection. The microarray approach has been extended to transfected cell microarrays, RNAi living cell microarrays, virus microarrays, and tissue microarrays. This article reviews chemical strategies for making microarrays and applications of microarrays in chemical biology.

As the molecular parts list for cells and organisms continues to grow, a key challenge is to identify the function of each component within the context of the cellular system. Increasingly, researchers are choosing to adopt high-throughput, discovery-oriented studies aimed at systems of biomolecules in addition to traditional reductionist studies of the structure or function of a specific biomolecule. Studies of complex biological systems benefit from large-scale and global analyses as the interacting parts can be analyzed simultaneously, which leads to hypotheses about how the components come together to effect processes such as development, disease, or evolution. Several high-throughput methods have been developed to study the function and regulation of biomolecules, including nucleic acids, proteins, and metabolites. In particular, microarray technology has emerged as a revolutionary platform to analyze all types of biomolecules in a highly parallel fashion.

Biologic Background

Microarrays were introduced in the 1990s for use in genomic studies (1–4). Microscopic features of probe nucleic acids, including oligonucleotides, cDNAs, or PCR products that correspond to predicted or known mRNAs, are deposited on a stable, solid substrate such as glass or silicon. Taking a cue from the Southern blot, the affixed probes are hybridized with cDNA from the sample of interest. Thousands of probes can be accommodated on a single microarray providing an opportunity to interrogate whole genomes (5). DNA microarrays, otherwise known as DNA chips, are valuable tools for gene expression profiling (6), comparative genomic hybridization (6), genotyping (7), chromatin immunoprecipitation (8), and in vitro studies of protein–DNA interactions (9, 10). DNA microarray technology has also had a significant impact on medicine by facilitating connections between physiologic states and gene expression patterns in studies of cancers, disease progression, and cellular responses to toxins or therapeutics (11). DNA microarray technology is now widely accessible to researchers through commercial microarray products and academic genome centers.
The miniaturized and highly parallel microarray format has also become a common platform in applications that involve other types of biomolecules (Table 1). Shortly after the advent of DNA microarrays, small molecules and proteins were captured in the microarray format (12, 13). Microarrays of carbohydrates (14, 15), lipids (16), peptides (17), cells (18), viruses (19), and tissues (20) have also been reported. Why has the microarray format become so attractive for studying diverse types of biomolecules? Assay miniaturization is a key advantage of microarray-based assays. Miniaturization reduces the amount of sample required for the assay and increases the density of samples that may be analyzed simultaneously. Microarrays are also easy to manufacture and store. Most types of microarrays are stable for up to six months under proper storage conditions. Benefiting from advances in automation, replicate arrays can be processed in parallel, which allows researchers an opportunity to evaluate thousands of probes across a variety of sample conditions simultaneously. These advantages make the microarray format attractive to researchers in chemical biology with an interest in studying responses of transcriptomes or proteomes to small molecules. Additionally, microarrays provide an attractive format to screen precious small molecules, such as natural products and compounds coming from combinatorial libraries, against collections of nucleic acids, proteins, or cells. Advances in microarray-related technologies, including the use of epoxide-coated slides and attachment via N-hydroxysuccinimide (NHS) activated esters, this approach obviates the need for additional coupling catalysts. Readily commercially available epoxide-coated glass slides have been used to capture hydrazide-tagged small molecules and carbohydrates (28, 29). Most surface capture methods take advantage of a reactive functional group that is introduced as part of their synthesis and biases the orientation of the small molecule on the surface. Motivated by the need to increase molecular diversity on SMMs, nonselective approaches to capturing compounds have been adopted. Bradner et al. (30) reported the use of an isocyanate-mediated capture strategy to print nearly 10,000 known bioactive small molecules, natural products, and small molecules originating from several diversity-oriented syntheses. Isocyanates react with a variety of nucleophilic functional groups, thereby increasing the number of small molecules, from natural or synthetic sources, that may be printed on a single surface. Kanoh et al. (31) prepared microarrays of approximately 2000 natural products and drugs by photo-cross-linking compounds on trifluoromethylaryldiazarine-coated surfaces. Using this approach, photogenerated carbenes react with the printed compounds in a manner that is independent of the functional group. Both the isocyanate and the photo-cross-linking strategies present the possibility of printed compounds that occupy multiple modes of orientation within a given spot, which effectively increases the number of binding modes that a given probe protein can sample. Several surface-capture methods applied to SMMs have also been used to prepare protein microarrays, including the use of epoxide-coated slides and attachment via Staudinger ligation (32, 33). A different attachment strategy has been developed in the context of fabricating protein microarrays and have been reviewed previously (34, 35). Commonly, aldehyde-coated and epoxy-coated slides have been used to capture covalently proteins in a heterogenous fashion by reacting with amino groups (13, 35). As mentioned, retaining the protein function is a key concern when using covalent chemistry to prepare microarrays, and thus, several groups have pursued noncovalent fabrication of functional protein microarrays.

### Strategies for Preparing Microarrays and Methods for Detecting Interactions

The first step of any microarray experiment involves design and fabrication of the chips containing probe molecules of interest. Immobilization methods should take both orientation of display and molecular stability into account. Stability is an especially important concern in the area of protein microarrays as many applications require that individual proteins retain their conformation and function (23). Most types of arrays are prepared by immobilizing the biomolecules on chemically treated glass microscope slides using either microcontact spotters or piezoelectric deposition. Microcontact lithography, using either masks or optical methods, is another common method for fabricating microarrays and is used routinely to prepare oligonucleotide arrays (3, 24). Several capture strategies have been developed for microarrays and include both covalent attachment of the probes to surface and noncovalent deposition (Table 2). Both approaches have proven useful in making arrays of nucleic acids, small molecules, and proteins.

### Covalent capture strategies

It is common for microarrays to include biomolecules that are attached covalently to a glass or silicon surface. For spotted microarrays, biomolecules are coupled using a variety of attachment chemistries (Table 2). Most advances in attachment chemistry have been driven by the preparation of small-molecule microarrays (SMMs) as small organic molecules tend to have more diverse functional groups than biopolymers. Many attachment chemistries have been reported and reviewed elsewhere (25, 26). Most of these approaches involve mild and selective coupling reactions. The first SMMs made use of a Michael addition reaction that involves molecules containing free thiols printed onto slides coated with vinyl sulfone or maleimide groups (12). Although this strategy proved successful, it was not general as most compound libraries do not contain a high proportion of free thiols. Many more compounds that come from both combinatorial libraries and natural product collections contain amino groups. Although these compounds may be coupled to carboxy-modified glass via amide bond formation, Chang and coworkers (27) chose to print a library of amine-containing molecules on slides coated with N-hydroxysuccinimide (NHS) activated esters. This approach obviates the need for additional coupling catalysts. Readily commercially available epoxide-coated glass slides have been used to capture hydrazide-tagged small molecules and carbohydrates (28, 29). Most surface capture methods take advantage of a reactive functional group that is introduced as part of their synthesis and biases the orientation of the small molecule on the surface. Motivated by the need to increase molecular diversity on SMMs, nonselective approaches to capturing compounds have been adopted. Bradner et al. (30) reported the use of an isocyanate-mediated capture strategy to print nearly 10,000 known bioactive small molecules, natural products, and small molecules originating from several diversity-oriented syntheses. Isocyanates react with a variety of nucleophilic functional groups, thereby increasing the number of small molecules, from natural or synthetic sources, that may be printed on a single surface. Kanoh et al. (31) prepared microarrays of approximately 2000 natural products and drugs by photo-cross-linking compounds on trifluoromethylaryldiazarine-coated surfaces. Using this approach, photogenerated carbenes react with the printed compounds in a manner that is independent of the functional group. Both the isocyanate and the photo-cross-linking strategies present the possibility of printed compounds that occupy multiple modes of orientation within a given spot, which effectively increases the number of binding modes that a given probe protein can sample. Several surface-capture methods applied to SMMs have also been used to prepare protein microarrays, including the use of epoxide-coated slides and attachment via Staudinger ligation (32, 33). A different attachment strategy has been developed in the context of fabricating protein microarrays and have been reviewed previously (34, 35). Commonly, aldehyde-coated and epoxy-coated slides have been used to capture covalently proteins in a heterogenous fashion by reacting with amino groups (13, 35). As mentioned, retaining the protein function is a key concern when using covalent chemistry to prepare microarrays, and thus, several groups have pursued noncovalent fabrication of functional protein microarrays.
Noncovalent microarrays

Noncovalent fabrication methods have been used to make microarrays of nucleic acids, small molecules, and proteins (Table 2). Slides coated with aminosilane or poly-L-lysine have been used to capture randomly oligonucleotides (36), proteins (37), and cells (18) via electrostatic interactions or passive adsorption. Similarly, DNA, proteins, and carbohydrates have been arrayed on nitrocellulose-based substrates (38–40). Homogenous orientation may be achieved using affinity tags. For example, large collections of His-tagged proteins have been printed on nickel-coated slides (41). Alternatively, probe biomolecules can be biotinylated and printed on streptavidin-coated surfaces (42). Taking advantage of the highly specific fluoros affinity interaction, Pohl and coworkers (43) noncovalently captured fluoros-tagged carbohydrates on fluoroalkylsilane-coated slides. Winsinger and coworkers (44) prepared SMMs containing a PNA-encoded tetrapeptide acrylate library via sequence-specific hybridization to an oligonucleotide microarray. This elegant approach allows encoding combinatorial libraries and immobilization on-array via self-assembly. Finally, both microarrays and microdroplets have been adapted to the microarray format in an effort to carry out experiments in solution (45, 46).

Detection methods

A rather important planning step involves choice of detection method. Whether using DNA microarrays in whole-genome expression profiling or using small-molecule microarrays to identify new ligands for a protein target of interest, some method of detection is required to locate probe-sample interactions. Typically, probes are labeled with fluorescent, chemiluminescent, radioactive, or affinity tags. Most applications involve a fluorescent readout and the use of a fluorescent microarray slide scanner. A variety of fluorescent reagents, including reactive dyes, fluor-labeled proteins, and fluor-labeled secondary antibodies, are commercially available and considered safer than radioactive labels. Detection strategies may include combinations of different label types. For example, a microarray may be incubated with biotinylated protein followed by incubation with fluorescently labeled streptavidin. Potential disadvantages of label-based detection include overlabeling of protein samples that results in loss of protein conformation or activity. Care should be taken not to label a critical functional group in a small molecule or protein required to bind its target probe. Label-free approaches are gaining momentum in the field of microarrays (47). In particular, surface plasmon resonance (SPR) detection has been used successfully to detect interactions of proteins applied to small-molecule microarrays (48) and will likely prove useful in high-throughput studies that involve protein microarrays.

Applications of Microarrays in Chemical Biology

Microarrays have served as tools for investigations in chemical biology. DNA microarrays are used to study the effects of small molecules on gene expression (49–51). Small-molecule microarrays are used for ligand discovery and enzyme specificity profiling (14–17, 26) as well as for high-throughput, cell-based phenotypic screens (52) and as diagnostic tools (22, 53). Protein microarrays are used for studying interactions with other proteins, nucleic acids, and small molecules, including lipids, carbohydrates, and drugs (23). Protein microarrays are also used as analytical tools to profile complex protein mixtures, such as fractionated cell lysates, in an effort to study antibody specificity, measure changes in protein abundance, or characterize disease states. The microarray approach has

been extended to transfected cell microarrays (18), RNAi living cell microarrays (52), virus microarrays (19), and tissue microarrays (20), all of which may be future tools for characterizing the effects of small molecules. A brief sampling of representative applications of microarrays in chemical biology is presented.

Microarrays of nucleic acids
DNA microarrays enable genome-wide measurement of transcriptional responses to small molecule treatment. Typically, drugs and bioactive compounds from target-oriented assays or phenotypic cellular assays are probed in an effort to gain insight into mechanism of action (49). While a great deal of information is gained from these experiments, it is still difficult to draw conclusions about mechanism within isolated datasets. Rather, systematic and comparative analyses using databases of transcriptional profiles have proven valuable in this regard. Lamb et al. (50) described The Connectivity Map as a publicly accessible reference collection of transcriptional profiles in human cultured cells treated with small molecules, including FDA-approved drugs and bioactive tool compounds. By comparing the profile of a novel small molecule to those of known therapeutics, compounds may be annotated as resembling compounds from a known therapeutic class or novel in genomic signature. Additionally, the Connectivity Map project aims to describe genomic signatures of physiological and disease states. In combination with pattern-matching tools, the authors make connections between drugs, genes, and diseases. Specifically, genomic signatures were used to recognize drugs with common mechanisms of action, discover unknown mechanisms, and identify new compounds with therapeutic potential. The authors proposed expanding this resource by profiling all FDA-approved drugs and inhibitory RNAi targeting a wide selection of genes in a panel of diverse cell lines. Individual researchers may perform their own Connectivity Map analysis by using a web-based tool (www.broad.mit.edu/ctmap). In an effort to create target identification hypotheses for small molecules positives in phenotypic screens, Butcher et al. (51) used a microarray approach to monitor effects of gene overexpression on yeast growth in the presence of small molecules. A collection of roughly 3900 Saccharomyces cerevisiae strains harboring different overexpression plasmids was monitored for changes in growth in response to treatment with a small molecule. As a proof of concept, the authors identified genes that, when overexpressed, affect yeast growth in the presence of the natural product drug rapamycin. Target of rapamycin protein (TOR) was successfully identified as candidate rapamycin target and several new genes were implicated in the TOR pathway. The authors used the same microarray-based method to identify candidate targets for LY-83583, a suppressor of rapamycin-induced growth inhibition. Finally, Amin and coworkers used DNA microarrays to interrogate sequence specificity of several fluorescent-labeled DNA-binding molecules, including engineered polyaniline molecules and proteins (10). The cognate site identifier (CSI) microarrays allow rapid and unbiased examination of sequence space and the authors propose using the arrays to determine the sequence preferences of all metazoan DNA-binding proteins and DNA-binding small molecules.

Small-molecule microarrays
The primary use of SMMs to date is ligand discovery. Advantages, including throughput and rapid access to SAR, and disadvantages, including false negatives caused by orientation, have been reviewed previously (26). Typically, a protein of interest is incubated with the array and binding interactions are visualized using a fluorescent readout. Fluorescence intensity is used to rank positive interactions. As most SMM readouts do not correlate directly with affinity, secondary assays, such as thermal-shifts or SPR, are used to confirm positives and to study both the kinetics and the affinity of binding (26). Representative interactions discovered using SMMs are shown in Fig. 1. Interactions of varying affinities that involve proteins from different functional classes, including transcription factors, cytokines, and enzymes, have been discovered. For example, uretupamine and haptamide bind and perturb the functions of two yeast proteins involved in transcriptional regulation and nutrient-sensing (55, 56). Several ligands with differing molecular scaffolds have been identified for calmodulin using SMMs. Calmodioxane (57) and calmodophilin (58) are products of diversity-oriented syntheses executed by Schreiber and coworkers. NPC-15437, which is a known inhibitor of protein kinase C, binds to calmodulin preferentially when Ca²⁺ is present in incubation buffer (26). Hsieh-Wilson and coworkers (59) used chondrin sulfates microarrays to identify chondrin sulfate-E tetrasaccharide as a ligand for tumor necrosis factor alpha (TNF-α) and demonstrated that the compound disrupted a cytokine-cell surface receptor interaction. Selective inhibitors of closely related cytokine proteases, catherpin F and catherpin K, were identified using the PNA-encoded tetrapeptide acrylamide microarrays prepared by Urbina et al. (44). Small-molecule ligands have also been identified for human IGF (25), FKBP12 (60), and A urora A kinase (61). SMMs have also been used to identify high-affinity interactions between RNA secondary structure motifs and small molecules (62). Microarrays containing drug-like small molecules and carbohydrates have proven very useful for studying carbohydrate-cell interactions because the surface presentation mimics interactions at cell surfaces (22, 63). Enzyme activity assays may also be performed in the SMM format. Yao and coworkers (64) used nanodroplet SMMs for profiling 400 hydroxamate-containing peptide analogs against two matrix metalloproteases and identified selective inhibitors with IC₅₀ values in the nanomolar range. Finally, Dordick and coworkers (65) disclosed a very exciting new application that involves on-array synthesis of natural product analogs using in vitro metabolic pathway construction. The authors demonstrate that these microarrays serve as a platform for synthesis and screening by identifying three inhibitors of Fyn tyrosine kinase.

Protein microarrays
The first functional protein and peptide arrays were micropatterned using lithographic methods in 1992 (66). Several years later, McDade and Schreiber (13) reported spotted functional protein microarrays capable of detecting protein-protein interactions, protein-ligand interactions, and biochemical activities.
Figure 1  Representative protein–ligand interactions discovered using small-molecule microarrays. (Adapted from Refs. 26, 27, 44, and 55–62.)

Since initial reports, protein microarrays, including peptides, domains, full-length proteins, antibodies, and lysates, have been used in a variety of applications that are reviewed elsewhere (23). MacBeath and coworkers (67) have used protein microarrays to build quantitative protein interaction networks between ErbB receptors with Src homology 2 (SH2) domains and phosphotyrosine binding (PTB) domains. The authors discovered several new binding interactions and proposed that the oncogenic potential of receptor tyrosine kinases may be a function of alterations in binding promiscuity because of changes in EGFR and ErbB2 protein concentrations as both proteins are notably overexpressed in several cancers. The same research group used a similar approach to examine binding of 157 mouse PDZ domains to 217 genome-encoded peptides in an effort to obtain a broad view of selectivity (68). Snyder and coworkers (69) prepared microarrays that contain 282 yeast transcription factors and probed them with fluor-labeled oligonucleotides in an effort to link sequence to binding. Using this approach, the authors defined the binding site of an uncharacterized DNA-binding protein and determined that several of its target genes are involved in stress response and oxidative phosphorylation. The same research group performed biochemical activity analyses on yeast proteome chips to identify in vitro substrates for protein phosphorylation (70). Protein microarrays are also useful tools for target identification (71). As outlined in Fig. 2, Huang et al. (71) prepared biotinylated versions of small molecules known as SMIR3 and SMIR4 that scored as positives in a chemical genetic modifier screen. The labeled compounds were applied to a yeast proteome chip followed by incubation with fluorescently labeled streptavidin. In this fashion, the authors identified lists of candidate protein targets for each compound. One of these proteins, Ybr077cp, was the subject of follow-up studies to confirm the interaction in vivo. Several research groups have used protein and antibody arrays for profiling activities in complex fractions such as whole lysates or proteomic fractions (Fig. 3). Cravatt and coworkers (72) have employed activity-based protein profiling (ABPP) using active-site-directed probes to profile the functional state of enzymes in proteomes. The authors first treated proteome fractions with fluorescent activity-based probes and then applied the fractions to microarrays that contain antibodies against enzymes of interest. Labeled enzymes will be captured so long as a complementary antibody is present. Miah and coworkers (73) developed a method for analyzing the dynamic glycosylation status of cells by profiling differentially fluor-labeled membrane fractions on microarrays that contain lectin proteins. In analogy to gene-expression profiling, the authors propose this method as a means to make comparisons between glycosylation patterns in different cell states. Finally, reverse-phase protein microarrays, where cell lysate samples are...
target identification using yeast proteome microarrays. (a) Using a chemical genetic modifier screen, Huang and coworkers (71) identified small-molecule inhibitors of rapamycin (SMIRs) that suppress the antiproliferative effect of rapamycin in S. cerevisiae. (b) Biotinylated derivatives of SMIR3 and SMIR4 were synthesized for incubation with proteome microarrays in an effort to identify putative protein targets. (c) Binding of biotinylated SMIR3 and SMIR4 to proteins on a yeast proteome chip that contains ∼5,800 proteins was detected using Cy3-labeled streptavidin. Nine proteins bound to SMIR3 with one protein, Tep1p, annotated as a strong binder. Thirty proteins bound to SMIR4 and four proteins were annotated as strong binders, including Rot1p, YBR077wp, YBR193wp, and Mep1p.

Although less developed relative to microarrays of biomolecules, living microarrays will no doubt play an increasing role in chemical biology. Current applications of this technology include high-throughput and localized transfection (18), high-throughput phenotypic screening of small molecules (52), and loss-of-function screens using RNAi (19, 54). The data gained from these types of experiments should be highly complementary to that gained from the effects of evaluating small molecules using the other microarray platforms. To make the most of the various microarray platforms, standardized array data outputs will be required to address issues that surround reliability and reproducibility of data generated in a microarray format (76). A additionally, databases equipped with Web-based analysis tools will be needed to make the large amount of information generated using microarrays available for public scrutiny (77, 78).

Microarrays in Chemical Biology

Figure 3 Changes in protein abundance levels in response to alterations of cell state (e.g., disease or treatment with a small molecule) can be monitored using microarrays. (a) By analogy to transcriptional profiling, antibody microarrays may be used to profile fluorescently-labeled protein fractions. In this scheme, proteins enriched in the compound-treated sample, relative to untreated cells, provide red microarray features. Proteins depleted in the compound-treated sample appear as green features. Proteins that do not change in abundance result in yellow features. Proteins that are absent from the samples, resistant to labeling, or overlabeled such that they no longer recognize the printed antibody give no fluorescent signal. (b) Alternatively, protein fractions from cell lysate samples may be printed on microarrays. Replicate arrays are then probed with different fluor-labeled antibodies of interest to monitor changes in protein abundance. In this scheme, lysate features that contain proteins of interest will be fluorescent (red), whereas lysates that do not contain the protein are not fluorescent (black). Fluorescently labeled control proteins, such as BSA or streptavidin, or antibodies are included as reference points in the arrays (green).

doi: 10.1002/9780470048672.wecb393

Nuclear Magnetic Resonance (NMR) spectroscopy is a powerful method to determine the structure of biomacromolecules and their complexes in solution. It allows determination of the dynamics of proteins, RNA, DNA, and their complexes at atomic resolution. Therefore, NMR spectroscopy can monitor the often transient weak interactions in the interactome of proteins and the interaction between proteins and small-molecule ligands. In addition, intrinsically unstructured proteins can be investigated, and first reports of structure determination of membrane proteins in the immobilized state (solid state) are developing. This review will introduce the fundamental NMR observables as well as the methods to investigate structure and dynamics, and it will discuss several examples where NMR spectroscopy has provided valuable information in the context of Chemical Biology.

Chemical Biology

Research in Chemical Biology is dedicated to the design and targeted synthesis of novel molecules of small or large molecular weight to investigate how they maintain, modulate, regulate, or interfere with cellular function or even change the function, morphology, and differentiation status of entire cells. The structure-function relationship that leads to the understanding and prediction of cellular function is at the heart of chemical biology. Molecules exert function through their chemical properties, which are determined by the dynamic spatial arrangement of their atoms, their interactions with other molecules, their stabilities against degradation, and their localization within the cell.

Chemical Biology encompasses more aspects than the development of novel high-affinity ligands for targets of pharmaceutical interest alone. However, if the latter is understood as the art of developing novel chemical entities toward new drugs, then Chemical Biology has a tremendous impact on the understanding of key properties of molecules that may induce specific cellular responses or help maintain cellular function.

NMR Spectroscopy

Nuclear magnetic resonance (NMR) spectroscopy is a noninvasive and nondestructive spectroscopic technique that allows determination of the constitution and relative configuration of molecules, the characterization of the dynamic three-dimensional (3D) conformation of molecules, and their interaction with other molecules. NMR spectroscopy detects the characteristics of nuclear spins; the most commonly studied nuclei are the spin-1/2-particles 1H, 13C, 15N, and 31P. NMR observables sensitively depend on their chemical surroundings of individual atoms. Therefore, NMR spectroscopy can derive information about the conformational dynamics and interactions of molecules in solution and at ambient temperature. In addition, thermodynamic and kinetic information about the interaction of molecules can be derived on a per-atom basis.
Biochemical NMR spectroscopy is applicable to both liquid- and solid-state samples. Liquid-state NMR spectroscopy, in which molecules are dissolved in a variety of different solvents and studied at ambient temperatures, is a powerful tool to derive information on the structure of proteins and nucleic acids, as well as their complexes with each other and small molecules, ions, and solvents. Liquid-state NMR can be applied not only to native folded states of proteins, but also to intrinsically unstructured proteins as well as proteins in their unfolded state and under nonphysiological conditions (i.e., in organic solvents).

Figure 1 provides an overview on the number of protein structures determined by liquid-state NMR spectroscopy. NMR spectroscopy can detect the conformational dynamics, which are also referred to as conformational switching of RNA molecules that exist in different stable states. Solid-state NMR spectroscopy investigates molecules as powders or crystals and has become a powerful tool for the investigation of membrane proteins and their complexes with small peptide agonists. In addition, protein amyloid fibers and polymers can be investigated.

Furthermore, NMR spectroscopy can study intrinsically unstructured proteins and noncoding RNAs uniquely, which includes their structural transitions induced when encountering molecular targets. The technique can be applied to systems under defined conditions (in vitro), but proteins can also be investigated within cells (in vivo). NMR can monitor the concentration fluxes of complex mixtures, which are extracted from tissue or within body fluids. These fluxes are important for understanding the metabolic state of an organism (metabonomics). In this context, NMR has been applied to characterize the metabonomics of entire organisms such as Caenorhabditis elegans.

In this review, we present the basic observables and tools in liquid-state NMR spectroscopy followed by examples of the application of NMR in chemical biology. We will focus on the application of NMR spectroscopy to study proteins in solution.

Basic NMR Observables

In NMR spectroscopy, signals of NMR-active nuclei with spin $i$ (e.g., $^1$H, $^{13}$C, $^{15}$N, $^{19}$F, and $^{31}$P) have Lorentzian line shapes with center peak positions referred to as chemical shift $\delta$. Their linewidths at half height $\Gamma_{1/2}$ depend on the overall correlation time for rotational tumbling $\tau_c$ of the molecule that is proportional to the size of the molecule, and on possible local conformational or chemical exchange processes. Figure 2 shows the one-dimensional (1D) proton spectrum of a small molecule, which is an inhibitor of the kinase p38, dissolved in dimethyl sulfoxide (DMSO). The integral of each signal corresponds to the number of different protons that cannot be superimposed by symmetry operations or that are equivalent because of dynamic averaging. Magnetically nonequivalent atoms generate higher-order spectra; this phenomenon will not be discussed here.

Expansions of three regions in the spectrum on the right hand side of (Fig. 2) show how protons display different line shapes according to their chemical environments. The protons in exchange with residual water in the DMSO solvent, such as the urea protons (H1 and H2), exhibit exchange broadened signals (Fig. 2a), whereas nonexchangeable protons (e.g., H3) (Fig. 2b) have sharp signals. The aromatic protons are coupled to each other through scalar $J$-couplings (vide infra), which results in the higher-order spectrum with a complex peak pattern shown in (Fig. 2c).

In the following five paragraphs, the basic NMR observables will be introduced briefly, for a more thorough introduction we recommend “Spin dynamics, basics of nuclear magnetic resonance” by Malcolm H. Levitt (1) or “NMR: the toolkit” by Peter Hore et al (2).

Chemical shift

The most important NMR parameter is the chemical shift $\delta$, which is derived from the Larmor frequency of a given nucleus $\gamma$ that resonates in a magnetic field. The chemical shift is measured in parts per million (ppm) relative to a reference compound.

The Larmor frequency of a given nucleus depends on the gyromagnetic ratio $\gamma$ (a physical property of the nucleus) and the magnetic field. The electron density that surrounds the nucleus results in an additional magnetic field that opposes the external field and thereby slightly alters its Larmor frequency.

\[ \delta = \frac{\gamma B_0}{2 \pi} \]

The chemical shift can be influenced by chemical exchange, molecular dynamics, and other through scalar $J$-couplings (vide infra), which results in the higher-order spectrum with a complex peak pattern shown in (Fig. 2c).

Chemical shift

The most important NMR parameter is the chemical shift $\delta$, which is derived from the Larmor frequency of a given nucleus $\gamma$ that resonates in a magnetic field. The chemical shift is measured in parts per million (ppm) relative to a reference compound.
Nuclear Magnetic Resonance (NMR) Spectroscopy: Overview of Applications in Chemical Biology

This modulation of the main field is referred to as shielding, and the shift of the NMR frequency leads to characteristic chemical shift values for the different functional groups or certain environments.

The NMR signal of a nucleus will appear at an average chemical shift value. In case of the three protons of a methyl group, such averaging comes about from fast rotation around the CC-bond that connects the methyl group to the rest of the molecule; the rotation leads to identical chemical shifts for the three protons. Slow molecular motions on the NMR timescale (see the section entitled “Dynamic information from line shape analysis”) can lead to one nucleus having two peaks due to two different conformations. On the intermediate timescale, the averaged NMR signal will be broadened and may disappear. Thus, the NMR chemical shift values are very sensitive probes of the local structure and conformation.

Different methods exist that predict protein secondary structure elements from chemical shift values [e.g., Chemical Shift Index (CSI) (3) and Probability-based protein Secondary Structure Identification using combined NMR chemical-shift data (PSSI)] (4). These methods are based on the statistics of database analysis of chemical shift values from a range of peptides and proteins of known secondary structure. Chemical shifts have also been used to predict backbone torsion angles by software such as Torsion Angle Likelihood Obtained from Shifts and Sequence similarity (TALOS) (5).

More recently, software has been developed that predicts 1H, 13C, and 15N chemical shift values of proteins from either 3D structure files, for example, SHIFTS (6), SHIFTX (7), and SPA RTA (8), or from the mere amino acid sequence using SHIFTY (9). First results have been reported on the de novo structure determination of proteins using fragment-based chemical shift predictions and molecular modeling (10, 11).

Spin-spin coupling (J-coupling constant)

The 1J-coupling, which is also known as the indirect spin-spin-coupling or scalar coupling, develops from interactions between electrons and nuclear spins of atoms n bonds apart, where there is a slight energetic preference for the nuclear spin to have the same direction as the nearest electron spin. Briefly, this phenomenon is known as the Pauli Exclusion Principle (stating that two fermions cannot occupy the same quantum chemical state simultaneously) that leads to tiny but measurable energy differences depending on the spin states of covalently bonded atoms. The J-coupling will split the NMR signal of each nucleus into multiplets depending on its number of NMR active neighbors (i.e., the amount of different spin states available within the coupled spin system). Typically, scalar couplings are observed for nuclei that are connected by up to three bonds. In rigid systems such as aromatic rings, however, they may even be observable across up to five bonds. The size of the coupling between two nuclei is termed the J-coupling constant. The multiplicity of a signal is determined by the number of chemically equivalent nuclei that couple to the nucleus of interest by through-bond interactions, usually one, two, or three bonds apart.

Vicinal 1J-coupling constants provide valuable information for the determination of biomacromolecule conformation. The structural information is derived from Karplus equations (12) that provide empirical relationships between dihedral bond angles, and the 1J-coupling. Karplus equations obey the following general formula:

\[ 1J(\phi) = A \cdot \cos^2 \phi + B \cos \phi + C \]

where \( \phi \) defines the torsion angle; and A, B, and C are either empirically calibrated or calculated from quantum chemistry. A given 1J-coupling may correspond to up to four different torsion angles, but this ambiguity can be resolved by measuring...
which are indicative of secondary structure, can be defined and measured as the Nuclear Overhauser Effect (NOE) (16). The NOE effect arises from dipolar relaxation effects. This interaction between dipoles of the internuclear vector in the magnetic field persists and increases with the gyromagnetic ratio ($\gamma$) of the two nuclei each possessing a magnetic moment that creates a local magnetic field that will be sensed by the neighboring nucleus. The interaction strength of two magnetic dipoles depends on the internuclear distance ($d_{AB}$) and the orientation ($\theta_{AB}$) of the internuclear vector that connects A and B and the external magnetic field.

In isotropic solution, the dipolar coupling is averaged to zero through molecular rotational tumbling with a characteristic correlation time $\tau_c$. Yet, on shorter timescales, fixed orientations of the internuclear vector in the magnetic field persist and induce dipolar relaxation effects. This interaction between dipoles causes relaxation by transfer of magnetization between different NMR active nuclei and is called the NOE. The NOE effect is strongest between protons as they have large gyromagnetic ratios, and NOEs are generally observed between protons that are situated within 5 Å of each other.

Partial alignment introduces a residual dipolar coupling on a spin pair like the backbone $^1$H-$^1$C bond. A $^1$H-$^1$C spin pair in isotropic solution will, in a coupled spectrum, yield a doublet with a splitting the size of the $^1$J-coupling. In an anisotropic solution, however, the splitting observed is the sum of the scalar coupling ($^1$J$_{CB}$) and the residual dipolar coupling ($^1$D$_{CH}$). The size of the residual dipolar coupling depends on the orientation of the bond vector relative to the molecular alignment tensor.

One important application of RDC measurements is the structural refinement of biomolecules that consist of several domains that are connected by more or less flexible linkers. Because of the flexibility of the linker and the distance between domains, $^1$J-couplings and NOE restraints will frequently not be sufficient for correct determination of the relative domain orientation. The addition of RDC restraints in structure calculation not only refines the biomolecular structure but also allows the relationship between structure and function to be studied. Interactions with other biomolecules and ligand binding may induce an intramolecular rearrangement of the relative orientation of domains that is detectable through RDC measurements (23, 22).

**Relaxation**

Relaxation, or the return of nuclear spin magnetization to the equilibrium state, occurs essentially by two different physical processes that allow the nuclear spins to exchange energy with their surroundings: one that occurs parallel to the direction of the external magnetic field (longitudinal) and one that is transverse to the external field. The longitudinal relaxation time $T_1$, or spin-lattice relaxation, develops from interactions with neighboring unexcited nuclei (the lattice) that affects the component of magnetization in the direction of the external magnetic field. The transverse relaxation time $T_2$, or spin-spin relaxation, develops from dispersion of magnetization between excited neighboring spins that have magnetic moments orthogonal to the external field. The longitudinal relaxation time in the rotating frame, $T_{1w}$, is the relaxation time of magnetization that has been spin-locked perpendicular to the external field (23, 24).

$T_1$ reports on fast dynamics on a timescale of ps-ns, whereas $T_2$ relaxation depends on both fast and slower dynamics (ps-ns and μs-ms). The experimentally measured $T_2$ relaxation times include an exchange contribution that can be measured by a Carr-Purcell-Meiboom-Gill (CPMG) pulse train (25, 26) or an effective spin-lock field (27-29). The combination of $T_1$ and $T_2$ measurements allows determination of the contribution of chemical exchange to the relaxation time. Furthermore, relaxation dispersion experiments have been developed to measure slow time-scale μs-ms dynamic processes (30-35).

Heteronuclear NOEs (e.g., $^1$H-$^15$N or $^1$H-$^1$C hetNOEs) are obtained by measuring HSQC-type spectra (see the section entitled “Two-dimensional heteronuclear correlation experiments”) with and without proton saturation. The hetNOE is extracted from the difference in the signal amplitude of these measurements and reports on the fast dynamics of the heteronuclear bonds (ps to ms timescale). Maximal hetNOE values are observed when the bond vector tumbles at the same frequency as the entire protein, whereas faster motion with respect to overall tumbling leads to smaller hetNOEs.
The conformational dynamics of a biomolecule can be determined by measuring the relaxation properties of the heteronuclear bond vectors (e.g., the protein backbone $^{1}H$-$^{15}N$ bond). Regions of a protein that are unstructured or flexible (e.g., loops and tails) will typically show larger $T_2$ and $T_1$ values and smaller $T_2^*$ values and hetNOEs than the rigid well structured core of the molecule. Distinct changes in the flexibility of a biomolecular structure caused by ligand binding can therefore be probed using a combination of heteronuclear relaxation experiments.

Relaxation is strongly dependent on molecular motions. The overall random molecular tumbling, which is expressed in the rotational correlation time $\tau_\nu$, governs the overall relaxation process. Larger molecules have slower tumbling motions that lead to higher $\tau_\nu$ values. However, local dynamics and independent domains can modulate the relaxation parameters, which account for differences in their flexibility and mobility.

Typically, relaxation times are interpreted in the framework of a model-free analysis (36-38), and the general order parameter $S_2$ of a given heteronuclear bond can be extracted. $S_2$ defines the spatial restriction on a per-residue basis of a target protein. Unique information can be obtained about the changes that occur to a target molecule on ligand binding by measuring $S_2$ before and after the binding event. The order parameter varies between 0 and 1, which spans from completely unrestricted internal motion of the bond vector ($S_2 = 0$) to complete rigidity ($S_2 = 1$). Dynamics that are equal to or faster than the overall correlation time can be measured by the order parameter (39, 40).

Experimental Techniques

NMR spectroscopy provides important information on molecular structure and dynamics, but certain limitations apply for the study of biomolecules. The sample conditions need to be optimized toward stability at high concentrations without exceeding a salt concentration of roughly 300 mM (leading to increased NMR pulse length). To reduce $N$-H exchange, the solution should be buffered to a pH between 5 and 7. Distinct chemical shifts allow monitoring of individual atom types, but dispersion is rather low (on the sub-ppm scale) and easily produces spectral overlaps especially for larger molecules. The size of the molecular target (e.g., protein or RNA) also restricts NMR experiments because of relaxation effects. It is, however, possible to reduce these relaxation effects greatly by partial or selective deuteration.

To reduce spectral overlap, 1D NMR can be extended to higher dimensional NMR experiments. Two-dimensional (2D) experiments that correlate protons through J-couplings or dipolar couplings include $^1$H-$^1$H COSY (43), $^1$H-$^1$H TOCSY (42), and $^1$H-$^1$H NOESY (43, 44). Particularly helpful are 2D het-teronuclear experiments, which correlate protons with directly bound carbon or nitrogen atoms. Furthermore, a variety of 3D and higher-dimensional experiments has been developed that are essential for assigning large biomolecules (45). In contrast to protons, NMR-active and stable isotopes $^{13}C$ and $^{15}N$ both have low natural abundances, and proteins are therefore typically expressed in Escherichia coli bacteria that grow in a minimal medium that contains only $^{12}$C, $^{13}$N labeled precursors, which allows proteins to be studied in isotope labeled form. Recently, expression media have also been established to express isotope-labeled proteins in sf9 cells (46) or HEK293 cells (47).

Typical protein concentrations are between 0.1-1 mM in 0.3-0.5 mL of buffered solutions that correspond to approximately $10^7$-10^8 molecules per NMR sample for detailed structural studies, but it can be as low as 10^5 for more analytical purposes.

Sensitivity can furthermore be increased up to fourfold by using cryogenic probe technology, in which the radio frequency (RF) transmitter and preamplifier coils are super-cooled to 20K by helium gas that ensures higher signal-to-noise of the electrical signal. Vacuum insulation around the RF coil allows the NMR sample situated only millimeters away from the coil to be measured at ambient temperature.

The development of higher magnetic field strength has also been vital to improve both resolution of NMR spectra (proportional to $B_0$), where $n$ is the dimensionality of the NMR experiment and sensitivity (proportional to $B_0^n$).

A rather new way of overcoming spectral overlap for proteins is selective isotope labeling of one or several amino acid types, which results in less-crowded $^1$H-$^15$N spectra with cross-peaks from the labeled residues only. The same is possible for RNA where nucleotides can be selectively isotope enriched. In addition, methods for segmental labeling of parts of the biomolecules have been developed for proteins (48, 49) and for RNA (50).

One-dimensional NMR spectroscopy

The very high resolution of the chemical shifts gives information on a per-residue basis, and it also leads to spectral crowding in simple experiments. Figure 3 shows three very different 1D proton spectra of the 14-kDa protein called $\alpha$-lactalbumin, in three different states: native folded, molten globule, and unfolded (urea denatured).

The folded state (Fig. 3a) shows sharp lines and a large degree of chemical shift dispersion. The side-chain methyl groups positioned in the interior of the protein can be in close contact with aromatic rings that induce ring current effects. Methyl groups are often shifted toward very low ppm values (between 0.5 and -0.5 ppm). The molten globule state (Fig. 3b) is a partially folded, highly dynamic protein state that contains some stable secondary structure elements, but with a dynamic tertiary structure. The time scale of the interconversion between different states is typically slow, of the order of milliseconds, which leads to significant line broadening. No side-chain methyl groups are as well shielded as in the folded state, and therefore they show chemical shift values larger than 0.5 ppm. The unfolded state (Fig. 3c), but the total lack of secondary structure elements leads to sharper lines than in the molten globule state.

Protons have large gyromagnetic ratios and are therefore highly sensitive NMR nuclei. The high sensitivity in combination with their high abundance in biomolecules has made protons the nuclei of choice in biomolecular NMR. However,

other nuclei can also be detected directly for specific purposes. 31P is a moderately sensitive NMR nucleus present in the nucleic acid backbone and in the side chains of phosphorylated proteins. Its chemical shift is highly sensitive, and 31P is therefore a useful probe of structural changes.

19F is almost as sensitive as 1H and therefore is well suited for direct detection. However, for biomolecular NMR, it is of limited interest, as it does not occur naturally in biomolecules; instead, it has to be introduced by chemical modification or labeled precursors for biosynthesis. In small drugs, 19F can be used as a metabolic tracer for interaction studies or as a contrast agent in imaging applications. NMR active isotopes 13C and 15N are not only scarce but also have the disadvantage of low NMR sensitivity. Traditionally, they have therefore only been observed indirectly through neighboring protons. Recently, experiments have been developed to detect either 13C or 15N directly both for proteins (51) and RNA (52, 53).

Two-dimensional homonuclear correlation experiments

A 2D NMR experiment consists of a series of 1D experiments, in which the magnetization is transferred from one nucleus to another. This experiment is followed by a delay called the evolution time, where the spins are allowed to precess freely. Incrementing the evolution time in successive experiments results in a 2D spectrum that correlates protons that have exchanged magnetization during the evolution time.

In the 1H-1H COSY (correlation spectroscopy) experiment (41), magnetization is transferred via the J-coupling and shows correlations between protons three bonds apart. The cross peak usually shows a characteristic antiphase-square pattern, but it may be split even more by additional passive couplings that lead to spectral crowding and loss of intensity. For small molecules, the COSY spectrum may suffice for assignment of the proton resonances. For larger molecules, such as peptides, the COSY-experiment is used in combination with other homonuclear experiments, especially because the spectral region of the aliphatic protons is often too crowded to allow unambiguous assignment.

In the 1H-1H-TOCSY (Total Correlation Spectroscopy) experiment (42), magnetization is also transferred via the J-coupling, but an additional isotropic mixing step leads to the correlation of all spins within a given spin system. In the case of a small peptide, the amide backbone protons show cross peaks to all side-chain protons of the same amino acid residue, which facilitates the identification of amino acid type by their characteristic peak patterns and circumvents the problem of overcrowding in the COSY spectrum. The individual amino acid residues (spin systems) are finally connected by distance information obtained from the 1H-1H-NOESY (Nuclear Overhauser Effect Spectroscopy) experiment (44), in which the correlation is transferred via the dipolar coupling. Cross-peaks may be observed for protons that are up to 5 Å apart from each other. For a small peptide (Fig. 4), this information is sufficient for a sequential assignment. A closely related experiment is ROESY (Rotational frame nuclear Overhauser Effect Spectroscopy) (44, 54), which is complementary to the NOESY in respect to its dependency on the correlation time of the molecule studied. With increasing size, the NOESY cross-peaks display a sign change from positive to negative, and the signal intensity is very low close to the transition point. This low NOE signal intensity is often the case for medium-sized peptides in which case the ROESY experiment is preferable. The signal intensity in the ROESY spectrum is also dependent on the size of the molecule, but the sign is always negative.
Nuclear Magnetic Resonance (NMR) Spectroscopy: Overview of Applications in Chemical Biology

Two-dimensional heteronuclear correlation experiments

Introducing a heteronuclear dimension reduces the signal overlap by using the additional chemical shift dispersion of the heteronuclei and facilitates assignment of biomolecules. The Heteronuclear Single Quantum Correlation (HSQC) experiment yields a spectrum that correlates the chemical shift of a $^1$H spin with that of a covalently bound $^{13}$C or $^{15}$N spin (55). In a $^1$H-$^{15}$N HSQC spectrum, every peak represents the correlation of an amide $^1$H-$^{15}$N bond, which shows correlations for both backbone and side-chain amides of proteins and nucleotide imino protons of RNA. Equivalently to the 1D case (Fig. 3), different folding states of a protein will lead to distinctly different $^1$H-$^{15}$N HSQC spectra; these states are shown for $\alpha$-lactalbumin in folded, molten globule and unfolded states in (Fig. 5a-c). Chemical shift dispersion is clearly much larger in the folded state than in the molten globule or unfolded states. This increased chemical shift dispersion facilitates analysis of larger proteins in their native, folded state, as much less signal overlap is observed compared with the unfolded states. The highly flexible molten globule shows significant line broadening of signals; therefore, many peaks are not visible. In the unfolded state, most peaks reappear, but the signal overlap in the proton dimension is significantly worse than in the folded case as all amide protons are equally solvent accessible and therefore experience similar degrees of shielding from the external magnetic field. Contrarily, the nonexchanging $^{15}$N nuclei typically retain high chemical shift dispersion in the unfolded and molten globule states.

Figure 4  Heteronuclear 2D spectra of the 8mer peptide EVVTLYWR in 90 % H$_2$O, 10 % D$_2$O. (a) Representation of coherence transfer pathways for COSY (solid arrows), TOCSY (dotted arrows) and NOESY (dashed arrows) experiments. (b) Section of COSY spectrum displaying the backbone H$^N$-H$^\alpha$ correlations, additionally the side-chain H$^N$-H$^\alpha$ correlations of R8 is visible in the upper right-hand corner. The H$^N$-H$^\alpha$ correlation of E1 cannot be detected because of solvent-exchange broadening of the N-terminal amino group. (c) Section of TOCSY spectrum that displays the correlations of the backbone H$^N$ with all protons within the amino acid side-chain. (d) Section of ROESY spectrum that displays correlations between backbone H$^N$-H$^\alpha$ intraresidual as well as to the neighboring (i-1) amino acid. The cross peaks to the (i-1) amino acid have higher intensities. Thus, a "sequential walk" is possible (arrows) that allows identification of the position of amino acids within the peptide chain. Additionally the H$^\alpha$ of E1 can be assigned (first arrow on the left).
Nuclear Magnetic Resonance (NMR) Spectroscopy: Overview of Applications in Chemical Biology

Similar to the HSQC experiment, multiple quantum coherences can be used to correlate protons with $^{13}$C-coupled heteronuclei. The information content of the Heteronuclear Multiple Quantum Correlation (HMOC) experiment (56) is equivalent to the HSQC, but the sensitivity can be improved in certain cases. Additionally, by proper tuning of delays and phase cycling, it can be transformed into the heteronuclear multiple bond correlation experiment (57–59), which results in correlations between $^1$H- and $^2$H-coupled nuclei.

For large biomolecules, fast relaxation of the transverse magnetization becomes a serious problem that leads to poor spectral resolution with broad or lacking signals. In a coupled $^1$H-$^{15}$N HSQC spectrum, cross-peaks will appear as multiplets, in which the different components of the multiplet have significantly different line widths because of constructive or destructive interactions of the two main relaxation mechanisms: dipole–dipole relaxation and relaxation caused by the chemical anisotropy. The TROSY (60) experiment (Transverse Relaxation Optimized Spectroscopy) overcomes much of the problem of fast transverse relaxation by selecting the one component of the multiplet, in which these relaxation effects almost cancel each other out, which thereby renders spectra with single sharp peaks even for very large biomolecules. The TROSY experiment relies on the fact that the chemical shift anisotropy scales with the magnetic field whereas dipole–dipole relaxation is field independent, and the maximal TROSY effect is only obtained at high magnetic field strength (above 14.1 Tesla), where it has significantly extended the range of biomolecules amenable to NMR spectroscopy.

Applications of NMR Spectroscopy to Chemical Biology

In this article, some examples are shown of the application of NMR spectroscopy in chemical biology. We put emphasis on experiments that characterize interactions of proteins and small molecular weight ligands. These interactions can be mapped either by characterizing the target protein (protein-observed experiments) or the ligand (ligand-observed experiments). Finally, the method of structure calculation based on NMR-derived data is briefly introduced.

This introductory review cannot possibly cover the whole range of techniques in a field as multifaceted as NMR spectroscopy. We therefore refer to review articles published during the last decade (63–67).

Protein-observed experiments

Binding of a ligand will cause diverse effects on a protein, many of which can be probed by NMR spectroscopy of isotopically enriched protein. Depending on the used isotopes and the labeling pattern, such studies can be both costly and time consuming. Nevertheless, protein-observed experiments offer more detailed information about the binding event than what can be obtained from ligand-observed methods. Especially, they map out the dynamic and often remote (e.g., allosteric) response of the protein receptor on binding of a small molecule. Changes in the chemical environment of each nucleus are indicated by chemical shift perturbations, either directly induced by ligand binding or via spectral crowding and allow for new assignment strategies for proteins (45) and nucleic acids (62). Experiments such as TOCSY-HSQC and NOESY-HSQC combine homonuclear and heteronuclear techniques, whereas triple-resonance experiments such as HNCO, HNCA, or HNCACB (Fig. 6) correlate three different NMR-active nuclei (e.g., along a protein backbone and are therefore used in suitable combinations to assign proteins) (45).

Multidimensional NMR experiments

Two-dimensional experiments may be extended to higher-dimensional experiments by including additional incremented evolution times into the pulse sequence separated by mixing sequences. The basic building blocks for these experiments are usually 2D homonuclear techniques like TOCSY (42) and NOESY (44) or the heteronuclear INEPT-transfer experiment (Insensitive Nuclei Enhanced by Polarization Transfer) (61). Combinations of these experiments alleviate the problem of spectral crowding and allow for new assignment strategies for proteins (45) and nucleic acids (62). Experiments such as TOCSY-HSQC and NOESY-HSQC combine homonuclear and heteronuclear techniques, whereas triple-resonance experiments such as HNCO, HNCA, or HNCACB (Fig. 6) correlate three different NMR-active nuclei (e.g., along a protein backbone and are therefore used in suitable combinations to assign proteins) (45).
induction of structural changes. This method allows immediate distinction of different binding sites and is a particular advantage of NMR screening experiments that is not possible in most, if not all, alternative-screening techniques. Hydrogen-deuterium exchange experiments provide information about solvent accessibility and participation in hydrogen-bonding networks. Changes in the line shape of NMR signals may elucidate folding intermediates and pathways, whereas relaxation studies probe thermodynamic and kinetic properties.

Chemical shift perturbations (CSPs)

The location of a ligand-binding site can be determined for small to medium-sized proteins that are uniformly 15N labeled and where the amide signals have been assigned by NMR spectroscopy. 1H-15N HSQC spectra are recorded in the absence and presence of a ligand (NMR titration experiments), and the observed changes in the amide chemical shift or signal intensity of the amino acid residues that bind the ligand indicate the location of the binding pocket.

This approach can be extended to larger targets by the TROSY experiment in combination with different labeling strategies (e.g., selective labeling of specific amino acids or deuteration). Deuteration replaces the nonexchangeable 1H atoms by 2H, which thereby reduces T2 relaxation significantly (68–70). To map a ligand-binding site by CSPs, it is not necessary to have a complete assignment of the protein. Per-atom information about binding events can be gained for large, only partially assigned proteins, in which structure calculation based on NMR data is not yet possible.

Arginine side chains are often involved in intermolecular contacts, therefore assignment of the 1H-15N side-chain groups allows mapping of ATP binding on kinases to be studied by CSPs as well as binding of RNA or DNA (71).

The relation between ligand binding and CSPs is not only dependent on the proximity of the ligand to the residues that show chemical shift changes. Conformational rearrangements of the protein/biomolecule as well as allosteric effects may cause significant CSPs of residues distant from the binding pocket. Reliable determination of the binding pocket is possible by comparing the CSPs induced by a series of structurally similar ligands (72).

An interesting example of the application of CSP studies is the ribosomal L11 protein (Fig. 7). Complex formation with its natural RNA substrate results in very large CSPs of the amide resonances that correspond to the binding surface on the C-terminal domain of the L11 protein. Addition of the antibiotic thiostrepton induces tighter binding of the N-terminal domain to the RNA, which again results in significant chemical shift changes (73).
A nuclear magnetic resonance (NMR) spectroscopy: overview of applications in chemical biology

Another interesting example of the effect of ligand binding on protein backbone $^{1}H-^{15}N$ signals is the p38$\alpha$ kinase. Certain ligands can bind not only to the ATP binding site but also to an allosteric hydrophobic pocket situated in an Asp-Phe-Gly (DFG) loop. This loop is highly conserved among kinases, and ligands that bind this allosteric site are called DFG-out ligands, as they require the kinase to undergo a conformational change. X-ray structures of p38$\alpha$ show that the Phe side chain of the DFG motive is displaced by 10 Å when bound to DFG-out ligands compared with the apo state (74, 75). This displacement is not observed when the kinase is complexed with ligands that only bind to the ATP binding site (DFG-in ligands) (76).

Investigations of this DFG-in/out phenomenon by NMR spectroscopy reveal dynamics that are not obtainable from static X-ray crystallographic studies (77). The kinase in its free form is in a slow DFG-in/out equilibrium. This equilibrium is not disturbed by a DFG-in ligand, whereas a DFG-out ligand disrupts the motion forcing the kinase into the DFG-out conformation. Cross peaks that develop from residues in the DFG-loop disappear because of conformational interconversion on the intermediate NMR timescale that leads to extensive line broadening. This mechanism is illustrated in (Fig. 8) of two $^{1}H-^{15}N$ TROSY spectra of p38 selectively labeled with $^{15}N$ phenylalanine. The first spectrum of the apo state contains cross peaks from 12 of 13 Phe residues. The missing peak corresponds to the Phe residue in the DFG-loop and only appears during addition of a DFG-out ligand as shown in the second spectrum, which proves that the conformational equilibrium of the free kinase is disrupted by this allosteric ligand.

This DFG-in/out phenomenon was first observed for the Abelson kinase where the ligand gleevec (78, 79) was found to bind both the ATP binding site and the allosteric binding pocket in the DFG-loop. This mechanism is observed not only for the Abelson and p38 kinases (74, 80, 81) but also for Raf (82) and KDR (83).

The lack of signals caused by the flexible nature of the kinase in the free state is observed for most of the activation loop as well as other highly conserved domains (84). The same pattern of missing peaks from these domains is also seen for the protein kinase A (PKA) (85).

SAR by NMR
To reduce the effort of chemical synthesis in drug discovery, the structure-activity relationship (SAR) method uses results from the chemical shift perturbation experiments (SAR by NMR). Optimizing the binding properties of initial hits from a high-throughput screening process without additional knowledge of the exact binding site and orientation is challenging. The SAR by NMR approach, which was developed by Stephen W. Fesik of Abbott Labs, is based on enhancing binding properties of small molecules to the protein surface by linking two active compounds together. First, smaller fragments are screened for binding, and initial hits are optimized toward stronger binding. Second, two compounds that bind to close, but not overlapping, sites on the protein surface are connected by a linker of appropriate length (Fig. 9). Strong dual-site binders can be generated from two initial relatively weak single-site binders with interaction sites close together on the protein surface by connecting them with a linker of suitable length.
Nuclear Magnetic Resonance (NMR) Spectroscopy: Overview of Applications in Chemical Biology

Figure 8 1H-15N TROSY spectra of p38α: (a) In the free state and (b) After binding a DFG-out ligand. The ligand structure is depicted in the upper left corner of the bound spectrum. The phenylalanine residue 169 situated in the DFG loop appears during binding. (c) Schematic representation of the effect of DFG-in ligand (SB203580) versus DFG-out ligand on the conformational exchange of p38 (1P38), the activation loop is indicated by an arrow.

Figure 9 Flow diagram of the SAR by NMR procedure. In case of completely independent binding of two ligands: Left: primary screening can be performed individually for each ligand. Ligands binding to two independent sites are linked, which enhances ligand-binding affinity. Right: for allosteric binders, screening for a second ligand should be done in the presence of a primary ligand.

Optimizing the linker is important because the free energy of binding for the composite ligand ΔG is not just the sum of the binding enthalpies for the individual ligands A and B (ΔH_A and ΔH_B, respectively), but it includes an intrinsic entropic penalty term ΔS depending on rigidity and orientation of the linker. The origin of this entropic loss is the conformational adaptation the ligand undergoes during binding.

Mechanistically, inhibition must not necessarily block the active site itself, but it can exert allosteric effects on the substrate-binding pocket, which thereby enhances or suppresses enzymatic activity. Additional considerations regarding enzymatic reactions are discussed in Reference 86. SAR by NMR has been successfully applied to various systems (i.e., for disrupting intracellular protein-protein binding (87) as well as cytokine-receptor interaction (88)). High-affinity enzyme inhibitors have been developed by this technique (e.g., for the metalloproteinase Stromelysin (89) and the protein tyrosine phosphatase 1B (90)).

Hydrogen/deuterium (H/D) exchange

Protein hydrogen atoms bound to N, O, or S are in constant exchange with solvent protons, and therefore they can be exchanged readily by deuterium. The exchange reaction can be followed by measuring a series of 1H-15N correlation spectra (e.g., HSQC, HMBC, or TROSY) after the solvent exchange. Residues that are buried in the core of the protein are not as solvent exposed as residues on the surface of the protein and will therefore exchange more slowly. Equally, protons that are
involved in hydrogen bonding are not as prone to exchange as non-hydrogen-bonded protons.

One of the most elegant experiments that uses the H/D exchange phenomenon is the characterization of protein folding by Miranker et al. (91). In addition, useful information can be obtained about protein-protein interactions, in which residues at the interaction surface will be solvent accessible before the complexation but not after. Domain reorientation of a protein during binding of a ligand can result in some amino acid residues being buried in the interior of the protein and therefore showing significantly different exchange times before and after binding.

Changes in secondary structure of the target protein during ligand binding can also be extracted from H/D exchange measurements as secondary structure elements, such as α-helices and β-sheets, which are highly stabilized by hydrogen bonds. This is not the case for the more flexible loop regions or domains.

Experimentally, H/D exchange for a stable globular protein sample can normally be performed by lyophilizing the sample and redissolving it in the same amount of D_2O as there was H_2O before lyophilizing to ensure that the buffer concentration remains.

The effect of this exchange reaction on a protein proton in the binding pocket will depend on the difference in Larmor frequency (chemical shift) between the free and bound form compared with the exchange rate. When exchange rate and difference in Larmor frequency are comparable, the reaction is in the intermediate exchange regime, and useful information can be obtained from line shape analysis. Slow intermediate exchange in which the exchange rate is slower than the difference in Larmor frequencies leads to cross-peaks from both the free and bound state. Fast intermediate exchange, however, produces only one single peak at the average chemical shift value. When the exchange rate and frequency difference are equal (the crossover point), the signal is broadened in between the two states.

Proteins at ambient temperature exhibit conformational dynamics on a wide range of time-scales (Fig. 10). And, studies of such dynamics have been shown to be particularly important to understand the pharmacological properties of kinases (vide infra).

Line shape analysis is used to study exchange processes as described by the relative population of the different states (mole fractions), line widths of the signals, and their frequency separation Δν (93). It is assumed that the lifetimes are significantly longer than the rotational correlation time τ_ω, and that spin-spin couplings do not interfere.

Starting from the simplest case of slow exchange between the free and ligand-bound form of an NMR signal from a biomacromolecule, this exchange situation will be indicated by two distinct peaks that do not change position but only vary in intensity. More complex exchange mechanisms may lead to overlaying changes in line shapes and can be simulated by models that are more complex. A nice example is the introduction of an additional fast exchange step between the free form and an intermediate form that subsequently is in slow exchange with the ligand-bound form. In this case, the peak that corresponds to the ligand-bound form will only increase in intensity during titration with the ligand. The peak of the free form, however, will not only decrease in intensity, but also change position toward the averaged peak position of free form and intermediate.

Even more elaborate peak patterns will develop if additional intermediates are in fast exchange with the free form or if alternative ligand-bound forms are present.

The simulated ^1H-line shapes of a ^15N HSQC spectrum of a protein signal during titration with an inhibitor are shown in (Fig. 11). The expected line shapes for three different binding mechanisms of increasing complexity have been simulated for a protein concentration of 0.1 mM. The ligand concentration increases from 0 to 0.1 mM (blue through red lines), and the ligand has a binding affinity of 1 μM. The line shapes for a direct key-lock mechanism are shown in (Fig. 11a). This mechanism is the simplest conceivable mechanism and the first model to use when fitting experimental NMR line shapes. Even when a simple key-lock mechanism is presumed, the line shape can look different depending on the off-rate of the reaction.

A slow reaction on a high μs time scale or slower leads the sharp peak of the free protein to disappear at the same time as a sharp peak of the complex appears. An off-rate in the μs time regime or faster will result in a line that shifts from its original position to the position of the bound form (Fig. 11a). The peak evolves from its free form to a broadened line shape that sharpens again at the end of the titration. Failure to reproduce the measured line shape by any parameter set of a certain model means that the complexity of the model has to be increased. Figure 11b shows the behavior expected from a single intermediate mechanism, whereas (Fig. 11c) presumes binding of the ligand in two different ways, of which only one species reacts to the complex structure. For each model, the input parameters, such as off-rates, are varied until the resulting line shapes fit the experimental data. In case of line broadening of the amide protons because of exchange with solvent water the line shapes of the nitrogen may also be simulated (93–96).

Thus, it is possible to calculate the off-rates of protein-ligand interactions observed for individual amino acid residues of the protein of a verified reaction mechanism. A nice example that shows various cases was recently published for the Apo-Cellular Retinol Binding Protein (97).
Nuclear Magnetic Resonance (NMR) Spectroscopy: Overview of Applications in Chemical Biology

Figure 10 The different processes amenable to NMR spectroscopy are indicated above the time arrow, below are the typical time windows for different molecular motions and events.

(a) (b) (c)

Figure 11 Simulation of line shapes of a reaction according to the binding model: (a) Two-state reaction. (b) Two-state reaction with one intermediate and (c) Two-state reaction with two possible intermediates. Protein concentration is 0.1 mM. Titration in equal steps until an equimolar amount of ligand is reached (0, 0.01, 0.02, ..., 0.1 mM). The signals of P and PL are separated by $\Delta \nu = 150$ Hz. The sequential steps in the titration change color from black to gray.

An example of dramatic change of line shapes is observed when the p38$\alpha$ kinase is bound to the previously mentioned DFG-out ligand. p38$\alpha$ is activated by dual phosphorylation of two conserved residues in the activation loop. The $^{31}$P spectrum of the apo state (Fig. 12) shows two broad peaks; during addition of a DFG-out ligand, one of these is shifted. Both peaks show significant narrowing, which indicates that ligand binding hinders the flexibility not only of the DFG motif but also of the entire activation loop, as the phosphorylation sites are situated 11 and 13 residues downstream of the amino acid chain from the DFG loop.

Line shape analysis may be complemented or verified by measuring chemical exchange by NMR by relaxation dispersion experiments. Relaxation dispersion is based on measuring a series of CPMG-based relaxation rates at different temperatures. Excited state intermediates in folding reactions or ligand-accessible intermediates can thereby be probed, even when they constitute as little as 1% of the entire population.

Dynamic information from relaxation studies

The heteronuclear relaxation properties as measured by $T_1$, $T_2$, $T_1^*$, and hetNOEs contain valuable information about molecular dynamics of biomolecules.

The relaxation data shown in (Fig. 13a) describe the dynamics of the ribosomal protein L11 before (blue) and after (red) complexation with the GTPase region of 23S rRNA and of the subsequent binding of the antibiotic thiostrepton to the protein-RNA complex (in green). L11 consists of an N- and a C-terminal domain. The latter shows a flexible loop region in the free form around residues 86-96, which is evident by small values of $^{1}H$-$^{15}N$ hetNOEs, large $T_2$ values, and correspondingly low order parameters. During binding to 23S rRNA, this loop region shows a significant reduction of both hetNOEs and $T_2$ relaxation times, which indicates a rigidification of the region. This finding is shown in (Fig. 13a) with blue arrows. The overall correlation times that describe random tumbling of the C- and N-terminal domains are similar in the free form.
of the protein, which indicates that the protein domains tumble together more or less like a rigid body. During addition of RNA, both domains show a reduction of the correlation times, which indicates binding of the RNA to the protein; however, the effect is much more pronounced in the C-terminal domain, which indicates that this region is most tightly bound. When adding thiostrepton to the complex, the $T_1$ relaxation times of the N-terminal domain match the ones of the C-terminal domain, which indicates that the thiostrepton locks the N-terminal domain to the RNA, thus creating a stable protein-RNA-ligand complex. The highly flexible parts of the protein are shown on the structures below the relaxation data (Fig. 12b). The color coding goes from yellow for highly flexible over gray to blue for "nonflexible" regions.

Obtaining such detailed information about the dynamics of a complexation reaction is labor intensive. To obtain these data, it was necessary first to assign the protein in its free form as well as in complex with RNA and RNA-antibiotic by a series of 3D NMR spectra of $^{31}$P, $^{1}H$, $^{13}$C, triple-labeled samples. The labor intensity of dynamic studies like this is, however, offset by the invaluable insights into the detailed dynamic driving forces behind biological processes uniquely obtainable by NMR.

From dynamics to thermodynamics

For a comprehension understanding of ligand binding, the thermodynamics of the association process must be taken into account. On this topic, we follow the line of discussion of Steve Homans (99). The binding constant is related to the Gibbs free energy of binding in the following manner: $\Delta G = -RT \ln K$, where $\Delta G$ is composed of an enthalpic and an entropic term ($\Delta G = \Delta H - T\Delta S$), the former representing the structural features and the latter constituting the changes of dynamic properties of ligand, protein, and solvent. Although the binding event is mainly enthalpy driven, the entropic component should not be underestimated. Using only the enthalpic term as a measure of binding strength will lead to incorrect evaluation of the data. In some cases, the entropic term accounts for a difference in Gibbs energy that will distinguish between a mediocre and a tight binder (about 4 kcal mol$^{-1}$). Microscopic techniques such as isothermal titration calorimetry can determine the overall thermodynamic parameters of binding events, whereas a microscopic view on the mechanism can only be obtained by NMR. Using the relaxation methods described above, a per-residue analysis of protein dynamics is possible. Especially for ligand binding, no other technique will provide such detailed account of the binding mechanism. For the major urinary protein, an interesting effect of ligand binding has been observed (100). The increase in protein backbone flexibility during ligand binding results in an entropic contribution to the Gibbs free energy of binding of a magnitude comparable with other driving components. The elucidation of such processes in microscopic detail that NMR can provide may lead to a reassessment of the governing factors of ligand affinity, as this might well be a general mechanism of small ligand binding.

Not only are protein backbone dynamics accessible to relaxation studies, but also side-chain dynamics can be measured. Different techniques that quantify the relaxation of $^{13}$C or $^1H$ nuclei are also available (101-104). The focus usually lies on the dynamics of methyl groups that require elaborate isotopic labeling schemes to obtain either $^{13}$C$^2$H$^2$O or $^{13}$C$^2$H$^2$O$^2$ isotopomers (105). This finding has enabled determination of the order parameters of methyl group rotation axes. In the case of calmodulin, which is a calcium binding protein, it has been shown that complex formation with a peptide leads to nonuniform entropy changes along the protein backbone and side chains. Whereas the backbone only shows small changes in its motional characteristics, some side chains close to the binding site are restricted in their motion. Simultaneously, the motional entropy of more remote side chains increases, which thereby compensates for the entropy losses at the binding site (106, 107).

A nice example of the power of dynamic NMR spectroscopy is the work by Kem and coworkers (108, 109) on the action between enzymatic activity and the kinetics of structural dynamics in the coupled network of proteins. These NMR methods provide greater insight into the complex thermodynamic mechanisms of molecular recognition, which thereby supplies the field of Chemical Biology with unique and invaluable information.

Ligand-observed experiments

Analysis of binding events by observing the NMR signals of the ligand rather than the biomolecular target is an alternative to protein-observed experiments. This approach is attractive to screen large libraries of compounds in a cheap and efficient manner, because expensive isotopic labeling of target or ligand is not required. It is even possible to screen mixtures of ligands using distinct spectral features of each ligand to identify the biologically active compound. Another advantage of ligand-observed drug screening is that it allows all biological targets, regardless of size, to be studied by NMR spectroscopy. This approach is especially useful when dealing with cells, viruses, or membrane proteins. $\alpha$-Coupled receptors and ion channels are membrane proteins that are highly interesting as drug targets but are difficult to express in high yields, which renders isotopic enrichment of such proteins costly. Furthermore,
Nuclear Magnetic Resonance (NMR) Spectroscopy: Overview of Applications in Chemical Biology

Figure 13 Relaxation parameters of protein-RNA-ligand interactions of the L11 system. Free L11 (blue), L11, and RNA (red) and L11, RNA, and Thiostrepton (green). RNA binding shows effects on all parameters, pronounced for certain residues in the C-terminal domain (arrows), whereas the additional Thiostrepton binding leads to an increase in $T_1$ of the N-terminal domain. Binding of RNA locks the two domains in a fixed orientation relative to each other and strongly restricts the motion of the C-terminal domain. See color insert.

the required presence of phospholipids in samples of membrane proteins increases the size of the complex, which restricts the use of protein-observed measurements even more because of fast $T_2$ relaxation (63). Contrarily, size restrictions do apply to the ligand, as the distinction between ligand and target is based on their difference in molecular weight. Therefore, ligands must be much smaller than the target. The binding event of a ligand to a biological target will transfer magnetization from target to ligand, which alters the NMR spectrum of the ligand. To observe binding of a ligand, it should usually be in medium to fast exchange with the target that corresponds to moderate binders with $K_D$ values in the mM to $\mu$M range.

Saturation transfer difference NMR (STD-NMR)

STD-NMR (110) observes magnetization transfer from protein to ligand molecules that are in fast exchange between the free and bound state. The protein is excited selectively by irradiating at a frequency specific to protein signals, typically the protein side-chain protons. A large excess of ligands ensures that the fraction of ligand molecules bound to the target at any one time is negligible. The transfer of magnetization from a large saturated protein to a bound ligand is, however, very efficient, and a fast $k_{off}$ rate of the ligand ensures that a measurable fraction of the free ligand has been bound to the protein during the course of the experiment. This fraction remains saturated throughout the experiment and does not contribute to the ligand NMR spectrum, which reduces the signal intensity. The fraction of ligand molecules that have been bound to the protein during the experiment can be calculated from the difference of two 1D spectra with and without protein saturation. The large excess of ligands also ensures that the amount of ligand molecules that will bind to the target more than once is negligible. The STD effect of a ligand-binding event is strong when the protein is large, even if the ligand only transiently binds to the protein, as the magnetization transfer depends on the molecular weight of the macromolecular complex and is very efficient for large complexes but inefficient for small molecules. STD-NMR cannot readily distinguish between specific and nonspecific binding events. Therefore, an extension of STD-NMR involves the titration of a protein-inhibitor complex with a test ligand that will compete with the inhibitor in fast exchange for the same receptor-binding site on the protein. This situation
the kinase-reporter-ligand sample decreases the STD reporter signals in comparison with the reference spectrum in the absence of any competitor.

Target protein are accented by a grey box. The test ligand competes with the reporter ligand for the binding site.

(a) Stepwise addition of the test ligand to the NMR sample. The resonances of the reporter ligand deplete faster when titrated with the more potent ligand B as observed from the fitted curve of the titration data (Ligand A: stars, Ligand B: squares).

(b) Analogous procedure with a more potent ligand.

(c) The resonances of the reporter ligand deplete faster when titrated with the more potent ligand B.

The competition between an inhibitor of known binding properties to the target will dominate the spectrum.

In a fast-exchange situation with a large excess of ligands compared to receptors, the $K_D$ value derived from NMR experiments is comparable with the $IC_{50}$ value (i.e., the concentration of the inhibitor required to reduce the target activity by 50%). The $IC_{50}$ values are usually derived from biochemical assays; from an inhibitor of known $IC_{50}$ value, it is therefore possible to derive relative $IC_{50}$ values for compounds in competition with this inhibitor by NMR spectroscopy.

The competition between an inhibitor of known binding properties, which is also called a reporter-ligand, and a ligand for the same binding site is used in NMR reporter assays as illustrated in (Fig. 14). The reporter ligand must be highly soluble and have strong, quantifiable NMR resonances. Competing ligands are titrated to the NMR sample that contains a target protein and reporter ligand, and the reduction of the reporter signals corresponds to the fraction that has been displaced from the binding site by the competing ligand. By selecting a reporter-ligand of low affinity toward the target protein, it is even possible to detect binding of high-affinity or poorly soluble ligands (112-114), as well as ligands in slow exchange with the target (115).

Other methods similar to the STD experiment are WaterLOGSY (Water-Ligand Observed via Gradient Spectroscopy) (116) and NOE pumping (117). WaterLOGSY is based on the transfer of magnetization from biomolecule to ligand via bulk water, whereas NOE pumping relies on first suppressing all ligand signals and then transferring magnetization via an NOE experiment from biomacromolecule to the fraction of ligand molecules that have been bound.

Exchange-transferred NOE spectroscopy (et-NOESY)

Similar to the STD experiment, exchange-transferred NOE spectroscopy (et-NOESY) provides information about a binding event between a small molecule and a high molecular weight biomolecule, even when the biomolecule itself is not amenable to NMR studies because of broad line widths, low solubility, or fast $T_2$ relaxation.

The principle of et-NOESY (118-120) is applied to low-affinity protein-ligand complexes where exchange is fast on the NMR timescale. High molar excess of the ligand is used (typical ligand to receptor site ratios range from 10 to 50); therefore, the resonance line shapes are governed by the properties of the unbound ligand in solution (i.e., sharp signals caused by slow $T_2$ relaxation). The et-NOESY observed, however, are caused by the conformational change of the ligand in the binding pocket. The efficiency of magnetization transfer caused by NOE effects depends on the overall correlation time of the molecular complex and becomes more efficient for larger complexes. For small molecules, the NOE is positive and weak, whereas it is negative and strong for large biomolecular complexes. Therefore, the cross-relaxation measured by the NOE transfer within the ligand when it is bound to the target will dominate the spectrum.

The NOEs from the bound state are transferred into the free state of the ligand when it leaves the binding pocket. To observe NOEs from the bound state, the off-rate ($K_{off}$) of the ligand must be much faster than the cross-relaxation rate, only then is the initial build up of the NOE proportional to the cross-relaxation rate (121). Based on the internuclear distances obtainable from

\[
K_I = \frac{c_I (K_0 - K_D)}{1 + K_0 + K_D}
\]
the NOEs it is possible to deduce the conformation of the ligand when bound to the target.

The inversion of sign between NOEs from small and large molecules simplifies measurement of et-NOEs for binding studies of small ligands < 1 kDa and large targets. For larger ligands, such as ligand-peptides, two et-NOESY spectra are recorded in the presence and absence of target protein. By subtracting the two spectra, it is possible to distinguish between NOEs that develop from target-bound ligands and ligands that have not been bound.

The combination of STD-NMR and et-NOESY experiments provides information on ligand protons in direct contact with the binding pocket as well as the overall ligand structure. The two experiments thus complement each other in elucidating the binding surface of a target of otherwise unknown structure.

**NOEs and isotope-filtered NMR experiments**

In the strong binding regime, the measurable NOEs between the biomolecule and the bound ligand can be exploited to derive the 3D complex structure. A common approach involves uniform labeling of the biomolecule with $^{15}$N and $^{13}$C isotopes, whereas the ligand remains unlabeled (122). To distinguish between the intra-molecular NOEs of the biomolecule, the intra-molecular NOEs of the ligand and the intermolecular NOEs that occur at the binding interface, isotope-filtered NOESY experiments are used. The proton magnetization that originates from either $^{1}$H-$^{13}$C or $^{1}$H-$^{15}$N atom pairs is either filtered out or selected (123, 124).

The 3D $^{13}$C- and $^{15}$N- filtered NOESY experiments are used to identify NOE restraints within the biomolecule itself. Intra-molecular NOE restraints of the ligand can be assigned from the $^{12}$C, $^{15}$N-filtered NOESY experiment, which suppresses the signal of $^{13}$C- and $^{15}$N-attached protons of the biomolecule. The intermolecular NOEs between the ligand and biomolecule can be detected by a combination of selection and filtering out of proton magnetization in the 3D $^{12}$C, $^{15}$N-ω-filtered NOESY $^{1}$H, $^{13}$C HSQC experiment, which observes the interface between the two molecules as observed in the 2D projection in Fig. 15.

The information derived from the analysis of this example was used as distance restraints for calculation of the 3D structure of the complex of calmodulin, a calcium-binding protein, and a peptide ligand. The amino acid sequence of the peptide ligand, C20W, corresponds to the N-terminal part of the calmodulin-binding domain of the plasma membrane calcium pump (125).

**Structure calculation based on NMR data**

To provide new insights in the biological context of biomolecules, obtaining structural information is frequently essential. The tertiary structure of molecules with accuracy at the atom level can be calculated using NMR-derived data on intra-molecular atom distances and angles. Many biomolecules form complexes with each other, and the nature of these complex formations can be deduced from intermolecular distances and determination of the interaction surfaces in combination with computational docking procedures to determine their global structure.

![Figure 15](image_url)

**Figure 15** 2D $^{1}$H, $^{1}$H projection of the $^{12}$C, $^{15}$N-ω-filtered 3D NOESY $^{1}$H, $^{13}$C HSQC spectrum that contains only intermolecular NOEs between the double-labeled protein (Calmodulin, resonance assignment in black) and a bound peptide ligand (in light grey). Only contacts between the protein and the peptide ligand are observed. Assigned cross-peaks are indicated in the spectrum.
Simulated annealing

Traditionally, the structure of biomolecules and macromolecular complexes are solved by NMR using proton-proton NOEs that are translated into distances. In addition to NOEs, the structures may be refined using additional NMR data, such as coupling constants, RDCs, chemical shifts, and hydrogen bonds. Many programs and protocols are available for calculation of NMR structures (e.g., XPLOR-NIH (126), CNS (127), CNX (Accelrys, San Diego, USA), CYANA (128, 129), and ARIA (130)). Structural calculations using simulated annealing (SA) and molecular dynamics (MD) require a forcefield with the molecular topology and parameters to define the atomic masses, bond lengths, charges, angles, planarity, and connectivity information of the entire macromolecule (131). Most biomolecular NMR structures are calculated by SA with MD in either Cartesian or torsion angle coordinate space. The torsion angle dynamics protocol allows simulation of longer time intervals and higher temperatures than dynamics in Cartesian space and is thus very efficient for the calculation of NMR structures (128, 132). The SA algorithm generally starts from an extended conformation of the macromolecule and proceeds from a high temperature stage over slow cooling-down stages to a final energy minimization at low temperature. This protocol is commonly repeated multiple times in an iterative way to recalibrate the NOE-based distances. The final NMR structures are often refined in explicit solvent to improve the structure quality significantly (133).

HADDOCK

The conventional NMR approach for determining biomolecular complex structures is based on a time-consuming process of collecting intermolecular NOEs and complementing RDCs. A newer approach uses the easily obtainable chemical shift perturbations from NMR titration experiments in combination with computational docking. The HADDOCK (High Ambiguity Resolved Docking) approach uses the experimental NMR data of the intermolecular interactions as Ambiguous Interaction Restraints (AIRs) to drive the docking process (134). Residues that show significant chemical shift changes during interaction are designated as active. Residues that show less significant changes and/or are surface neighbors of the active residues are called passive. The AIR is accordingly defined as an ambiguous intermolecular distance between any atom of an active residue and any atom of an active or passive residue of the partner molecule in the complex. The HADDOCK approach uses CNS for structural calculations and protocols derived from ARIA for automation. Generally, the docking protocol starts with calculating many random orientations in which the partner molecules are positioned far away from each other. After a rigid-body docking, the best scoring solutions in terms of intermolecular energies are refined in torsion angle space using a multistage, semi-rigid simulated annealing protocol. Subsequently, the structures are refined in explicit water in Cartesian space. Next to protein-protein docking, HADDOCK has also been applied to model protein-DNA, protein-RNA, protein-oligosaccharide, and protein-ligand complexes (135, 136). The HADDOCK protocols allow the usage of additional NMR data, such as RDCs (137) and diffusion anisotropy data (138). Furthermore, HADDOCK is able to perform solvated docking (139), as water molecules in the interaction interface play an important role in mediating biomolecular interactions. These implementations lead to improved accuracy and quality of the final complex structures. The HADDOCK method can calculate models of multicomponent complexes and can easily be applied to drug design.

RDC-based structure refinement

RDCs are especially useful for determining the relative orientation of different partner molecules in a complex or of different domains within a single macromolecule in a complex. When two domains of a macromolecule are connected by a flexible linker and NOE data between those domains is scarce or lacking, RDCs can be used to determine the exact orientation of the domains with respect to each other. In the case of ribosomal L11 protein, these additional orientational restraints have been used to solve the structure of the protein in its free form as well as in complex with its RNA binding partner and an antibiotic (vide supra) (73, 140). The relative orientation of the two domains that are connected by a short linker and oriented in solution (Fig. 16). Using 3668 distance restraints (26.4 per residue), 77 TALOS-derived dihedral angle restraints, and 102 J-couplings derived from the backbone Hα-HN of the structure of the two domains of the ribosomal L11 protein.

Figure 16. Structure calculation purely based on NOE and dihedral angle restrictions often fails to determine proper domain orientations. By incorporating the long-range orientation parameters that RDCs provide, it is possible to overcome this problem and to define relative orientation of the two domains of the ribosomal L11 protein.
be determined unambiguously because of the limited amount of interdomain NOEs. To calculate the overall structure of the full-length protein, an additional 429 RDCs were measured and incorporated in the structural calculation. This step allowed the exact determination of the relative orientation of both domains (73). This result is in good agreement with the fact that the two domains tumble together as a rigid body, based on the dynamic measurements (Fig. 13).

The same method has been applied to measure the L11 domain orientation when the protein is in complex with its RNA partner or both RNA and thiostrepton antibiotic. The additional RDCs revealed a rearrangement of the N-terminal domain of L11 placing it closer to the RNA after binding of thiostrepton. HADDOCK has been used to calculate a model of the ternary structure of the L11 protein in complex with RNA and antibiotic. Based on the orientational data, the dynamics and the docking model, it seems that thiostrepton locks the domain conformation of L11 in a rigid (inhibitory) state. The antibiotic thiostrepton interferes with the interaction of elongation factors to this L11-RNA region, which has a dramatic effect on the level of protein synthesis by the ribosome.

Oriental restraints, which are derived by paramagnetic labeling of a single domain of a protein, are especially important for the analysis of domain-domain interactions (141). The paramagnetic tag induces anisotropic alignment, which is scaled for the two domains of the protein according to their relative domain mobility.

**LIGDOCK and SOS-NMR**

In the weak binding regime, intermolecular NOEs between biomolecule and ligand are usually not exploitable in protein-observed experiments. Instead, other NMR-derived information is used as an experimental restraint for molecular docking procedures to solve the protein–ligand structure. The readily obtainable 1H chemical shift perturbations (CSPs) of the protein amide resonances caused by ligand binding are often used as experimental restraints. During the molecular dynamics simulation, penalty energies calculated from these experimental restraints together with conventional intermolecular van der Waals energies or electrostatic interactions guide the protein–ligand complex toward an energy minimum. This minimum represents a physically reasonable structure that fulfills a maximum number of restraints introduced by NMR-derived information. Accuracy of the NMR structure, as judged by comparison with observed experiments. Instead, other NMR-derived information is used as an experimental restraint for molecular docking procedures to solve the protein–ligand structure. The readily obtainable 1H chemical shift perturbations (CSPs) of the protein amide resonances caused by ligand binding are often used as experimental restraints. During the molecular dynamics simulation, penalty energies calculated from these experimental restraints together with conventional intermolecular van der Waals energies or electrostatic interactions guide the protein–ligand complex toward an energy minimum. This minimum represents a physically reasonable structure that fulfills a maximum number of restraints introduced by NMR-derived information.

**SOS-NMR** is a method for measuring the L11 conformation of thiostrepton. HADDOCK has been used to calculate a model of the ternary structure of the L11 protein in complex with RNA and antibiotic. Based on the orientational data, the dynamics and the docking model, it seems that thiostrepton locks the domain conformation of L11 in a rigid (inhibitory) state. The antibiotic thiostrepton interferes with the interaction of elongation factors to this L11-RNA region, which has a dramatic effect on the level of protein synthesis by the ribosome.

Oriental restraints, which are derived by paramagnetic labeling of a single domain of a protein, are especially important for the analysis of domain-domain interactions (141). The paramagnetic tag induces anisotropic alignment, which is scaled for the two domains of the protein according to their relative domain mobility.

**LIGDOCK and SOS-NMR**

In the weak binding regime, intermolecular NOEs between biomolecule and ligand are usually not exploitable in protein-observed experiments. Instead, other NMR-derived information is used as an experimental restraint for molecular docking procedures to solve the protein–ligand structure. The readily obtainable 1H chemical shift perturbations (CSPs) of the protein amide resonances caused by ligand binding are often used as experimental restraints. During the molecular dynamics simulation, penalty energies calculated from these experimental restraints together with conventional intermolecular van der Waals energies or electrostatic interactions guide the protein–ligand complex toward an energy minimum. This minimum represents a physically reasonable structure that fulfills a maximum number of restraints introduced by NMR-derived information.
Nuclear Magnetic Resonance (NMR) Spectroscopy: Overview of Applications in Chemical Biology

Figure 17. Molecular docking guided by NMR-derived information. (a) The complex structure of PTP1b with a ligand (modeled structure in green/yellow) calculated from CSPs only corresponds well with the X-ray reference structure (blue). (b) The cluster of lowest energy structures calculated for p38α and ligand SB203580 shows two possible orientations (c) that differ in their ability to form a hydrogen bond to the Met109 amide group. Additional information is needed to clarify the binding mode. See color insert.

Figure 18. SOS-NMR using deuterated and selectively protonated protein can resolve ambiguity of ligand orientation. (a) Bottom: 1D 1H NMR reference spectrum that shows the resonances of the ligand SB203580. Middle: 1D 1H STD spectrum recorded in the presence of p38α. Top: 1D 1H STD spectrum recorded of a sample prepared according to the SOS procedure of perdeuterated kinase and unlabeled isoleucine residues. A pronounced STD effect for the H1 and H4 protons and only weak effects for the H6 and H5 protons resolves ambiguity of ligand orientation in the binding pocket. (b) Distance analysis of the reference X-ray structure.

especially mass spectrometry, NMR is a very valuable tool for this task. The role of NMR has been evaluated for analytical strategies in metabolomic research (151) and pharmaceutical discovery (152, 153).

Magnetic resonance imaging has long been used for clinical diagnostic purposes, often in combination with relaxation-enhancing contrast agents. Recent development of lipid nanoparticle systems as carriers of relaxation enhancers to specific targets (154) makes imaging methods applicable to the field of chemical biology.

Supported Lipid Bilayers: Development and Applications in Chemical Biology

Volker Kiesling, Marta K. Domanska, David Murray, Chen Wan and Lukas K. Tamm,
University of Virginia, Charlottesville, Virginia

doi: 10.1002/9780470048672.wecb663

Lipid bilayers supported on solid substrates were developed almost a quarter century ago as a new model membrane system to study fundamental properties of biological membranes and their constituent lipid and protein molecules, as well as for numerous practical applications. In this review, we summarize the development of supported bilayer-based model membrane systems of increasing complexity while always keeping in mind their primary purpose, which is to reproduce the complex fluid structure of biological membranes to mimic cell membrane-based molecular processes as close to physiological reality as possible. This process must include maintaining the structure and fluidity of the lipid bilayer, as well as the structure and function of reconstituted membrane proteins. We start the review with a general description of a contemporary picture of a generic biological membrane and proceed with an account of how supported membranes recapture different physiological aspects of biological membranes, such as membrane fusion, cell adhesion, or membrane permeability. Supported membranes are particularly good models for reproducing the fluidity of cell membranes even when different liquid lipid phases coexist. They are also superb models for measuring ligand-receptor interactions between membrane-bound receptors and soluble or membrane-bound ligands. The chemical biology of these and many other lipid–lipid, lipid–protein, and protein–protein interactions that have been investigated in supported bilayers are summarized in several sections that form the main body of this review. The article closes with summaries of practical procedures to prepare and characterize supported bilayers.

Since the lipid bilayer was accepted as the basic principle of design for biological membranes more than 40 years ago, researchers have developed model systems to study numerous aspects of biomembrane structure and function. Large multilamellar liposomes have been used frequently in early X-ray diffraction and calorimetric studies that characterize the structure and thermodynamic properties of lipid bilayers. Sonication of these structures leads to small unilamellar vesicles, which are excellent model systems for numerous spectroscopic and binding studies with model membranes. Other experiments require larger or even “giant” unilamellar vesicles, produced by extrusion through filters or swelling from solid lipid deposits with or without applied electric fields. For some applications, such as recording electrical currents across membranes or measuring the mobility and lateral organization of membrane constituents, planar bilayer geometry is advantageous. To this end, single unsupported planar bilayers are suspended with or without solvent in a small orifice in a Teflon septum that separates two chambers that are electrically connected to equipment that can record currents from single molecular channels (1, 2). A wealth of information on the molecular properties of ion channels, toxins, and other membrane-interactive proteins and substances has been obtained using such planar bilayer recordings.
A different planar model membrane design was developed in the early 1980s mainly from research conducted in Harden McConnell’s laboratory at Stanford University—the supported lipid bilayer. The biological motivation driving these early studies was to provide planar model membranes for observation by epi-fluorescence microscopy and to use them as surrogate targets for studying molecular interactions in immunological synapses between antigen-presenting cells and T-cell receptor-bearing lymphocytes. A precursor of the supported lipid bilayer has been the supported lipid monolayer, in which a lipid monolayer is deposited on a long-chain alkylated substrate (3). This early design using silane chemistry for alkylation was later superseded with sulfur chemistry on slides with thin evaporated gold surfaces. However, because these systems mimic only half a bilayer and cannot accommodate integral membrane proteins, which provide so many key functions to biological membranes, they are not considered in this article.

In a quest to produce a model system that more faithfully resembles biological membranes and that also allows the functional reconstitution of integral membrane proteins, we have developed the supported bilayer as a new model membrane system (4, 5). Supported bilayers have since become widely used in many different areas of chemical, biological, and materials research. A plethora of fundamental studies of bilayer and membrane properties to their phase behavior; membrane protein binding; membrane protein structure; electrophoresis and microanalysis of membrane components; functional studies of membrane receptors, pores and channels; interactions with components of bound cells, viruses, and cellular organelles; and so on. This article is organized in four main sections: We will first briefly review current concepts of cell membranes and how supported bilayers can be used as models for cell membranes. We will then describe biophysical properties and chemical interactions that govern the structure, stability, and use of supported bilayer membranes in biological analysis. The article will close with two sections on procedures that are commonly used to prepare and characterize supported bilayers.

**Supported Bilayers as Models for Cell Membranes**

Biological membranes are formed by a lipid bilayer with embedded proteins. The bilayer-forming lipids have polar headgroups that face the aqueous surroundings of the membrane as well as two hydrophobic tails that face the interior of the membrane. A key feature of cell membranes is that they are both fluid but still highly ordered in the membrane plane, as has been captured in the early conception of the fluid mosaic model of biological membranes (6). Lipids move laterally at a fast rate with a lateral diffusion coefficient on the order of 1 μm²/s, but they cross the membrane by flip-flop only once every few hours (7). The slow kinetic rate of lipid flip-flop allows the cell to establish asymmetry across the bilayer, which, with the input of energy, can be maintained for the entire lifetime of a cell. Membrane proteins come in different varieties. Some have sequences that cross the membrane, and therefore they are called integral membrane proteins. Other membrane proteins, such as the peripheral membrane proteins, are attached to the membrane surface either electrostatically or by means of covalent linkage to single or multiple lipid tails. A third class of membrane proteins dip into only one leaflet of the bilayer, where they are stabilized by hydrophobic interactions with the lipids in the bilayer. Regardless of the specific nature of membrane attachment and incorporation, membrane proteins can diffuse relatively rapidly in the plane of fluid membranes. However, they never cross the lipid bilayer except during biogenesis, which requires specialized machines called translocons that translate newly synthesized polypeptide chains across cell membranes in a complicated and still poorly understood energy-requiring process (8).

The notion of a biological membrane represented by a uniform sea of lipids with proteins freely floating in this environment has been significantly revised in the last decade or so (Fig. 1a) (9). It has become increasingly clear that biological membranes are laterally structured even if they are still predominantly fluid with regard to in-plane diffusion of protein and lipid components. First and foremost, membranes are highly crowded with proteins. Although the crowding varies greatly between different biological membranes (e.g., being very high for energy-converting membranes in mitochondria and photosynthetic organelles and rather low for membranes of myelin sheaths that wrap around and electrically insulate neurons), it is clear that membrane proteins do not act independently in membranes but often form clusters of interacting species. In a typical average cell membrane, about a quarter to half of the total cross-sectional area may be occupied by protein. If one considers proteins that have larger extramembranous domains than transmembrane domain cross-sections, the area fraction covered with protein may reach up to one third of the entire membrane surface. Thus, membrane proteins and lipids are both solvents and solutes at the same time. An alloy of hydrophobic proteins and lipids may describe the true nature of biological membranes more accurately than a dilute two-dimensional solution of proteins in a vast sea of lipids. Second, unlike commonly prepared model membranes, biological membranes contain thousands of different lipid species (10). The lipid species distinguish themselves by many different headgroup classes and chain compositions as well as an expansive combinatorial diversity of these structural elements. A very large amount of data has been accumulated over the past four decades on the structures, energetics, and phase properties of pure single and two- or three-component lipid bilayers as summarized in two monographs (11, 12). We know from this data that high- and low-melting lipids tend to separate into different domains than transmembrane domain cross-sections, the area fraction covered with protein may reach up to one third of the entire membrane surface. Thus, membrane proteins and lipids are both solvents and solutes at the same time. An alloy of hydrophobic proteins and lipids may describe the true nature of biological membranes more accurately than a dilute two-dimensional solution of proteins in a vast sea of lipids.

Even though cholesterol (substituted by other steroids in plants) is chemically classified as a lipid, the molecule is better grouped into a special category, which is distinct from membrane proteins and (phospho- and sphingo-) lipids, when discussing its role in biomembrane structure and function. Cholesterol constitutes between 25% and 40% of the total lipid plus cholesterol fraction of most typical cell membranes. These numbers translate into a 33–66% fraction of the noncholesterolic lipids, or considering its smaller size, about a 10–20%
...are referred to as liquid-ordered (lo) phases. Cholesterol-rich phases exhibit more chain order and there-...
environments. Another area where supported bilayers offer distinct advantages is studies of the kinetics of ligand binding to membrane-bound receptors (22). Supported membranes have also been used successfully to measure protein-mediated fusion of vesicles, for example in virus entry (23) or exocytosis (24).

On the analytical practical side, there is much interest in using supported membranes with incorporated ion channels as biosensors for various analytes (25–27). Another interesting application is to separate membrane components in situ by electrophoresis in supported membranes (28, 29). Such techniques could have a significant future impact on the proteomics of membrane proteins, that is, an area that is currently underdeveloped because of difficulties with appropriately separating membrane proteins in complex mixtures by more standard techniques. Finally, supported membranes continue to provide very interesting engineered substrates that mimic natural cell surfaces to trigger the differentiation of adjacent cells such as in the previously mentioned immunological synapses (30).

**Interactions Between Lipid and Protein Components in Supported Bilayers**

A key feature of biological membranes is their graded fluidity. Any useful membrane model system must strive to preserve the characteristic fluidity of lipid and protein components. This concept clearly has been a great challenge in this field. Although it is relatively easy to maintain the fluidity of the lipid components and peripherally attached protein components as demonstrated already in the earliest publications on supported bilayers (5, 31), to achieve the same result with integral membrane proteins has proven to be much more difficult. It is known that the gap between supported membranes and solid glass or quartz supports is on the order of 1 to 2 nm (32, 33), and this gap is filled with a layer of water that is sufficient to lubricate the lower leaflet of the bilayer to permit rapid lipid diffusion (Fig. 1b). However, this gap is not large enough to accommodate integral membrane proteins with significant extramembrane domains. Such proteins are generally immobilized by interaction with the glass support. Much research activity has been directed in the last decade to uncouple such unwanted non-physiological interactions, by increasing the gap distance with intercalated water-soluble polymers, either by simple physisorption or covalently attached to one or both surfaces by forming tethers between the substrate and the membrane (Fig. 1c). In the following section, we summarize strategies that have been successful for creating polymer-supported bilayers. The subsequent sections proceed in turn to brief summaries of lipid-lipid interactions, lipid-protein interactions, and protein-protein interactions in supported bilayers, and then to studies of membrane fusion and cell adhesion using supported membranes as a model for one membrane in these membrane-membrane interactions. The final sections summarize recent advances in patterning supported membranes and using supported membranes as novel analytical tools in chemical biology. Depending on the particular application, bilayers directly supported on solid substrates or (tethered) polymer-supported bilayers are preferred as will be mentioned in each case.

**Polymer-supported bilayers with and without tethers**

The idea of using polymer-supported bilayers has been around for more than a decade (34), but it became practical for chemical and biological applications only more recently. Early versions have used relatively short distances to link the monolayer to the solid substrate and thereby increase their durability for practical applications (25, 35). Because these approaches do not increase the gap distance between substrate and membrane and therefore have not been used to reconstitute integral membrane proteins functionally, they will not be discussed here.

Our group has developed a polyethylene glycol (PEG)-based polymer support for bilayers on glass, quartz, or oxidized silicon (36). PEG that consists of 77 subunits bridges a phospholipid on one end and a silane group on the other end, which allows the covalent tethering of the lipopolymer to free silanols on the silicon dioxide surface. In all, 25% of the reconstituted integral membrane protein cytochrome b diffused freely in supported bilayers that contained 3% of the lipopolymer in the proximal leaflet. Integral membrane SNARE proteins were 80% mobile with a diffusion coefficient of 0.8 μm²/s in this system (37). The distance between the substrate and membrane increased from 2 to 4 nm without and with the polymer, respectively (33). A similar approach was introduced by Naumann’s group, who used 3-octadecylamine(poly(ethyleneoxazoline)-8988) and octadecyl(poly(ethyleneoxazoline)-5822) with 85 and 56 monomer units, respectively, as lipopolymers in their bilayers (38). In this case, the lipopolymers were photo-cross-linked to the glass via a benzophenone silane photocoupling agent. The tethered polymer obstructs lipid diffusion at high concentrations but not at low concentrations (39). The increased stability of the monolayer that faces the substrate allows the preparation of asymmetric supported bilayers that contain separated regions of liquid-ordered and liquid-disordered phases. Lipid raft mixtures in the substrate-proximal layer induce registered raft domains in the distal layer (40, 41). Sackmann’s group used lipopolymers that contain polymerized 2-methyl-2-oxazoline of different lengths to integrate the large transmembrane cell receptor integrin αβ (42). In all, 20% of the integrins were mobile with a relatively low diffusion coefficient of 0.03 μm²/s. A different approach to form a cushion between the solid support and membrane uses the Langmuir-Blodgett technique to transfer several layers of triglycylsilyl cellulose onto a glass substrate. When supported bilayers were formed on this substrate by direct vesicle fusion, 25% of the reconstituted integrins were mobile with a diffusion coefficient of 0.6 μm²/s (43).

**Studies of raft-like lipid domains in supported bilayers**

Substantial literature has been published on studies of lipid domains in supported bilayers. Many have investigated lipid mixtures with coexisting gel and liquid-crystalline phases by atomic force (AFM), spinfluorescence, and near-field fluorescence microscopy (NSOM) (see, for example, References (44–45)).
Other studies have focused on (“raft”) lipid mixtures that form coexisting I_d and I_u phase domains in the presence of cholesterol (19,48–50). AFM studies are usually carried out on mica substrates, which have the advantage of being atomically flat but are less hydrated than glass or quartz substrates that are commonly used in fluorescence microscopic studies. Although higher resolution is achieved by AFM than by optical microscopy, the bilayers are more tightly coupled to the substrate and are not always fluid on mica. Fluorescence has the advantage that different molecular fluorescent dyes can be used to probe different aspects of complex lipid bilayers, such as diffusion, order, and phase partitioning, but it has the obvious disadvantage that the behavior of the probe is observed, which may or may not reflect the behavior of the host lipids accurately. Judicious choices must be made when selecting lipid probes for different purposes.

Typical “raft” lipid mixtures contain about equimolar sphingomyelin, phosphatidylycholine, and cholesterol. Studies have shown that the area of I_d phases in such bilayers depends linearly on the cholesterol concentration and that a percolation threshold exists at about 25 to 30 mol % cholesterol, where I_d domains become connected and I_u domains become disconnected (19). Because this mixture is at about physiological concentrations of cholesterol, cells may use shifts in cholesterol concentration as a switch to connect different groups of membrane proteins and thereby regulate their function.

An exciting new development in supported bilayer technology is that bilayers with asymmetric lipid distributions can be prepared. Although it is not so difficult for gel phase lipids with very low diffusion coefficients, it is much more challenging with fluid phase bilayers. However, these challenges have been solved recently (18). It is now possible to study phase coupling across the mid-plane of bilayers with coexisting I_d and I_u phases (40, 41). The observation that I_u phases can be induced in lipid mixtures that mimic the inner leaflet of cell membranes that do not exhibit such phases on their own has important potential consequences on signal transduction in cell membranes. Although they do not prove the raft-hypothesis of signal transduction in cells, these experiments provide the first experimental evidence that fluid lipid bilayers with physiologically relevant lipid compositions can transmit signals across the mid-plane of membranes by inducing new lipid phases on the other side.

Protein–lipid interactions in supported bilayers

Protein–lipid interactions and particularly peptide–lipid interactions have been studied in supported bilayers by attenuated total reflection (ATR)/FTIR spectroscopy. A slightly dated, but still valid comprehensive review on this method applied to supported bilayers has been published (20). Because IR light probes the vibrational properties of different classes of covalent bonds, this method is useful to examine lipids, peptides, and interactions between the two in the same sample. The most common parameter for assessing lipid structure and order is to study the stretching vibrations of the lipid acyl chains, for example as a function of peptide concentration or temperature. Such studies have lead to the conclusion that fusion peptides from viruses increase the lipid chain order of fluid phase bilayers and that this property correlates with the biological activity of the viral peptide sequences (51). Another prominent band in the FTIR spectra of lipids develops from the ester carbonyl vibration. This band is sensitive to the hydrogen-bonded structure and thus hydration properties of the bilayer interface. The carbonyl ester band has been shown to change during interaction with some fusion peptides (52). Lipids also have an effect on peptide structure. For example, influenza and HIV fusion peptides are induced to form α-helices in bilayers at low concentration, but they transition into β-sheets at higher concentration (53, 54).

Structural transitions are readily followed by monitoring the amide I and II IR bands when the system is changed from an H2O to a D2O buffer (56). Binding of proteins to supported bilayers may be studied quantitatively by total internal reflection fluorescence microscopy (TIRFM), as shown, for example, in binding studies of antibodies to lipid haptens (57, 58). Fast kinetics of antibody fragment binding and unbinding to supported bilayers have been studied in detail by combining fluorescence correlation spectroscopy with TIRFM (59).

A different aspect of lipid–protein interaction that is conveniently studied in supported bilayers is the lateral diffusion of proteins and lipids and their influence on each other. The regulatory lipid phosphatidylinositol-biphosphate (PIP2) slows the diffusion of syntaxin in supported bilayers (37). Conversely, increasing syntaxin concentrations decrease the diffusion of PIP2 to a lesser extent that of phosphatidylserine. In another system, in which the transmembrane domain of the fibroblast growth factor receptor was incorporated into supported bilayers, lipid and protein diffusion were measured (60). Although protein diffusion was slow (0.006 μm2/s), lipid diffusion was fast (2.6 μm2/s).

Protein–protein interactions in supported bilayers

Much current interest exists in lateral interactions between two or more integral membrane proteins. Several membrane-bound receptors are activated by such interactions during ligand binding. In addition, the interaction between individual transmembrane helices is key to membrane protein folding and has thus received a lot of attention. Although these kinds of interactions are more often studied in nonsupported model membranes, the Hristova group has recently used supported bilayer formats to examine helix–helix interactions between the transmembrane domains of the human fibroblast growth factor receptor (21). Fluorescence resonance energy transfer measurements of fluorescein- and rhodamine-labeled peptides in supported bilayers show that these transmembrane domains dimerize with a sequence-specific dimerization energy of −3.6 kcal/mol. Meaningful measurements of such interaction energies require that the proteins are laterally mobile in the supported membranes, which was verified in this system (60).
Membrane fusion with supported bilayers

Membrane fusion is a key process in cell biology that takes center stage in membrane biogenesis, fertilization, virus entry, and other events. Our group began studying membrane fusion in supported bilayers 14 years ago. Influenza virus hemagglutinin (HA) (i.e., the protein that mediates virus entry into cells by membrane fusion) was reconstituted into supported bilayers. The physiological pH-dependent fusion of liposomes to the plasma membrane of neurites has been studied in supported bilayers. Several fusion-related structural transformations of HA were recorded by FTIR spectroscopy (61, 62). The fusion of single virions to supported bilayers has also been reported recently (63).

Recently, SNARE-mediated fusion (i.e., the process that leads to neurotransmitter release in synaptic transmission) has been reconstituted in a supported bilayer format in four different laboratories including our own. The general design of these experiments is illustrated in Fig. 2. Fix et al. (24) observed that 15% of the docked vesicles fused within 15 seconds, which yielded a fusion rate of ~7 x 10^{-5} s^{-1} in POPC bilayers at a cocrystallized syntaxin1/SNAP25 protein/lipid concentration of 1:300. The fusion probability increased 40-fold after Ca^{2+} addition. Bowen et al. (64) observed thermally induced fusion with a rate of 0.07 s^{-1} within 120 sec after triggering. Liu et al. (65) showed that 77% of the reconstituted synaptobrevin vesicles fused within 100 ms after docking rate, 40 s^{-1}) to syntaxin or syntaxin/ SNAP25 complexes in POPC/DOPS bilayers at a protein/lipid ratio of 1:30,000. The results of these three groups are different from each other, and each of these experiments had peculiar aspects which may be caused by the immobile reconstitution of the SNARE proteins in the supported bilayers (66). The independence of fusion on the presence of SNAP25 in the reconstitutions of Bowen and Liu is puzzling because it contradicts in vivo as well as in vitro fusion results. Preliminary work from our laboratory is in much better agreement with the biological literature on this process.

Cell adhesion and signaling in supported bilayers

Supported bilayers have been used since their inception as surrogate cell surfaces to stimulate immune cells in artificially created immunological synapses. For example, Brian and McConnell (67) have reconstituted major histocompatibility complex (MHC) proteins into supported bilayers and used these planar membranes to stimulate cytotoxic T-cells via specific T-cell receptor interaction. A nitorgen presentation and signaling through the T-cell receptor have been studied in this system in several follow-up papers as summarized by Watts and McConnell (68). The approach of these early studies (and several others that followed) has experienced a recent renaissance because of improved imaging technologies and because we have learned in the interim how to manipulate supported membranes to form specific controllable spatial patterns (see the next section). These newer approaches are exciting because they have allowed investigators to manipulate spatial patterns in the immunological synapse and thereby ask biologically important new questions with regard to the mechanism of cell-induced cell signaling. Mossman et al. (30) have used laterally constrained bilayers to induce novel patterns of T-cell receptor and intracellular adhesion molecule (ICAM) distribution in MHC-stimulated cells. The authors used a GPI-linked version of the MHC in the supported bilayers to circumvent problems of lateral mobility of the native integral membrane protein in un-cushioned bilayers. Wu et al. (69) demonstrated the compartmentalization of IgE-receptors in rat basophilic leukemia cells when they stimulated these cells with lipid-hapten bound IgE in nano-fabricated bilayer patches.

A dhesion of different immune cells to one another or to epithelial cells has also been studied using planar bilayer models. For example, lymphocyte function-associated protein-1 (LFA-1) promotes cell adhesion in inflammation (i.e., a reaction that can be mimicked by binding to purified ICAM-1 in supported membranes (70)). Similarly, purified LFA-3 reconstituted into supported bilayers mediates efficient CD2-dependent adhesion and differentiation of lymphoblasts (71). This work was followed by a study in which transmembrane domain-anchored and GPI-anchored isoforms of LFA-3 were compared (72). Because this research occurred before the introduction of polymer cushions and because the bilayers were formed by the simple vesicle fusion technique, the transmembrane domain isoform was immobile, whereas the GPI isoform was partially mobile. By comparing results with these two isoforms at different protein densities in the supported bilayer, the authors showed that diffusible proteins at a sufficient minimal density in the supported membrane were required to form strong cell adhesion contacts in this system.

In another study, epithelial cells were bound via their integrin receptors to supported bilayers that presented the
Supported Lipid Bilayers: Development and Applications in Chemical Biology

RGD-peptide, which is the classic integrin ligand (73). The cells spread on RGD presenting membranes but not on control membranes that lacked this peptide. In a similar approach, a laminin-derived peptide was presented on supported bilayers and shown to mediate the spreading and partial differentiation of neuronal subventricular zone progenitor cells (74). The authors observed a strong nonlinear relationship between surface concentrations of the peptides and conclude that this approach may provide novel conditions for growing stem cells with only a limited and controlled amount of differentiation induction.

### Patterning supported bilayers

To use supported bilayers as platforms for screening assays, different approaches have been taken to pattern the membrane on the surface. One goal is to observe the membrane interaction of substances simultaneously with supported bilayers of different composition. Bilayers can be subdivided into different areas by diffusion barriers erected on the substrate or by blotting patches of membrane with polydimethylsiloxane (PDMS) stamps (75). A combination of these techniques may be used to form patterned membranes of different composition. Barriers may be formed from metal or metal oxides by standard lithographic techniques or by stamping proteins onto the substrate (76). Originally, homogeneous supported membranes have been patterned photolithographically using deep-UV light (77). Using photolithography in combination with a polymer lift-off technique, patterned lipid bilayers with patches measuring 1 to 76 µm may be formed (78). A rather approach uses the flow of vesicle suspensions within microfluidic devices to deposit membranes of different compositions at the same time (75). Supported bilayers of different compositions on the same substrate are conveniently addressed with different solutions of analytes flowed through micro-channels in PDMS (79).

Using supported bilayers as platforms for chemical sensing and analysis

Because of their planar geometry, supported bilayers are predestined for biological and chemical sensor applications. The basic concept is to couple the high specificity and sensitivity of molecular membrane receptors to substrates that integrate optical-electronic circuits (25–27). In combination with the described patterning techniques, supported membranes should provide a nearly ideal physiological environment for high-throughput sensing with biological membrane receptors or channels in chip-based arrays. However, despite their great promise, economically viable commercial applications have so far not yet been used because of a series of obstacles that still must be overcome. Nanoscopic and microscopic defects in fluid supported lipid bilayers most often lead to low electrical resistance and therefore make them unsuitable for high-sensitivity electronic detection. In some approaches, this problem has been overcome by linking the lipid bilayer with very short and dense tethers to the substrate. However, doing so prevents the incorporation of larger membrane receptors and channels.

Another approach is to prepare black lipid membranes with solvent over microscopic or nanoscopic holes in the substrate (80-82), or by using giant vesicles that adhere to the substrate (83). Although high-resistance seals have been obtained, long-term stability has not yet been achieved with these systems. In cases where highly insulating membranes are established, the conductivity of ligand-gated ion channels or larger pores may be recorded (25, 84). Alternatively, the conductivity may be probed by measuring the impedance (26) or with metal-free field-effect transistors that have the advantage of avoiding electrochemical perturbations (83). Optical detection is suitable for applications such as immunoassays when the molecules of interest can be addressed by fluorescent- or gold-labeled antibodies (79). As is true for electronic biosensors, optical biosensors designed for routine practical applications must be robust and stable for a long time. Lippolymers that stabilize supported bilayers against air exposure are also helpful in this case (85).

### Procedures to Prepare Supported Bilayers

Supported lipid bilayers with or without reconstituted membrane proteins are prepared by one of three methods described below and illustrated in Fig. 3. Methods details can be found in Reference 86.

**Langmuir-Blodgett/Langmuir-Schafer (LB/LS) technique (4, 5)**

This technique is historically the first method to prepare supported bilayers. A lipid monolayer is spread from a desired lipid solution in organic solvent onto a water surface in a Langmuir trough. After evaporation of the solvent, the monolayer is compressed slowly to reach a surface pressure of 32 mN/m (thought to be the equivalence pressure of a bilayer) and equilibrated. A carefully cleaned hydrophilic substrate (glass, quartz, oxidized silicon, etc.) is then rapidly submerged into the trough and slowly withdrawn with a dipper mechanism while a constant surface pressure is maintained. This step transfers a single monolayer of lipids known as the LB layer onto the substrate. A second monolayer known as the LS layer is then spread and compressed on the trough in the same fashion. The LB-coated substrate is attached to a suctioning tip, and its face is gently lowered to contact the LS monolayer at the air/water interface for a few seconds. To complete the bilayer, the slide is then pushed through the interface and placed on a cover slip fitted with two spacers of water-resistant double-sided tape that had been previously placed at the bottom of the trough. After removal of the supported bilayer sandwich from the trough, the water between the surfaces may be exchanged by flow-through with any desired buffer while always maintaining full hydration of the bilayer. Some investigators have prepared peptide-containing supported bilayers by placing peptides in the first or second monolayer.

**Vesicle fusion (VF) technique (67)**

This technique is the simplest method for forming supported bilayers. Much literature is available on the mechanism and
Figure 3 Methods for supported bilayer formation and membrane protein reconstitution. (a) and (b) LB/LS method. A lipid monolayer is spread at the air-water interface of a Langmuir trough and transferred to a solid substrate while keeping the surface pressure constant. A second monolayer is transferred by horizontal apposition of the first transferred monolayer and collection of a counter-piece with spacers. (c) Direct VF method. Membrane vesicles are flown into a chamber with a clean surface substrate on top. After about an hour of incubation, they form a supported bilayer on the substrate and excess vesicles are flushed out. (d) LB/VF method. The procedures depicted in panels (a) and (c) are combined leading to an asymmetric bilayer with an asymmetric protein distribution. Although this method can also be performed without a polymer, it is shown here with the polymer transferred during the LB step.

kinetics of vesicle spreading on hydrophilic substrates, which is not reviewed here. Although it is simple, the method tends to result in bilayers with more defects, and the orientation of membrane proteins cannot be controlled in this method. Small or large unilamellar pure lipid vesicles or proteoliposomes are prepared by standard liposome preparation or membrane protein reconstitution methods. A clean hydrophilic substrate is placed in a flow-through chamber, and the vesicles are injected and incubated with the surface for 30–60 minutes. Excess vesicles are washed out by extensive rinsing with a buffer. This method has also been used to make polymer-supported bilayers, in which case the surface of the support is pre-treated with the polymer using conditions that depend on the particular polymer being used.

Langmuir-Blodgett/vesicle fusion (LB/VF) technique (87)

This method is a combination of the other two methods. In our opinion, it is the most gentle method to reconstitute membrane proteins into supported bilayers and to prepare supported bilayers with fragile coexisting liquid phases of lipids. A LB monolayer is prepared on a hydrophilic substrate as described above. To prepare tethered-polymer supported bilayers, a suitable lipopolymer may be included at a concentration of a few mol % at this stage. With some lipopolymers, it is necessary to cure the slide (by light, temperature, zero humidity, etc.) at this stage. The monolayer-coated slide is then placed in a custom-built flow-through chamber, and vesicles or proteoliposomes are injected and incubated with the surface for 30–60 minutes (pure lipid vesicles) or 60–120 minutes (proteoliposomes). Excess vesicles are washed out by extensive rinsing with buffer. Because the second monolayer is completely vesicle derived and because membrane proteins are introduced as proteoliposomes only in the second step, they tend to be unidirectionally oriented in the supported bilayer as can be verified with quenching antifluorophore antibodies (23, 37) or by FLC microscopy (33).

Procedures to Characterize Supported Bilayers

Microscopy

The simplest way to examine the quality and integrity of supported membranes is to include a fluorescent lipid probe such as n’-tetrabenzoxa-diazol (NBD)-PE or rhodamine-PE and to look for
their uniform appearance on a standard epifluorescence microscope. Many artifacts can be detected readily and eliminated with this very simple test. Higher-resolution images can be obtained by AFM or NSOM. These techniques are useful to detect small defects in the 10 to 500 nm range that might escape detection by standard wide-field optical microscopy. Because supported bilayers are only stable under water, these imaging modalities must be carried out under water. AFM probes height profiles, but NSOM and epifluorescence microscopy permit the labeling of specific chemical structures or physical properties of the structures by using different fluorescent probes. It is often necessary to discriminate surface from bulk fluorescence, for example when measuring the binding of fluorescent ligands to supported membranes. This result is conveniently achieved with TIRFM, which has a typical 1/e illumination depth of 50 to 100 nm from the surface, which depends on refractive indices, angle of incidence, and wavelength of light. Brewster angle and surface plasmon microscopies are also surface-selective optical imaging techniques, which do not require the fluorescent labeling of the membrane, but rather depend on lateral changes of refractive index in the sample.

Lateral diffusion

A next and very important level of characterization of supported bilayers is the measurement of the lateral mobility of their constituents. Because biological membranes and their proper function are defined by their fluidity, to recreate this characteristic is imperative for biology-motivated work. In addition, lateral diffusion measurements on supported bilayers can easily detect many artifacts that may go unnoticed by simple microscopic inspection. For example, deposited membranes may look completely uniform but may not show any long-range lateral diffusion when vesicles or membrane fragments that are smaller than the resolution of the light microscope are densely packed on the substrate surface. Two techniques are common to determine the diffusion of fluorescently labeled lipids or proteins in supported bilayers: FRAP and SPT. The lateral diffusion coefficient and fraction of mobile molecules are obtained from either measurement.

In FRAP, a brief pulse of intense laser light is used to photobleach fluorophores partially in a small area of the sample. The recovery of fluorescence caused by diffusion of labeled molecules into the bleached area is then observed over time, while care is taken to minimize additional photobleaching. In spot photobleaching the light is focused to a circular spot, which reflects the Gaussian beam profile of the laser. During recovery, the half-width of the bleached area decreases whereas the intensity increases. The diffusion coefficient and mobile fraction are extracted from the time course and the amplitude, respectively, of the recorded recovery curve (88). In a variant called periodic pattern photobleaching, the bleach pulse projects a stripe pattern of a Ronchi ruling onto the sample, which permits integration over a larger area and therefore an increased signal/noise (89).

SPT is the preferred technique when more detail on different populations of moving particles in a heterogeneous system is required. Although the information content of SPT is much higher than that of FRAP, it is much more demanding on instrumentation and statistical evaluation procedures. SPT has been introduced to the characterization of supported bilayers in 1995 (90) and has been used frequently since then. In practice, the technique is best used in combination with TIRF microscopy and high-sensitivity charge-coupled devices. Typical labeling ratios of the lipid bilayer are 1:100 fluorescent probes:lipids. The reconstructed particle trajectories and appropriate statistics can be analyzed to distinguish between diffusion, anomalous diffusion, confined diffusion, and directed motions.

Bilayer structure

Neutron reflectivity has been used to characterize the transverse organization of supported bilayers structurally (32, 91). The lateral structure of lipid bilayers on solid supports may also be characterized by grazing incidence X-ray diffraction, although this technique has so far been mainly used on monolayers at the air-water interface. Vibrational spectroscopies open interesting windows to look at details of lipid structure in supported bilayers. FTIR spectroscopy has several bands that are characteristic of the state of lipid order and hydration in supported bilayers (20). An interesting relatively recent method to study the organization of supported bilayers, particularly with respect to their asymmetry, is sum frequency vibrational spectroscopy (SFVS) (92). Signals develop in this nonlinear form of vibrational spectroscopy only when symmetry is broken (i.e., when the type, structure, and number of lipids are unequal across the mid-plane of the supported bilayer). A complementary technique to study lipid asymmetry, or more specifically fluorescent probe asymmetry, is FLIC microscopy, in which the average distance of fluorophores from an oxidized silicon mirror surface is measured interferometrically (18).

Protein secondary structure and orientation

Two methods have been used to determine the secondary structure of supported bilayers: polarized ATR-FTIR spectroscopy and oriented CD spectroscopy. SFVS may also be applied to study peptide and protein structures in supported bilayers. Polarized ATR-FTIR spectroscopy is sensitive enough that high-quality spectra can be obtained from a single bilayer. Beta-sheet structures are readily distinguished from alpha-helical and random structures, and the orientations of alpha-helices are determined from the linear dichroism of the peptide amide I bands (20). Multiple stacks of supported bilayers have to be used to gain enough sensitivity to determine the structure and orientation of alpha-helices in lipid bilayers by oriented CD spectroscopy (60, 93).

Conductance and impedance

Pure lipid membranes are electrical insulators with a specific capacitance of ~1 µF/cm², which separate two electrolytic compartments. The conductance of biological membranes is mainly determined by highly specialized proteins that act as ion channels. For supported membranes to mimic the electrical properties of a biological membrane, it is necessary to measure its electrical characteristics. Even very small defects that are not
visible by microscopy increase the conductance significantly. If the membrane is supported by a conductive substrate like gold or indium tin oxide, then it is possible to measure the impedance by applying A.C. voltages with frequencies up to 100 kHz and by measuring the magnitude and phase of the current. The conductance and capacitance of the supported membrane is determined from the evaluation of the entire electrical circuit, which includes resistance and capacitance of the electrode and if necessary alternative electrical paths around the membrane (94). A similar approach uses metal–field effect transistors that probe the electrical potential at the transistor gates that face the cleft beneath the supported membrane. The electrical membrane parameters are extracted from the voltage transfer from the electrolyte bath to the transistor gates (83).

Conclusion

In conclusion, supported bilayers have evolved into a reliable model membrane system since their first inception almost a quarter century ago. Numerous basic research questions regarding the structure and function of biological membranes and applications that range from biosensing to proteomic analyses have been addressed with this system. We anticipate more growth and an even more prominent role of this tool in basic and applied membrane research in the decades to come.

Glycan arrays are powerful tools for high throughput analysis of carbohydrate–macromolecule interactions. A glycan array is composed of many different carbohydrate structures immobilized on a solid support in an orderly arrangement. This review describes the challenges and considerations in the development of a glycan array. Various array formats, immobilization techniques, and assay systems are discussed. In addition, several interesting applications of glycan array technology are described, such as assessing the specificities of carbohydrate-binding lectins and antibodies, profiling antiglycan antibodies in serum as biomarkers of disease, and evaluating carbohydrate-dependent cell binding.

DNA and protein microarray technology has revolutionized the way scientists study complex biological processes. These arrays consist of thousands of nucleic acids or proteins immobilized on a solid support. The array format allows one to rapidly evaluate interactions with a large number of molecules simultaneously. For example, one can examine the expression profiles of thousands of genes in a single experiment.

Glycan arrays are an equally powerful technology for the evaluation of carbohydrate–macromolecule interactions. Analogous to DNA and protein arrays, glycan arrays contain many different carbohydrates affixed to a solid support. This review will focus on development strategies, challenges, and applications of glycan arrays. Several other reviews have been published over the last few years (1–4).

Biological Background

Carbohydrates, biopolymers composed of monosaccharide units, play a central role in a wide range of biological processes such as protein folding, inflammation, and development. In addition, glycans undergo dramatic changes in expression during the onset and progression of many diseases such as rheumatoid arthritis and cancer. Unfortunately, progress toward defining the specific roles of most carbohydrates and understanding the relationships between structure and function has been frustratingly slow. Furthermore, efforts to exploit altered expression for therapeutic benefit have only been successful in a limited number of cases.

Molecular recognition is a fundamental element for both basic and applied carbohydrate research (see cross references: Glycan–glycan interactions, Glycan–protein interactions, and Sugar–lectin interactions in cell adhesion). Many important biological processes involve specific interactions between a carbohydrate-binding protein (lectin) and a glycan. For example, one early stage of inflammation involves interactions of selectins with carbohydrate ligands. Carbohydrate–protein interactions are also directly involved in diseases. For example, many pathogens such as the influenza virus, E. histolytica, and H. pylori bind carbohydrates on the surface of host cells as a key step of infection (5). For many other carbohydrate-binding proteins, however, the biological functions are still unknown. For example, most lectins used routinely as research reagents are isolated from plants. Although used in the laboratory for many years, the biological roles of many of these proteins are not well understood. As a result, there has been significant interest in identifying natural and unnatural ligands that can be used to modulate the activity of carbohydrate-binding proteins. Lectins and glycan-binding antibodies are also used extensively as research tools, diagnostics, and therapeutic agents. Information on the specificities of these proteins is critical for interpreting results and selecting the best clinical candidates.

Although analysis of carbohydrate–macromolecule interactions is crucial for glycochemistry, it remains a challenging area of science. First, carbohydrates can be exceedingly difficult to obtain, especially in homogeneous form. With limited access to the ligands, one cannot easily assess recognition. Second, traditional methods used to evaluate carbohydrate–protein interactions such as monosaccharide and oligosaccharide inhibition studies, isothermal calorimetry (ITC), surface plasmon resonance (SPR), and enzyme-linked lectin assays (ELLAS) can be labor intensive or require large quantities of each carbohydrate.
A as a result, these methods are not well suited for high throughput evaluations. Finally, one must consider the issue of valency. In most cases, interactions between a single carbohydrate ligand and a single binding domain of a protein (referred to as monovalent binding) are very weak. The affinity of monovalent binding events is typically too low to withstand the washing involved in common biochemical assays such as enzyme-linked immunosorbent assays (ELISAs), Western blots, and immunohistochemical staining. However, most carbohydrate-binding proteins possess two or more binding sites or assemble into functional units with multiple binding sites. As a result, they can simultaneously bind two or more carbohydrate ligands (referred to as polyanalytic binding) leading to a high overall affinity or “avidity.” A key feature that probe interactions between carbohydrates and proteins must account for the unique aspects of polyanalytic recognition. For example, the ligands should be presented in a polyanalytic context. In addition, the spacing and orientation of ligands will affect the ability to form a polyanalytic complex.

As a result of the difficulties mentioned above, researchers have been developing alternative methods to study carbohydrate-protein interactions. Array technology is specifically designed for high throughput evaluations of molecular recognition events. Miniaturization facilitates the process by allowing minimal use of reagents and other hard-to-obtain components. In the following sections, the development and application of glycan array technology are described.

Fabrication of Glycan Arrays

Fabrication of a glycan array involves several interrelated factors: choosing a solid support format, choosing a method to attach glycans to that solid support, and obtaining appropriately functionalized carbohydrates for immobilization.

Array formats

A recent trend of modern glycan arrays can be traced back to the method of separating a complex glycolipid mixture using thin-layer chromatography, then probing the “array” with a carbohydrate-binding protein (6). Recently, most glycan arrays are created on either microtiter plates or glass microscope slides (see Fig. 1).

The microtiter plate array format involves immobilizing carbohydrates in wells of 96-, 384-, or 1536-well microtiter plates (see Fig. 3a). Each carbohydrate component is spatially separated from other components within the plate. Two of the primary advantages of a microtiter plate format are cost and simplicity. Carbohydrates can be distributed into wells using multichannel pipetters, and assay results can be measured using standard plate readers. Thus, the equipment and supplies needed for the array are relatively inexpensive and common. However, microtiter plates generally require larger amounts of each carbohydrate and can accommodate a smaller total number of components per support unit.

An alternative to the microtiter plate format is a glass microscope slide. Slides can come in various layouts. The array developed by Glycominds, Ltd. contains 200 microwell’s with a single carbohydrate in each well (7). The miniaturized wells use a smaller amount of material than a microtiter plate but retain spatial separation of components (see Fig. 3b). A second format involves spotting components directly onto the slides. One of the key differences is that all the carbohydrates are in the same “well” (see Fig. 3c). Consequently, recognition of each component is compared under identical assay conditions and well-to-well variation is minimized. In addition, microarray printers used for producing DNA microarrays can be used to print very small features (50–200-µm spots) with high precision allowing for tens of thousands of spots on each slide.

As a result, much smaller quantities of material are required and the total capacity is considerably higher than a microtiter plate. However, a microarray printer and high resolution scanner are required. A glass slide can also be modified to create 2–16 macrowells on a glass slide (see Fig. 3d). In this format, an entire array is printed in each well.

Several three-dimensional (3-D) approaches to glycan arrays have also been published, including fiber optic bead-based glycan arrays (see Fig. 3e) (5) and hydrogel arrays (9).

Methods for immobilizing carbohydrates

The methods of attachment to the solid support can be divided into two broad categories: covalent and noncovalent. Several factors should be considered. First, the ligands should be stable to immobilization, storage, and assay conditions. Second, the immobilized ligands should be accessible to the receptors, which are usually in solution. Third, the method should be efficient.

One of the most straightforward methods for immobilizing ligands is noncovalent attachment (4, 9–18). This method involves adsorption onto surfaces using noncovalent forces such as hydrophobic interactions, charge-charge interactions, and charge-dipole interactions (see Fig. 2a). A key feature is that the immobilized ligands must withstand routine screening and assay conditions. In general, lower molecular weight hydrophilic molecules, such as monosaccharides and oligosaccharides, show poor retention on solid supports when directly attached by noncovalent methods. In contrast, polysaccharides, glycoproteins, and glycolipids are well retained and can be directly arrayed on modified solid supports.

In one of the first reports of a carbohydrate microarray, underivatized polysaccharides and glycoproteins were immobilized directly on nitrocellulose-coated glass slides (10). In a further demonstration of the feasibility of noncovalent immobilization of underivatized glycans, Willaet et al. reported microarrays of glycoproteins, proteoglycans, and polysaccharides on oxidized black polystyrene slides (11). Modified neutral and anionic dextran polysaccharides have also been synthesized and printed on semicarbazide-coated glass slides (12).

One strategy for noncovalent attachment of smaller monosaccharides and oligosaccharides involves coupling them to a lipid tail or other hydrophobic moiety, which provides suitable retention on a solid support. This strategy was exemplified by arrays of synthetic and natural oligosaccharides as neoglycolipids or glycolipidoligosaccharide derivatives affixed to nitrocellulose-coated slides (13) and microtiter plates (14). Alternative approaches include covalent attachment to solid supports using a

Cu(I)-catalyzed 1,3-dipolar cycloaddition (15); reductive amiation reactions between underivatized oligosaccharides and immobilized aminolipids on microtiter plates (16); and urea formation between amino-derivatized sugars and tetradecyl isocyanate adsorbed on microtiter plates (17). Formation of hydrogel microarrays of amino-saccharides and polyacrylamide glycoconjugates has been reported. Here, glycans were printed on hydrophobic glass surfaces with polymerizable monomers, and then polymerization was induced by photoactivation to form 3-D gel elements comprising the glycans (4, 9).

An elegant alternative approach for noncovalent interaction relies on fluorous-fluorous interactions. A glycan array of monosaccharides and disaccharides bearing anomeric fluorous tags was noncovalently immobilized on fluorous-derivatized glass slides (19, 20). The attachment method is compatible with a wide range of functional groups and has been successfully used to probe carbohydrate-protein interactions.

Glycan arrays have also been developed to take advantage of the noncovalent, but extraordinarily strong, biotin-streptavidin interaction. The Consortium for Functional Glycomics developed a glycan array consisting of biotinylated oligosaccharides and amino acid glycoconjugates immobilized on streptavidin-coated 384-well microtiter plates (21, 22). Another biotin-streptavidin “sandwich” glycan microarray was produced by self-assembly of biotinylated alkylithiols on a gold substrate, followed by coating with streptavidin and printing of biotinylated polyacrylamide glycoconjugates (23).

An alternative to noncovalent approaches is covalent attachment of ligands to the surface. Methods for covalent attachment can be broadly categorized as follows: 1) condensation with the aldehyde of a reducing sugar, 2) nucelophilic addition to or displacement of a group on an activated surface or sugar, 3) cycloaddition, and 4) insertion reactions (see Fig. 2b). Some derivatization methods, for example, condensation and reductive amination, lead to ring opening of the reducing end sugar, whereas other methods result in indeterminate anomeric configurations, depending on the reaction conditions and point of attachment. The linker used to connect the sugar to the surface is an important consideration because it can affect recognition and accessibility of the ligands. In choosing an ideal linker, the issues to consider include the chemical nature and composition (hydrophobic vs. hydrophilic), stability, length, and flexibility of the linker.

Unmodified sugars have been attached to various hydrazide- and amino-derivatized slides by condensation or by reductive amination, which proceeds by reduction of the intermediate Schiff base (see Fig. 2b.1). This strategy was used for immobilization of free oligosaccharides onto hydrazide-derivatized plates (24) and various unmodified carbohydrates (monosaccharides, disaccharides, and polysaccharides) on hydrazide-coated glass slides (25). Later, immobilization of free oligosaccharides on hydrazide-derivatized self-assembled monolayer (SAM) of gold-coated glass slides was also reported (26). The formation of oximes between reducing end aldehydes of sugars and amino-oxy groups has been explored in the fabrication of glycans arrays. This method was explored for the immobilization of monosaccharides, disaccharides, and oligosaccharides on amino-oxy glass slides and successfully used for making a functional glycan array of oligosaccharides on amino-oxy-functionalized glass slides (27). However, stronger signals were observed for hydrazide-coated slides in comparison with amino-oxy-coated slides (25). Several glycans...
### Figure 2: Immobilization strategies. (a) A schematic representation of noncovalent adsorption. The lipid tail of a neo-glycolipid adheres to a hydrophobic surface via noncovalent interactions. (b) Strategies used for covalent immobilization of glycans.

Arrays have also been reported where the simple condensation of aldehydes and amines was used to covalently attach the saccharides. Deaminated heparin oligosaccharides bearing aldehyde groups were attached to amine-coated glass slides as Schiff bases without further reduction (28), while aldehyde and amino functionalized monosaccharides and disaccharides were immobilized on amine- and aldehyde-coated slides, respectively (29, 30). It should be noted that reductive amination results in opening of the reducing end sugar whereas condensation can lead to changes in anomeric configuration or mixtures of anomers at the reducing end.

An alternative strategy used in the covalent attachment of glycans to solid supports is nucleophilic addition or displacement. In this method, the decision about where to install the nucleophile and the electrophile—on the sugar or on the solid support—rests with the researcher, but could be influenced by the ease of installation and availability of derivatized reaction partners. Glycan arrays involving the Michael addition of maleimide-linked carbohydrates and thiol-coated glass slides (see Fig. 2b.2) have been created and used to probe lectin–carbohydrate interactions (31, 32). The transposition of the reacting functional groups has also been reported where glycans arrays were fabricated using thiol-linked sugars on maleimide-functionalized glass slides (33, 34) and on self-assembled monolayers presenting maleimide groups (35).

Epoxide-opening reactions have also been used to covalently attach carbohydrates, glycoproteins, and neoglycoconjugates to glass slides (see Fig. 2b.3). One report demonstrated the feasibility of immobilizing hydrazide-functionalized small molecules, including monosaccharides, on epoxide-coated slides and further showed that hydrazide-containing ligands react more rapidly with the epoxide-coated surface than thiols and amines (36). The use of epoxide-coated slides is relatively common for the fabrication of protein microarrays. One advantage of using epoxide-coated surfaces is the potential indiscriminate reactivity of epoxides to nucleophiles such as amines, thiols, and alcohols. However, it is important to note that the reactivity of these nucleophiles often depend on the pH conditions during printing. The development of glycan arrays of neoglycoconjugates and glycoproteins on epoxide-coated slides has been described (37, 38). In this report, neoglycoconjugates were synthesized by conjugating to lysine residues on serum albumin through activated carboxyl-bearing linkers, and then printed directly onto epoxide-functionalized glass slides.

The facile reaction of amines with N-hydroxysuccinimide (NHS)-activated carboxyl groups, and the concomitant formation of a stable amide bond, has been exploited in the fabrication of glycan arrays (see Fig. 2b.4). This method has been used for covalent attachment of amine-presenting glycans ranging in size from monosaccharides to glycoproteins on NHS-activated slides (39, 40). In one report, oligosaccharides were derivatized with photocleavable amine-bearing linkers used to attach the ligands to a porous silicon surface presenting NHS groups (41). Oligosaccharides labeled with fluorescent 2,6-diaminopyridine have also been printed on NHS-activated glass slides (42). An array of monosaccharides and oligosaccharides was created by the reaction of p-aminophenyl-glycosides with cyanochrome-activated linkers on wells of microtiter plates (7).

In the fabrication of bead-based glycan arrays, glycopeptides and bovine serum albumin neoglycoproteins were conjugated to the carboxyl-presenting beads using water-soluble carbodiimides. The beads were spatially arrayed into microwells for
screening with lectins (8) or assayed for lectin binding as a suspension (43).

Covalent immobilization of glycans by cycloaddition (see Fig. 2b.5 and insertion reactions (see Fig. 2b.6 and 2b.7) has been used in the creation of arrays (44–47). Cyclopenta-diene-carbohydrates were arrayed on self-assembled monolayers alkanethiols presenting benzocyclooctene through pentacyclic organometallic links (44). An efficient Diels–Alder reaction between the modified glycan and the support and the reduction of non-specific interactions by the use of the glycol linker are highlights of this report. One attachment method that portends the development of functional group-independent reactions where any underivatized molecule can be immobilized is the use of insertion reactions. In one report, various glycoproteins were printed on polymeric surfaces presenting arylfluoromethyl disorbidines. The surfaces were photoactivated resulting in formation of a covalent bond between the solid support and the printed ligand by carbene C–H insertion (46). In an alternative formal insertion strategy, glycans arrays were created by printing underivatized carbohydrates on SAM’s presenting phthalimide groups, which, on photoactivation, undergo hydrogen atom abstraction and recombination of radicals to form a covalent bond (47).

Obtaining glycans for an array

Preferably, one would like access to a representative set of naturally occurring monosaccharides and oligosaccharides, polysaccharides, glycopeptides, and glycolipids and their synthetic analogs. However, obtaining a diverse set of carbohydrates in a format compatible with the immobilization strategy remains a major challenge for glycan array development. Current arrays contain around 30–300 different components (see Table 2). This level of diversity can provide useful information but represents only a small fraction of the total diversity of carbohydrate structures found in nature. Including glycans from animals, plants, and bacteria, there are over 10,000 different structures that have been identified and characterized to date. Therefore, one of the principal challenges for the future advancement of glycan array technology is developing strategies to obtain much larger sets of carbohydrate ligands.

One method that has been used to acquire carbohydrates is isolation and purification from natural sources such as human or animal tissue, milk, urine, plants, and bacteria (see cross reference: Isolation of glycans). A access to homogenous carbohydrate structures can be challenging due to the difficulties in separation of complex mixtures, identification of carbohydrate(s) contained within each fraction, and preparation of sufficient quantities from the limited amounts present in a particular sample. A fortuitously, mixtures of unknown composition can be used to survey a broad repertoire of the glycome. On identification of a mixture containing one or more members with interesting receptor-binding properties, the mixture can then be deconvoluted by further fractionation and separation by routine analytical techniques (13).

A second method that has been invaluable for accessing glycans is chemical synthesis (see cross references: Glycan synthesis, key reaction of; Glycan synthesis, key strategies for; Glycan synthesis, protection and deprotection steps of; and Glycopeptides and glycoproteins, synthesis of). This approach can provide both natural and unnatural structures that can be very useful for probing relationships between structure and function. Although there have been tremendous advances in our ability to synthesize carbohydrates both in solution and on solid phase, carbohydrate chemistry remains a challenging area of organic chemistry. Progress on the synthetically tractable carbohydrate libraries (48–50), automated carbohydrate synthesis (51), and one-pot multicomponent synthetic strategies (41, 52, 53) will substantially aid glycan array development.

Enzymes can be powerful tools for obtaining carbohydrates as well (54). Chemoenzymatic synthesis of oligosaccharides involves the use of glycosyltransferases or glycosidases for the regio- and stereo-selective formation (typically between unprotected reaction partners) or hydrolysis of glycosidic bonds, respectively. In some cases, one reaction partner is obtained by traditional solution or solid-phase chemical synthesis, followed by enzymatic glycosylation. In other cases, synthesis begins with enzymatic cleavage and continues with more traditional chemical synthesis methods.

Evaluation of Binding

Once a glycan array is constructed, one needs to develop a method to evaluate binding of proteins, cells, viruses, or other macromolecules to the array. The general process involves carrying out the assay, detecting signals on the array, and analyzing processing the results. Although the overall process appears straightforward, assay development can be very challenging. Importantly, every step in the process from fabrication to assay conditions to detection must be successful to produce a signal. As a result, it can be difficult to determine which step or steps need to be optimized, especially when no signal is observed. Therefore, assay development typically requires systematic variation of many parameters. Additional considerations include sensitivity, signal-to-noise ratios, reproducibility, flexibility, and dynamic range.

The vast majority of array assays have used fluorescence as the detection method due to the high sensitivity and the availability of detectors such as fluorescent plate readers for microtiter plates and high resolution DNA microarray scanners for glass microarray slides. Therefore, the following discussion will focus on assay development coupled with fluorescent detection.

Non-specific adsorption

One important general consideration is non-specific binding. Proteins and other macromolecules can adsorb to surfaces leading to high background signals and low signal-to-noise ratios. One common approach to prevent non-specific adsorption is to cover or block any "sticky" surface areas with a noninterfering receptor-binding properties, the mixture can then be deconvoluted by further fractionation and separation by routine analytical techniques (13).

A second method that has been invaluable for accessing glycans is chemical synthesis (see cross references: Glycan synthesis, key reaction of; Glycan synthesis, key strategies for; Glycan synthesis, protection and deprotection steps of; and Glycopeptides and glycoproteins, synthesis of). This approach can provide both natural and unnatural structures that can be very useful for probing relationships between structure and function. Although there have been tremendous advances in our ability to synthesize carbohydrates both in solution and on solid phase, carbohydrate chemistry remains a challenging area of organic chemistry. Progress on the synthetically tractable carbohydrate libraries (48–50), automated carbohydrate synthesis (51), and one-pot multicomponent synthetic strategies (41, 52, 53) will substantially aid glycan array development.

Enzymes can be powerful tools for obtaining carbohydrates as well (54). Largest published array:

#### Directly labeled receptors

The most straightforward method for generating a fluorescent signal is directly labeling the protein or macromolecule of interest with a fluorophore (see Fig. 3a). Prior to incubating on the array, the receptor is conjugated to a fluorophore such as fluorescein, Cy3, or Cy5. One typically obtains 1-5 molecules of fluorophore per molecule of receptor. With a limited number of fluorophore molecules, this approach generally has the lowest sensitivity. In addition, covalent labeling of a protein can sometimes interfere with the functional properties of a protein. Nevertheless, this approach has been used successfully in many reports (19, 20, 32-34, 42, 46, 56-59).
Labeled secondary reagents

An alternative to direct labeling of a receptor involves the use of a secondary reagent that specifically binds the primary receptor of interest (see Fig. 3b). For example, a mouse monoclonal antibody can be detected with polyclonal anti-mouse antibody secondary reagents. In general, the array is incubated in the presence of the primary receptor such as a lectin or antibody. After washing away unbound receptor, the array is incubated with the secondary reagent. To generate a signal, the secondary reagent may be labeled with a fluorophore. One advantage of this method is that it is possible to get multiple secondary reagents binding to each molecule of primary receptor leading to increased sensitivity. Alternately, the secondary reagent may be conjugated to an enzyme such as horseradish peroxidase or alkaline phosphatase. To generate a signal, the array is incubated with a substrate that can be converted into a fluorescent product thus generating a large increase in fluorescent signal. Alternatively, a solution-phase fluorescent substrate is converted into a reactive intermediate that can covalently attach to the surface. In this case, soluble substrate is washed away and immobilized fluorophores are detected. The primary advantage of the enzyme-linked approach is sensitivity. As each molecule of enzyme can generate many molecules of fluorescent product, the signal is amplified. Moreover, the signal can be enhanced by increasing the length of time the substrate is incubated with the enzyme. In addition to enhanced sensitivity, use of a secondary reagent allows detection of receptors in the presence of complex mixtures of other proteins due to the specific binding between the primary and secondary proteins. For example, human serum contains a wide variety of different proteins and other components. With the aid of a secondary reagent, glycan-binding antibodies present in human serum can be profiled as biomarkers of disease (see below). Naturally, this approach is limited to situations where a secondary reagent is available.

Other methods of detection

Although labeled receptors and secondary reagents can be very useful, they are not suitable for all applications. Attachment of a label can disrupt binding, and secondary reagents are not available in all cases. Label-free assay systems have been used in protein microarrays to overcome these problems and are potentially useful in glycan array technology. Surface plasmon resonance imaging (60), mass spectrometry (61), oblique-incidence reflectivity difference (OIR-D) scanning microscope (62), and...
Kelvin nanoprobe (63) are some of the tools that have been adopted for label-free assay systems.

**Processing of assay signals**

Processing of signals and analysis of large datasets can present a major challenge for array technology. Several software programs have been used in combination with glycan arrays such as GenePix, ImageJ, QuantArray, ArrayWinX, and ScanRay. As glycan arrays increase in size, the need for bioinformatics tools will increase significantly.

**Applications of Glycan Arrays**

Glycan arrays have been used to evaluate the specificity of carbohydrate-binding antibodies and lectins used as research tools, diagnostics, and therapeutic agents. In addition, they provide useful information for increasing our basic understanding of molecular recognition of carbohydrates. Glycan arrays are also emerging as useful tools for biomarker discovery.

**Identification and characterization of carbohydrate-binding proteins**

Glycan arrays have been used to evaluate the specificity of numerous plant, animal, and microbial lectins.

Plant lectins are used routinely as research tools, diagnostic agents, and therapeutic agents. Plant lectins are frequently used as an initial screen of a glycan array to verify that the assay works. Numerous papers also describe the use of glycan arrays for more comprehensive analysis of plant lectin specificity (38, 40, 43, 64, 65). Although these proteins have been studied for years, array screening has uncovered novel binding properties illustrating the utility of high throughput, unbiased screening.

In addition to published results, the Consortium for Functional Glycomics lists results for many lectins and other proteins on its website.

A notable lectin plays an important role in many biological processes, and information on ligand binding is essential for development of agonists/antagonists. One interesting example is DC-SIGN, a calcium-dependent (C-type) lectin expressed on dendritic cells. DC-SIGN is known to bind HIV and facilitate infection of T cells. DC-SIGN has been profiled on glycan arrays and found to bind blood group antigens, ganglioside terminal sugars, and mannose oligosaccharides (22, 66). The related proteins SIGN-R1 through SIGN-R8 have also been evaluated (67, 68). Dectin-1, another C-type lectin-like receptor on leukocytes that mediates phagocytosis and inflammatory mediator production in innate immunity to fungal pathogens, was profiled using a glycolipid microarray (69). It was shown to bind clusters of 11-13 gluco-oligosaccharides. The scavenger receptor C-type lectin (SRCL) was profiled on a glycan array and was found to bind Le^b^ and related triosaccharides (70). A glycan array was also used to evaluate binding properties of the rat alaglyco-protein receptor, Kupffer cell receptor, macrophage-galactose lectin, and human scavenger receptor C-type lectin (71, 72).

Based on their galactose-binding preferences, the lectins were classified into two categories: one group selective for Lewis antigens and the other showed broad selectivity for various Gal/GalNAc-containing residues. A glycan array consisting of Le^b^, SL^b^, and their sulfated analogs was used to profile siglecs (73). This analysis revealed that the sulfite groups on the carbohydrate epitopes act as modulators of siglec binding.

Through the use of a glycan array, mouse Siglec-F and human Siglec-8 (21) expressed on esoinophils were also shown to recognize 6-sulfogalactose Le^b^ (74). A polysaccharide microarray was used to study interactions between dextran polysaccharides and platelet-derived growth factor BB isofrom (12). A chondroitin sulfate microarray was used as a screening tool to identify an antagonist for a therapeutically important proinflammatory cytokine, tumor necrosis factor-α (29). Another animal lectin profiled with glycan arrays include galectin-1 (75), galectin-4 (76), mannose 6-phosphate receptor (77), dectin-2 (78), Manilla clamt lectin (79), and Langerin (67).

Bacterial, viral, and microbial lectins are a third class of important proteins that have been screened on glycan arrays.

One of the most interesting applications of glycan arrays involved profiling hemagglutinins from pathogenic strains of influenza A virus including the pandemic 1918 strain (80, 81). Avian viruses were found to preferentially bind sialic acid with alpha 2-3 linkages while human viruses bound alpha 2-6 linkages. The difference in specificity provides a potential explanation for the variations in infectivity and pathogenicity. A group of bacterial toxins and cells, Salmonella typhimurium, Listeria Monocytogenes, Escherichia coli, staphylococcal enterotoxin B, cholera toxin, and tetanus toxin, has also been profiled on a glycan array (82). Several lectins with potent antiHIV activity such as cyanovirin, scytovirin, and microcuvirin have been evaluated on glycan arrays (58, 83).

Another important application of glycan arrays is assessing the specificity of glycan-binding antibodies (37, 58, 84-87). Carbohydrate-binding antibodies are important research tools, diagnostics, and therapeutic agents. Information on specificity is critical for the proper interpretation of results or selection of clinical candidates. For example, antibody 2G12 is known to neutralize a broad range HIV-1 isolates in a carbohydrate-dependent manner. Profiling using a glycan array illustrated that the peptide backbone is not required for binding and that the antibody has a preference for Manα1-2Man linkages (58, 84). A glycan array comprising the tumor antigen Globo H and its fragments was used to profile two monoclonal antibodies against Globo H and serum from breast cancer patients (86). This array showed that the fucose residue was essential for recognition by the monoclonal antibodies but not for the serum antibodies. In another glycan array study, various antibodies and lectins that have been used for decades to monitor the expression of the tumor-associated Tn antigen were found to cross-react with other human glycans (37). The results suggested that information on the expression of the Tn antigen used for the development of diagnostics and vaccines may be inaccurate. The antimalaria antibody MG96 was evaluated in an effort...
to identify suitable carbohydrate antigens for a malaria vaccine (85).

**Profiling serum antibodies as biomarkers for disease**

Glycan arrays have also been used to measure levels of antiacarbohydrate antibodies in patient serum as diagnostic or prognostic markers (10, 88–93). A glycan array was used to measure the antiacarbohydrate antibody levels in eight Hodgkin’s lymphoma patients (92). From the study, elevated antibody levels against four carbohydrate epitopes were detected in the lymphoma patients. Blood samples from multiple sclerosis and Crohn’s disease patients were screened on a glycan array for elevated antibody expression (93). In another report, a glycan array was used to profile 167 multiple sclerosis patient sera (93). From this study, antibodies to Glc1–4GlcNAC were identified as novel biomarkers for relapsing/remitting multiple sclerosis. A set of 72 Crohn’s disease patient sera was also profiled using a microarray (94). It was reported that antichitobioside and antiaminobiose antibodies are novel serologic markers associated with Crohn’s disease.

**Characterization of cell and virus binding**

Cell–cell recognition can be a complex process involving multiple interactions between different proteins and glycans. In some cases, the specific proteins involved are not known or are not functional on their own. In addition, cell binding can trigger signaling cascades or other responses. As a result, evaluation of binding of whole cells to glycans can be very useful and several reports have demonstrated successful screening of cells on glycan arrays. Examples include screening of E. coli strains (25, 94), chicken hepatocytes and CD4+ human T-cells (95), and Helicobacter pylori (96). Viruses and viral capsids have also been screen on glycan arrays (97, 98).

**Identification of enzyme substrates and inhibitors**

Glycan arrays have also been used to identify inhibitors of enzymes. Inhibitors for the enzyme fucosyltransferases were discovered from a library of triazole-containing compounds using a glycan array (99). Due to the importance of aminoglycosides as therapeutic agents and the attractiveness of RNA as a drug target, a number of aminoglycoside–glycan arrays have been developed. One aminoglycoside array was used for the high throughput analysis of glycan–RNA interactions (100). The molecular recognition between oligonucleotide mimics of aminoglycoside-binding sites in the bacterial 30S ribosome and various aminoglycoside–ribosomes and various aminoglycoside–antibiotics has been studied by the use of a glycan array (101). Another aminoglycoside–membrane microarray was developed to assess the potency of these glycans as improved antibiotics (59). The interactions between aminoglycosides and two aminoglycoside acetyltransferases implicated in antibiotic resistance were analyzed. The array analysis showed that some of the aminoglycoside mimetics inhibit the aminoglycoside acetyltransferases, and thus have potential as improved antibiotics.

**Conclusions**

Glycan arrays have emerged as powerful tools for analysis of carbohydrate–macromolecule interactions. As research tools, they are being used to identify ligands for glycan-binding proteins and evaluate specificity of carbohydrate–binding proteins. In a clinical setting, glycan arrays hold enormous potential for the development of diagnostic and therapeutic agents. For example, several studies have demonstrated the utility of glycan arrays for profiling antiglycan antibodies in serum as diagnostic markers of disease. As the technology matures, the range of applications and capabilities will continue to expand and glycan array analysis is anticipated to become routine in chemistry, biology, and clinical laboratories.

Databases and informatics tools are central to rapid acceleration in the progress of the genomics and proteomics fields. Glycomics, an emerging paradigm in the age of postgenomics, involves understanding the structure–function relationship of glycans in fundamental biological processes. In comparison with genomics and proteomics, the advancement of glycomics has faced unique challenges in the pursuit of developing tools, biological readouts, and an informatics platform to investigate glycan structure–function relationships. These challenges are because of the structural diversity and heterogeneity in glycans that develops from their complex non-template biosynthesis. This review focuses on areas of technologies for sequencing glycans and the importance of developing a bioinformatics platform to integrate the diverse data sets generated using the different technologies to allow a systems approach to glycan structure–function relationships. Although aspects of glycan analysis and integration of glycomics data sets have been covered in earlier reviews, this review brings these aspects together for both linear and branched glycans.

Glycosylation, or the attachment of complex carbohydrates (glycans) to proteins, is the most extensive and complex form of posttranslational modification and is required for the functional diversity to generate extensive phenotypes from a limited genotype. Glycans can be classified broadly as linear and branched, based on their chemical structure. Branched glycans (Fig. 1) are present as N-linked and O-linked glycosylation on glycoproteins or on glycolipids (1, 2). The majority of linear sugars are glycosaminoglycans (GAGs) that contain long polymers of sulfated disaccharide repeat units that are O-linked with a core protein to form a proteoglycan aggregate (3) (Fig. 1). The known intracellular roles of protein glycosylation include facilitating and stabilizing the protein folding process and targeting proteins to various intracellular compartments (1, 2). The glycans present on the glycoproteins and proteoglycans at the cell surface and the cell–extracellular matrix (ECM) interface are instead in an environment of many proteins including growth factors, cytokines, immune receptors, enzymes, and others. The ubiquitous distribution of glycans at the cell–ECM interface results in their involvement in the dynamic interplay between the cell and its environment. Glycans thus play a central role in fundamental biological processes such as development, cancer, infection, and immunity (4–8). The numerous biological roles of glycans are attributed to their specific interactions with a variety of proteins. Therefore, glycans modulate protein activity at the cell–ECM interface.

Informatics approaches are emerging as critical tools to accelerate understanding of the structure–function relationships of genes and proteins in fundamental biological processes. Such approaches involve storing, integrating, manipulating, analyzing, and mining sequence, structure, and biological-function information on genes and proteins at the molecular, cellular, tissue, and higher levels. The need for informatics tools continues to grow in the face of rapid data evolution from single-gene or protein level to complex high-throughput data sets on multiple genes or proteins at multiple levels (molecular, cellular, etc.). In the case of glycans, comprehending structure–function (or sequence–activity) relationships presents unique challenges when compared with genes and proteins. The biosynthesis of glycans is a non-template-driven process that involves the coordinated expression of several glycosyltransferases (and sulfotransferases in the case of GAGs), some of which have additional tissue-specific isoforms (1–3, 5). The complex biosynthesis and the lack of a proofreading machinery lead to an inherent heterogeneity and large diversity of glycan structures. Owing
Glycan Sequencing and Data Integration for Glycomics

Figure 1  Linear and branched glycans. Shown in figure are the different classes of glycan in their symbol nomenclature. The directionality of the glycans is from the nonreducing end at the top to the reducing end at the bottom with the arrows indicating the extension at the nonreducing side. The links between monosaccharides contain the anomeric configuration of the monosaccharide (α-alpha and β-beta) and the oxygen atom in the reducing end monosaccharide to which it is linked. The common terminal sugars in N-linked and O-linked branched glycans are shown in a dotted box (α3/6 indicates α3 or α6 link for the sialic acid). In the case of GAGs, representative chains of heparan sulfate (HS), chondroitin sulfate (CS), and dermatan sulfate (DS) are shown.

to their mode of biosynthesis, ubiquitous subcellular distribution, and the glycoprotein diversity that develops from one or more glycosylation sites, glycans additionally always need to be considered as a heterogeneous mixture of different chemical structures when isolated from cells and tissues. These challenges have hampered the development of analytical techniques that accurately can define the chemical structures on the ensemble of glycans isolated from glycoproteins, cells, or tissues. An understanding of the biochemical basis for glycan-protein interactions is complicated more by the multivalency and graded affinity that involve an ensemble of glycans making multiple contacts with multivalent protein binding sites (3, 9, 10).

In light of the above complexities, it is evident that developing an informatics platform is critical to decode the structure-function relationships of glycans. Informatics-based approaches are especially key to decode the sequence of glycans because no automated sequencing strategies are available similar to those that are found for DNA and proteins. Additionally, a need has developed to cut across diverse data, ranging from glycan biosynthesis, glycan characterization, and glycan-protein interactions, to take an integrated system or glycomics approach to delineate glycan structure-function relationships. This review is divided into two parts to provide a perspective on the development and application of informatics tools for glycans. The first part covers the critically needed informatics tools that sequence glycans to decode their sequence diversity. The second part covers the development of an informatics platform that bridges multiple data sets collected using different technologies to provide a systems framework for understanding glycan structure-function. These arguments are illustrated using examples of both linear and branched sugars.

Decoding Glycan Diversity: Strategies for Sequencing Glycans

The complete set of glycans in a given cell (analogous to the genome or proteome of a cell) includes different types of glycoconjugates such as glycolipids, glycoinositolphospholipids, glycans attached to proteins in the form of glycoproteins, peptidoglycans, and proteoglycans. Decoding the complete chemical structure (analogous to the primary sequence of DNA and protein) of each of these glycans in the entire repertoire mentioned presents a formidable challenge. Many efforts have focused on the isolation and characterization of glycans from glycoproteins (for branched glycans) and proteoglycans (for linear GAGs).

Isolation of glycans from glycoproteins

Two distinct approaches characterize glycans on glycoproteins. The first approach involves releasing the glycans and characterizing the structures of the entire ensemble of these released glycans. The second approach instead fragments the entire glycoprotein to glycopeptides and characterizes the peptide and glycan component of each glycopeptide. The second approach involves characterization of glycoproteins in terms of the distinct glycan structures at each of their glycosylation sites. Glycans can be released from glycoproteins by using either chemical methods, such as hydrazinolysis (N-linked)
and β-elimination (O-linked), or enzymatic methods that use PNGase F or A (N-linked). Currently, no generic enzymatic methods are available to release O-linked glycans. The enzy-

The next level of characterization involves matching the frag-

mentation patterns of the parent ion from the MS² (and possibly higher order MS³, MS⁴, ..., MSⁿ) data to reference data sets and de-

termining the sequence of glycans (Table 1) (17–28). It should be

noted that a trade-off occurs between the accurate characteriza-
tion of the exact glycan structure and high-throughput analysis of several glycans in a given sample. In the case of a typical high-throughput data set such as MALDI-MS profile of glycans isolated from cells/tissues, a set of compositions and glycan topologies are assigned to a given mass peak based on biosyn-

thetic constraints. The GlycoMod program (17) available on the Ev- 

PAzy website provides an automatic calculation of possible monosaccharide compositions for a given parent ion mass. The 

Carbonator software (18) provides an automated annotation of a MALDI-MS glycan profile with glycan topologies selected from a library of topologies generated using biosynthesis rules. These programs provide a quick read of the graphical represen-
tation of glycan topologies for an entire repertoire of glycans in a biological sample.

The above MS methods and data interpretation tools are valuable to obtain rapidly the most probable structures of an entire ensemble of glycans isolated from cells and tissues. Determining the exact structure of each glycan (in a mixture), including the anomeric configuration of each sugar and the specific link ab initio, remains a formidable task. One approach toward this task employs exo-glycosidases that specifically cleave monosaccharides from the nonreducing end of a glycan. The HPLC chromatographic profile of parent glycan sample and the shifts in peaks that result from treatment with the exo-glycosidases are matched with reference chromatographic profiles of known glycan structures using software tools to derive the exact structure of glycans in the sample (26, 31). Nuclear magnetic resonance (NMR) spectroscopy is another valuable tool to obtain link information in glycans (32). The characteristic NMR chemical shifts and coupling constants of various glycans have been compiled in databases to facilitate the assignment of glycan structures based on NMR data (Table 1). Such approaches for fine structure characterization of glycans have limitations when considering biological samples composed of a diverse mixture of glycans. The requirement of high sample amounts (in the case of NMR) and multiple steps of exo-glycosidase treatment for larger glycan mixtures complicate the use of these techniques for high-throughput analysis. In the case of linear sugars such as GAGs, because of the heterogeneity in the chain length and sulfation pattern (Fig. 1), their isolation from biological samples results in a mixture of different chain lengths and compositions. To determine the sequence of individual GAG oligosaccharides in a mixture, it is necessary to subfractionate them based on size and charge and then to purify these fractions to homogeneity. The chain length of a homogeneous GAG oligosaccharide isolated in this manner is typically 4–8 disaccharide repeat units. It is difficult to determine the exact sequence of a GAG chain (particularly for highly sulfated GAGs) that is greater than 10 disaccharide repeat units. Given that GAG–protein binding specificity typically involves chain length of 2–5 disaccharide units, sequencing these chains does provide important information on the structure-function relationships of GAGs (3). The two main areas for generating tools for the characterization of GAGs have been the development of chemical and enzymatic tools for the controlled and specific depolymerization or modification of a GAG chain and the development of analytical tools based on chromatography, electrophoresis, MS, and NMR techniques (see Reference 3 for details). Informatics-based methods have also been developed to capture the information density of GAGs and to enable the application of data from a combination of tools as constraints to sequence GAGs (27, 28). The underlying rationale of these approaches is to begin with a comprehensive master list of GAG sequences that represents the entire sequence space for a given chain length and overall composition (monosaccharide or disaccharide units). The data from a series of GAG depolymerization/modification profiles (mass
spectrometry, electrophoresis, and chromatographic) serve as constraints to reduce this master list in an iterative fashion to the final sequence or set of probable sequences that satisfy all the constraints. These strategies provide an unbiased approach to sequencing GAGs through elimination of sequences from a master list that do not satisfy the experimental constraints.

### Integrated Informatics Platform for Glycans

The type of data sets needed to fully define structure-function relationships of glycans goes beyond the complex analytical data for structural characterization of glycans. Several international collaborative efforts (Table 2) recognize the need for an integrated glycomics approach and are developing novel resources and technologies to better understand glycan structure-function relationships. The data sets and databases developed by these initiatives revolve around three main components that are discussed in detail below (summarized in Table 3): 1) glycan structures, 2) glycan biosynthesis pathways, and 3) glycan-protein interactions.

#### Glycan structures database

The common goal of all the major glycomics initiatives is the development of a database of glycan structures in parallel with the analytical data sets (described above). The common source for the initial set of glycan structures to seed different glycan databases was the CarbBank database. This database was discontinued in the 1990s because of a lack of resources that was required to sustain its development and ensure the quality of glycan structures based on extensive curation. The diversity in the sugar building blocks of glycans, the link between the sugars and two-dimensional topology (degree and extent of branching), offers challenges in the development of standardized data formats to represent glycan structures across different databases. Because of this obstacle, independent data formats were developed in the various international initiatives to encode glycan structures in databases. An important issue develops from the ambiguities in glycan structure that result from incomplete assignment of their exact structure. These ambiguities include unspecified links, anomeric configurations, and uncertainties in the connectivity of a specific sugar (typically terminal sugar) or a set of sugars to a particular two-dimensional glycan topology.

Consequently, different databases employ disparate mechanisms to manage these ambiguities; they represent ambiguities as they are or deconvolute them into a set of likely exact structures. An important feature of the glycan structures databases is the tools to query the database using parameters such as monosaccharide composition, substructure, and mass. Different algorithms have been developed to search, score, and compare glycan structures using tree matching methods, scoring matrices, and dynamic programming tools. The interpretation of the search results from these tools is still demanding primarily because of the lack of standardized definitions of glycan structures across different databases. Querying different glycan structures databases using the same query parameters often gives dramatically different results in this context.

### Glycan biosynthesis pathways

The Consortium for Functional Glycomics (CFG) has led a collaboration with Japanese and European initiatives to develop a comprehensive annotation of the enzymes involved in glycan biosynthesis. Currently, these annotations are disseminated using glycosylation pathway interfaces and glycosyltransferase databases of the CFG, KEGG glycans, Complex Carbohydrates Research Center (CCRC), and CAZy. The CFG has developed customized DNA microarrays that appropriately represent glycan biosynthesis and binding protein genes to study their expression pattern. Hundred of samples representing various tissues and cell types have been analyzed on the CFG glyco-gene microarrays. The focus of experiments includes the analysis of different tissues and binding protein genes to study their expression pattern. A valuable resource for quantitative analysis of gene expression is the quantitative real-time PCR analysis of glycan-related genes from the CCRC.

This table includes open access online web-based resources for glycomics. Each resource is associated with a specific type of glycan structure, analytical data, or glycan-protein interactions. Some examples include CFG Glycan Structures Database, Glycosciences Glycan Structures Database, Glycome DB, KEGG Glycan Structures Database, Bacterial Carbohydrate Structures Database, Glycobase, Glycoconjuate DB, CFG MALDI-MS Glycan Profile of Cells and Tissues Database, SUGABASE NMR DB, CCRC NMR and MS Data, CFG GBP DB, Thorkild's Lectin Page, CFG Glycan Array Screening Data, Lectines 3D, GlycoEpitope DB, SugarBindDB, CFG GT DB, KEGG GT DB. These resources provide valuable information for researchers working in the field of glycomics.
The data generated from these analyses have uncovered novel glycan recognition motifs for these diverse range of samples analyzed. The CFG and other groups have also developed specific databases for GBPs and other lectins (from plants and bacteria) that capture the sequence, three-dimensional structure, known glycan binding specificities, and other information from the proteins (Table 3).

Data integration for glycomics

Clearly, a need to cut across multiple data sets to understand the structure-function relationships of glycans is apparent. A critical component that permits this process is the bioinformatics platform used to store, integrate, and process the information generated by the above methods and to disseminate this information in a meaningful fashion via the Internet to the scientific community worldwide (35, 50). To capture complex relationships between diverse data, it is necessary to develop an object-based relational database. Three primary objects are found in glycomics data sets: GBPs, glycan biosynthetic enzymes, and the glycan structures. The different methodologies that generate data sets are organized into secondary and other levels of objects with defined interrelationships and relationships to the primary objects. The overall scheme for data integration in the CFG databases is shown as an example (Fig. 3). The key identifiers to uniquely define the primary objects include the glycan structure represented in the internal database format, primary sequence (or accession numbers such as GenBank and SwissProt) of the GBPs, and glycan biosynthetic enzymes. The relationship of primary to secondary data objects is established using object-based keys such as sample, protocols, and data keys. Unlike in the case of the primary objects, it is challenging to define standardized criteria that can determine the uniqueness of the secondary objects (such as sample information) because of the lack of standardized ontologies to describe sample and protocol information for glycomics. To address this challenge, a key step would require outlining metadata standards for obtaining various glycomics data sets, including mass-spectrometric glycan analysis data and glycan-protein interaction data. It is important, for example, to capture mass spectrometer instrument settings, internal standards, and other experimental conditions used to characterize glycans from a given sample. The blueprint of the object-based relational database is a data model that captures data definitions and interrelationships between the data sets using the specific object-based identifiers, which is quite complex.
Glycan Sequencing and Data Integration for Glycomics

Figure 2  Multivalent glycan–protein interactions. Shown on the left is a schematic of multivalent interactions between branched N-linked and O-linked glycans on glycoproteins with CRDs glycan binding proteins. The binding specificity is critically governed by the chemical structure and three-dimensional topology of the glycan ligand motif and the multivalency. Given that the glycan ligand motif can be present on the same or different glycoproteins, it is important to characterize the ensemble of glycans isolated from a given cell. Shown on the right is a schematic of GAG–protein interactions. GAGs are typically involved in facilitating the assembly of protein–protein complexes, enzyme–inhibitor complexes, and ligand–receptor complexes on the cell surface and thus play important roles in extracellular signaling. The schematic shows an example of HS GAG (H-glucosamine; I–iduronic acid) wherein the chain length, chain conformation, and sulfation pattern governs whether an active or inactive protein–protein complex is assembled.

It is important, therefore, to develop a software architecture that keeps this complexity hidden from the user during the actual data acquisition and dissemination. The three-tier software architecture containing a back-end relational database to store the data and annotate relationships, a middleware application layer that communicates between the database and the user interface, and the top layer that comprises the user interfaces to the database is best suited for this purpose. This software architecture facilitates the easy deposit of data into the database, which is organized automatically into the relational tables by the middleware application layer.

Central to this data integration is an ability to link orthogonal data sets derived from identical, or similar, samples. For example, the gene expression profile of a specific tissue or cell line isolated from a given strain of transgenic mice needs to be automatically associated in the database with orthogonal information such as glycan profile, histological staining, and immunological profile from a similar or identical sample. Such integration would permit researchers to cut across multiple data sets and begin posing questions such as "Does the expression of glycosyltransferase correlate with glycan profile of that tissue?" or "Can the pathological analysis of the tissue be explained on the basis of gene expression profile?" The bioinformatics platform ultimately needs to support computational tools that perform data mining analysis on the large-scale glycomics data sets. The prediction of glycan structures based on gene expression profiles of glycan biosynthetic enzymes (41) is now enabled because of the user-friendly access to diverse data sets via relational databases.

Significance and Future Directions

Glycomics is an emerging field that adds new dimensions to both technology development and obtaining an understanding of fundamental biological processes in this age of postgenomics. The two fundamental questions advancing glycomics are as follows: 1) How do we define glycan diversity in the context of biosynthesis and specificity in modulating a biological process and 2) how do we define specificity in the context of multivalent glycan–protein interactions? It is important to consider these questions in light of the numerous efforts underway to discover novel glycan-based biomarkers and therapeutic targets (51–54). In the case of biomarker discovery, two distinct approaches are found. The glycomics approach begins with the discovery of a specific glycan ligand motif specifically involved in a biologically important glycan–protein interaction. The use of this motif as a biomarker then is investigated by studying the expression of this motif as a part of glycan structure
or glycan biosynthesis enzymes that generate this motif in different biological samples. The other approach is more of a high-throughput analytical approach that relies on the various analytical and informatics tools to characterize glycan structures in different samples and to identify unique markers based on differential expression of specific structures in a given sample. The generation of diverse data sets and their integration via an informatics platform is critical to both approaches. From an informatics perspective, the key issues that need to be addressed are as follows: 1) developing standardization and quality control of the data, 2) developing consistent format for representation and transfer of complex glycan structures across different databases, and 3) developing robust ontologies and structured vocabulary for glycomics (35).

A significant portion of the high-throughput data sets on glycan analysis and glycan-protein interactions are fairly recent, and therefore a critical need is found to standardize the generation of these data so they can be compared across data sets generated by different initiatives (35). Also, awareness is increasing of the need to develop data exchange formats, such as X ML, for consistent description of glycan structures and glycomics data sets across different large-scale glycomics initiatives (19). Leading glycomics initiatives recently agreed to adopt the Glyde-II XML format (52). The next step toward standardization of glycan structure databases is to establish the standards for incorporating glycan structures into a database to develop the glycan database into an international resource similar to GenBank and SwissProt. Collaborative discussions between the large-scale glycomics initiatives to address these issues are notable steps toward advancing glycomics.

Acknowledgments

This work was supported by the National Institute of General Medical Sciences Glue Grant U54 GM62116. The authors thank the CFG members, the members of Bioinformatics Core (B) of CFG, for the work described in this review, and V. Sasisekharan for critical reading of the manuscript.

References

Figure 3 Data integration in glycomics. An example of integrating the diverse data sets generated by CFG to the three primary databases viz glycan structures, GBP, and GT is shown. The arrows indicate the connectivity between the objects using the primary identifiers for genes, proteins, glycan structures, and samples analyzed. This integration enables seamless navigation across these data sets. For example, starting from a glycosylation pathway, it is possible to navigate to a specific glycan structure whose biosynthesis involves a particular enzyme. If a glycan ligand motif present on the glycan array is a part of this glycan structure, it is possible to determine which of the samples analyzed on the array gave good binding signals to this motif. If any of the samples analyzed are mammalian GBP, then it is possible to access an entire portal of information on that particular GBP.
Glycan Sequencing and Data Integration for Glycomics

Differential Scanning Calorimetry to Study Lipids and Lipid Membranes

Ruthven N.A.H. Lewis, David A. Mannock, and Ronald N. McElhaney, University of Alberta, Edmonton, Alberta, Canada

doi: 10.1002/9780470048672.wecb049

Differential scanning calorimetry (DSC) is a relatively rapid direct and nonperturbing thermodynamic technique for studying the thermotropic phase behavior of hydrated lipid dispersions and of reconstituted lipid model and biological membranes. DSC can accurately and reliably determine the temperature, enthalpy, entropy and cooperativity of a wide variety of lipid phase transitions and how these parameters are influenced by variations in hydration, and in the pH and the ionic strength and composition of the aqueous phase. A too, the effects of the presence of membrane-associated sterols, peptides and proteins, as well as toxins, drugs, and other agents, on the thermotropic phase behavior of lipid membranes can be determined. Under appropriate conditions, DSC can also characterize the kinetics of some lipid phase transitions. The thermodynamic data provided by DSC, therefore, can provide valuable information about the phase state and organization of lipid assemblies and about how the structure and physical properties of lipid model and biological membranes are modulated by other membrane constituents and by the environment. However, because DSC is a thermodynamic and not a structural technique, it is most valuable when applied in conjunction with a direct structural technique, such as X-ray diffraction, and with nonperturbing spectroscopic methods, such as nuclear magnetic resonance and Fourier transform infrared spectroscopy.

Lipid Mesomorphic Phase Behavior

Membrane lipids are invariably polymorphic: that is, they can exist in a variety of kinds of organized structures, especially when hydrated. The particular polymorphic form that predominates depends not only on the structure of the lipid molecule itself and on its degree of hydration, but also on such variables as temperature, pressure, ionic strength and pH (see References 11 and 12 and article Lipids, Phase Transitions of). However, under physiologically relevant conditions, most (but not all) membrane lipids exist in the lamellar or bilayer phase. In the lamellar phase, the lipid bilayer is stabilized by hydrophobic interactions between the hydrocarbon chains in the interior of the lipid bilayer and by polar interactions with the glycerol backbone and polar headgroup regions of the host lipid bilayer. In addition to playing a structural role in determining the topology and stabilizing the active conformation of peripheral and integral membrane proteins, the physical properties of the lipid also markedly influence the activity and thus presumably the conformation and dynamics of many membrane proteins (4–8, but see 9). Specifically, the physical state (lamellar gel versus liquid-crystalline), fluidity, hydrophobic thickness, lipid lamellar/nonlamellar phase propensity (lipid shape), surface charge and surface-charge density, as well as various mechanical properties of the lipid bilayer (10), all modulate the thermal stability and activity of many membrane-associated enzymes, transporters and receptors. Therefore, understanding the thermotropic phase behavior and organization and thus the specific functions of the large number of lipid classes and molecular species that comprise biological membranes, remains a major challenge in membrane biology generally. In this brief review, we consider the applications of DSC to lipid model and biological membranes to address in particular the role of lipid fluidity and phase state and to some degree the role of lipid lamellar/nonlamellar phase propensity in membrane structure and function.
and is also the most biologically relevant. This cooperative phase transition involves the conversion of a relatively ordered gel-state bilayer, in which the hydrocarbon chains exist predominantly in their rigid, extended, all-trans conformation, to a relatively disordered liquid-crystalline bilayer, in which the hydrocarbon chains contain several gauche conformers and exhibit greatly increased rates of intramolecular motions. The gel-to-liquid-crystalline phase transition is accompanied by a pronounced lateral expansion and a concomitant decrease in the thickness of the bilayer, as well as by a small increase in the total volume occupied by the lipid molecules. Evidence also shows that the number of water molecules bound to the surfaces of the lipid bilayer increases during hydrocarbon chain melting. Thermodynamically, the gel-to-liquid-crystalline phase transition occurs when the entropic reduction in free energy that results from hydrocarbon chain isomerism counterbalances the decrease in bilayer cohesive energy that results from the lateral expansion and from the energy cost of creating gauche rotational conformers in the hydrocarbon chains.

Gel-to-liquid-crystalline phase transitions can be induced by changes in temperature and hydration, as well as by changes in pressure and in the ionic strength or pH of the aqueous phase. In this article, we will concentrate on thermally induced phase transitions because these have been studied most extensively and are of direct biological relevance, particularly for organisms that cannot regulate their own temperature. However, hydration-induced (lyotropic) and pressure-induced (barotropic) phase transitions also occur, and these may also be biologically relevant under special environmental circumstances. Finally, phase transitions induced by alterations in pH and in the nature and quantity of ions in the aqueous phase that surrounds the bilayer are also possible, and these transitions may also be of importance in living cells. However, a detailed discussion of these types of lipid phase transitions is beyond the limited scope of the current article, and interested readers should consult appropriate reviews for detailed information on this topic.

Pure synthetic lipids often exhibit gel-state polymorphism, and phase transitions between various forms of the gel-state bilayer can occur. Although we will illustrate this behavior for a common phospholipid, dipalmitoylphosphatidylcholine (DPPC), gel-state transitions will not be emphasized here because with only one known exception (13), they do not seem to occur in the heterogeneous collection of lipid molecular species found in biological membranes. Moreover, certain synthetic or naturally occurring lipid species can exist in liquid-crystalline nonlamellar phases, especially three-dimensional reversed cubic and hexagonal phases. Although the actual existence of nonbilayer lipid phases in biological membranes has never been demonstrated under physiological conditions, the propensity to form such phases likely plays major roles in membrane fusion and other processes (see Reference 14). Moreover, evidence suggests that the relative proportion of bilayer-prefering and nonbilayer-prefering lipids may be biosynthetically regulated in response to variations in temperature and membrane lipid fatty acid composition and cholesterol content in some organisms. Thus, lipid species that in isolation may form nonlamellar phases may have important roles to play in the liquid-crystalline bilayers found in essentially all biological membranes. The transitions between lamellar and nonlamellar lipid phases have been reviewed in detail by us and others elsewhere (see References 14 and 15).

Differential Scanning Calorimetry

As mentioned earlier, the technique of DSC has been of primary importance in studies of lipid phase transitions in model and biological membranes (see References 16–18). The principle of DSC is comparatively simple. A sample and an inert reference (i.e., a material of comparable thermal mass that does not undergo a phase transition within the temperature range of interest) are simultaneously heated or cooled at a predetermined constant rate (dT/dt) in an instrument configured to measure the differential rate of heat flow (dE/dt) into the sample relative to that of the inert reference. The temperatures of the sample and reference may either be actively varied by independently controlled units (power compensation calorimetry) or be passively changed through contact with a common heat sink that has a thermal mass that greatly exceeds the combined thermal masses of the sample and reference (heat conduction calorimetry). For our purposes, the sample would normally be a suspension of lipid or membrane in water or an aqueous buffer, and the reference cell would contain the corresponding solvent alone. At temperatures distant from any thermotropic events, the temperatures of the sample and reference cells change linearly with time, and the temperature difference between them remains zero. The instrument thus records a constant difference between the rates of heat flow into the sample and reference cells, which, ideally, is reflected by a straight, horizontal baseline. When the sample undergoes a thermotropic phase transition, a temperature differential between the sample and reference occurs, and the instrument either actively changes the power input to the sample cell to negate the temperature differential (power compensation calorimetry) or passively records the resulting changes in the rate of heat flow into the sample cell until the temperature differential eventually dissipates (heat conduction calorimetry). In both instances, a change develops in the differential rates of heat flow into the sample and reference cells, and either an exothermic or endothermic deviation from the baseline condition occurs. On completion of the thermal event, the instrument either re-establishes its original baseline condition or establishes a new one if a change in the specific heat of the sample has occurred. The output of the instrument is thus a plot of differential heat flow (dE/dt) as a function of temperature in which the intensity of the signal is directly proportional to the scanning rate (dT/dt).

The variation of excess specific heat (dE/dt) with temperature for a simple two-state, first-order endothermic process, such as the gel-to-liquid-crystalline phase transition of a single, highly pure phosphatidylcholine (PC), is illustrated schematically in Fig. 1. From such a DSC trace, several important parameters can be determined directly. The phase transition temperature, usually denoted Tm, is that temperature at which the excess specific heat reaches a maximum. For a symmetrical curve, Tm represents the temperature at which the transition from the...

gel-to-liquid-crystalline state is one-half complete. However,

for asymmetric traces, which are characteristic of certain pure

phospholipids and many biological membranes, the $T_m$ does

do not represent the midpoint of the phase transition, and a $T_{1/2}$

value may be reported instead. Once normalized with respect

to the scan rate, the peak area under the DSC trace is a direct

measurement of the calorimetrically determined enthalpy of the

transition, $\Delta H_{cal}$, usually expressed in kcal/mol. The area of the

peak can be determined by planimetry or by the cutting

and weighing technique; alternatively, the calorimeter output

can be digitized, and the $T_m$ and $\Delta H_{cal}$ can be calculated by a

computer. Because at the phase transition midpoint temperature

the change in free energy ($\Delta S$) of the system is zero, the entropy

change associated with the transition can be calculated directly

drop from the equation:

$$\Delta S = \Delta H_{cal} / T_m$$

where $\Delta S$ is normally expressed in cal/K·mol$^{-1}$.

The sharpness or cooperativity of the gel-to-liquid-crystalline

phase transition can also be evaluated from the DSC trace.

The sharpness of the phase transition is often expressed as the

temperature width at half-height, $\Delta T_{1/2}$, or as the temperature

difference between the onset or lower boundary of the phase

transition, $T_0$, and the completion or upper boundary, $T_l$, or

$\Delta T = T_l - T_0$. The $\Delta T_{1/2}$ values may range from $0.1$ C for very pure synthetic phospholipids to as much as $10-15$ C for biological membranes. From the $T_m$ and $\Delta T_{1/2}$ values determined for a particular phase transition, the van’t Hoff

enthalpy, $\Delta H_{vH}$, can be approximately determined from the relationship:

$$\Delta H_{vH} \approx 6.9 T_m / \Delta T_{1/2}$$

From the ratio $\Delta H_{m}/\Delta H_{vH}$, the cooperative unit size (CUS) in molecules can be determined. The CUS is a measure of the degree of intermolecular cooperation between phospholipid molecules in a bilayer; for a completely cooperative, first-order

phase transition of an absolutely pure substance, this ratio

should approach infinity, whereas for a completely noncoopera
tive process, this ratio should approach unity. Although the

absolute CUS values determined should be regarded as tentative,
because this parameter is markedly sensitive to the presence

of impurities and may be limited by instrumental parameters,
carefully determined CUS values can be useful in assessing the

purity of synthetic phospholipids and in quantitating the degree

of cooperativity of lipid phase transitions.

It must be stressed that the thermodynamic parameters de

rived from DSC measurements will be valid only if measure

tments are performed under conditions where the instrument

response is true to the properties of the sample (so-called

high-fidelity DSC) and if the thermotropic process being stud

ied is at equilibrium throughout the measurement. In practice,

this statement means that the measurement must be made with

a high-sensitivity instrument operating with a modest thermal

load at scan rates that are slow relative to the thermal time con

stant of the instrument and to both the width and half-life of the

thermotropic process under investigation. For processes such as

the gel-to-liquid-crystalline phase transition of certain single,

pure synthetic phosphatidylcholines, this condition is rarely a

problem because such processes are usually rapid enough to

be effectively free of kinetic limitations even at moderate scan

rates. However, processes such as the pretransition and the

subtransition of synthetic saturated phosphatidylcholines are

known to be kinetically limited at all temperatures and scan rates

at which calorimetric observation is feasible (16–18). For such

processes, their thermodynamic parameters cannot be reliably

measured by DSC.

Another aspect of the thermodynamic equilibrium problem

that should be considered is the question of whether the system

is at equilibrium before the calorimetric scan is initiated. In

many DSC studies of model and biological membranes, the

sample is placed in the calorimeter and cooled fairly rapidly

to a low temperature, and a calorimetric heating scan then is

begun relatively quickly. Because, as was mentioned above,

the kinetics of lipid phase transitions in complex systems are

not well studied and because the rates of reversible lipid phase

transitions are generally considerably slower when proceeding

from a higher-temperature to a lower-temperature state than the

reverse, the possibility exists that the system under study may

not be at thermodynamic equilibrium when the calorimetric run

is begun. This possibility can be the case even if no exothermic

events are observed during heating. For this reason, it is always

advisable to cool the sample slowly and to investigate the effect

of variations in the "annealing" time at low temperatures on the

DSC results obtained.

We stress here that although DSC is in principle a rela

tively straightforward physical technique, its theoretical ther

modynamical and kinetic basis is not trivial but should be well

understood as it applies to equilibrium and nonequilibrium ther

motropic lipid phase transitions of various types and to either

heat conduction or power compensation instruments. Moreover,
some care must be taken in sample preparation, selection of

sample size, and sample equilibration before data acquisition;

in the choice of suitable scan rates, starting temperatures, and

ending temperatures during data acquisition; and in the anal

ysis and interpretation of the DSC thermograms obtained. An

adequate treatment of these issues is not possible in this brief

section.
induced rotational excitations of the hydrocarbon chains. Thus, the DPPC molecules are progressively overcome by thermally interchain interactions that favor a crystalline-like packing and its motion is also severely restricted. The polar headgroup contains only a few bound water molecules, rotation about their long axes is very severely restricted. The hydrocarbon chains that are tilted slightly with respect to the interfacial area. Thus, the Lβ phase is less tightly packed and much more strongly hydrated than is the Lγ phase. The Lβ′ phase of DPPC forms very slowly when cooling to low temperatures and requires about 3.5 days at 0°C to fully form; if a heating run on a DPPC sample not annealed at low temperature is performed, no subtransition will be detected, which indicates the importance of lipid samples being at thermal equilibrium before analysis by DSC. In fact, the DPPC subtransition was discovered by Stutevant and coworkers (20) when a DPPC sample was inadvertently cooled and left over the weekend before a DSC heating scan was initiated. A dilation increases in temperature result in a marked increase in the long-axis rotational rates of the hydrocarbon chains, and at the pretransition temperature, the Lγ phase converts to the so-called ripple or Pβ phase. In the Pβ phase, the extended hydrocarbon chains seem to remain tilted with respect to the normal to the local bilayer plane but behave as if they are packed in a distorted orthorhombic lattice, and undergo relatively slow, restricted rotational motion about their long axes. The polar headgroup now contains about 15–18 waters of hydration and exhibits slow, hindered rotation on the NMR timescale.

*The phase transition temperature of the subtransition and the ΔT1/2 values of the subtransition and pretransition are overestimated because of kinetic limitations, even at the lowest heating scan rates feasible. The data listed were obtained from Reference 41.

### Figure 2: A typical high-sensitivity DSC heating thermogram of a multilamellar, aqueous suspension of DPPC which has been annealed at 0–4°C for 3–5 days prior to commencement of heating. The subtransition, pretransition and main phase transition temperatures are denoted by Ts, Tp and Tm respectively.
are rotationally symmetric, packing into a hexagonal lattice. The cross-section areas of the hydrocarbon chain thus show a small increase at the pretransition temperature. The interfacial area increases much more substantially, however, because of the displacement of each lipid molecule along its long axis with respect to its neighbor. The increased area occupied by the polar headgroups allows them to rotate almost freely, although the degree of hydration does not seem to change. In contrast to the Lc and Lp phases, the bilayer is no longer planar but exists as a series of periodic, quasi-lamellar segments.

With increasing temperature, the formation of gauche rotational conformers in the hydrocarbon chain becomes increasingly favorable until at the gel-to-liquid–crystalline phase transition temperature, chain melting occurs. Spectroscopic and thermodynamic studies have shown that the hydrocarbon chains of DPPC in the melted or Lp phase contain about four gauche bonds per chain, mostly, but not entirely, in the form of kink (gauche-trans-gauche) sequences. As the melting of the hydrocarbon chains produces a marked increase in cross-section area and effectively shortens the length of the chains, the bilayer expands laterally and thins at the main phase transition. Although the hydrocarbon chains exhibit rapid flexing and rotation in the Lc phase, they are on average oriented normally to the bilayer plane and pack in a loose hexagonal lattice. This increase in the cross-section area per molecule results in an increase in the area available to the polar headgroup, with the result that rotational motion becomes fast on the NMR timescale, and the hydration at the bilayer interface increases, in part because of the partial exposure of more deeply located polar residues, such as the carbonyl oxygens of the fatty acyl chains, to the aqueous phase.

The pattern of thermostropic phase behavior exhibited by an aqueous dispersion of any lipid molecular species will vary considerably, depending on the length and structure of the hydrocarbon chains, the structure and charge of the polar headgroup, the nature of the linker (ester or ether) of the hydrocarbon chains to the glycerol or sphingosine backbone, and other chemical features of the lipid under study. Also, the degree of hydration and the pH and ionic composition of the aqueous phase can affect lipid thermostropic phase behavior profoundly. However, even a cursory discussion of this topic is beyond the scope of this article, and the reader is referred to recent reviews for more detailed information (16–18).

Phospholipid mixtures

Although studies of the thermostropic phase behavior of single-component multilamellar phospholipid vesicles are necessary and valuable, these systems are not realistic models for biological membranes that normally contain at least several different types of phospholipids and a variety of fatty acyl chains. As a first step toward understanding the interactions of both the polar and apolar portions of different lipids in mixtures, DSC studies of various binary and ternary phospholipid systems have been carried out. Phase diagrams can be constructed by specifying the onset and completion temperatures for the phase transition of a series of mixtures and by an inspection of the shapes of the calorimetric traces. A comparison of the observed transition curves with the theoretical curves supports a literal interpretation of the phase diagrams obtained by DSC. For a summary of the first high-sensitivity DSC studies of binary phospholipid–cholesterol mixtures and a description of how phase diagrams can be constructed from DSC data, the reader is referred to an early review by Mabrey and Sturtevant (21); for a compilation of the results of later DSC and other studies on other phospholipid mixtures, the reader is referred to Marnas (22).

The effect of cholesterol

The occurrence of cholesterol and related sterols in the membranes of eukaryotic cells has prompted many investigations of the effect of cholesterol on the thermotropic phase behavior of phospholipids (see References 23–25). Studies using calorimetric and other physical techniques have established that cholesterol can have profound effects on the physical properties of phospholipid bilayers and plays an important role in controlling the fluidity of biological membranes. Cholesterol induces an "intermediate state" in phospholipid molecules with which it interacts and, thus, increases the fluidity of the hydrocarbon chains below and decreases the fluidity above the gel-to-liquid–crystalline phase transition temperature. The reader should consult some recent reviews for a more detailed treatment of cholesterol incorporation on the structure and organization of lipid bilayers (23–25).

Recent high-sensitivity DSC studies of cholesterol–DPPC interactions have revealed a complex picture of cholesterol/DPPC interactions (26). At cholesterol concentrations from 0 to 20–25 mol %, the DSC endotherm consists of two components (see Fig. 3). The sharp component exhibits a phase transition temperature and cooperativity only slightly reduced from those of the pure phospholipid, and the enthalpy of this component decreases linearly with increasing cholesterol content, becoming zero at 20–25 mol %. In contrast, the broad component exhibits a progressively increasing phase transition temperature and enthalpy with a progressively decreasing cooperativity over this same range of cholesterol content. A bove cholesterol levels of 20–25 mol %, the broad component becomes progressively less cooperative, the phase transition midpoint temperature continues to increase, and the transition enthalpy continues to decrease, eventually approaching zero only at cholesterol concentrations near 50 mol %. These results suggest that at low cholesterol concentrations, cholesterol-poor and cholesterol-rich domains coexist, with the former decreasing in proportion to the latter as cholesterol concentrations increase. In fact, a cardinal point in the cholesterol/DPPC phase diagram at about 22 mol % had been predicted from the earlier model-building studies, which calculated that the cholesterol molecule could interact with a maximum of 7 adjacent phospholipid hydrocarbon chains (or 3.5 phospholipid molecules) and thus that free phospholipid would exist only at cholesterol concentrations below this value. This model also explains the decreasing enthalpy of the broad component observed above 22 mol % cholesterol because an increasing proportion of phospholipid molecules would interact with more than one cholesterol molecule rather than with the more flexible hydrocarbon chains of adjacent phospholipids and, thus, progressively decrease and eventually abolish the cooperative chain-melting phase transition.
The effect of cholesterol on the thermotropic behavior of PC bilayer also varies significantly with the structure, particularly the degree of unsaturation, of the hydrocarbon chains, and with more highly unsaturated PCs exhibiting a reduced miscibility with cholesterol and other sterols. Moreover, the structure of the lipid polar headgroup is also important in determining the effect of cholesterol on the host lipid, as is the structure of the sterol molecule itself. For more information on the application of DSC to the biologically important area of lipid–sterol interactions, the reader is referred to recent reviews (23–25).

The effect of small molecules

Several lipid-soluble small molecules, including drugs like tranquilizers, antidepressants, narcotics, and anaesthetics, produce biological effects in living cells. Although some of these compounds are known to produce their characteristic effects by interacting with specific membrane proteins, others seem to interact rather nonspecifically with the lipid bilayer of many biological membranes. The effect on the gel-to-liquid-crystalline phase transition profile of synthetic PCs of over 100 hydrophobic small molecules that produce biological effects has been studied by DSC (27). At least four different types of modified transition profiles can be distinguished: In so-called type C profiles, the addition of the additive shifts T_m usually (but not always) to a lower temperature while having little or no effect on the cooperativity ($\Delta T_{1/2}$) or $\Delta H_{cal}$ of the transition; other physical evidence suggests that additives that produce this behavior are usually localized in the central region of the bilayer, which interacts primarily with the C9–C16 methylene region of the phospholipid hydrocarbon chains. Type A profiles are characterized by a shift in $T_m$, usually to a lower temperature, an increase in $\Delta T_{1/2}$, and a relatively unaffected $\Delta H_{cal}$ during the addition of the appropriate small molecules; these additives seem to be partially buried in the hydrocarbon core of the bilayer, which interacts primarily with the C2–C8 methylene region of the hydrocarbon chains. In type B profiles, a shoulder emerges on the main transition, the area of which increases in conjunction with a corresponding decrease in the area of the original peak as the concentration of additive increases. The total area of both peaks is relatively unchanged, at least at low additive concentrations. Additives that produce type B profiles generally reside at the hydrophobic–hydrophilic interface of the bilayer and interact primarily with the glycerol backbone of the phospholipid molecules. Finally, type D profiles exhibit a discrete new peak that grows in area at the expense of the parent peak as the additive concentration increases; normally, however, the final $\Delta H_{cal}$ and $\Delta T_{1/2}$ values of the new and
original peaks are not greatly different. Type D additives usually seem to be located at the bilayer surface and interact with the phospholipid headgroup. Although this classification is useful, not all small molecules produce one of these four types of DSC profiles. Whether a consistent relationship exists between the type of transition profile produced by a small molecule and its physiological effects remains to be determined.

The effect of transmembrane peptides

DSC has been used to great effect to study the effect of the incorporation of α-helical transmembrane peptides on the thermotropic phase behavior of various phospholipid bilayers. Because most integral membrane proteins contain one or more α-helical transmembrane segments, such studies are relevant to the mechanisms by which the physical properties of the membrane lipid bilayer modulate the structure and activity of such proteins. In this regard, several investigations have been carried out using DSC and many other physical techniques to understand how the presence of transmembrane peptides affects the organization and dynamics of the host lipid bilayer and vice versa. Such studies have examined the effects of systematic variations in the length and structure of model α-helical transmembrane peptides on lipid bilayer organization and dynamics, and how the effects of such peptides are themselves affected by the hydrophobic thickness and chemical composition of the host phospholipid bilayer. These important studies are ongoing, and the reader should consult recent reviews for more information.

The effect of membrane antimicrobial peptides

DSC has also been used to study the effects of a wide variety of antimicrobial peptides on the thermotropic phase behavior of different lipid bilayers. These studies again are highly biologically relevant because the primary mode of action of most antimicrobial peptides is the perturbation and permeabilization of the lipid bilayers of the target membrane, and these agents have considerable promise as antibiotics, especially to treat multiple drug-resistant pathogenic bacteria. Again, the reader should consult recent reviews for more information on this topic.

The effect of membrane proteins

Because of their obvious relevance to biological membranes, the effect of several peptides and proteins on the thermotropic phase behavior of single synthetic phospholipids or phospholipid mixtures has been studied by many groups (see 16, 17). It was originally proposed by Papahadjopoulos et al. (32) that polypeptides and proteins could be considered as belonging to one of three types according to their characteristic effects on phospholipid gel-to-liquid–crystalline phase transitions. Type 1 proteins typically produce no change or a modest increase in Tm, a slight increase or no change in ΔT1/2, and an appreciable and progressive increase in ΔHcal as the amount of protein added is increased. These proteins normally do not expand phospholipid monolayers nor alter the permeability of phospholipid vesicles into which they are incorporated. Type 1 proteins are “hydrophilic” proteins that are thought to interact with the phospholipid bilayer exclusively by electrostatic forces and, as such, normally show stronger effects on the phase transitions of charged rather than zwitterionic phospholipids. Type 2 proteins produce a decrease in Tm, an increase in ΔT1/2, and a considerable and progressive decrease in ΔHcal; phospholipid monolayers are typically expanded by such proteins, and these proteins normally increase the permeability of phospholipid vesicles. These proteins, which are also hydrophilic, are believed to interact with phospholipid bilayers by a combination of electrostatic and hydrophobic forces, initially adsorbing to the charged polar headgroups of the phospholipids and subsequently partially penetrating the hydrophilic–hydrophobic interface of the bilayer to interact with a portion of the hydrocarbon chains. Finally, type 3 proteins usually have little effect on the Tm or ΔT1/2 of the phospholipid phase transition, but ΔHcal decreases linearly with protein concentration. Type 3 proteins are “hydrophobic” proteins that markedly expand phospholipid monolayers and increase the permeability of phospholipid vesicles. These proteins are thought to penetrate deeply into or to span the hydrophobic core of anionic or zwitterionic lipid bilayers and, thus, to interact strongly with the phospholipid fatty acyl chains and essentially to remove them from participation in the cooperative chain-melting transition. It should be noted, however, that some type 3 proteins may also interact electrostatically with phospholipid polar headgroups, particularly with those bearing a net negative charge.

The results of more recent DSC and other studies of lipid-protein model membranes clearly indicate that the classification scheme originally proposed is not completely appropriate for naturally occurring membrane proteins (see Reference 17). Thus, none of the water-soluble, peripheral membrane-associated proteins studied thus far exhibit classical type 1 behavior (no change or a modest increase in Tm, a slight increase in ΔT1/2, and an increase in ΔH of the chain-melting transition). Therefore, it seems doubtful whether natural membrane proteins ever interact with phospholipid bilayers exclusively by electrostatic interactions. However, a few examples of membrane proteins do exhibit more-or-less-classical type 2 behavior. These examples include the myelin basic protein and cytochrome c, all of which usually reduce the Tm, increase the ΔT1/2, and substantially reduce the ΔH of the chain-melting transition of anionic phospholipids. Strictly speaking, few if any membrane proteins actually exhibit classical type behavior as originally defined (no change in the Tm or ΔT1/2 and a progressive linear reduction in the ΔH of both neutral and anionic phospholipid phase transitions with increasing protein concentration). This is because, with the advent of high-sensitivity calorimeters and the availability of pure phospholipids, it has become clear that all integral membrane proteins reduce the cooperativity of gel-to-liquid-crystalline phase transitions, as indeed would be expected from basic thermodynamic principles. Moreover, some type 3 proteins exhibit a nonlinear decrease in ΔH with changes in protein levels, whereas others can produce at least moderate shifts in the Tm of phospholipid phase transitions. However, if we relax the original type 3 criteria...
somewhat, then several integral, transmembrane proteins can be said to exhibit "modified" type 3 behavior.

The classification scheme of Papahadjopoulos et al. (32), appropriately modified for type 3 proteins, is still of some use in studies of lipid–protein interactions, although some proteins, at least under certain conditions, do not fall neatly into any of these three categories. It seems that all naturally occurring membrane proteins studied to date interact with lipid bilayers by both hydrophobic and electrostatic interactions and that different membrane proteins differ only in the specific types and relative magnitudes of these two general classes of interactions. It is also clear that the behavior exhibited by any particular membrane protein can depend on its conformation, method of reconstitution, and relative concentration, as well as on the polar headgroup and fatty acid composition of the lipid bilayer with which it is interacting (see Reference 17).

Although DSC and other physical techniques have made considerable contributions to the elucidation of the nature of lipid–protein interactions, several outstanding questions remain. For example, it remains to be definitively determined whether some integral, transmembrane proteins completely abolish the cooperative gel-to-liquid–crystalline phase transition of lipids with which they are in direct contact or whether only a partial abolition of this transition occurs, as is suggested by the studies of the interactions of the model transmembrane peptides with phospholipid bilayers (see above). The mechanism by which some integral, transmembrane proteins perturb the phase behavior of very large numbers of phospholipids also remains to be determined. Finally, the molecular basis of the complex and unusual behavior of proteins such as the concanavalin A receptor and the Acholeplasma laidlawii B ATPase is still obscure (see Reference 17).
strong upward shift in the Lα phase transition temperature that this membrane lipid strongly stabilizes the Lα phase and destabilizes the H2 phase of DEPE, indicating that it has a conical shape with a large polar headgroup volume relative to the volume of the hydrocarbon chains. In fact, this lipid forms a normal micellar phase in water in isolation from other membrane lipids (31).

A. laidlawii is notable in this regard is the phase preference of glycerylphosphoryl(diacylglycerol, which strongly destabilizes the reversed hexagonal phase and which actually prefers the normal micellar phase in isolation (36) (see Fig. 4). The presence of normal, lamellar, and reversed phase-prefering lipids in a single membrane has important implications for understanding the physical basis of lipid organization and biosynthetic regulation in this organism and possibly in other organisms. We also showed that the characteristic effect of the individual A. laidlawii membrane lipids on the lamellar/reversed hexagonal phase transition temperature of the phosphatidylethanolamine matrix is not well correlated with their polar headgroup intrinsic volumes. This result indicates that the effective cross-section area of the polar headgroups of these lipid species must be strongly influenced by factors such as charge, hydration, orientation, and motional freedom as well as by intrinsic headgroup volume.

The approach discussed above to determine quantitatively the effect of various membrane phospho- and glycolipids on the lamellar/nonlamellar phase behavior of a host phospholipid/ethanolamine or similar matrix has been applied to determine the relative shape, and thus the effect on the monolayer curvature of the host bilayer, of several agents, including sterols, peptides, detergents, and drugs (see Reference 14). Such studies can be very useful in providing insight into the function and mechanism of action of these agents on biological membranes.

DSC Studies of Biological Membranes

The A. laidlawii membrane was used by Stein and colleagues (37) to show for the first time that biological membranes can undergo a gel-to-liquid-crystalline lipid phase transition similar to that previously reported for lamellar phospholipid-water systems. These workers demonstrated that when whole cells or isolated membranes are analyzed by DSC, two relatively broad endothermic transitions are observed on the initial heating scan. The lower-temperature transition is fully reversible, varies markedly in position with changes in the length and degree of unsaturation of the membrane lipid fatty acyl chains, is broadened and eventually abolished by cholesterol incorporation, and exhibits a transition enthalpy characteristic of the mixed-acid synthetic phospholipids. Moreover, an endothermic transition that has essentially identical properties is observed for the protein-free total membrane lipid extract dispersed in excess water or aqueous buffer, which indicates that the presence of membrane proteins has little effect on the thermotropic phase behavior of most membrane lipids. In contrast, the higher-temperature transition is irreversible, is independent on membrane lipid fatty acid composition or cholesterol content, and is absent in total membrane lipid extracts, which indicates that the higher temperature transition results from an irreversible thermal denaturation of the membrane proteins. A comparison of the enthalpies of transition of the lipids in the membrane and in water dispersions indicates that at least 75% of the total membrane lipids participate in this transition. Evidence was also presented that the lipids must be predominantly in the fluid state to support normal growth. These results were later confirmed and extended by Reinert and Stein (38) and by Melchior et al. (39), who showed that the gel-to-liquid-crystalline lipid phase transition is a property of living cells and that about 85-90% of the lipid participates in the gel-to-liquid-crystalline phase transition. These studies provided strong, direct experimental evidence for the hypothesis that lipids are organized as a liquid-crystalline bilayer in biological membranes, a basic feature of the currently well-accepted fluid-mosaic model of membrane structure.

Representative high-sensitivity DSC initial heating scans of viable cells, isolated membranes, and total membrane lipid dispersions are shown in Fig. 5; in this instance, cells, membranes, and lipids were made nearly homogenous in elaidic acid (13). The fully reversible gel-to-liquid-crystalline lipid phase transitions observed in cells and membranes essentially have identical phase transition temperatures, enthalpies, and degrees of cooperativity, which suggests that membrane lipid organization in these two samples is very similar or identical. In contrast, the midpoint of the chain-melting transition of the membrane lipid dispersion is shifted to a higher temperature, exhibits a greater enthalpy, and is considerably less cooperative than in cells or membranes, which suggests that native membrane lipid organization has been perturbed during extraction and resuspension of the membrane lipids in water. The thermal denaturation of the proteins in the cells and membranes has absolutely no effect on the peak temperature or cooperativity of the lipid phase transition. However, about 15% of the lipids do not participate in the
membrane lipid transition centered near the rat liver inner mitochondrial membrane reported a narrower membrane transition (44). However, a more recent study of these results, except that the outer membrane transition seemed chondria and of isolated inner and outer membranes confirmed and in extracted lipids (42). A later study of both intact mito-
phase transition centered at 0°C. DSC and other techniques. The earliest work with whole mi-
are low in cholesterol, have been studied by several groups using higher cooperativity than does the membrane lipid dispersion and membranes exhibits a similar temperature maximum and a higher cooperativity than does the membrane lipid dispersion favors the former interpretation.

The presence of high levels of cholesterol in many eukaryotic membranes, particularly plasma membranes, abolishes a discrete cooperative gel-to-liquid–crystalline membrane lipid phase transition in these systems. Thus, no lipid phase transitions could be detected by DSC in the cholesterol-rich erythrocyte (40) or myelin (41) membranes. The thermotropic behavior of rat liver microsomal membranes, which contain moderate levels of cholesterol, has been studied by DSC. An early study using conventional DSC revealed a single reversible, broad phase transition occurring between ~15°C and ~5°C in both intact membranes and isolated lipids (42). A more recent high-sensitivity DSC study confirmed the absence of a reversible phase transition above 0°C (43). Rat liver mitochondrial membranes, which are low in cholesterol, have been studied by several groups using DSC and other techniques. The earliest work with whole mi-
tochondrial revealed a reversible broad gel-to-liquid–crystalline phase transition centered at 0°C in mitochondrial membranes and in extracted lipids (42). A later study of both intact mito-
chondria and of isolated inner and outer membranes confirmed these results, except that the outer membrane transition seemed to occur at a slightly lower temperature than did the inner membrane transition (44). However, a more recent study of the rat liver inner mitochondrial membrane reported a narrower membrane lipid transition centered near ~10°C; by artificially increasing cholesterol content some 10-fold to about 30 mol %, the inner membrane gel-to-liquid–crystalline phase transition could be lowered and broadened, and its AH° transition was reduced to less than one tenth that of the native membrane (45). It has also been reported that in beef heart mitochondrial inner membranes, a broad reversible endothermic phase transition centered at ~10°C occurs.

DSC has been used to study the individual protein com-
ponents of biological membranes of relatively simply protein composition and the interaction of several of these components with lipids and with other proteins. The red blood cell mem-
brane, which has been most intensively studied, exhibits five discrete protein transitions, each of which has been assigned to a specific membrane protein. The response of each of these ther-
mal transitions to variations in temperature and pH as well as to treatment with proteases, phospholipases, specific labelling reagents, and modifiers and inhibitors of selected membrane activities, has provided much useful information on the interactions and functions of these components in the intact erythrocyte membrane (46–49). Similar approaches have been applied to the bovine rod outer segment membrane (50) and to the spinach chloroplast thylakoid membrane (51).

Lipids are hydrophobic or amphiphilic low-molecular-weight substances with a low solubility in water. Glycerophospholipids, sphingolipids, and cholesterol are the building blocks of cellular membranes, and triacylglycerols are the major molecular storage forms of metabolic energy. Various lipids serve as signaling substances either as first or second messengers in signal transduction; as autocrine, paracrine, or endocrine regulators; or are covalently bound to cellular proteins. Several diseases are caused by, or at least associated with, alterations in lipid metabolism, such as inherited disorders of lipid metabolism, atherosclerosis, diabetes, obesity, or Alzheimer’s disease.

Lipidomics is the determination of a lipid profile of a given source under given conditions with the aim to understand lipid function in a biologic system. This understanding might be achieved by correlating changes in this composition with physiologic or pathophysiologic alterations of the system. Current research focuses on the determination of lipid profiles, which is attempted predominantly by the combination of extraction and separation techniques coupled with mass spectrometry. A major challenge is the variety of molecular lipid species found in a given cell. This article provides an overview on current methodologic approaches that find application in lipidomics. Because the function of a lipid can be associated critically with its distinct subcellular or even suborganellar localization, some limitations of this approach are discussed also.

Lipidomics (1) is the approach to determine and to understand the lipid profile of a given biologic source in terms of systems biology (2). This “understanding” requires information about the interacting partners. Systems biology requires a comprehensive set of quantitative data that can be interpreted by bioinformatic approaches to obtain insight into structure and dynamics of a given system. Current attempts to treat the hydrophobic part of the metabolome in this respect face technological problems that must be overcome to determine lipid profiles comprehensively and accurately. With the advent of modern mass spectrometric techniques, metabolic snapshots of parts of the lipidome have become possible. They can be compared with corresponding snapshots of other genotypes and with those obtained under pathologic conditions or after drug treatment. Such differences can be visualized in the form of a network model to correlate compositional differences with functional aspects. However, the information on the levels of all lipid classes in a relevant system, such as an organ, tissue, or cell type, is often incomplete or even entirely missing. This incomplete system is, in part, caused by the large heterogeneity found among cellular lipids, and also by the structural complexity especially of glycolipids, the unavailability of appropriate standard substances, and difficulties with the extraction and ionization of certain lipid classes such as the phosphatidylinositol phosphates. Moreover, decades of lipid research taught us that not only is the concentration of a lipid critical, but also its subcellular distribution can be critical for its function (3). This article provides a brief overview on current techniques used within lipidomics.

Lipids

Lipids are a structurally heterogeneous group of low molecular compounds with common solubility properties. The majority of lipids is only slightly soluble in water, but they can be extracted from biologic sources with organic solvents. Lipids can be defined as hydrophobic or amphiphilic small molecules that originate entirely or in part by carbanion-based condensation of thioesters such as fatty acids, polyketides, and their derivatives, or by carbenium ion-based condensation of isoprene units such as the terpenes, which include the steroids. A recently suggested nomenclature and assignment system for lipids will facilitate the data exchange and processing required in lipidomics (4). It consists of a 12-digit code for each molecular lipid species and classifies lipids into eight categories: fatty acyls, glycerolipids, glycerophospholipids, sphingolipids, sterol lipids, prenol lipids, saccharolipids, and polyketides (4). The first two letters of the alphanumeric Lipid-ID are a fixed database designation, the next two letters specify the category, and the numbers specify class, subclass, and the individual lipid. In this way, also more hydrophilic lipid derivatives can be considered within the field of lipidomics. The structures of selected lipids are shown in Fig. 1.
Lipid aggregates

Lipids differ not only in their chemical structures but also in the types of aggregates that they form in the aqueous environment of a living cell. Highly hydrophobic lipids are fats and oils, which are used as storage forms of metabolic energy. In an aqueous environment, these substances aggregate to lipid globules. Within cells, these lipids are deposited as insoluble droplets of up to 200 \( \mu m \) in size especially in the cytoplasm of adipocytes. Closer examination of these aggregates found in vivo reveals a highly metabolically active and organized complex-layered structure of an own organelle, in which triacylglycerols, diacylglycerols, cholesterol, and cholesterol esters are surrounded by a phospholipid/lysophospholipid monolayer, together with accessory proteins (5). In addition, amphiphilic lipids contain structural elements of higher polarity. Dependent on their molecular shape, these lipids form different supramolecular aggregates in an aqueous environment. The most important feature of amphiphilic lipids, with a cylindrical shape like many glycerophospholipids and sphingolipids, is their ability to form lamellar phases spontaneously, the structural basis of biologic membranes. Cone-shaped lipids with small hydrophilic headgroups such as phosphatidylethanolamine (PE), phosphatidic acid (PA),...
by flippases and floppases, but it can also be destroyed actively. The asymmetric distribution is maintained actively. Phosphates are localized predominantly on the cytoplasmic leaflet (PS), the PE, and also the phosphatidylinositols and their (ceramide-1-phosphorylcholine; SM) are found predominantly in the apical and basolateral membranes of a polarized cell. Although glycosphingolipids (with glucosylceramide as an exception) are found exclusively on the extracellular leaflet, phosphatidylcholine (PC) and sphingomyelin (SM) can show the coexistence of different lipid phases at a given temperature. This differential miscibility can lead to lipid microdomains that might also be found in biologic membranes under physiologic conditions. A crucial role for membrane properties is played by the sterols, cholesteryl in animals, stigmasterol in plants, and ergosterol in lower eukaryotes. Within evolution, they became available after the occurrence of higher oxygen concentrations in the ancient atmosphere (see Mourizen (7)) and enabled eukaryotic cells to form the so-called liquid ordered membrane phases. This liquid is essential for membrane stability, impermeability, and for the function of many membrane proteins. Within lipidomics, the analysis of membrane-forming lipids, or "structural" lipids, such as phospholipids and cholesterol, can be distinguished from "mediator-lipidomics" (8). In the latter, highly bioactive lipids are determined, which are present usually in very low concentrations but are found in greater amounts in response to extracellular stimuli. Lipid mediators are substances such as the eicosanoids, platelet activating factor, LPA, sphingosine-1-phosphate, and ceramide-1-phosphate. Because "structural" lipids determine the function of membranes and can be altered under pathophysiologic conditions, both lipid classes have to be determined in a comprehensive approach.

Membranes

Biologic membranes serve several vital functions such as compartmentalization, maintenance of gradients, signal transduction, and many others. Depending on their source, membranes differ in their total lipid composition, but they also show lateral heterogeneity as well as differences between their two leaflets. Although glycosphingolipids (with glucosylceramide as an exception) are found exclusively on the extracellular leaflet, phosphatidylcholine (PC) and sphingomyelin (ceramide-1-phosphorylcholine; SM) are found predominantly in the apical leaflet, and the aminophospholipids phosphatidylethanolamine (PE), the PE, and also the phosphatidylinositol and their phosphates are localized predominantly on the cytoplasmic leaflet (6). This asymmetric distribution is maintained actively by flipases and floppases, but it can also be destroyed actively by scramblases in response to signals. For example, surface exposure of PS is a sign of pathologically altered cells (10). Lateral differences in lipid compositions cause microdomains to develop that account for differences in bilayer thickness and, subsequently, protein transport. Although it is still a matter of debate how these lipids are organized laterally, on which time scale the resulting microdomains ("rafts") exist and with which functional relevance (11), lipid compositions differ not only between such short-living microdomains, but also between the apical and basolateral membranes of a polarized cell.

Although information on the spatial distribution of membrane lipids can be important (3), most mass-spectrometric approaches used in lipidomics focus currently on the determination of total lipid composition. An advanced mass-spectrometric surface analysis technique, however, secondary ion mass spectrometry (SIMS) determines lipid compositions within different areas of freeze-fractured cells (12). This technique and related imaging techniques will become important tools in lipidomics. Different local concentrations of phosphoinositides are one of the many examples of the involvement of lipids in signal transduction processes (13). Lipid mediators can act not only as membrane components, but also as autocrine and paracrine mediators (14); when bound to proteins, lipids fulfill crucial functions. Starting with the pioneering work of Rudolf Schoenheimer on cholesterol, it has been recognized that lipid metabolism and transport are tightly controlled processes. More recently, the molecular mechanisms that underlie lipid homeostasis have been recognized (15). Much of the interest in lipidomics results from new possibilities for the understanding, diagnosis, and treatment of human diseases caused by disturbances of this homeostasis. Therefore, determination and interpretation of lipid profiles is the aim of lipidomics. A key discipline within lipidomics is lipid analysis. Mass-spectrometric methods, however, allow not only the determination of lipid classes that share a common head group, such as PC or SM, but also the distribution of molecular species that develop by combination of different acyl chains, which can be determined with high sensitivity.

Lipid Analysis

Lipid analysis starts with sample preparation, followed by extraction of the lipids from their biologic matrices. The resulting crude lipid extracts can be subjected directly to extensive and global mass spectrometric (MS) analysis, which is an approach sometimes called " shotgun lipidomics." Alternatively, lipids or lipid classes are separated prior to analysis, either by gas chromatography (GC), liquid chromatography (LC), thin layer chromatography (TLC), or—in less frequently—capillary electrophoresis (CE). These methods are coupled online or offline to mass spectrometry or tandem mass spectrometry (M/S/M; e.g., GC/MS, LC/MS, LC/MS/MS, CE/MS). In both cases, structural heterogeneity and complexity of lipids provide a huge amount of data. Accordingly, bioinformatic treatment of the data is used increasingly to facilitate data handling and evaluation. Sample preparation and lipid extraction

In many cases, sample preparation is mandatory prior to lipid extraction. This crucial process might include tissue homogenization, determination of dry weights, cell numbers, protein content, or DNA content for normalization purposes. The addition of internal standards is not only used to control extraction efficiency, but also required for lipid quantification by mass spectrometric analysis, in which an ion current is translated into a lipid concentration. Many standard lipids that can be distinguished from endogenously occurring lipids by using rare
Ionization (APCI), can be less than 30% in classic Folch and Bligh Dyer extraction, recovery of the acidic lipids PA and phosphatidylglycerol (PG) and must be validated to ensure reliable results. For example, the time, and temperature influence the recovery of extracted lipids lipid alteration or decomposition (16).

Because of the heterogeneous nature of lipids, no single extraction method exists that extracts all lipids efficiently. Lipid extraction can be achieved by liquid-liquid extraction, Soxhlet extraction, or solid-phase extraction. In 1957, Folch developed a popular method by which many lipids are extracted using a mixture of chloroform and methanol in a volume ratio of 2:1. The extraction is followed by a wash step with water and is frequently applied for total lipid determination. The occasional formation of emulsions is a disadvantage, and more hydrophilic lipids like gangliosides are separated into the upper phase. To date, most extractions are performed by a method introduced by Bligh and Dyer in 1959 or by modifications of this method. In this case, the extraction is carried out by a monophasic mixture of chloroform, methanol, and water in a volume ratio of 1:2:5. Changing the ratio to 2:2:1.8 (V/V/V) leads to a phase separation, in which most lipids can be recovered from the lower phase. Proteins precipitate mostly between the two phases. It must be considered that quantitative lipid extraction by either of these methods might require repeated re-extraction, and that lipid exposure to air or enzyme sources might lead to lipid alteration or decomposition (16).

Extraction parameters such as solvent type, mixture ratios, metal ion concentration, pH of the aqueous phase, extraction time, and temperature influence the recovery of extracted lipids and must be validated to ensure reliable results. For example, the recovery of the acidic lipids PA and phosphatidylglycerol (PG) can exceed 80% in both Folch and Bligh Dyer extraction, where these lipids can become bound to proteins tightly (17).

Lipids bound to proteins covalently are only released under appropriate conditions, which depend on the type of lipid-protein linkage. For example, ceramides bound to the cornified envelope in the human skin (18) can be extracted after mild alkaline hydrolysis of the ester linkage between lipid and protein.

Mass spectrometry

The dynamic development of mass spectrometry has had a huge impact on lipid analysis. Currently, a variety of suitable mass spectrometers is available. In principal, a mass spectrometer consists of an ion source, a mass analyzer, and an ion detector. The typical features of each instrument (Fig. 2) result mostly from the types of ion source and mass analyzer. To date, the ionization techniques applied to lipid analysis include Electrospray Ionization (ESI) or nano-ESI, Atmospheric Pressure Chemical Ionization (APCI), Matrix-Assisted Laser Desorption/Ionization (MALDI), and, more recently, Atmospheric Pressure Photo Ionization (APPI) and Desorption Electrospray Ionization (DESI).

For the majority of analytical tasks in lipidomics, ESI and nano-ESI are the most common choices. ESI uses a high cone voltage to produce single- or multiple-charged ions from an analyte-containing solution by creating a fine spray of highly charged droplets. In the case of high flow rates, this process can be assisted pneumatically by nitrogen as drying gas. ESI is a soft ionization method that can be run without fragmentation of the analyte molecules. It is suitable for membrane lipids (19). Generally, neutral lipids show poor ionization efficiencies in classic ESI, so that additional measures like adduct formation, derivatization, or application of nano-ESI are required. Typical drawbacks of ESI include signal suppression in complex matrices and varying adduct patterns.

Nano-ESI is a miniaturization of ESI with enhanced sensitivity and reduced signal suppression. It can be carried out either as classic offline approach analysis or as online nano-flow LC/MS, which are both attractive for lipidomics. Performance differences regarding the mass spectrometric response may result from different conductive coatings of the used sample capillaries and the used ionization mode. Many lipid classes, which include glycerophospholipids (20–22); sphingolipids (23, 24); triacylglycerols, cholesterol, and ergosterol (25); and cholesterol esters (26), have been analyzed using ESI and nano-ESI (20).

This approach has already been extended for automated (21) and high-throughput investigations (26).

APCI is complementary to ESI for compounds of limited polarity (27). In APCI, the analyte solution is subjected to a heater of 400–500 °C. The resulting plasma is ionized at a corona discharge needle with the help of nitrogen. The nitrogen molecules transfer the charge onto the analyte molecules in an indirect fashion. Because of the heat, the ionization conditions are less soft than ESI, and sensitive molecules may show fragmentation. The solvent plays a less dominant role for ionization than in ESI. This result can be beneficial in case of normal phase LC/MS approaches with organic solvents such as chloroform or hexane. Adduct formation can be reduced when suitable conditions are used. APCI has been used to analyze ceramides (28), sphingomyelin (29), triacylglycerols, as well as cholesterol and its oxidation products (30).

APPI is derived from APCI, but instead of the corona discharge needle, the ionization takes place after irradiation with a krypton lamp that emits photons of 10.0-10.6 electron volt. Different methods with and without dopant have been recommended. APPI, in combination with LC, has been used to analyze glycosphingolipids (31). In addition, APPI has been reported to be more sensitive and efficient than APCI and ESI for the analysis of fatty acid esters and acylglycerols (32, 33). Because the method has not found widespread use to date, it is too early to estimate its potential.

MALDI is another soft-ionization method, but in contrast to ESI and APCI, it is carried out in solid state. The analyte is placed onto a metallic plate together with an UV-absorbing matrix. Usually, the matrix consists of aromatic acids, which are cocrystallized with the sample. Irradiation of suitable positions on the target with a laser of appropriate wavelength causes analytic desorption and ionization. MALDI is used widely in the...
analysis of proteins and polymers. Recently, it has also been applied to the analysis of lipids and in particular glycolipids (34). MALDI is a qualitative method that normally provides no quantitative results. The matrix used, the heterogeneities within the matrix, analyte concentrations, and preparation techniques influence the results greatly. MALDI is mostly used offline. LC/MALDI coupling can be implemented via fraction collection and automated target preparation. Compared with ESI, MALDI is more tolerant to salts and other disturbing components. DESI is performed by directing electrosprayed-charged droplets onto a surface for analysis under atmospheric conditions. The collision of the charged droplets with the surface leads to the ionization and desorption of the analyte (35). Then, the ions produced in the gas phase are sampled by an atmospheric interfaced mass analyzer. DESI has been used to create two-dimensional images related to the distribution of lipid species in human tissues (36).

Mass analyzers differ in sensitivity, accuracy, and resolution. Among others, they include quadrupole, triple quadrupole (TQ), ion trap, linear ion trap, time of flight, Fourier transform ion cyclotron resonance, and hybrid combinations such as quadrupole-time of flight (Q-TOF) analyzers.

The deliberate generation of fragments is a valuable tool in structure elucidation and quantification. It is mainly carried out as a second mass analysis after determination of the mass per charge (m/z) ratio of the molecular ions. This approach is called tandem mass spectrometry and it can be carried out either as tandem-in-space using a triple quadrupole (or combinations of a quadrupole and another mass analyzer), or as tandem-in-time using an ion trap. The latter also allows multiple-stage mass spectrometry (MS^n). On the other hand, a triple quadrupole allows different MS/MS scan modes, namely product ion scan, precursor or parent ion scan, and neutral loss scan.

TQ mass spectrometers (Fig. 2) have been used frequently for lipid analysis. They consist of three quadrupoles, Q1, Q2, and Q3, which are located in a row, with Q2 as the fragmentation cell filled with an inert collision gas (e.g., argon). A product ion scan starts with selecting a lipid species of a certain m/z-value in Q1, fragmenting it through collisions with the collision gas (collision-induced dissociation; CID) in Q2, and determining the m/z values of the fragments in Q3. Usually, this scan type is used to ascertain characteristic fragments and fragmentation conditions such as the suitable CID energy. Parent (precursor) ion scan (PIS) is the conversion of the product scan. Here, Q3 is fixed to m/z values of desired fragments, whereas the corresponding parent molecular ions are scanned in Q1. PIS is used to identify lipid classes and individual lipid species according to characteristic charged fragments of their functional head groups or their backbones. Neutral loss scan (NL), finally, represents the loss of a neutral fragment from a charged parent molecule. In this case, both Q1 and Q3 are used to scan, but with a constant mass offset. NL has been frequently used to analyze a variety of lipids. For example, many phospholipids have been identified recently according to the NL of their fatty acids in the positive ionization mode. A structural identification
Lipidomics

Figure 3  Tandem electrospray mass spectrum (positive mode) of lactosylceramide, which shows the neutral loss of two hexose residues.

These scan modes or combinations of them have been used not only for identification, but also for quantification of lipids. In this context, multiple parent ion scan (MPIS) of head group and backbone (fatty acids) fragments has been shown recently to be suitable for the determination of individual phospholipid amounts relative to an internal standard. This analysis has been performed directly from crude lipid extracts by using a modified Q-TOF mass spectrometer (21). On the other hand, multiple reaction monitoring (MRM) is applied frequently for lipid quantification. MRM is a technique based on monitoring compound-specific transitions of precursor ions to product ions. In addition to specificity, sensitivity and selectivity are key advantages of MRM. This advantage is particularly valuable for the quantification of small compound amounts and/or by the occurrence of increased background levels. An interesting application of MRM is the quantification of many endogenous sphingolipids carried out by Zheng et al. (37). In a single LC run, multiple combinations of specific precursor-ion/product-ion transitions can be obtained, monitored, and applied to achieve sensitive quantification of individual lipid species.

As mentioned above, two different mass spectrometric approaches to lipid analysis exist: The first one is performed directly from lipid extracts without prior chromatographic separation and is referred to as "shotgun" lipidomics. Here, lipid classes are separated in the ion source according to their intrinsic electrical properties (24). Detailed and unambiguous structural and quantitative analysis of individual species is obtained by means of multiplexed mass spectrometry using NL, PIS, and combinations of them. A remarkable contribution to this field is the analysis of ceramides, cerebrosides (β-glycosyl ceramides), and phospholipids by Han. Refinements of this approach using advanced mass spectrometers have led to additional improvements.

On the other hand, the complexity of the lipid mixtures that compose a variety of isobaric compounds as well as the signal suppression effects during MS ionization frequently require a chromatographic separation. Therefore, LC/MS and LC/MS/MS are valuable tools. Zheng et al. (37) have developed a normal phase LC-ESI-MS/MS method that allows the separation of sphingolipid classes and the subsequent quantification of molecular sphingolipid species, which includes ceramides, glucosylceramides, lactosylceramides, and sphingomyelin in one run. Others have shown that a combination of MALDI-MS and ESI-MS/MS with thin layer chromatography (TLC) enables a successful analysis of gangliosides (38) and of low abundant phosphoinositides (39), respectively.

Bioinformatics

The amount of data obtained by mass spectrometry is enormous, particularly when many lipid classes or several lipid species are investigated simultaneously. As such, manual management of the different data sets is impractical. For this reason, various attempts have been initiated to create software that is capable of evaluating and handling the generated data sets in a qualitative, quantitative, and comparative manner. One example is the software called Lipid Profiler, which has been used to achieve automated identification, deconvolution, and absolute quantification of lipids. This software is capable of handling large data sets and can provide a comprehensive analysis of lipid species.
of glycerophospholipid species analyzed by MPIS (21). A further model is given by a collection of computer algorithms referred to as the computational lipid analysis program, which has been developed to monitor time- or treatment-dependent changes in cellular phospholipids (40–42). This program consists of data handling routines and a package of multistep statistical analysis and is based on normalization of the raw signal intensities observed at a particular m/z value. Such normalization allows the comparison of dynamic changes within different phospholipid profiles. As in other fields of systems biology, the interest on developing management systems for the amount of generated mass spectrometric data is increasing.

The mentioned data management systems are only first steps toward comprehensive lipid databases and global lipid networks. An example for such a data bank is LIPIDMAPS (http://www.lipidmaps.org), which covers structures and annotations of biologically relevant lipids (43). The structures originate from the core laboratories of the LIPIDMAPS consortium and their partners. In this database, users can search the LIPID MAPS proteome database using either text-based or structure-based search options. In addition to LIPIDMAPS, other databases in Europe (http://www.lipidomics.net) and Japan (http://www.lipidbank.jp) have been initiated.

After maturation of the technology used for lipid analysis, bioinformatics will be needed to correlate quantitative data on lipid concentrations with those of the enzymes and other proteins involved in lipid metabolism on the mRNA and proteome level. These data might be generated from experiments that use RT-PCR, DNA-microarrays, cellular fluorescence imaging, or flow cytometry (44). To this end, an important role in lipidomics will be exchange and integration of data from genomics and proteomics. Thus, the entire lipidomics approach must be understood as a part of system biology, including the above-mentioned fields.

Applications and Challenges

Lipid metabolism is a tightly regulated process. Alterations in lipid metabolism and aberrant lipid levels have been associated with frequently occurring diseases, for example, atherosclerosis, pancreatitis, diabetes, cancer, schizophrenia, neurodegenerative and respiratory diseases, and Parkinson or Alzheimer disease. Therefore, lipidomics found entrance into diagnosis and drug development, such as in the discovery and optimization of biomarkers, therapeutic targets, and lead compounds (1). In addition to this field, lipid levels can be altered in rare inherited disorders of lipid metabolism, or in response to drugs such as the large group of cationic amphiphilic drugs that are used, for example, antidepressants, neuroleptics, -Adrenoceptor antagonists, or Antihistaminics. A growing group of inherited disorders is known to affect lipid metabolism. Examples are defects in proteins required for cellular lipid trafficking (44), other defects impair sphingolipid metabolism (45), and even others might be unrecognized causes of even apparently unrelated diseases such as mental disorders or epilepsy (45). Although most of the genetic defects underlying these diseases and the identities of the major storage substances are known for more than a decade, the detailed changes in lipid composition and the pathogenic mechanisms that lead to the different phenotypes are far from clear. An improved understanding of the pathogenesis of these and other diseases can be expected from the application of lipidomics to this field.

Because of the inherent difficulties in lipid analysis, a comprehensive treatment of the lipidome in terms of systems biology has not been achieved to date, but it will be attempted for systems of reduced complexity. For example, alterations of all lipid classes in response to genetic and pharmacologic changes will be analyzed in murine macrophages by the multicentered LIPIDMAPS consortium. Recently, the protein and lipid composition of synaptic vesicles isolated from rat brain have been determined by mass spectrometry (46). With the exception of cholesterol, whose content of about 40% is very high in the vesicles, the lipid analysis confirmed data obtained by classic lipid analysis. But because ESI-MS allows determination of the chain length distribution in phospholipids, these data have been collected also for this (undisturbed) system. From a certain cell type via a certain vesicle type, let us mention a certain lipid. Cardiolipin is a bacterial lipid, and in eukaryotes it is the only phospholipid synthesized in the mitochondria. The chain length distribution of molecular cardiolipin species of rat liver and bovine heart is known for fifteen years. Changes in cardiolipin content, acyl chain composition, and cardiolipin peroxidation affects mitochondrial function and can contribute to human diseases like ischemia, hypothyroidism, aging, heart failure, and cardiakoskeletal myopathy (47).

Usually, lipidomics is understood as a way to determine the global lipid composition of a sample like tissues or cells. On the subcellular level, however, lipid content of certain organelles, the function of the lipid patterns, as well as the identity of the interacting partners is an actual area of research. For example, the lipidome of the nucleus, where a remodeling of phosphatidylcholine to molecular species with saturated acyl chains takes place, is analyzed currently not only with “static” but also with “dynamic” lipid profiling with the aid of stable isotope labeling (48). Indirect methods like antibody staining or photoaffinity labeling were necessary to determine lipid sorting associated with the maturation of intralysosomal membranes: Membranes of lysosomes are prepared for their lyosomal degradation by reduction of their cholesterol content and enrichment of a lipid characteristic for intralysosomal membranes, bismonosyglycerol)-phosphate (45). Novel lipid species have been discovered by mass spectrometric analysis. Knowledge of their structure and occurrence is required for the understanding of their function for the organism in health and disease, which includes a potential use as biomarkers. Only three examples for the growing number of such discoveries are mentioned briefly here. Fatty acid amides such as N- arachidonylthanolamine and N-oleoylthanolamine are signaling substances found in the brain. Within “targeted lipidomics,” the structures of low abundant acylamides like N- arachidonyl- dopamine and N- arachidonyl-glycerine have been determined by a combination of HPLC and ESI-MS (49). These lipids act in part as endogenously occurring cannabinoids and can regulate pain, immune function, reproduction,
and appetite. A second example is the discovery of 3-ketohyd-
droceramides. This metabolite is usually not found because
the precursor lipid, 3-ketosphinganine, is reduced rapidly. But
it occurs in cultured cells that overexpress serum palmito-
yltransferase and that are supplied simultaneously with sufficient
amounts of the metabolic precursors serine and palmitic acid
(17). Under these conditions, the capacity for ketone reduction
seems to be exhausted, and excess ketosphinganine is acylated
by one or more of the cellular acyltransferases. A final example
is the discovery of a protein-bound glycosphingolipid. Knock-
out animals as source offer the advantage of greater amounts
of otherwise not detectable metabolites. In mice deficient in
the degradation of glucosylceramide, a novel posttranslational
modification has been identified. In the animals, glucosyce-
ramides \( \omega \)-hydroxylated in the acyl residue are bound covalently
to proteins of the cornified envelope of the skin (50). Covalently
bound lipids are essential not only for organ development, but
also for the function of the human skin (18).

As mentioned before, knowledge of total lipid composition
is not necessarily sufficient to understand lipid function. For
example, the total cholesterol content of neurons from mice with
a deficiency of the Niemann–Pick disease C1-protein is not
different from that of control animals. Closer examination of
this animal model of the human Niemann–Pick disease, type C1,
however, revealed that the cholesterol level in cell bodies is
increased drastically at the expense of that in distal axons (51).
A determination of members of all lipid classes present in a
tissue is still difficult, and analysis of lipids within different
areas of a cell [e.g., by IMS (see above)] requires sample
preparation by freeze fracture. For the analysis of some prob-
tems, techniques such as metabolic labeling with radioactive
biosynthetic precursors might be appropriate. Results obtained
in experiments with artificial (e.g., fluorescence-labeled) lipids
must be interpreted with care because of entirely different prop-
eties compared with that of their native counterpart. After a
period of development of methods for analysis, data processing,
exchange, and visualisation, a significant impact of this tech-
nology on our understanding of lipid metabolism and function
can be expected.

Further Reading

Lipid structure and dynamics are keys factors for cell life. Phospholipids are essential in signalling pathways as they are recognition sites at the membrane surface. Other lipids such as cholesterol and sphingomyelin are crucial molecules in maintaining membrane integrity and are involved in membrane domains (rafts). NMR both with its liquid and solid-state facets is a very powerful tool for deciphering both the structure and the dynamics of various classes of lipids. Lipids extracted from membranes and dissolved in organic solvents can reveal their molecular structure when observed with multinuclear one-dimensional or two-dimensional solution NMR. Multinuclear, wide-line, solid-state NMR brings information on the nature of the membrane phase (lamellar, hexagonal, isotropic, etc.), its dynamics (diffusion, fluid/gel, or liquid-ordered with cholesterol) and the molecular structure of embedded lipids when using the Magic Angle Spinning technique.

NMR Interactions in Liquids
One-dimensional (1-D) NMR spectra in liquids are made of
very sharp lines whose linewidth is less than 1 Hz, because
the internal magnetic interactions that modulate the applied
external magnetic field are averaged to isotropic values (iso) by fast
(frequencies of 10^{-2}-10^{-15} Hz) isotropic tumbling of molecules
in solution. Chemical shielding (\delta) and indirect spin-spin (J)
interactions remain, which lead to one-dimensional (Hz) spectra
(N resonant nuclei):
\[
\delta(i) = \sum_{i} \nu_{iso}^{i} + \sum_{i<j} J_{ij}
\]

The sharp line positions, \nu_{iso}^{i}, are often converted into a mag-
netic field-independent variable, the well-known chemical shift,
\delta, which is expressed in parts per million (ppm) relative to
the magnetic field. Three types of information can be obtained
from a high-resolution 1D-NMR spectrum: 1) the NMR line
position, the chemical shift, reports on the isotropic local elec-
tric environment of the nucleus (atom) in the molecule. This
in principle allows identification of small molecular species us-
ing known table of chemical shifts. 2) Some lines exhibit fine
structure; they are split into multiplets (doublets, triplets, etc.),
which lead to information on the number of nearest-neighbor-
ning nuclei having an indirect spin-spin interaction (J). This
process is also used for molecular structure identification. 3) The
line intensity (area) is proportional to the number of magneti-

cal nuclei which means that NMR is a quantitative
method that can be used for finding the proportion of different
species in mixtures. For more complex molecular structures or
for lipid mixtures, 1-D-NMR is limited because spectra contain
thousands of lines. Two-dimensional (2-D) or three-dimensional
(3-D) NMR is then used. The principle of these experiments
is to apply a pulse sequence that will separate magnetic in-

cations or make correlations between them. For instance, a

correlation spectroscopy-type sequence (COSY, TOCSY, etc.)
will allow identification of pieces of molecular structure by cor-

relation of chemical shifts of different nuclei through J-coupling.
Through-space information can be obtained using pulse se-
quences (NOESY or ROESY) that afford measurement of direct
spin-spin interaction, which is inversely proportional to the
sixth of the distance separating nuclei. This information affords
reconstruction of the three-dimensional molecular structure at
atomic resolution.

Anisotropy of NMR Interactions in Membranes
or in Solid Aggregates
In liquid-crystalline media or in aggregates, molecular motions
are much slower and are anisotropic. Two consequences result:

Individual NMR lines may span several thousand hertz and
depend on the orientation of molecules with respect to the mag-
netic field (1-4):
\[
\nu_{A}(\beta, \alpha) = \nu_{iso} + A \left( \frac{3\cos^2\beta - 1}{2} + \frac{\nu_{iso} \cos^2\alpha \sin^2\beta}{2} \right)
\]

In cases where the asymmetry parameter \nu_{iso} is zero, when axial
symmetry exists for structural or dynamical reasons as in lipid
membranes, the equation simplifies to
\[
\nu_{A}(\beta, \alpha) = \nu_{iso} + A \left( \frac{3\cos^2\beta - 1}{2} \right) S
\]

\nu_{A}(\beta, \alpha) is the frequency of an individual NMR line, \alpha the azi-
muthal angle between the main axis of symmetry (lipid rotation axis for instance, \alpha in Fig. 2a) and the mag-
netic field direction B_{0}, and S the order parameter (0 to 1)
linked to dynamics. \nu_{iso} stands for the isotropic frequency as
detected in purely isotropic liquids. The constant A depends on
the internal magnetic interaction of interest: direct spin-spin or
dipolar interaction (D), chemical shielding interaction (s), or
electric quadrupolar interaction (Q). The D interaction is found
when two nuclei are close in space (few Angstrom) and when

An example of a line broadening due to the dipolar interaction
is shown in Fig. 1a.
it dominates $^1$H spectra; $\sigma$ mainly accounts for $^{31}$P, $^{19}$F, and $^{15}$N spectra; and $Q$ is only found for nuclei with a nuclear spin greater than one half that possess an electric quadrupolar moment ($^{2}$H, $^{14}$N, $^{17}$O, etc.). The indirect spin-spin interaction ($J$) is so weak compared with the other interactions that it is barely detected in solid-state spectra. As observed in Fig. 1a–c, the NMR lines shift during change in orientation of the membrane plane (angle $\beta$) with respect to the magnetic field. A doublet appears for $D$ and $Q$ interactions (Fig. 1a); it is considered here that only one pair of spin-1/2 nuclei interacting ($^1$H-$^1$H, $^1$H-$^13$C, etc.) or one spin-1 nucleus ($^2$H, $^{14}$N). This doublet collapses when the axis of motional averaging is oriented at the magic angle $\beta_m = 54.7^\circ$ with respect to $B_0$. Liposomes or cells usually do not orient in magnetic fields. Because these large ($\mu$m) entities slowly reorient, compared with the NMR frequencies, all membrane orientations ($\beta$ varying from 0 to 90$^\circ$) lead to a so-called “powder spectrum.” Traces of Fig. 1a–g are powder spectra for $\sigma$, $D$, and $Q$ interactions under conditions of axial symmetry as described by Equation 3, whereas traces in Fig. 1h stand for $\sigma$ and $Q$ interactions where no axial symmetry exists (Eq. 2) as in the pure solid state. As observed in Fig. 1, solid-state NMR lineshapes span several hundred kilohertz (“wide-line”); they are very different depending on the NMR interaction and depend on whether the sample is oriented. In some cases, interactions may be of the same strength, and for many nuclei (e.g., protons in lipids), spectra may become very complex.

Spectra and the effect of motional averages

As observed in Figs. 1 and 2, considerable differences exist between spectra for samples that are in the pure solid state and for molecules in solution, because of the considerable differences in motional regimes. Motions that may be detected by NMR range from picoseconds to seconds and can be intramolecular, involving bond rotations, and molecular such as rotation-diffusion of the entire molecule or collective (i.e., because of concerted diffusion of molecules in a bilayer [hydrodynamics]). Both spectra and relaxation times ($T_1, T_2$, etc.) may bring dynamical information. One of the powers of wide-line, solid-state NMR resides in the fact that motional processes with correlation times $\tau_c$
Figure 2. Isotropic NMR spectra. (a) Lipid–water dispersion in nonrotating mode (lack of high resolution). (b) Schematics of a lipid-containing rotor spinning at the magic angle. (c) High-resolution $^{13}$C spectrum of cholesterol (insert), proton-decoupled, and edited such as CH$_3$/CH show positive peaks and CH$_2$/quaternary, negative. (time for reorientation in a given phase) shorter than the reciprocal of the spectrum width will modify the observed line shape (4, 5). Figure 1 shows the effect of consecutive fast axial motions on NMR powder spectra; it has to be looked at from bottom to top, considering a hierarchy in time of motions (i.e., going from the fastest to the slowest). Intramolecular motions (Fig. 1g) typically occur at $\sim 10^{-12}$ s and average the static magnetic interactions ($\sigma$, $D$, $Q$) leading to axially symmetric lineshapes of smaller width. The molecular and collective motions ($\sim 10^{-9}$–$10^{-10}$ s) produce additional averaging that reduces the linewidth more (Fig. 1f). As a general statement, all anisotropic motions of $\tau_c$ shorter than 1 µs will reduce spectra width, which is simply translated in terms of less and less ordering (i.e., a reduction of the order parameter $S$ of Eq. 3). A special case is also shown in Fig. 1e: a fast motion that is present in hexagonal phases. Here the lipids are distributed along long tubes around which a fast rotation occurs. Because the new rotation axis makes an angle of 90$^\circ$ with respect to the former bilayer normal, this fast rotation leads to a geometry-induced reduction by a factor of two of the spectrum width, compared with a bilayer-type spectrum. In the case of the $\sigma$ interaction, this fast rotation leads to an inversion in the symmetry of the lineshape. Finally, the effect of an isotropic motion is shown in Figure 1d; the consequence of such motion is a complete canceling of the angular-dependent term of Equation 2 (i.e., all solid-state interactions vanish). The spectrum is then that of a sample in the liquid state where only the isotropic $\sigma$ and $J$ interactions are present. It must be mentioned here that isotropic motions may occur in membrane phases (i.e., the local structure may be organized (micelles, small vesicles, cubic phases, etc.), but the tumbling of the small (1 to 30 nm) object or the fast lateral diffusion on highly curved structures may lead to spectra of liquid-state NMR). Interestingly, for intermediate sizes (30 nm to 500 nm), the NMR lineshape is in between that of liquids and solids and may be used for determining vesicle size (6).

A special case of motional averaging: magic angle sample spinning

As fast spinning around a molecular axis leads to efficient averaging of the solid-state interactions, placing the sample inside a tube that spins at several kilohertz around an axis that is oriented at $\beta_m = 54.7^\circ$ (Fig. 2a) should in principle cancel the angular-dependent term of Equation 2. This result is what is obtained for lipid aggregates or membranes, the spectrum being left with the isotropic terms of $\sigma$ and $J$ interactions, as in pure liquids. How far lines can be narrowed depends on several...
Because the motions are activated thermally, their activation 31P and 1H chemical shifts \( \text{inverse HMQC-TOCSY} \) cases of a lipid mixtures pseudo-3-D experiment allowing correlated resonances. In this table are also reported 1H chemical shifts of lipids except for double-bond resonances or carbonyl resonances are falling in the same range and do not allow sorting by their head group and backbone resonances. The chain in chloroform. These two classes of lipids may be differentiated by their head group and backbone resonances. For phosphorus-containing lipids, 31P NMR can be applied in both liquid and membranous states and allows sorting various phospholipid classes.

**Analysis of hydrated lipid aggregates using solid-state NMR**

In the following discussion, some examples of wide-line NMR used to probe structure and dynamics of lipids in hydrated systems are presented.

**Lipid phases, transition temperatures**

As demonstrated in Fig. 1, wide-line NMR spectra are good tools to determine in which hydrated phase a lipid may be. This process has been used widely to determine phase diagrams (e.g., Dipalmitoylphosphatidylcholine(DPPC)-cholesterol using 2H-NMR (8) and Phosphatidylethanolamine(PE)-cholesterol (9, 10) with 1H and 31P NMR). Fig. 3a reports a temperature-composition diagram of short-chain and long-chain PC mixtures (11, 12). This system may form Lamellar phases (L), small disks (D), and isotropically tumbling very small objects (I) depending on composition and temperature. The small (40-80-nm) disks are called bicelles and are oriented by magnetic fields, with their normal parallel or perpendicular to the field \( B_0 \). Fig. 3a (inserts), which leads to unambiguous spectral assignment using the naturally abundant 2H and 14N nuclei as reporters (Fig. 3b).

An isotropic line is obtained for isotropically tumbling objects (800 ppm, bottom). Two (2H) or four (14N) sharp lines corresponding to small-chain and long-chain lipids are detected for disk normal oriented perpendicular or parallel to the field (middle), and an isotropic line superimposed on a powder pattern is observed for a biphase region where lamellar and isotropic phases coexist (top). Because phase diagrams are tiresome to build, partial phase changes can nonetheless be obtained by following spectral changes with temperature or hydration. PE or monoglycosyldiglycerides favor the appearance of hexagonal phases (13), lysolipids, diglycosyldiglycerides, and diacylglycerols of isotropic phases (14). Raising or lowering gel-to-fluid phase transition temperatures \( T_m \) can be followed by wide-line NMR (1H, 14N, 31P): Calcium-neutralization of negative head group changes of dialyglycerophosphatic acids increases \( T_m \) (15), whereas the addition of unsaturated lipids such as sea urchin Phosphatidylglycerol decreases \( T_m \) (14, 16).

**Bilayer internal dynamics: order parameters, membrane thickness, sterols**

Besides monitoring morphological changes on hydrated systems, wide-line NMR can also report on internal membrane dynamics (i.e., determine the membrane fluidity when in the lamellar fluid state). This is where the concept of order parameter takes place. Order parameters \( S \) are time and space averages of the quantity \( \langle \cos^2 \theta - 1/2 \rangle \). They can be expressed at the intramolecular level describing the fluctuation.

nd: not determined. Range numbers (e.g., 127.52–132.51) indicate that there are more than 2 lines in the range that cannot be assigned with confidence. Numbers separated by '/' (e.g., 127.83/129.89) indicate that two lines of indicated chemical shifts exist, which cannot be assigned with confidence. Primes stand for positions in sn-2 chain.
of bonds, at the molecular level, picturing the angular reorientation of molecules, or at the mesoscopic scale reflecting membrane deformations (4, 5). When expressed with respect to the local axis of symmetry, S values range from 1 to 0 and are simple tools to say whether a system is rigid (S ≈ 1) or liquid-like (S ≈ 0). As indicated in Equation 3, S is measured directly from the spectrum width. The best magnetic interaction to deal with when measuring order parameters is the quadrupolar interaction (C–2H bonds); however, the dipolar or the chemical shielding interaction can also be used (17). In Figure 4a (18) is shown a deuterium wide-line bicelle spectrum of fully 2H-labeled DMPC together with the molecule showing labeled positions. Assignment was made based on selective labeling (3, 19), and except for hindered positions, the smaller the doublet the smaller S. Chain ends and head group are very mobile, and positions 2–8 display the same high ordering called the “plateau” of order parameters. Relaxation times T1 can also report on membrane dynamics. Figure 4c shows how 1/T1 varies with labeled position. It is observed that both the acyl chains and the head group are dynamic, particularly toward the ends.

Orientation of molecules in membranes

Equation 2 indicates that frequency lines depend on the orientation of molecules with respect to the magnetic field. The spectrum is used to determine the average orientation of molecules in the membrane knowing the orientation of the membrane plane with respect to B0 and atomic coordinates of the rigid molecule of interest. Whereas bicelle membranes naturally orient in the field, classic membranes must be sandwiched in between glass plates that are oriented macroscopically by means of a goniometric device. The orientation of 2H-labeled cholesterol in membranes has thus been determined by combining neutron coordinates and wide-line deuterium NMR. Cholesterol is vertical in the membrane, which offers the minimum molecular area to optimize lipid packing, whereas α-cholesterol, the non-naturally occurring isomer is tilted (25). Labeling of lipid head groups also afforded measuring changes in orientation at the membrane surface during variation of the electric field (pH) (26).
Membrane dynamics from picoseconds to millisecond

From measurement of relaxation times, a minute analysis of intramolecular, molecular, and collective motions that occur in a membrane during temperature changes may be accomplished [Fig. 5 (5)]. Correlation times are plotted in a log scale as a function of the reciprocal of temperature in order to have a direct reading of activation energies from the slopes of the lines: the steeper the slope, the higher ${E_a}$. In the gel phase ($L_{β'}$, $P_{β'}$), only intramolecular ($τ_{1,2,3}$) and molecular motions ($τ_{//}$, $τ_{⊥}$) occur whose $τ_c$ ranges from the millisecond to the nanosecond. On going to the fluid $L_α$ phase, above $T_m$, an increase occurs by 3 orders of magnitude of the motion speeds. Intramolecular motions go into the picosecond range that is barely detected by NMR. Collective modes of motions (membrane large-scale deformation) come into play only in the fluid phase. The addition of cholesterol to this system levels off the large temperature-induced change in $τ_c$ at $T_m$ (27). Lateral diffusion of molecules in the membrane plane can also be measured using a combination of oriented samples and pulsed gradient sequences (28). Indication of restricted diffusion as for domain formation was found in “raft” mixtures of sterols and sphingolipids.

Chemical Tools and Techniques

Chemicals

Natural lipids are extracted following known procedures (29). Synthetic lipids are also prepared according to reported procedures (30). Many lipids are available commercially. Membranous lipids can also be prepared directly from cells using several detergent-centrifugation steps.

Sample preparation

Lipids for solution NMR are dissolved in deuterated organic solvents (CDCl$_3$, CD$_3$OH, DMSO, etc.) at concentrations varying from µM to mM. Solutions are transferred into
NMR of Lipids

The classic battery of solution NMR experiments is used for lipids in solution or spinning at the magic angle (31). For samples that are under the form of aggregates, cross-polarization experiments are often used to enhance signals of low concentrated and/or diluted nuclei (13C, 31P) by taking advantage of the proton reservoir from which the magnetization may be transferred (31). The most used 1-D sequences for static experiments are spin-echoes that refocus the chemical-shielding, dipolar or quadrupolar interactions and cope with the quickly damping signals often observed in solids (2). These sequences are implemented into 2-D variants capable of correlating dipolar/quadrupolar interactions versus chemical shielding (32). Measurement of relaxation times and diffusion constants are made using classic sequences (inversion recovery, echoes, gradients) that are merged with spin-echo sequences.

Conclusion and Perspective

NMR is the only nondestructive and quantitative method capable of bringing the atomic 3-D structure and dynamics of lipids both in solution and in aggregated form. The only drawback of the method is its relatively modest sensitivity: It requires micrograms to milligrams of material. However, NMR is an ongoing science that still develops both by inventing new sequences and by developing new technologies (high field and cryoprobes). It is expected that detection limits will be lowered and that analyses will be made in living materials.

Tools for Detection of DNA Polymorphisms

Sascha Sauer, Max-Planck-Institute for Molecular Genetics, Department of Vertebrate Genomics, Berlin, Germany
doi: 10.1002/9780470048672.wecb464

DNA polymorphisms, such as single nucleotide polymorphisms (SNPs) and short tandem repeats (STRs), are used as genetic markers in linkage and association studies to dissect monogenic and polygenic traits. Structural variation and DNA methylation are additional sources of genetic variation and are becoming increasingly important, particularly in the analysis of cancer. In this article, biologic background, basic chemistries, and currently used technologies for the detection of these polymorphisms are presented with a focus on SNP analysis.

Biologic Background

Variations in DNA sequence between individuals are termed "DNA polymorphisms." In biology, a polymorphism—which derives from ancient Greek "many" and morph "form"—generally is defined as the occurrence in the same habitat of two or more forms of a trait in a population in such frequencies that the rarer form cannot be maintained only by recurrent mutation. Evolutionary forces act on genetic polymorphisms when organisms with different polymorphism alleles reproduce with varying degrees of success. With the availability of the reference sequence of the human genome along with a growing number of additionally sequenced genomes, genetic analysis, which includes genotyping of DNA polymorphisms, enters a new stage of research (1).

Many geneticists aim to study multifactorial traits in humans caused, among others, by genetic constitution and environmental factors. Genotyping, the determination of the specific allelic composition of a genome, a set of genes or a single gene, is a key element in these studies (2). Currently, statistical genetics relies heavily on linkage and association approaches. In general, linkage analysis uses DNA polymorphisms such as short tandem repeats (STRs) (mainly microsatellites) and SNPs as markers to assign chromosome map position to genes by genetic crosses prescribed in databases. Presently, over 10,000 STR sequences are described in databases. Presently, over 10,000 STR sequences are published for the human genome. A selected, informative subset of polymorphic microsatellites is applied readily in forensics. They are used to identify and trace potential criminals because of their individual genetic "barcode" that consists of a combination of varying microsatellite alleles at a few genomic loci. The Federal Bureau of Investigation in the United States has selected 13 STR loci to generate an individual human genetic profile. These profiles are stored in DNA databanks such as CODIS (http://www.fbi.gov/lab/codis/index.html). The ratio of STR genotyping and fingerprinting is based on previous approaches using time-consuming restriction fragment length polymorphism (RFLP) analysis (4). RFLP analysis is performed by using a restriction enzyme to cut the DNA specifically at

Outlook
Single nucleotide polymorphisms (SNPs)

SNPs are single-base substitutions, with the minor allele that occurs at least for 1% in a population (5). Otherwise, they would be termed point mutations. Often, single-base deletions and insertions are included in this definition. The majority of SNPs were discovered in DNA sequencing projects during the last decade. Presently, around 10 million human SNPs are stored in public databases such as dbSNP (http://www.ncbi.nlm.nih.gov/SNP/). Not all are validated and confirmed in all major populations. As STRs, SNPs can be used for several genetic applications, such as linkage and association analysis, diagnostics, and forensics.

Moreover, the haplotype of SNPs—the combination of SNP alleles that is found on a single chromosome of a given individual—is important in association analysis (6). Unfortunately, molecular haplotyping procedures are presently very expensive and not amenable to automation. Therefore, many researchers use statistical methods to infer haplotype pairs from multilocus genotypes (7). Resulting haplotypes are prone to misclassification, particularly if a large number of heterozygous SNPs are analyzed. The international HapMap project (http://www.hapmap.org/index.html.en) started in 2002 to compare human genome sequences of different reference populations to identify chromosomal regions where genetic variants are shared (i.e., haplotypes of SNPs). Nowadays, tag SNPs that comprise several redundant SNPs are used for whole-genome association scanning (8). In these genotyping experiments, several hundred thousand SNPs are analyzed in a limited number of about 100 selected individuals. The restriction in DNA samples is mainly because of the high cost of these experiments. However, first indication of chromosomal regions that contribute to the traits under investigation can be gained by such studies. A limited number of SNPs (∼1–1000) is used subsequently to investigate selected genomic regions in upsampled numbers of DNA samples. Resulting genotypes are explored either for direct association of causative SNPs or for indirect association of SNPs in an allelic association (often termed linkage disequilibrium) with causative loci.

Structural variations

Another class of polymorphisms that becomes increasingly important is structural variations (9). These variations are defined broadly as genomic alterations such as reciprocal translocations, deletions, duplications, insertions, and inversions. Structural variations involve segments of DNA that are larger than 1 kb, and they can be either microscopic or, in many cases, submicroscopic. Submicroscopic structural variants range from ∼1 kb to 3 Mbp in size and their analysis with current molecular biologic procedures is still much more complicated than the analysis of simple polymorphisms such as SNPs. The most important structural variations in the human genome are copy number variations (CNVs), which include large insertions, deletions, and duplications. CNVs are defined as a segment of genomic DNA, which is 1 kb or larger in size and occurs at a variable copy number compared with a reference genome. As for SNPs, a CNV is termed a copy number polymorphism if a variation occurs for at least 1% in a population. CNVs are known to be involved in several diseases of gene dosage, such as Angelman syndrome. CNVs are also involved in complex (multifactorial) diseases such as cancer; therefore, many researchers suggest a CNV analysis step should be added to all disease association studies, which are based currently on SNPs. Similar to SNPs, databases of structural variation presently are built up for the human genome. The human genome contains ∼3 x 10^6 base pairs, and it is estimated that the nucleotide content of CNVs per genome is about 10–30 million base pairs.

Methylation variation position (MVPs)

'S'-methylation of cytosines at CpG dinucleotides in genomic DNA is another source of DNA variation, which, in contrast to stable SNPs, can vary depending on the developmental stages and the tissues of an organism. These digital variations are called methylation variable position (MVP) (10). "CpG islands" are a large number of CpG dinucleotides adjacent to each other that occur in regulatory genomic regions. As SNPs, MVPs or patterns thereof can predispose to or indicate human diseases such as colon cancer. Moreover, the combination of SNP alleles with MVP alleles, called "haplotype," can lead to differential phenotypes. For example, by modifying regulatory genomic regions such as promoters, MVPs could cause differential gene expression as a result of varying binding efficiencies of RNA polymerase complexes.

Chemistry

In general, the underlying principle of almost all biochemical reactions discussed in this article is the well-known Watson-Crick DNA base-pairing rule; the purine adenine (A) forms a base pair with the pyrimidine thymine (T), and the purine guanine (G) forms a base pair with the pyrimidine cytosine (C) in DNA duplexes. Weak hydrogen bonding is the chemical mechanism that specifies the base-pairing rules. Moreover, electrostatic repulsion and stereoechemical criteria inhibit other potential base-pairing constellations.

DNA modification chemistry

Only some examples of DNA modification chemistry that provide the basis for many different biologic applications can be mentioned here. One development of importance was beyond doubt the introduction of phosphoramidite chemistry for nucleotides and automated synthesis of oligonucleotides in the 1970s (11). Double-strand specific intercalating dyes, such as ethidium bromide and more recent dyes such as SYBR Green I (a cyanine dye), are useful particularly in the analysis of DNA products. The development of sensitive reporter molecules such as fluorescent dyes has also been crucial for the analysis of nucleic acids. These dyes are attached chemically to nucleic acids and nucleotides (12). DNA modification chemistry was also crucial for the development of nonnatural nucleotides
that are substrates of natural or engineered enzymes, such as 2',3'-dideoxynucleotide triphosphates (ddNTPs), used commonly as polymerization terminators in Sanger sequencing and primer extension (13). These dideoxynucleotides lack a 3'-OH group required for the formation of a phosphodiester bond between two nucleotides during DNA strand elongation. Recently, the company Solexa applied chemically modified reversible terminator nucleotides tagged with removable fluorescence dyes between two nucleotides during DNA strand elongation. Recently, the company Solexa applied chemically modified reversible terminators to target DNA sequences that contain an SNP. The difference in thermal stability between a perfectly matched and mismatched hybridization probe and its DNA target is used to distinguish between the SNP alleles. The thermal stability of such a hybrid depends on the nucleotide sequence that flanks the SNP, and additionally on the stringency of the reaction conditions (i.e., temperature and ionic strength). This problem complicates multiplex allele-specific hybridization for genotyping several SNPs simultaneously, but it can be mitigated by careful selection of SNPs on the basis of their performance in hybridization assays. In general, to interrogate a single SNP, several allele-specific oligonucleotide probes are used (16). For example, DNA microarrays are designed to carry four sets of ten allele-specific oligonucleotides that correspond to both strands of the SNP alleles with matched and mismatched probes for each SNP and four additional nucleotide positions flank the polymorphic site. For highly parallelized SNP genotyping, the requirement of such oligonucleotide panels for a SNP results in large arrays. SNP genotypes are assigned according to their joint fluorescence patterns obtained by 40 hybridization reactions for each SNP. The analysis of these patterns is performed by classification-based or model-based algorithms, which are tailored to this application. Two microarrays with a probe feature size of 8 μm that carry 2.5 million different probes per array were applied to analyze over 100,000 SNP genotypes in an individual DNA sample (16). Manufacturing DNA microarrays with oligonucleotides at such high density is performed routinely by using photolithographic techniques and combinatorial synthesis of the oligonucleotide probes on the arrays (17).

Dynamic allele-specific hybridization (DASH) (18) is another hybridization-based approach. DASH, the hybridization state of a duplex formed between PCR products that contain SNPs and allele-specific oligonucleotides is observed dynamically by fluorescence detection of double-strand specific SYBR Green I incorporation. The denaturation profile caused by increasing the temperature steadily during hybridization can be monitored by decreasing fluorescence signals. SNP genotypes are detected according to different melting temperatures of allele-specific oligonucleotides. DASH can be performed in different formats using, for example, membranes or microarray surfaces.

Enzyme-assisted SNP genotyping procedures based on DNA polymerase reactions and/or ligase reactions provide highly specific detection of SNP alleles (see Fig. 1). Primer extension and ligations are significantly less dependent on the DNA sequence context compared with hybridization; therefore, they enable genotyping of most SNPs using similar reaction conditions. An obvious advantage of enzyme-based SNP typing compared with conventional allele-specific hybridization is that it reduces the number of oligonucleotides required for multiplex SNP analysis.

DNA ligation is highly specific enzymes that join two adjacent and perfectly matched DNA strands to a template such as genomic DNA or a PCR product (19). Ligated products can be amplified and detected. This principle has been exploited in the oligo ligation assay and related procedures.

Primer extension reaction has become one of the most widely used methods for SNP genotyping because of its robustness and flexibility (15). In this reaction, an extension primer hybridizing to both strands of the SNP under investigation, is extended with a thermostable DNA polymerase. The simplest reaction principle is allele-specific hybridization of oligonucleotides to target DNA sequences that contain an SNP. The difference in thermal stability between a perfectly matched and mismatched hybridization probe and its DNA target is used to distinguish between the SNP alleles. The thermal stability of such a hybrid depends on the nucleotide sequence that flanks an SNP, and additionally on the stringency of the reaction conditions (i.e., temperature and ionic strength). This problem complicates multiplex allele-specific hybridization for genotyping several SNPs simultaneously, but it can be mitigated by careful selection of SNPs on the basis of their performance in hybridization assays. In general, to interrogate a single SNP, several allele-specific oligonucleotide probes are used (16). For example, DNA microarrays are designed to carry four sets of ten allele-specific oligonucleotides that correspond to both strands of the SNP alleles with matched and mismatched probes for each SNP and four additional nucleotide positions flank the polymorphic site. For highly parallelized SNP genotyping, the requirement of such oligonucleotide panels for a SNP results in large arrays. SNP genotypes are assigned according to their joint fluorescence patterns obtained by 40 hybridization reactions for each SNP. The analysis of these patterns is performed by classification-based or model-based algorithms, which are tailored to this application. Two microarrays with a probe feature size of 8 μm that carry 2.5 million different probes per array were applied to analyze over 100,000 SNP genotypes in an individual DNA sample (16). Manufacturing DNA microarrays with oligonucleotides at such high density is performed routinely by using photolithographic techniques and combinatorial synthesis of the oligonucleotide probes on the arrays (17).

Dynamic allele-specific hybridization (DASH) (18) is another hybridization-based approach. DASH, the hybridization state of a duplex formed between PCR products that contain SNPs and allele-specific oligonucleotides is observed dynamically by fluorescence detection of double-strand specific SYBR Green I incorporation. The denaturation profile caused by increasing the temperature steadily during hybridization can be monitored by decreasing fluorescence signals. SNP genotypes are detected according to different melting temperatures of allele-specific oligonucleotides. DASH can be performed in different formats using, for example, membranes or microarray surfaces.

Enzyme-assisted SNP genotyping procedures based on DNA polymerase reactions and/or ligase reactions provide highly specific detection of SNP alleles (see Fig. 1). Primer extension and ligation are significantly less dependent on the DNA sequence context compared with hybridization; therefore, they enable genotyping of most SNPs using similar reaction conditions. An obvious advantage of enzyme-based SNP typing compared with conventional allele-specific hybridization is that it reduces the number of oligonucleotides required for multiplex SNP analysis.

DNA ligation is highly specific enzymes that join two adjacent and perfectly matched DNA strands to a template such as genomic DNA or a PCR product (19). Ligated products can be amplified and detected. This principle has been exploited in the oligo ligation assay and related procedures.

Primer extension reaction has become one of the most widely used methods for SNP genotyping because of its robustness and flexibility (15). In this reaction, an extension primer hybridizing upstream of the SNP under investigation, is extended with ddNTPs and/or ddNTPs by a thermostable DNA polymerase. The DNA polymerase elongates the 3'-end of the primer in a temperature-cycled reaction by incorporating nucleotides that are complementary to the DNA template, which leads to a linear amplification of products of SNPs. The reaction terminates at the first nucleobase in the template where a nucleotide occurs that is complementary to one of the ddNTPs in the template. Depending on the reaction conditions, the extension products can be small.

DNA sequencing reactions

Using a modified protocol of the primer extension reaction, the so-called chain termination protocol, several different products (sequencing ladders with sizes up to about 1000 bases) are obtained. Essentially, this principle is applied in the Sanger sequencing method developed by Frederick Sanger et al. in the 1970s (13). This procedure requires a DNA template such as a PCR product, a primer, a DNA polymerase, and a mix of deoxynucleotides (dATP, dGTP, dCTP, and dTTP) and dideoxynucleotides (ddATP, ddGTP, ddCTP, or ddTTP) that terminate DNA strand elongation. The dideoxynucleotides are added at significantly lower concentration than the standard deoxynucleotides to the reaction mix. Stochastic incorporation of a dideoxynucleotide into the nascent DNA strands terminates extension, which results in various DNA fragments of different lengths. Detection can be performed on gel-based or capillary-based systems using radioactively or nowadays fluorescently labeled nucleotides or primers. Although this method was applied very successfully, for example, to sequence the human genome, some nucleotide repeat-rich genomic regions such as telomeres, centromeres, and AT-rich intergenic repeats have often proved difficult to analyze with polymerase-based sequencing protocols (1).
Also in the 1970s, Maxam and Gilbert developed a "chemical sequencing" method, which is still useful for the study of DNA–protein interactions, nucleic acid structure, and epigenetic modifications (20). Similar chemistry was later used for SNP detection methods by chemical mismatch cleavage, a variant of enzymatic mismatch cleavage. The Maxam–Gilbert procedure requires radioactive labeling at one end and purification of the DNA molecule to be sequenced. Chemical treatment that uses four specific reactions (G, A+C, C, and C+T) produces breaks at a small proportion of one or two of the four nucleotide bases in the DNA template. Thus, a variety of labeled DNA fragments is generated, from the labeled terminus to the first fragmentation site in each molecule. The fragments are size-separated by polyacrylamide gel electrophoresis with the four reactions arranged side by side. To visualize the products, the gel is exposed to a film for autoradiography, which yields an image of DNA fragment ladders in four columns from which the sequence can be interpreted.

A new DNA sequencing approach developed by Solexa (www.illumina.com) uses massively parallel sequencing of millions of fragments by reversible terminator-based sequencing chemistry (14). The method relies on the attachment of randomly fragmented genomic DNA to a planar, optically transparent surface and solid-phase DNA amplification to generate a high-density flow cell with more than 10 million clusters, each of which contains about 1000 copies of template per cm². The DNA templates are sequenced in parallel on the surface by using a four-color sequencing-by-synthesis procedure, which applies reversible terminators with removable fluorescence. This procedure generates sequences with high accuracy and minimizes artifacts with homopolymeric DNA base repeats. Short sequence reads of about 25 bases can be aligned against a reference genome and genetic differences can be detected by applying specific software.

Pyrosequencing is another novel procedure for DNA sequencing that—as the Solexa sequencing method—also relies on the sequencing-by-synthesis principle (21). This method is based on a chemiluminescent enzymatic reaction, which is triggered when DNA polymerization occurs. Each time a nucleotide is incorporated specifically into a growing DNA chain by a polymerase accompanied by release of pyrophosphate in an equimolar quantity to the amount of incorporated nucleotide, a cascade of enzymatic reactions is activated. First, ATP sulfurylase converts pyrophosphate quantitatively to ATP in the presence of adenosine 5′-phosphosulfate. The newly synthesized ATP induces a luciferase-mediated conversion of luciferin to oxyluciferin, which produces visible light in amounts that are proportional to the number of nucleotides incorporated. It can be detected by a charge-coupled device camera and observed as a signal in a so-called pyrogram. Apyrase is used to degrade unincorporated dNTPs and excess ATP continuously. When this enzyme completes degradation, another dNTP is added (one at a time). Alpha-thio triphosphate-dATP is used as DNA polymerase substrate because it is not recognized by the luciferase. As the process continues, the complementary DNA strand is synthesized and the nucleotide sequence is determined by reading the signals in the pyrogram. Currently, sequences of up to 150 DNA bases can be reliably read by this technique (www.454.com).

Sequencing by ligation can be accomplished through a series of iterative cycles of ligation reactions, in which a sequencing primer is added followed by a pool of fluorescently tagged...
B-mer oligonucleotide probes (22). The probes are designed in sets of four, in which the fifth base serves as the interrogating base. After ligation, the array is washed, imaged, and the probes are cleaved away. Once the dye is removed, the native DNA strands remain so that the ligation, detection, and cleavage cycles can be repeated. This process allows a signal to be generated at the 10th base in the second cycle, at the 20th base in the third cycle, at the 20th base in the fourth cycle, and so on. The intervening bases are detected using different nested sequencing primers. The whole process is repeated until all intervening positions in the sequence are imaged. The ligase approach could be less vulnerable to repeat-rich regions compared with the polymerase-based approaches. For more information, the reader is referred to the Applied Biosystems website (www.appliedbiosystems.com).

The last three methods described belong to the second-generation sequencing approaches. For DNA polymorphism analysis, a current bottleneck in the widespread application of these methods consists in the lack of an efficient template preparation procedure to focus on selective sequencing of genetically or medically relevant genomic regions.

DNA amplification

Efficient DNA amplification methods were important for many genetic applications in the last two decades. The polymerase chain reaction (PCR), developed in the 1980s, is a crucial molecular biology method to replicate short stretches of DNA enzymatically without using a living organism (in vitro) (23). Kjell Kleppe et al. (24) already conceived the principles of PCR in 1971 (24). Kary Mullis et al. (23) established first PCR protocols in the 1980s at the biotechnology company Cetus. They also used thermostable DNA polymerases from thermophilic bacteria such as Thermus aquaticus, which were isolated and first studied functionally by Kaledin et al. (25).

PCR has become a standard method to reduce the complexity of genomes that consist of millions or billions of bases, and to increase specificity of the copy number of short stretches of DNA templates to levels required for analysis. PCR has been refined and extended to several applications, such as genotyping of DNA polymorphisms and quantitative mRNA expression analysis.

In general, during PCR, template DNA is denatured at a high temperature (~95 °C), which separates the double DNA strand, allows subsequent annealing of oligonucleotides called primers at lower temperatures (~55 °C), and extends nucleotide sequences along opposite strands at ~72 °C. This thermocycling process is repeated about 30 times, and it results in exponential accumulation of short DNA products (with sizes ~100–300 base pairs). Usually, PCR products are electrophoresed on agarose or polyacrylamide gels, which are made visible by DNA double-strand intercalating dyes and are validated by comparison with size standard markers.

Genetic markers such as SNPs or STRs can be amplified for genotyping by PCR using primers that anneal to unique flanking regions of these polymorphisms. STR genotypes can be analyzed easily according to their product sizes. PCR primers that flank microsatellite loci are simple and easy to use, but the development of correctly functioning primers can be a tedious and expensive process. In general, STR analysis, as well as amplification of repeat regions of a genome, suffers from slippage of the DNA polymerase, which leads to truncated products that are observed as "stutter bands" in electrophoresis.

A n strategy for DNA amplification represents the rolling-circle amplification—a mode of DNA replication used by bacteria and viruses to amplify circular plasmid DNAs—which generates molecules that look similar to lariats. A single primer is required to anneal to the target DNA and to synthesize a concatenated DNA strand that consists of thousands of copies using T7 polymerase, which also has a 3’–5’ exonuclease activity (26). In contrast to PCR, rolling-circle amplification is an isothermal method that is performed usually at 37 °C, which leads to linear and clonal amplification and takes place at the target DNA.

Parallelization of DNA sample preparation

A high degree of parallelization of sample preparation is of paramount importance to reduce costs in DNA genotyping and sequencing. The ability to perform highly parallel genomic assays to detect hundreds of thousands of SNPs simultaneously depends on two fundamental prerequisites: a highly parallel read-out and an intrinsically scalable, multiplexable sample preparation. The difficulty in optimizing multiplex PCRs consists in sequence-dependent differences in PCR efficiency. This difficulty increases exponentially with the number of genomic target regions to be amplified because of potential interactions between the PCR primers in the reaction mixture. This interaction leads to preferential amplification of undesired short "primer-dimer" artifacts. The multiplexing level that can be achieved by PCR is low (up to about 100 simultaneous reactions) and does not reach the level of high-parallel technologies based on miniaturized DNA microarrays or sequence read-out devices. However, current detection sensitivity of fluorescence or luminescence light scanners still requires an amplification step to generate a reasonable amount of DNA product.

A main bottleneck in DNA sequencing consists of the preparation of DNA samples from the bacterial colonies that contain a DNA library. In the Human Genome Project, each clone was picked individually and grown-up, and target DNA was extracted or amplified out of the clone (1). Recently, "polonies" (contraction of "polynucleotide colony") were used to prepare DNA templates for high-parallel DNA sequence analysis (27). Polonies represent discrete clonal PCR amplifications of a single DNA molecule, which is embedded in a polymer matrix by diffusion. Local amplification of a single DNA is performed by using a primer immobilized to the gel matrix. Several variations of this principle, such as bridge-PCR (28), can be employed, for example, by using planar surfaces and two immobilized primers (www.illumina.com). BEAMing (beads, emulsions, amplification, and magnetic)-based cloning on beads is a popular method to parallelize PCR amplification of many genomic loci in which a library of clones is grown on beads through the use of compartmentalized water-in-oil emulsion PCR (29). DNA and beads are diluted as far as, on average, a single micrometer-sized bead and a single target molecule co-occupy a single compartment (30, 31). PCR amplifies a clonal population of DNAs on the
A popular approach to reduce genomic complexity before SNP typing on high-density oligonucleotide microarrays consists of cleavage of genomic DNA by applying restriction enzymes and ligation of common adaptor sequences to the genomic fragments produced. Then, the adaptor sequences are used as binding sites for amplification by PCR using a single universal primer (15). The complexity of the human genome can be decreased by a factor of 50 using a single restriction enzyme followed by PCR with a universal primer to amplify fragments 250–1000 bp in size (see Fig. 2). This method allows for genotyping of 10,000 selected SNPs, located in the amplified fragments using allele-specific hybridization to oligonucleotides immobilized on high-density microarrays. The multiplexing level of this approach has been increased recently to 500,000 SNPs by applying a combination of two restriction enzymes for the complexity-reduction and amplifying larger PCR fragments up to 2000 bp in separate reactions. Recent SNP arrays allow for parallel genotyping of about 1,000,000 SNPs.

Carrying out the allele-specific reaction directly on genomic DNA, and subsequently applying PCR only to increase the number of detectable products, is a reverse, flexible approach to address the problem of amplifying a large number of genomic loci specifically (see Fig. 3) (32). One approach uses hundred or thousands of “circularizable” oligonucleotides called padlock or molecular inversion probes. These probes have two sequences that anneal complementary to adjacent regions in genomic DNA that contain SNPs, followed by an enzymatic step to close the circle allele-specifically. In the case of the padlock probes, the enzymatic step is an allele-specific ligation, whereas an additional gap-filling reaction for the molecular inversion probes is accomplished by a DNA polymerase followed by circularization using a ligase. The closed circles can be amplified exponentially by PCR or by rolling circle amplification. Circularizable probes allow for flexible in vitro genotyping in the range of 1000–100,000 SNPs in a single reaction (33). The application of generic microarrays that carry “molecular barcode” (tag) sequences to capture the amplified ligated products allow more flexible genotyping than the approach described in the previous paragraph.

Alternatively, oligonucleotide pairs are used to recognize the target DNA flanking the SNPs before enzyme-assisted genotyping (see Fig. 4). The allele-specific reactions produce templates, which were amplified subsequently by PCR using a primer for which universal binding sites have been inserted in the oligonucleotide pairs. Furthermore, in the probe oligonucleotides, molecular barcode sequences were incorporated, which were used to capture specifically the amplified products on beads that carry immobilized complementary DNA sequences. The beads were then assayed on optic fiber devices. This “Golden Gate” assay can be multiplexed to detect panels of about 2000 SNPs in parallel (34). Moreover, bead arrays were used for genome-wide genotyping of hundreds of thousands of SNPs (35). Therefore, a large number (about $10^6-10^7$) of fragmented copies of the genome were generated by whole-genome amplification using short random primers, and a

Figure 2: Genomic complexity reduction for microarray hybridization. Genomic DNA is digested with a restriction enzyme, and adaptors are ligated to the ends of resulting fragments. These fragments are amplified by using one of the strands of the adaptor as a primer. Fragments in the size range 250–1000 bp are amplified by PCR. The narrow size range of the PCR products represents ~400 base pairs which corresponds to a 50-fold reduction in genome complexity. To optimize efficient hybridization, the PCR products are fragmented by DNase I. The products are biotinylated and are subsequently hybridized to oligonucleotide microarrays. After a series of washing and signal generation steps, the fluorescence signals on the microarrays are scanned and genotypes are detected based on hybridization signal intensities.

Signal amplification method was applied to achieve sufficient fluorescence-detection sensitivity after genotyping. This procedure for whole-genome genotyping provides the basis for a new system to genotype a panel of about 300,000–550,000 human SNPs and is presently being extended to about 1,000,000 SNPs.

Specific analytical chemistry for structural variation detection

To define a structural variant, the analysis of structural variants relies on the comparison with a reference genome (9). Reference sequences such as the human genome sequence represent a hybrid assembly, which reflects the hierarchical mapping and sequencing approach that was applied (3). So far, no human DNA source has yet been defined as a standard reference control. The lack of a single reference DNA complicates both the identification and interpretation of the data, which is required for determining the hierarchy of mapping and sequencing methods used to detect variations on different studies and on standardization of databases, which contain information on structural variations.

Large structural variations are detected by microscopy-applying chromosome-banding methods using, for example, Giemsa

PCR Amplification + Labeling

Figure 3 Reaction steps of the molecular inversion probe assay from Affymetrix illustrated for a heterozygous SNP. Oligonucleotides that contain target-specific regions (red), binding sites for PCR primers (gray), and molecular barcode sequences for capture on a solid support (blue) are allowed to anneal directly to genomic DNA. The 3′-end of the upstream target-specific oligonucleotide probe is elongated by a DNA polymerase, followed by ligation to the downstream oligonucleotide. The resulting circular molecule is cleaved at a site between the PCR primers before and after PCR amplification, which is followed by fluorescent labeling. The labeled molecules are captured finally on GeneChip glass microarray that carries complementary molecular barcode sequences for fluorescence detection. With permission from Ref. (15).

staining of elongated prometaphase chromosomes to reveal discrete structural variations (9). Recent developments in fluorescence in situ hybridization (FISH) analysis (36) on interphase cells and metaphase chromosomes enable a more refined characterization of the extent of these variants. In high-resolution fiber FISH, oligonucleotide probes fluorescence labeled in different colors are hybridized to stretch chromosome fibers mechanically, which allows copy numbers to be counted directly.

Recently, whole-genome scanning array technologies and comparative DNA-sequence analyses such as clone-based comparative genome hybridization (array-CGH) revealed DNA variation, which involves genomic segments that are smaller than those that can be observed by microscopy (37). Copy number variants that are greater than 50 kb could be detected efficiently by CGH. Array-CGH can even be used to discover CNVs in formalin-fixed, paraffin-embedded clinical samples that imply varying levels of degradation. CGH procedures apply fluorescent dyes such as Cy5 to label fragments from a genome under investigation. The genomic fragments are hybridized competitively with a second differentially labeled reference genome using Cy3 tags to surfaces that are printed with cloned DNA fragments, which reveals eventually copy number differences between the two genomes under investigation. Capture on Bead Array

Figure 4 Reaction steps of the GoldenGate assay from Illumina. The fragmented genomic DNA is biotinylated and immobilized on avidin-coated microparticles. For polymerase extension and ligation reaction, a pair of allele-specific primers is used with similar functional blocks as the approach in Fig. 3. The allele-specific DNA molecules are amplified by PCR using universal primers that are tagged with fluorescence labels. The labeled molecules are finally captured on beads carrying complementary molecular barcode sequences for fluorescence detection. Finally, the beads are arrayed on optic fiber devices. With permission from Ref. (15).

Specific analytical chemistry for MVP detection

The analysis of MVPs requires some additional experimental steps compared with that for SNPs (39). One approach uses cleavage of genomic DNA by methylation-sensitive restriction enzymes. However, methylation-sensitive enzymes do not interrogate all CpG sites. About one-third of all CpGs in the human genome can be assayed using a combination of enzymes. Alternative procedures apply immunoprecipitation with methyl-binding protein or antibodies against methylated cytosines. The two approaches provided here are used in combination with highly parallel microarray detection.

The standard approach to analyze MVPs requires the conversion of the methylation difference into a sequence difference. This conversion is accomplished by bisulfite treatment of DNA, in which the 5’-methylcytosine remains stable while cytosines are deamminated (40). Using PCR amplification, these deaminated bases are converted to thymine bases. The amplicons that result can be detected by modified DNA sequencing methods, by array-based hybridization, or by application of SNP genotyping assays. Detection of cytosine alleles in these methods indicates a methylation position. For all bisulfite-based procedures, the challenges exist in dealing with the bad DNA quality because of harsh chemical conditions as well as the fact that the DNA strands are not complementary after bisulfite reaction. Furthermore, PCR efficiencies suffer from increased sequence redundancy.

Chemical Tools and Techniques

Nucleic acids research widely relies on optical detection using fluorescence or luminescence detection. Moreover, mass spectrometry and electro-chemical methods are useful depending on the specific application of these detection methods (41, 42). The reaction principles described in detail above and appropriate detection devices can be efficiently combined to tailor analytical methods for the detection of DNA polymorphisms with particular strengths depending on the application, which is illustrated for important SNPs genotyping methods in Fig. 5.
DNA sequencer tools

Capillary sequencers that use sensitive fluorescence detection in a 96-well or a 384-well format provide accurate detection of base sequences in a genome and are currently applied widely for DNA analysis problems. Semi-automated analysis of sequence traces can be accomplished by using software tailored to these applications. The DNA-sequencer can also be applied for SNP genotyping, for example, a 48-plex SNP genotyping method called SNPlex assay (www.appliedbiosystems.com). This technology is based on the allele-specific ligase reaction and the generation of 96 fluorescence-labeled products of 48 SNPs that are separated and detected on a capillary sequencer.

Currently, very promising “second-generation” sequencing technologies are of main interest to detect SNPs, MVPs, or structural variation. Key players in this area are the companies 454 (Roche), Solexa (Illumina), and Aurrencp Personal Genomics (Applied Biosystems). In general, these new sequencing technologies rely on the reduction of genome complexity based on fragmentation and the use of universal linkers and subsequent clonal amplification. The FLX sequencer of 454 uses BEAMing for sample preparation and pyrosequencing, which includes highly parallel luminescence read-out, by charge-coupled cameras devices. The 1G genome analyzer system of Solexa uses clonal amplification, primer extension with reversible terminators that carry removable fluorescence dyes, and highly parallel fluorescence read-out. Applied Biosystems’ SOLiD (Supported Oligo Ligation Detection) sequencing procedure relies on step-wise ligation of short oligonucleotides on arrayed DNA fragments and parallel fluorescence detection. For more details, the reader is referred to the websites of these companies. In these techniques, single molecule amplification is performed on haploid clones. Obtained sequences represent molecular haplotypes that could be assembled for large genomic regions. Current problems of all new sequencing techniques consist in dealing with the short sequence reads and in the large amounts of image data produced per run, which is in the range of several terabytes.

Microarray tools

For genetic studies that involve hundreds of thousands of genetic markers such as SNPs, the highly parallelized methods developed by Affymetrix and Illumina, which were discussed above intensely have become gold standards. However, optimized second-generation sequencing methods might overcome, or at least complement, these microarray techniques in the future. For small-scale applications, the combination of multiplex PCR with primer extension and parallel fluorescence detection on microarrays is useful. This approach is applied in the SNPStream assay from Beckman Coulter that allows the simultaneous generation and detection of about 40 SNPs.

To analyze structural variation efficiently, companies such as NimbleGen and Agilent Technologies offer oligonucleotide microarrays for direct (nonrepresentational) CGH. The resolution of these arrays is currently in the 30-50 kb range, which will probably increase as higher-resolution arrays become available. Dense SNP microarrays that provide genotype information have the additional advantage of being useful in copy number variation analysis that uses hybridization signal intensities. Signal
Another approach for SNP genotyping relies on competitive allele-specific hybridization of primers for PCR amplification, which consists of placing of the 3′-end of one of two primers allele-specifically and directly over the SNP position (see Fig. 3). Matching one of the alternative nucleotides ensures the specificity and the amplification of the PCR, which is observed by accumulating fluorescence of double-strand DNA-binding dyes like SYBR Green I (47). In general, mismatch amplification would be delayed by more than 10 cycles. The commercially available AmpliFluor procedure uses universal oligonucleotides to detect allele-specific amplification (www.chemicon.com). In general, all mentioned PCR-based methods represent simple SNP genotyping approaches in which all reagents are dispensed into a reaction well that is sealed with adhesive film and subjected to thermal cycling.

**Outlook**

In the last decade, several powerful sequencing and genotyping technologies have been developed. Additional refinements will be achieved certainly in the next years. Currently, DNA sequencing is in the focus of technology development. More sensitive and precise detection tools, as well as efficient templates and sequencing reaction principles, are being developed.

The power of fluorescence spectroscopy in the study of nucleic acids relies on the availability of hundreds of different fluorophores that span the visible spectrum of light and the possibility of using them to label oligonucleotides (short fragments of DNA or RNA obtained by chemical synthesis) specifically. Any sequence can be obtained with one or more fluorophores and fluorophore quenchers attached at preselected positions by linkages with suitable parameters to ensure the optimal properties for the fluorescent oligonucleotides. Fluorescent labeling of long DNA or RNA fragments is also possible by enzymatic methods. Fluorescence-based studies of nucleic acids are widely used in different areas such as basic research, molecular and clinical diagnostics, disease monitoring, therapeutic development, food technology, environmental sciences, and biotechnology. After a few words on biological and fluorescence backgrounds, the main labeling strategies will be developed and examples of biological questions that can be addressed with fluorescent oligonucleotides and the major types of fluorescence spectroscopy techniques will be reported.

Fluorescence-based studies of nucleic acids (NAs) rely on two key contributions of synthetic chemistry: the automatization of oligonucleotide (ON) syntheses (1) and the development of efficient methods for site-specific fluorescent labeling of these ONs (2–7). Many applications are based on the complementary hybridization between short fluorescent synthetic ONs (15–25 nucleotides in length) and the NA to be analyzed. ON sequences can also be chosen for assembling into structures that mimic those found in living biological systems, which provides tools for structural, dynamic, and interaction studies. Because the intrinsic fluorescence emission of the major nucleic bases is too weak to be used for detection, fluorescence-based studies have to rely on synthetically modified nucleotides with more desirable emissive characteristics or exogenous fluorescent labels (Fs). It is a challenge for the chemist to develop ON analogs that do not perturb the samples to be analyzed while providing the desired spectroscopic properties. Fluorescence-based techniques can be used both in solution and in solid-phase applications. In the last few years, the development of fluorescent ONs (FONs) that show a modified emission in the presence of the target has been the focus of intense research (2–7). These new FON probes simplify the analyses in vitro and provide the possibility of applications in living organisms. New strategies for specific enzymatic labeling of large NAs are also in development. Many reviews have been published over the last 3 years on the use of fluorescence to study NAs (2–7). After a brief account on biological and fluorescence backgrounds, this article will focus on the main strategies used to label ONs with Fs and examples will be given of biological questions that can be addressed with FON using the major fluorescence parameters.

Background

Biological background

The sequencing of the human genome provides the full genetic map of the NAs of a human being but lacks information as to how they are involved in the processes within cells. A analysis of the interindividual sequence variations in healthy and diseased people can help to identify and understand inherited or acquired pathologies as well as drug side effects (8). The ability to detect, localize, and quantify the different RNAs (pre-mRNA, mRNA, micro RNA) in living cells and tissues, in real time, will offer tremendous opportunities for biological and disease studies, and it will have a significant impact on medical diagnostics and drug discovery (8, 9). To understand RNA functions in the cell, it is also necessary to monitor their conformational changes directly during pre-mRNA splicing, ribosome assembly, and RNA processing. These different biological questions can be addressed...

with different ON probe structures conveniently labeled with selected Fs that exploit the main characteristics of fluorescence.

### Fluorescence background

Emission of light, which occurs when an F excited to the singlet state relaxes back to the ground state, can be characterized by parameters such as emission spectrum, fluorescence intensity (enhancement or quenching), fluorescence lifetimes, and anisotropy (10). The fluorescence exhibited by a given F depends on its intrinsic properties, its exposure to solvents, as well as its interaction with other environmental elements. In our applications, the F can interact with the labeled ON. Interactions of the ON with its target sequence or with other nucleic acid binding molecules induce additional contacts of the F leading to quenching or enhancement of the fluorescence. The fluorescence signal can also be modified by the use of more than one F (identical or different) or by a suitable fluorescent/fluorescent quencher (F/Q) pairs linked at convenient positions on the ONs. When two different Fs are in close proximity and the emission spectrum of the donor overlaps the excitation spectrum of the acceptor, energy is transferred from donor F to acceptor F in a distance-dependent manner that follows a nonradiative process (Förster). Another strategy to induce changes of the fluorescent signal consists in the use of modified fluorescent ONs that can adopt specific structures prone to changes during interaction with their targets. When two or more aromatic hydrocarbon molecules such as pyrene are in close proximity, an excited-state pyrene monomer and ground-state monomer can form an excimer state that fluoresces at a longer wavelength than the monomer emission (Birks). Fluorescence resonance energy transfer (FRET) and excimer formation coupled with quenching/unquenching strategies are the most frequently used fluorescence parameters because of the ease of their usage. Fluorescence lifetime and anisotropy measurements require more expertise and sophisticated equipment. Fluorescence detection and measurements can be performed with various instruments (spectrofluorometers, microplate readers, scanners, microscopes, and flow cytometers) that provide different pieces of information. The possibility of detection at different wavelengths associated with the suitable fluorescent labeling of ONs provides the possibility of multiplexing. Finally, progress made in the field of instrumentation associated with the development of very sensitive Fs allows detection at the single-molecule level (11).

### Nucleic Acids Labeling Strategies

Fluorescence labeling of NAs relies on chemical or enzymatic methods. However, intrinsic fluorescence emissions of the five most frequent natural nucleobases is too weak to be used for detection, and fluorescent labeling relies on synthetically modified nucleosides or exogenous Fs incorporated at convenient positions inside the ONs or NA sequences to provide the required spectroscopic properties.

**Different classes of Fs and F quenchers (Qs)**

Fs used to detect and study NAs involve nucleoside analogs, organic dyes, metal complexes, nanoparticles, and quantum dots (2-7). These Fs cover much of the visible spectrum and are available from many suppliers (12-14) (Table 1). Several Qs are also commercially available. A very useful study on F/Q pair efficiencies has been reported (15). Researchers are also continuously developing Fs and Qs with spectroscopically tuned properties to fit the requirements of new applications into different formats and new detection instruments (2-5).
Fluorescence Techniques for Nucleic Acids

Different chemical labeling strategies

Non-specific labeling

Many organic dyes bind to NAs by electrostatic and hydrophobic (including intercalation) interactions that are not specific to the NA sequence. They provide information about the amount of NA available in a sample. These applications mainly include staining of the NA in polyacrylamide and agarose gels as well as DNA quantification during real-time PCR or cell labeling. These compounds, which are available from many suppliers, are used in the presence of the targets is the focus of intense research because their use can simplify the analyses.

Specific labeling

The selective chemical covalent labeling of ONs (DNA and RNA) can be achieved by either the incorporation of modified fluorescent nucleosides or the covalent attachment of Fs (and Qs) at preselected positions on the ON (2-5, 16). Fluorescent nucleotide analogs include either modified bases (isomeric base analogs, purine analogs, extended base analogs, natural bases conjugated to Fs, etc.), or base replacement (polyaromatic Fs...). These analogs can be incorporated via their phosphoramidate or H-phosphonate derivatives during the ON synthesis on solid phase. The phosphoramidite derivatives of the most common organic Fs (fluorescein, rhodamine, a few cyanines), Q (dabcyl...), and nucleosides with pyrene and perylene pendant groups as well as functionalized supports that allow the incorporation of the Fs and Qs at the 3’-end of the ONs can be obtained from different suppliers (12-14). However, the direct incorporation of the Fs during the ON synthesis requires that the Fs or nucleoside analogs can withstand the chemical conditions needed for the deprotection step and that they are soluble in organic solvents. Another strategy consists in the postsynthetic attachment of Fs to various positions of ONs by specific reactions between convenient functional groups incorporated at preselected positions of the ONs and in the Fs. Many Fs with groups that can react with the amino or thiol functionalized linker incorporated into ONs are commercially available (12, 13). The preparation of FONs with new specific properties can be achieved by the refinement of the F structures together with the development of new linkage parameters. Commonly used positions are the 5’- or 3’-termini (3, 4, 15, 17, 18, 20-22, 25, 31, 32, 34-36, 39-41), internucleotidic position (29, 30, 32) and the 2’-position of the sugar residue (3 and 4, positioning the F in the minor groove) (Fig. 2). It is also possible to attach Fs to nucleobases typically at the 5-position of T(U) or C (positioning the F in the major groove), the 7-C carbon of 7-deazaadenine or 7-deazaguanine, and the 8-position of adenine or guanine (2-5, 16, 42 and 43). In addition to the amide, thiourea, and thioether bonds, other linkages such as amine, phosphoramidate, oxime, hydrazide, phosphothioamide, triazole, squarate, or disulfide can be used. The coupling reactions can take place in different solvents, aqueous buffers, or aqueous buffers/organic solvent mixtures depending on the F solubility (17, 18, 29-32, 35, 39). It is also possible to perform the coupling steps directly in methanol in the presence of crown-ether to solubilize the deprotected ON (31).

Multilabeling

The chemical strategy allows the positioning of Fs at many selected sites along the ON. When several Fs are involved, they must be linked to the ON probes in positions that enable the most efficient properties required (FRET (17, 39), excimer (35)). Tunable intensities of the excimer dependent on the pyrene number can also be observed (36).

Hybridization formats

The design of hybridization formats that enable important changes (fluorescence intensity increase or wavelength shifts) in the presence of the targets is the focus of intense research because their use can simplify the analyses in vitro and provide the possibility of applications in living organisms. The most frequently used involve binary probes (35), competitive hybridization probes (18), linear probes with only one F (2, 5, 16, 29, 31), and molecular beacons (MBs) (30-41).
Fluorescence Techniques for Nucleic Acids

Enzymatic labeling

The enzymatic incorporation of modified fluorescent nucleosides or analogs via their triphosphate derivatives is also possible using DNA polymerases (3). One of the most important examples of applying this labeling strategy concerns the methods for NA sequencing (42). More recently, a DNA sequencing method by synthesis on a solid surface has been proposed (43). This method is based on the four nucleotide 5′-triphosphates, which each contain a unique F with a distinct fluorescence emission at the base, modified at their 3′ position to be reversible terminators. This method has yielded the Solexa sequencing technology (44). However, the sequence-specific internal labeling of large DNA requires the development of other strategies as for example the use of DNA methyltransferase associated with a cofactor labeled with a F (45). A new strategy for the site-specific labeling of DNA and RNA is based on the expansion of the genetic alphabet by unnatural base pairs (46).

Selected Fluorescence Techniques and Applications

Different biological questions can be addressed using different ON probe structures conveniently labeled with a selected F that exploits the main characteristics of fluorescence, which is the most sensitive spectroscopic technique (10). Their definitions are widely reported in companion articles and will not be discussed here. The applications can be divided into different series. One application concerns synthetic FONs that mimic the different structures found in living systems and aims at structural, dynamics, and interaction studies in vitro. A closer

In vitro applications

Single-nucleotide polymorphism (SNP) analysis by fluorescence sensing and FRET

Most SNP genotyping assays detectable by fluorescence can be separated into four groups based on molecular mechanisms: primer extension, oligonucleotide ligation, invasive cleavage, and allele-specific hybridization (3, 47). Examples of specific hybridization applications are reported. Methods based on variations of the emitted light of nucleoside analogs inserted in the position opposite the mutation site on the DNA sequence to be analyzed have attracted a great deal of attention in the past few years. Most of these are based on the use of size-expanded base-discriminating fluorescent nucleosides or pyrene-labeled nucleosides. These FONs are attractive because they are easy to prepare and are cheap (2). A genotyping method without amplification of genomic DNA has been reported (34). It is based on the different conformations of a cationic polythiophene F in the presence of single- and double-stranded DNA that results in a fluorescence signal increase in the presence of the latter. Fluorescence can be enhanced via FRET by convenient labeling of

Figure 2 "The most frequently used positions for the covalent attachment of Fs onto the oligonucleotides."
Fluorescence Techniques for Nucleic Acids

Detection of terminal mismatches on DNA duplexes by fluorescence sensing
FON probes labeled at their 5'-ends with thiazole orange can discern perfect duplexes from those that involve a terminal mismatch, as well as those that involve mismatches at the penultimate or last two positions under nonstringent conditions (31).

Increasing the specificity of detection with binary probes
Duplexes of 15-25 base pairs are often too stable to be sensitive to the presence of a mismatched base pair. The division of the ON probes into two parts that lead to good selectivity of the NA recognition has recently been reported. These examples are autoligating probes detectable by FRET (19) or aptamers (37) assembled in the presence of the NA target. The formation of the complex resulted in a great increase in the fluorescence emission of the reporter molecule. A malachite green aptamer can discriminate 41 out of 42 possible single-nucleotide substitutions in a 14-mer DNA target (37).

Detection of DNA abasic site with light-up probes
The detection of an abasic site located at the central position of a 13-base pair duplex by a modified nucleobase inserted at the opposite position was signaled by a 7-fold enhancement of the fluorescence emission when compared with that of the perfectly matched duplex (38).

Detection of mRNA splicing by FRET and single-molecule spectroscopy
Two probes fluorescently labeled to undergo FRET can hybridize to areas flanking the splice sites of an RNA molecule and demonstrate a difference in FRET efficiency between spliced and unspliced mRNA as shown by both bulk solution and single-molecule spectroscopy measurements (33).

Multiplex pathogen detection
The development of a highly accessible and easily adaptable multiplex system for the detection of pathogens remains the ultimate goal in molecular diagnostic laboratories (48). By attaching the MB to bar-coded nanowires, it is possible to detect multiple target sequences with only one F (26), whereas multiplex detection by MBs in a homogeneous solution requires different F/Q pairs (20). Recently, MBs labeled with 6-FAM/BHQ-1 or Cy5/BHQ-2 quencher pairs were linked to microspheres of different sizes by a biotin-streptavidine linkage and used for the multiplex detection by flow cytometry. The average limit of detection for these beads specific for SARS coronavirus, HCV, PIV-3, and RSV was found to be 37 fmol (21).

FISH to size the telomeric sequences
The length of the telomere repeats at individual chromosome ends influences biological functions that range from aging to carcinogenesis (9). Measurements of the telomere length can be

achieved by fluorescence in situ hybridization (FISH). Recently, a flow FISH method has been developed (22).

**Probing nucleic acid structures, dynamics, and interactions**

Studies of the structural dynamics of NA in solution and their complexes are very important for the understanding of their functions in living organisms (4, 49). This research can be easily performed by using fluorescent base analogs that resemble natural ones with respect to their dimensions and hydrogen binding patterns (5). Among them, 2-aminopurine and pteridines have been used in numerous applications (5, 16). Alternatively, the covalent attachment of Fs at convenient positions of the NA to be analyzed can be performed to allow FRET to take
Detection of viral sequences by fluorescence sensing

The direct visualization of poliovirus NA in living host cells was achieved with MB, involving TAMRA as F and Dabcyl as Q, targeting the viral plus-strand RNA (25). The poliovirus plus strand was observed to display different distribution patterns at different post-infection time points in living vero cells.

The visualization of RNAs in living cells using FRET, excimer and light-up probes

Competitive hybridization probes (18), binary hybridization probes (35), MBs (40), light-up probes (29), and quenched auto-ligation probes (QUAL) (19) can be used. Among them, the quenched probe strategy offers the advantage of a decreased background signal in the absence of the RNA target. By using QUAL probes, mRNAs as well as 28S ribosomal RNA were detected in HL-60 cells by FC and were visible by confocal microscopy (19). A cell membrane-permeant couple of MBs designed to produce FRET in the presence of the target sequence was successfully used to detect human GAPDH and surviving mRNAs in living cells (41). Oligo-α-thymidylates that involve thiazole orange at the internucleotidic position were used to visualize the mRNAs intracellular distribution in HOS cells (29). The accurate detection of mRNA in living cells with F-ON probes requires homogenous distribution of the F-ONs throughout the cells. To make visible the cytoplasmic mRNAs in living cells, MBs were linked to bRNA (53).

Summary

In this article, we have attempted to show, through a few examples, the power of fluorescence strategies based on fluorescent oligonucleotides to study nucleic acids. This process has been made possible through chemistry that makes the synthesis of fluorescent oligonucleotides possible with the required properties suitable for experiments in varied formats including living cell experiments. We apologize to authors whose work has inadvertently not been cited. It is our hope that this article will stimulate further reading and help the design of new strategies.

Regulation of gene expression plays a central role in controlling and shaping the functions of a cell. Tools for quantification of the expression of individual genes have been available for years; but over the past decade, development of the microarray technology and accompanying bioinformatics tools has made it possible to generate comprehensive overviews of the transcriptional events in both diseased and normal cells and tissues. This review covers various approaches for transcript profiling from single genes to more global analyzes approaches. In addition, a detailed description of different microarray-based technology platforms will be provided, which all enable an essentially genome-wide characterization of the transcript levels. We also discuss the current challenges and future trends within transcriptional profiling, and we introduce briefly the next generation DNA sequencing technology that will enable a more detailed description of the entire transcriptome, which includes various small RNA species (e.g., microRNA) and other noncoding transcripts.

Transcription is the essential cellular and biochemical process that links the genetic information encoded in the genome (DNA) to the functionally active macromolecules, proteins, which carry out most tasks in a cell. Transcription generates an RNA transcript, and the process is regulated at multiple levels, which includes both synthesis and degradation of the transcript. To understand the complexity of this mechanism and to connect the process to the phenotype of an organism, we need to measure the transcript levels accurately under various situations and samples. In many cases, it is advantageous to do this in a genome-wide and unbiased manner.

Biologic Background

The central dogma of molecular biology states that genetic information flows from genes, via RNA, to proteins. In this flow of information, messenger RNA (mRNA) is generated in a process called transcription and is subsequently processed to yield a mature transcript. The transcriptome is the combined set of all transcripts present in a cell at a certain time, but it should be noted that mRNA is only a minor component of the entire RNA population of a cell. The cell contains highly abundant ribosomal RNA, transfer RNA, microRNA, small nuclear RNA, small nuclear RNA, and additional rare types of RNA, but the focus of this review is on the protein-coding mRNA transcripts. The maturation of these protein-coding transcripts consists of several distinct steps, all of which are regulated specifically (Fig. 1)

For years, it was assumed that the rate of RNA synthesis was the rate-limiting step that controls indirectly the amount of protein synthesized. However, this simplistic view has been replaced by results clearly showing that mRNA and protein levels do not always correlate fully, and that extensive regulation of mRNA transcript processing and availability for translation occurs.

A typical human cell contains approximately 300,000-500,000 transcripts, and most genes are transcribed at low to moderate level, whereas only a small number of genes encode for a large number of transcripts. The underlying assumption of most transcript profiling studies is that the pattern of mRNA transcripts in a cell at a certain time can be used to explain the phenotype of the cell and the activities within the cell. For
example, by comparing a cancer cell with a normal active pathway, signaling mechanisms in the cancer cells can be identified; in the next step, we can attempt to alter these pathways in treatment of the cancer.

Interestingly, another level of complexity has been added by research during the last few years that has shown that only a fraction of the transcribed loci generate protein-coding transcripts and that almost the entire genome is transcribed (1, 2). Even though these transcripts do not code for a protein, they may be functional in other ways; therefore, they constitute interesting target transcripts that may be analyzed using the same approaches as the protein-coding transcripts. This review will focus on analysis of the protein-coding transcripts, but it should be kept in mind that the same tools can be used to analyze of many other types of transcripts and RNA molecules as well.

This review is sectioned in the following way; a brief overview of the various approaches for transcript profiling is given in the section on Tools and techniques. In the section on Microarray-based transcriptional profiling, we provide a detailed description of the microarray technology, which enables essentially a genome-wide characterization of the transcript levels. The last chapter discusses the current challenges and future trends within transcriptional profiling.

Tools and Techniques

Essentially every cell in an organism is, at any given time, transcribing thousands of its genes in various quantities. As described in the previous section, the amount of an mRNA transcript is regulated, and an interest exists, from both basic science and clinical perspectives, in quantifying the transcripts levels accurately. The available techniques can be divided broadly into either gene-by-gene methods (see sections on Northern blot and Quantitative real-time RT-PCR) or global methods (see sections

![Diagram of gene expression processes](image-url)
on Sequencing-based transcriptional profiling and onward). The gene-by-gene methods aim at high-accuracy quantification of a low number of transcripts, whereas the global methods aim at a highly parallelized quantification of many transcripts, often even genome-wide. The focus of this review is on the microarray technology, which is the most widely used technology for genome-wide transcriptional profiling (see the section on Microarray transcriptional profiling). The other techniques are reviewed briefly below.

Northern blot

The northern blot technique allows quantification and size determination of a transcript in a complex mixture (e.g., the entire transcriptome) first by separating the transcripts by denaturing agarose gel electrophoresis, followed by a transfer to a membrane strip and hybridization with a labeled probe. Historically, Northern blotting has been used widely, but during the recent years, a shift toward more sensitive methods has taken place. These alternative methods are often less sensitive to RNA degradation, and they have a wider dynamic range.

Quantitative real-time RT-PCR

Quantitative real-time reverse-transcription PCR (qRT-PCR), which is the current “gold standard” for high-accuracy transcript profiling, provides superior sensitivity for analysis of transcript levels compared with other methods. A complex mixture of total RNA is converted to cDNA using reverse transcriptase with either random or gene-specific priming. Next, a 100–200 bp fragment is PCR-amplified using gene-specific primers that often target two different exons of the transcript, and the accumulation of the amplicons is monitored in real-time using a fluorophore that either specifically targets the amplicon and the accumulation of the amplicons is monitored in real-time or any double-stranded DNA. Theoretically, during an exponential phase of the amplification, each PCR cycle doubles the amount of product, which in log2 scale corresponds with a linear increase. Extrapolation of this linear increase back to the base-line level provides an estimate of the initial starting amount of mRNA.

Using qRT-PCR has many advantages, which makes it the method of choice for high accuracy—but low throughput—gene expression analysis for the following reasons: 1) it offers, at its best, a dynamic range of 7–8 log orders of magnitude; 2) it can achieve single-copy detection; 3) it can be carried out in one step; 4) it has low coefficients of variation facilitating detection of small differences between samples; and 5) design of specific amplicons allows for discrimination between similar transcripts, such as transcript isoforms or different gene family members. The drawback of the method is that genes must be targeted individually. Therefore, a large-scale approach is not feasible.

Sequencing-based transcriptional profiling

Recently, several platforms for high-throughput sequencing have been developed (see section on Next generation of sequence technologies), and these platforms offer an impressive improvement of the number of bases sequenced compared with previous technologies. However, use of standard capillary sequencing has also provided means for large-scale sequencing-based transcript profiling, albeit at lower throughput levels. These different sequencing-based methods are outlined briefly below and are discussed in more detail elsewhere.

Expressed sequence tag analysis

Expressed sequence tag (EST) sequencing generates random, 200–900 bp single-pass sequences of cDNA clones. The initial purpose of these sequences was to facilitate gene detection, but the technique has been used subsequently to estimate gene expression levels. The underlying assumption is that the EST sequences are generated randomly, and hence the EST counts correspond with the transcript’s abundance in the original sample. The main drawback is the low throughput (number of counts) caused by the high data generation costs (library generation and sequencing). Given that gene expression levels follow a distribution with many genes expressed at low levels and a few genes expressed at high levels, transcript profiling that uses EST technology enables reliable detection only of a small number of genes expressed at moderate or high levels.

Serial analysis of gene expression

Serial analysis of gene expression (SAGE) (10) was the first approach to provide large-scale absolute estimates of transcript frequencies, and it relies on a biotinylated primer, streptavidin-coated beads, and type IIIs restriction endonucleases that cleave outside the recognition site to generate short tags of each transcript. The tags are concatenated and sequenced using standard sequencing technology to derive a digital representation of the transcript frequencies (counts). In the original approach, SAGE was used to isolate approximately 14-bp 3′ tags, but the method has been later modified to allow for isolation of 5′ tags and of longer 26-bp tags.

Cap analysis of gene expression

Cap analysis of gene expression (CAGE) (11) uses 5′ trapping methods to isolate full-length cDNA s selectively and generates 20-bp tags from these. After isolation, the tags are ligated to yield ~700 bp of concatenated sequence, which is cloned into a vector and sequenced. The first-strand synthesis can be primed with random primers, which allows for analysis of polyA-negative transcripts. Recently, CAGE has been used for large-scale transcription start site mapping (12).

Massive parallel signature sequencing

In massive parallel signature sequencing (13), 3′ sequences of each transcript are isolated using biotinylated primer in the cDNA synthesis and are cleaved with a restriction enzyme that generates a cohesive end. Next, the 3′ signature sequences are...
ligated into specifically designed plasmid vectors that contain 32-nt oligonucleotide tags (in total 16.8 × 10^9 different tags), and amplified using PCR. Use of a large number of tags provides a unique tag for each 3' signature sequence, which is subsequently coupled to a 5-µm microbead. Each bead contains one type of capture tag complementary to one of the 32-nt oligonucleotide tags. Next, the captured signature sequences are sequenced on beads to yield 16–20 nt signature tags, which are counted to derive a global estimate of transcript levels.

Next generation of sequencing technologies

The technology development driven by the race toward low-cost sequencing of the entire human genome has provided the research community with new ultra-high-throughput DNA sequencers, which in the near future may open up for sequencing-based analysis to generate a global overview of the transcriptome. The new sequencing approaches include bead-based Genome Sequencer pyrosequencing instrument (454 Life Sciences, Branford, CT, USA) that produces more than 100 million bases of sequence per run, Solexa Clonal Single Molecule Array (Illumina, San Diego, CA, USA) producing up to one billion bases of sequence per run, and also the SOLiD sequencing chemistry (Applied Biosystems, Foster City, CA, USA) producing read lengths of almost 40 nt.

Common for all these techniques is that they are based on random fragmentation of the sample to be analyzed (e.g., a genome), ligation of adapter molecules to both ends of the fragment, and an amplification step (e.g., emulsion PCR for Genome Sequencer and the SOLiD technologies) on a solid-phase surface. This step is followed by the actual sequence reading step that is based on detection of fluorescence (Solexa and SOLiD technologies) or emitted light (Genome Sequencer) using a CCD camera. The large amount of data generated is a consequence of millions to tens of billions of sequence reads (10–300,000 for Genome Sequencer, tens of millions for SOLiD and Solexa). The read lengths are however significantly longer for the Genome Sequencer (200–300 nt) than for the other two technologies (25–35 nt). All platforms are expected to be improved in the near future.

In addition to de novo and whole-genome resequencing, all these technologies open up also for large-scale transcriptome analysis, possibly in combination with the approaches described above. For example, the Genome Sequencer platform has been used in several transcriptome analysis studies (http://www.454.com/news-events/publications.asp?cat=4).

Microarray technology

Since the first publications in 1990s (14–16), the use of the microarray technology for transcriptional profiling has become widespread with more than 25,000 publications in the NCBI’s PubMed database. In addition, the number of microarray hybridizations in two public data repositories (see section on Data sharing) is rapidly increasing, already approaching 250,000 hybridizations. Finally, today an entire industry exists that provides resources (e.g., arrays and reagents) and analysis support for the microarray community, which brings the technology within reach of essentially every researcher.

The term “microarray” refers to a solid-phase support on which multiple capture probes have been immobilized in an ordered fashion, and which participate in a capture reaction of a specific target molecule. Microarrays are used commonly to measure levels of mRNA transcripts, microRNAs, and proteins, but also to analyze characteristics of genomes (e.g., SNPs, gene copy number changes, and larger chromosomal gains and deletions). Since their first use in the mid-1990s, the different microarray platforms have been modified and improved extensively. The fundamental underlying advantage of the technique is that a simultaneous, highly parallelized measurement of thousands of different targets is possible; in some cases allowing for analysis of all known protein-coding transcripts.

A detailed description of the technology is provided in the section on Microarray-based transcriptional profiling.

In situ hybridizations

In situ hybridizations are based on labeled probes that base pair and identify target transcripts in fixed samples. This technology is the only approach to provide a snapshot of transcripts and their cellular localization. The probe is labeled either using a radioactively isotope, a fluorophore, or an antigen. After wash, the probes that hybridized to their target transcripts can be detected using autoradiography, fluorescence microscopy, or immunohistochemistry, respectively. Use of fluorescence or antigens allows for use of probes for multiple transcripts simultaneously, which allows identification of genes with overlapping expression patterns.

The in situ hybridization technique is used in several large-scale efforts to provide a comprehensive picture of the gene expression pattern in for example mouse embryos and brain (17).

Microarray-Based Transcriptional Profiling

A typical transcript analysis starts with isolation of total RNA, followed by cDNA synthesis and labeling. Next, the purified and labeled cDNA is applied onto a microarray that contains thousands of immobilized probes, hybridized, washed and scanned, and the signal for every probe estimated and analyzed (Fig. 2).

The aim of a typical microarray-based transcriptional profiling experiment is to identify target genes for downstream validation experiments, for example to identify genes that are expressed differentially after treatment with a certain compound. Likewise, the array technology can be used to verify a hypothesis, for example to verify that a compound does induce a certain expected effect. Furthermore, microarrays are used widely in various classification studies in which an initial set of samples with known “labels” (e.g., type of leukemia) are profiled, followed by a profiling of a different set of samples with unknown labels (e.g., patient biopsies) and assigning these into the previously identified classes based on their expression profile.
Typical workflow of a microarray experiment

This section describes the use of the microarray technology for transcriptional profiling. The section includes a summary of the experimental procedures (section on Experimental design), the most widely used array platforms (section on Platforms for Gene Expression Analysis), and briefly summarizes the data analysis steps, the software that can be used, and the public microarray data repositories (sections on Analysis of microarray data and Data sharing).

Experimental design

Microarray experiments should be designed to be maximally informative given a certain amount of resources, and they need to answer the primary questions of the experiment. Extensive reviews on experimental design are available elsewhere (18–20). The consequence of a nonoptimal design ranges from loss of statistical power and an increased number of false negatives to inability to answer the primary scientific question of the experiment. The number of available arrays is often determined by financial resources; therefore, one of the most important questions is to determine how to allocate the different samples to a given set of arrays (hybridization scheme) and what to replicate (e.g., biologic samples or hybridizations). In addition, selection of the array platform and the target preparation approach must be considered.

For Affymetrix (Santa Clara, CA) (see below) and for other single-channel experiments, the hybridization scheme is straightforward, but for two-channel platforms, the allocation of samples to arrays is important to prioritize the primary scientific question of the study. Furthermore, balanced designs should be used so that treatments are not confounded with technical issues such as dye assignments, batch of slides, or day of hybridization. Replication is carried out to control the three levels of variation in an experiment: biologic variation (e.g., differences between animals), technical variation (e.g., differences caused by the RNA amplification), and measurement error (e.g., uneven hybridizations). Statistical testing can be carried out on any of these levels, but interpretations of the results differ; is the purpose to analyze the difference between two mice (inference at the level of technical replicates), or is the purpose to generalize the results and to draw conclusions at the level of a population (inference at the level of biologic replicates)? It can be safely assumed that the purpose of most, if not all, experiments is to analyze differences at the population level; hence, biologic replication is essential.

Sample preparation

Direct analysis of complex samples such as unfractionated tissue is often of little value because of cellular heterogeneity. Consider bulk brain for example, which is a mixture of hundreds of different cell types. Unless a specific cell type is selected prior to mRNA extraction, the obtained gene expression profile will be a weighted average of the total gene expression of all different cell types. To enrich for a certain cell type or to obtain homogeneous samples several different approaches have been used. First, experiments can be designed to include sampling shortly after perturbation, which allows for monitoring of early events before secondary changes accumulate. Second, synchronized cell cultures can be used, which allows for analysis of cell cycle phase-specific gene expression patterns (21). Third, fluorescence-activated cell sorting that uses one or multiple fluorophore-conjugated antibodies to identify cells that express a combination of different cell-surface molecules provides a rapid and sensitive cell fractionation assay. Finally, laser-capture microdissection based on a microscopic evaluation of the sample and use of a computer-controlled laser to excise and to isolate specific cells into a collection vessel can be used.
Transcript Profiling: Tools for Transcript Profiling

Target preparation

Depending on the array platform, a labeled sample that originates from 1–20 μg of total RNA is required for each hybridization. This corresponds to 0.1–2 million cells (assuming 10 pg of total RNA per cell), which is obtainable in cell culturing studies. However, use of various sample preparation methods (see previous section) compromises the yield; hence, a target amplification method is often required. Linear T7-based in vitro transcription (IVT) typically yields 300–1000-fold amplification, and a higher amplification can be obtained by performing up to three consecutive rounds of amplification. A double-stranded DNA template that contains a T7 RNA polymerase binding site in the 5’ end is synthesized using the mRNA as template, and subsequently transcribed in a 3–12 hour isothermal IVT reaction during which the amplified accumulates RNA linearly. It should be noted that all samples used on Affymetrix arrays are subjected to IVT amplification. PCR-based exponential amplification methods are diverse and typically are based on ligation of linker sequences to both ends of double-stranded cDNA, followed by a limited number of PCR cycles to yield double-stranded DNA. Generally, these methods are assumed to introduce bias to the data because of transcript-length dependent or base composition differences in amplification efficiencies. To circumvent this problem, approaches have been developed that restrict the length of the template and make it more uniform (24, 25). The advantage of PCR-based methods over linear IVT methods is that a much faster and a higher amplification is achievable (26). Comprehensive literature reviews of target amplification approaches are available (27, 28).

Labeling using fluorophores is typically carried out in a prehybridization fashion for the spotted array platforms, and in a posthybridization manner for the Affymetrix platform. For Affymetrix arrays, biotin-modified nucleotides are incorporated into the aRNA, during the IVT step, and the dye coupling is carried out after hybridization using phycocerythrin-streptavidin and biotinylated anti-streptavidin-antibody conjugates. For spotted arrays, target labeling and incorporation of the fluorophore can be carried out either directly (the fluorophore is attached to the nitrogenuous base of one of the nucleotides) or indirectly (the fluorophore is attached to modified nucleotides after cDNA synthesis using a chemical coupling). Direct labeling is often affected by incorporation difficulties and differences in efficiency between the dyes. Indirect labeling avoids these problems by using only one type of modified nucleotide in the cDNA synthesis. Alternatively, an emerging approach, based on labeled platinum conjugates, can be used to label the RNA or DNA chemically (28). The possibility to omit all enzymatic steps makes this approach interesting and promising.

Hybridization

In the hybridization of the labeled target to the immobilized probe and subsequent washing, two opposing forces need to be balanced—too stringent conditions develop low signals, whereas too unspecific hybridizations yield compressed ratios with little differential expression. An extensive analysis of the conditions is beyond the scope of this review, but the main parameters that must be considered are probe length, hybridizations buffer composition, hybridization temperature, duration of hybridization, mixing, and wash stringency.

Scanning and image analysis

Typically, spotted microarrays are scanned at 5- or 10-μm resolution one channel at a time, which generates two 25-100 Mb 16-bit images. To facilitate the image analysis and visualization, the two images are overlaid to generate one 24-bit RGB pseudo-color image with the red, green, and yellow spots associated commonly with microarray data. Affymetrix arrays are scanned using only one wavelength. After scanning, and irrespective of array platform, the purpose of the image analysis step is to separate foreground and background pixels, to derive an estimate of the gene expression level for each feature, and to calculate various intensity and quality-control parameters (30). The background intensity is considered to represent the contribution of nonspecific hybridization to the slide surface and to the immobilized DNA. Various correction approaches have been described to account for this binding, but it should be noted that the subtraction issue is controversial, and the effect may vary depending on the dataset being analyzed (31).

Platforms for gene expression analysis

Multiple platforms are available for high-throughput, microarray-based, genome-wide transcriptional profiling. They mainly differ in the type of probe attached to the surface, the number of target samples that can be hybridized on each array, and the principal expression measurement (ratio for two-channel arrays and absolute level estimate for single-channel experiments). In addition, the target labeling and hybridization, image analysis, and initial low-level data analysis aspects often differ. At the high-level data analysis stage (where biological inference is sought), the data analyzes for the different array platforms converge, and the approaches and the interpretation of results generated are similar.

Several different microarray platforms have been compared in the Microarray quality control project using commercial RNA samples. This comprehensive study of reproducibility and variability, both within and between different microarray platforms, stated clearly that the data obtained using the microarray platform is generally of high quality. The study also included a large-scale analysis of the expression levels by quantitative RT-PCR, and these results allowed first time the microarray technology to be benchmarked against the current, “golden standard” technique (32).

The next section describes briefly the platforms that are used most widely for transcript profiling, starting with the two-channel platforms.

Spotted cDNA arrays

The relatively low cost of cDNA array production and the access to thousands of EST clones in the freezers in many laboratories and the commercial distribution of EST clone collections propelled the early development and popularity of the cDNA arrays in the late 1990s (15). The arrays are generated through PCK-amplification of cloned 200–4000 bp insert sequences using vector-specific primers. The double-stranded amplicons are

then purified (ethanol precipitation or filter plates), printed, and immobilized on coated glass slides. To avoid plate-handling errors, rigorous quality control steps, which include complete, partial, or random resequencing, and aarsene gel electrophoresis analysis of the purified clones is advantageous, but it is labor-intensive and costly.

The general advantages of the spotted cDNA arrays include the following: 1) the low cost of arrays that allow for design of experiments with extensive replication, 2) the possibility to use two-color detection and thereby reducing the number of arrays, 3) large-scale clone collections are widely available from multiple sources, 4) they are compatible with most target amplification protocols, and 5) they include established laboratory protocols. The drawbacks (many of which are shared with oligonucleotides and Affymetrix arrays, see below) include: 1) unspecific target-probe interaction because of long probes, 2) false negatives caused by drop-outs during probe preparation or array printing, 3) batch-to-batch variability in array production, 4) incomplete transcriptome coverage, 5) uncertainty over which region or isoform of a transcript is targeted with a given probe (the complete probe sequence is rarely known), 6) difficulties in maintaining high-quality probe collections (avoidance of evaporation, well-to-well contamination, plate rotation, etc.), and 7) confounded measurement of sense and antisense transcripts.

Spotted long-oligonucleotide arrays

Spotted arrays with (50–90 nt) oligonucleotides have been available for several years, and they offer a higher specificity than is achievable using the cDNA arrays. Using publicly available genome sequences, oligonucleotides are designed in silico for each gene in a genome. The melting temperatures are also taken into account to achieve uniform hybridization conditions. Typically, the oligonucleotides are bought presynthesized and are dissolved in appropriate printing buffer and printed. Use of presynthesized oligonucleotides offers several advantages. First, probes can be generated for any organism given that its genome sequence and gene predictions are available. Second, the probes are targeted to specific regions of genes, which allows for some differentiation of splice variants. Third, clone handling is reduced, minimizing the risk for plate or clone handling errors. Fourth, replacement plates are easy to obtain. Last, the probes are designed to have the same sense as the mRNA; hence, they are complementary to the labeled cDNA generated from the mRNA, and a confounded measurement between sense and antisense strands is avoided. In addition to many of the drawbacks listed for cDNA arrays (see points 2, 3, 4 and 6 in cDNA array section), the initial purchase investment for oligonucleotide collections is substantial.

Affymetrix genechip arrays

Affymetrix arrays are one of the most widely used platforms for transcriptional profiling. The probes are designed in silico and are synthesized directly on the array using photolithography (33, 34). Each gene transcript is interrogated by a “probe set,” which constitutes 11–20 different 25-mer perfect match (PM) probes and their corresponding mismatch (MM) probes. The MM probes differ from their PM probes by one mismatched base in the central position that functions to destabilize the probe-to-target complementarity. Depending on the data processing approach, the intensities from the MM probes can be used to correct the signal from the PM probes, but other approaches are available (35).

Several advantages exist with Affymetrix arrays. First, arrays and operating procedures are standardized, which allows for direct comparison of data between projects and laboratories. Second, the direct synthesis of the probes on the array avoids problems with plate handling and ensures that the batch-to-batch variability is minimized. Three, small feature sizes yield dense arrays, which allows for genome-wide transcriptional profiling with multiple probes per gene. Fourth, probes are single-stranded, and nonconfounded measurements between overlapping transcripts are obtained. The drawbacks include the inflexibility in probe content caused by the initially high production costs, and sample preparation always includes linear amplification (i.e., extra enzymatic steps that may introduce bias into the results).

Recently, Affymetrix also launched their exon arrays (i.e., arrays that use multiple probes to target essentially every exon of each transcript variant). This platform is the most detailed for analysis of gene expression levels, and it allows for identification of alternative splicing in addition to the standard genome-wide transcriptional analysis.

Affymetrix provides arrays that not only analyze expression levels of genes, but also interrogate the entire genome for transcriptional activity. These arrays are termed “tiling arrays,” and they contain probes that are more or less evenly spaced (approximately 35 bp) along the genome. The arrays have been used in several studies to identify extensive transcriptional activity from regions that were not considered to encode for genes. Typically, these arrays are used to provide a genome-wide transcriptional mapping or are used in chromatin immunoprecipitation studies.

Illumina’s beadarray platform

The BeadArray technology (Illumina, San Diego, CA, USA) allows for genome-wide transcript profiling using a bead-based, high-density microarray platform. The 3–5 μm beads are coated with hundreds of thousands of copies of a specific capture probe, and these beads are assembled into an array of beads on either a fiber-optic bundle substrate or planar silica slides with etched microwells. For transcript profiling arrays, the oligonucleotides are 50 nt long. Multiple beads per target transcript are used to generate a large redundancy in the data, which increases the precision of the final measurement. In addition, quality control steps in the oligonucleotide synthesis and bead attachment process ensures that the frequency of dropouts is kept low (36). In addition to transcript profiling, the BeadArray platform can also be used to analyze DNA, for example, in a comparative genomic hybridization experiment.

NimbleGen gene expression platform

NimbleGen arrays (NimbleGen Systems, Inc., Madison, WI) are similar to the Affymetrix arrays in that they have been produced using a light-directed probe synthesis approach, but they use computer-controlled micromirrors instead of masks to
The generation of the raw data is followed by an extensive analysis of the data. A detailed description of this analysis is beyond the scope of this review, but it is available in a recent review (37). Briefly, in most cases the analysis is divided into two sections: pre-processing of the data (low-level data processing) and subsequent data mining (high-level data processing). The purpose of the pre-processing is to identify and to correct for systematic and nonsystematic technical artifacts and other nonbiologic bias in the data. Steps that are typically included are correction of the hybridization background levels, exclusion of nonreliable data (e.g., dust particles on hybridization surface), log2-transformation of the data, and normalization to account for technical intra- and inter-slide differences. The high-level data mining include steps in which biologic inference are sought for; example, identification of differentially expressed genes using a moderated t-test (38, 39), identification of enriched (overrepresented) biologic themes from the Gene Ontology database (40), clustering analyzes to identify coregulated genes and patterns in the data, and various other dimension reduction and classification tools (41, 42).

A typical microarray experiment generates large quantities of data, and to analyze these data efficiently, both commercial and open-source software solutions have been developed. The open-source software have gained extensively in popularity, mainly because the availability of R packages that provide tools for analysis steps described in publications, a large user community that improves existing functions, the possibility to modify and to automate analysis steps, and the fact that the software is available at no cost. R is a programming language and an environment for statistical computing and graphics (43), and its functionality can be extended by packages such as the Bioconductor project (44), which provides a comprehensive collection of tools for all steps of microarray data analysis. TM 4 is another open-source software suite that provides an easy-to-use, java-based graphical interface (45).

Data sharing

To facilitate comparisons between experiments and especially meta-analyses, two raw data storage and exchange repositories are available: ArrayExpress, which is run by European Bioinformatics Institute (Cambridge, UK) (46), and Gene Expression Omnibus (GEO), which is run by the National Center for Biotechnology Information (Bethesda, MD) (47). Both accept submissions that fulfill the Minimum Information About a Microarray Experiment (MIAME) standards (48). The purpose of the MIAME standards is to ensure that all essential information regarding the experiment underlying a publication is available, and that the interpretation of the results can be carried out properly. An increasing number of journals are also requiring the data to be available publicly in the repositories to publish the results. Hence, it is not surprising that these repositories are widely used; ArrayExpress contains more than 2,500 experiments and over 80,000 hybridizations, whereas GEO has passed 6,000 experiments and 160,000 hybridizations (August 2007).

Practical Aspects and Future Trends

Since the early years of microarray technology, the field has matured rapidly and the technology development has resulted in numerous different platforms for genome-wide transcript profiling. With the availability of the genome sequence and gene predictions of an organism, probes can be designed easily, and arrays can be generated. In parallel with the development of the experimental platforms, tools and the statistical framework for the analysis have been developed strongly. Today, multiple excellent tools are available as both commercial and open-source software packages. The sheer magnitude of the data has also required development of data management systems that can efficiently store, back-up, and process large data sets in an efficient way. A together, during the last 15 years, the array technology has been shown multiple times to yield an accurate description of the transcriptional status of a large number of genes in a cell, but it has to be remembered that our understanding of the transcription process, the transcriptome and the central dogma itself is rapidly changing and that the transcript profiling technologies irrespective of platform need to adjust to this changing picture where new details are emerging continuously.

The new information gained on transcription of nonprotein-coding transcripts has changed the view of transcription in many ways during the recent years, and it has changed the requirements for transcript profiling. Future technology development will have to deal with improved separation of transcript isoforms, for example, to separate coding and noncoding (e.g., partial) versions of a transcript, and transcript strand assignment (i.e., sense or antisense transcription). In addition, the identification of transcription start site may be useful to understand in more detail how transcription is regulated. Furthermore, the sensitivity of the methods needs to be improved to measure transcripts of low abundance accurately.

The recently published genome of an individual human (49), together with development of the next generation of sequencing technologies, prepares ground for an exciting alternative to microarray-based transcription profiling. These new technologies have a capacity that is unmatched by the older sequencing approaches, and with extended read lengths additional information of the transcripts can be obtained, such as detailed
Transcript Profiling, Tools for

transcript isoform information. In combination with the information obtained on individual genomes, exciting possibilities to combine gene copy number variation and gene expression levels may emerge in the near future. Hence, the sequencing-based methods for transcript profiling not only will challenge the microarray-based transcript profiling methods, but also will complement them with additional detailed information of the transcripts and the genome from which they originate.

Electron Paramagnetic Resonance in Enzymology

Aimin Liu, Department of Chemistry, Georgia State University, Atlanta, Georgia

doi: 10.1002/9780470048672.wecb668

Electron paramagnetic resonance (EPR) is a versatile tool for chemical biology research. A remarkable wealth of information about the mechanistic enzymology has been obtained by EPR experiments. As an analytical method, EPR can obtain these two useful pieces of information in a study of enzymatic reaction mechanisms: 1) detection and complete description of free radicals and 2) characterization of the electronic structures of paramagnetic metal ions and their response to changes of the protein environment or substrate binding. The first feature has spurred the development of the new field known as radical enzymology; the second has enhanced the understanding of the mechanisms of metalloenzyme action. The potential of EPR spectroscopy to serve as an important biophysical tool for the future development of enzymology is highlighted by several selected examples.

Introduction

This article does not intend to be a survey of electron paramagnetic resonance (EPR) spectroscopy in chemical biology, but rather the focus is to provide an entry-level introduction to chemists who are interested in the research opportunities that EPR may provide for enzymology studies. The principles of this technique will be briefly described, as well as the breadth of the technique’s applicability to free radicals and metallo_centers in enzymology. Potential applications in the future will also be outlined.

History

EPR was first applied to biological materials in 1954 (1), 10 years after the discovery of an experimental approach to detecting electron spin resonance by the Russian physicist Zavoisky in 1944 (2, 3). This technique became useful for studying enzymes when a spectrometer that was capable of detecting about $10^{-10}$ moles of unpaired (nonbonding or “free”) electron spins in samples that contained about 0.15 milliliter of liquid water was developed by Townsend and colleagues in 1957 (4). The first successful application of this technique to elucidating the structure of substrate radicals in enzymatic reactions was in 1958 (5–7). In the ensuing 50 years, numerous seminal and classical contributions have been made to the development of enzymology by scientists employing EPR spectroscopy analytically.

Application

It is an advantage to analyze EPR samples of aqueous solution directly because the buffered solution is the most physiologically relevant condition. However, EPR samples are not restricted to samples in the solution state, gaseous and solid samples and single crystals can also be analyzed directly by EPR spectroscopy. The only absolute requirement for preparing an EPR sample is that it must contain unpaired electron spins or that such status can be achieved before EPR measurements by oxidation/reduction reactions. EPR spectroscopy can determine unambiguously free radicals that are present in the sample or radicals produced by oxidation or irradiation with light, X-rays, and γ-rays. Because paramagnetic transition metals contain unpaired electrons, EPR spectroscopy can determine the detailed geometric and electronic environment of the metal centers. This technique can also indicate the degree of molecular motion in a sample with unpaired electrons and analyze the populations in a heterogeneous sample that has two or more paramagnetic species. Its ability to focus on the paramagnetic active sites without interference from the rest of the diamagnetic species makes this technique an ideal method for mechanistic studies. Therefore, it is commonly employed in studies of the structure of enzyme active site, interactions between enzyme and substrate, conformational dynamics, electron transfer, and reaction kinetics.
Electron Paramagnetic Resonance in Enzymology

**EPR Basics**

As an analytical spectroscopic technique, EPR is similar in concept to the more widely used nuclear magnetic resonance (NMR) spectroscopy [see NMR: Overview of Applications in Chemical Biology]. In fact, EPR and NMR are complementary to each other. Both techniques detect magnetic moments, but NMR determines the chemical structures in solution, whereas EPR describes more precisely the electronic and chemical structures of a particular region of the biological system, such as electron transfer centers, metal ions, and an intermediate state of the enzyme or substrate. It is not possible to present a full description of the theory of EPR in an article with this scope. Therefore, only sufficient information is provided here to enable the readers to understand the practical aspects of this analytical tool in enzymology.

**Resonance and the Zeeman effect**

Electrons have “spin,” and when they are unpaired (or “free”), this “spin” gives them a measurable magnetic moment. In the absence of an external magnetic field, the electron’s magnetic moment will orient randomly. The electron with a spin quantum number $S = \frac{1}{2}$ can have two orientations ($m_s = \pm \frac{1}{2}$) in a magnetic field ($B_0$). Therefore, the electrons will align either parallel or antiparallel to the external magnetic field (Fig. 1). The orientation of unpaired electrons causes discrete energy levels (Fig. 2). The orientation antiparallel to $B_0$ is energetically higher than the parallel. The displacement of discrete energy levels is known as the Zeeman effect.

The two spin states ($M_s = \pm \frac{1}{2}$) of an $S = \frac{1}{2}$ electron have the same energy when $B_0$ is 0. In the presence of an external magnetic field, two discrete energy levels occur, and the electronic-Zeeman energy diverges linearly as the strength of the magnetic field increases. In the event that a constant electromagnetic radiation frequency is present, peak absorption of the energy will occur when the magnetic field strength is varied and tuned to the two spin states so that the electronic Zeeman energy matches the energy of the allowed spin transitions. At this point, resonances are observed. The detection of the first...
derivative of energy absorption of the radiation for transitions results in an EPR spectrum (Fig. 2).

For a spin \( S > \frac{1}{2} \) system, such as a system with 5 unpaired electrons each occupying an orbital, and all 5 pointing upward (i.e., in high symmetry), application of an external magnetic field yields uniformly spaced multiplet splitting of energy levels at \( \Delta E = \mu_B H \) for an unpaired electron with spin \( S = \frac{1}{2} \). This energy difference is predominantly because of the interaction of the sample’s unpaired electrons with the external magnetic field, and each \( M_s \) converges to a common origin at zero field. If the electrons are in an asymmetry environment, for example, some point upward and some downward, then the energy levels may not be uniformly spaced. A measurable parameter, zero-field splitting, has been introduced to describe the energy-level splittings of an electron spin (\( S > \frac{1}{2} \)) in the absence of an applied magnetic field (see the materials in the Further Reading section).

**g-factor**

The difference between the energies of the unpaired electron in the initial and final spin states of an allowed transition is \( \Delta E \), which can be described by the fundamental equation of EPR spectroscopy:

\[
\Delta E = h \nu = g \mu_B B_0
\]

where \( h \) is Planck’s constant \((6.6260695 \times 10^{-34} \text{ J s})\), \( \nu \) is the electromagnetic wave of frequency, \( \mu_B \) is the Bohr magneton \((9.2740093 \times 10^{-24} \text{ JT}^{-1})\), and \( g \) is the electron Zeeman factor. Equation 1 shows that \( \Delta E \) is proportional to \( B_0 \), a constant in a sample during an EPR measurement. The interaction between the electron and the nearby nuclei is called hyperfine interaction or hyperfine coupling. Such an interaction would cause additional splitting of the energy levels of unpaired electrons and, in turn, would produce multiplicity in EPR spectrum that requires spin Hamiltonian terms to describe the coupling of the spin system (see the Further Reading section). However, the number of the spectral lines in the EPR spectrum can be predicted by the following simple formula:

\[
g \propto \frac{n}{I+1} + 1
\]

where \( n \) is the number of the equivalent nuclei, that being coupled to and \( I \) is the nuclear spin number. Table 1 summarizes the nuclear spin of common elements that may be used in analyzing EPR data.

At 9.5 GHz, which is in the X-band frequency range, the magnetic field where the EPR signal should occur for a free electron can be calculated from Eq. 3, for example, \( B_0 = 714.4775 \times 2.002 3193 \times 9.5 \approx 3390 \text{ Gauss} \).

\[
B_0 (\text{Gauss}) = \frac{714.4775 (\text{Gauss}/\text{GHz})}{\nu (\text{GHz})}
\]

The value of \( g \)-factor is a measure of the coupling between the spin of an unpaired electron and an external magnetic field. It is not only dependent on the spin species but also on its environment. A single numerical value of \( g \) is applicable only to systems that behave isotropically. With anisotropic systems, a modified term that accommodates the variability of \( g \) with orientations relative to the external field is introduced as \( g \)-tensor. Three values, \( g_x \), \( g_y \), and \( g_z \), which represent principal \( g \)-values, \( B_{xx} \), \( B_{yy} \), and \( B_{zz} \) values of the \( g \)-matrix, are important EPR parameters.

**Hyperfine coupling**

The actual field at each spin species is not necessarily only the externally imposed magnetic field. In addition to this field, local fields from nearby nuclei may add to the external field. Nuclei can also have spins, and they possess an intrinsic spin angular momentum. It is common practice to represent the total angular momentum of a nucleus by the symbol \( I \) and to call it “nuclear spin.” Nonzero nucleus spins affect the local magnetic field where the unpaired electrons are located in a sample during an EPR measurement. The interaction between the electron and the nearby nuclei is called hyperfine interaction or hyperfine coupling. Such an interaction would cause additional splitting of the energy levels of unpaired electrons and, in turn, would produce multiplicity in EPR spectrum that requires spin Hamiltonian terms to describe the coupling of the spin system (see the Further Reading section).

However, the number of the spectral lines in the EPR spectrum can be predicted by the following simple formula:

\[
\text{Hyperfine splitting lines} = 2nI + 1
\]

where \( n \) is the number of the equivalent nuclei, that are being coupled to and \( I \) is the nuclear spin number. Table 1 summarizes the nuclear spin of common elements that may be used in analyzing EPR data.

Figure 3  Energy-level diagram and corresponding EPR signals at 9.6 GHz (X-band) with maximized resolution for an unpaired electron in an imposed magnetic field that interacts with a) a proton (nuclear spin I = ¹/₂), b) a ¹⁴N nucleus (I = ¹), and c) a ¹⁴N nucleus in which the energy levels are additionally split by a nearby proton. The spectra were produced by the EPR simulation program SimFonia for illustration of the hyperfine splitting purpose.
the hyperfine splitting lines = (2 × 1 + 1)2 × 1/2(2 + 1) = 2 × 3 = 6. These spectral lines are not always fully resolved. They could partially overlap, which would result in an EPR signal with a hyperfine structure.

An important EPR parameter, hyperfine coupling constant, A, is required to describe the hyperfine interaction. The A values can be obtained directly from EPR spectra whose equally spaced spectral lines are exhibited because of the hyperfine interactions (Fig. 3). In many cases, a matrix, known as A tensor, is required to describe the A values for a more complex anisotropic system.

Because of the hyperfine interaction, EPR is very sensitive to the local surroundings. From a chemical standpoint, this property provides a wealth of information such as the identity and number of atoms that makes up a molecule or complex and their distances from the unpaired electron. This information can often be translated, in favorable cases, into the molecular structure of the sample.

Much of the information EPR provides about the composition, structure, and bonding of a paramagnetic metal center is obtained through the analysis of the hyperfine coupling constants that represent interactions between the spin of the unpaired electron(s) and the spins of nuclei associated with the metal center. These coupling constants are calculated from splittings seen in the EPR spectrum. In many occasions, the splittings are not resolvable in conventional EPR spectroscopy. Advanced EPR spectroscopy, such as electron nuclear double resonance (ENDOR) and electron spin echo envelope modulation (ESEEM) spectroscopy, are necessary to retrieve the missing information (10). ENDOR and ESEEM provide an NMR spectrum of those nuclei that interact with the electron spin of the paramagnetic center, and such spectra display orders-of-magnitude-better resolution than the EPR spectrum of the center. Resolved features in these NMR spectra are characterized by frequencies, and these frequencies directly give the electron-nuclear coupling constants (see the materials in the Further Reading section).

Detection and characterization of enzyme-based free radicals

In the past three decades, evidence for enzyme-based protein radicals as the catalytic driving force or the key transient intermediate in enzymatic reactions has strengthened (11). Spectroscopic data from EPR suggest that these highly reactive species can be stored with remarkable stability inside an enzyme either as a transient intermediate or as a paramagnetic center and catalyze a wide range of biological reactions in electron transfer and oxidation/reduction.

It was not known that a protein could harbor a stable free radical derived from an amino acid residue until the discovery of the first tyrosyl radical from the smaller R2 subunit of the *Escherichia coli* ribonucleotide reductase (RNR) in the 1970s. RNR catalyzes the first committed step in DNA synthesis by reducing the hydroxyl group of all four types of ribonucleotide to produce the corresponding deoxyribonucleotides (12). RNR, thus, is an essential enzyme for all living organisms. The observation of an EPR signal with an asymmetric doublet centered at $g = 2.0047$ in the EPR spectrum and a sharp absorption peak at 410 nm ($\epsilon = 3250 \text{ M}^{-1}\text{cm}^{-1}$) of the optical spectrum led to the identification of a protein-based radical (13). This free radical has a half-life time of a matter of days at room temperature and is an integral part of the R2 subunit. It is essential for the enzyme activity. RNR, thus, has been introduced as “a radical enzyme” (14). Later, it was discovered that a transient cysteine-based thyl radical is formed at the expense of the tyrosyl radical during catalysis and that the transient thyl radical is responsible for the catalytic reduction of the ribonucleotide substrates (15, 16).

It would be expected that all tyrosyl radicals have similar spectroscopic properties; however, the characterized tyrosyl radicals exhibit distinct spectral features. From a spectroscopic point of view, at least three different EPR signals for tyrosyl radicals are found (Fig. 4). The EPR signal shown in Fig. 4a (trace a) is observed in the active form of E. coli RNR R2 protein, which exhibits a 1.8 mT hyperfine splitting (13). EPR signals similar to trace b have been found in *Mycobacterium tuberculosis* and *Salmonella typhimurium* RNRs, photosystem II (PSII), and many other enzyme-based tyrosyl radical intermediates (16, 19, 20). The most complex spectrum, trace c, exhibits the largest (ca. 2.1 mT) hyperfine splitting and is observed from mouse, yeast, and higher plant RNR R2 proteins. These radicals are the representative neutral tyrosyl radicals. The tyrosyl radicals in R2 proteins are stable because the free electron is delocalized to the phenyl ring and the radical center is shielded from reaction by a hydrophobic pocket.

Most known protein-based tyrosyl radicals, either stable or transient, exhibit a line shape that resembles one of the above line shapes unless they are strongly spin-coupled with another paramagnetic center, such as that found in galactose oxidase (17, 18). Although the observed EPR spectra are distinct, the differences in EPR spectral characteristics are mainly because of the dihedral angles $\theta_{xy}$ defined by the locations of the $\beta$-methylene protons, $\beta$-methylene carbon, ring carbon C1, and its 2p axis relative to the phenyl ring of the side chain (19). These dihedral angles (Table 2) can be determined from the...
Figure 4  a) X-band EPR spectra of tyrosyl free radical in (i) *E. coli*, (ii) *Mycobacterium tuberculosis*, and (iii) mouse ribonucleotide reductase R2 proteins (17). All spectra were obtained under nonsaturation conditions at 20 K. b) Spin density distribution of the unpaired electron obtained from isotope-labeling EPR studies. c) The distances between the phenolic oxygen of tyrosyl radical and the nearest Fe ion deduced from the relaxation properties of the tyrosyl radicals.

It should be noted that no structure analysis is available for the radical-containing form in the above enzymes with the exception of one radical-containing form obtained by oxidizing the existing crystals of *E. coli* R2 by H$_2$O$_2$ (22). It is rare to obtain the crystal structure of a biological radical within its catalytic site, although, indeed, some successes have been accomplished. One such case is the intermediate radical form of hydroxyethylidene-thiamine pyrophosphate (HE-TPP), which is visualized in a structure of the enzyme pyruvate ferredoxin oxidoreductase (PFOR) crystallized with HE-TPP (23). The radical is present in the structure because the thiazole ring is apparently puckered. Free radical intermediates are generally not sufficiently stable to survive crystallization and X-ray diffraction, thus EPR spectroscopy is often the most pertinent tool for comprehending the chemical properties of the radicals. Thus far, the electronic structure and orientation of the tyrosyl radicals in enzymes have all been determined by EPR-based techniques in conjunction with isotope-labeling of the radicals.

**The interaction between radical and other paramagnetic species**

EPR can often detect the interaction between radical and other paramagnetic species. The tyrosyl radical in RNR is generated by a nonheme di-iron cluster. It is visualized from the crystal structure of P700$^+$ of *H. pluvialis* at 2.8 Å resolution (24). The tyrosyl radical in RNR is in close proximity to the second Fe ion of the di-iron cluster.

$^2$Y$_D$• is one of the two tyrosyl radicals in PSII.
structures of the enzyme that the phenolic oxygen of the tyrosine is 5.3 Å away from the nearest iron ion in *E. coli* R2 and 6.8–6.9 Å in *Salmonella typhimurium* and *Mycobacterium tuberculosis* R2 proteins (24). This distance is unknown in the mouse R2 because the structure contains a partially occupied metal center (25). It is also uncertain whether the differences of the distance still exist in the tyrosyl radical-containing forms because the structures were determined in the absence of the radicals. EPR spectroscopy can be used to study these unresolved issues. Although the di-ferric center in R2 proteins is diamagnetic because of the antiferromagnetic coupling nature of the two high-spin ferric ions, the interaction of the di-iron center with the adjacent tyrosyl radical can be detected indirectly by EPR spectroscopy. When the tyrosyl radical was found in *E. coli* RNR R2 protein (α-type), it exhibited some unusual relaxation properties relative to an organic free radical that is not part of a protein. Later biochemical and biophysical studies attributed these unusual relaxation properties to the magnetic dipolar and to exchange interactions between the R2 free radical and the iron center. The interaction between the iron-centre and tyrosyl radical in mouse R2 (α-type) is strongest, whereas in *Salmonella typhimurium* and *Mycobacterium tuberculosis* R2 proteins (β-type), it is almost negligible. Therefore, the iron-radical distance must be shorter in mouse and yeast R2 proteins.

The EPR relaxation behavior can be analyzed quantitatively by measuring microwave power saturation profiles of the EPR signal of the radical at various temperatures. The EPR signal intensity increases in proportion to the square root of the microwave power until the onset of saturation of the spin system (26). The power saturation occurs when the rate of absorption of microwave exceeds the rate at which the system returns to equilibrium. A spectral parameter, *P*<sub>1/2</sub>, is used to describe quantitatively the microwave power saturation profile. In the RNR tyrosyl radical case, the *P*<sub>1/2</sub> values at four representative temperatures are given in Table 3. The most straightforward interpretation for the easily saturated radical spectra with very small *P*<sub>1/2</sub> values, as seen in *M. tuberculosis* R2, is that the tyrosyl radical is minimally influenced in its relaxation by the di-ferric cluster. This finding is reverse in mouse and yeast R2 proteins. To obtain the precise distance information in a biological system, advanced techniques such as ESSEM would be more pertinent than the continuous-wave EPR spectroscopy.

Electron Paramagnetic Resonance in Enzymology

EPR Characterization of Metallocofactors

For the metalloenzymes (see Metallo-Enzymes and Metallo-Proteins, Chemistry of) with a paramagnetic metal center, NMR spectroscopy may have limitations because the lines of the nuclei near the metal are often broad (see NMR for Proteins). X-ray crystallography reveals the location of atoms when the diffraction quality of crystals is obtainable; however, it does not illustrate the electronic structure, the oxidation state of the metal ion, and the charge distribution, which are the real determinants of the activity of active site in metalloenzymes. Therefore, even with the crystal structure, information about transient or intermediary steps still is needed to understand electron or atom transfer mechanisms and enzymatic reactions. For this purpose, spectroscopy is indispensable, and for obtaining information about paramagnetic centers, EPR-centered methods, including pulse techniques and the technique of electron-nuclear double resonance at high- and low-field, are uniquely suited. The application of EPR spectroscopy for the characterization of metalloenzymes has recently been reviewed in several elegant articles (see the Further Reading section). In this section, three examples will be described to highlight the potential of EPR spectroscopy for characterization of metalloenzymes.

Electronic structure of paramagnetic centers in enzymes and the response to chemical, redox, and environmental changes

In a recent combined biochemical and spectroscopic study, the RNR R2 protein from Chlamydia trachomatis (Ct), a human pathogen, is shown to employ a novel enzyme-bound MnIVFeIII cofactor to initiate catalysis in the R1 protein (33). This heterodinuclear cofactor exhibits an S = 1 ground spin state, which results from antiferromagnetically coupling of the MnIV (d3, S = 3/2) and FeIV (d5, S = 5/2) ions (34). It is reduced to an EPR-active MnIIIFeII form when the Ct R2 protein is treated with the substrate analog 2'-diphosphate (N3-ADP) in the presence of R1 and adenosine triphosphate (ATP) (33). This observation suggests that the MnIVFeIII cofactor can generate protein and substrate radicals in the R1 site during the catalysis. The MnIVFeIII cluster is proposed, therefore, to be a functional equivalent of the MnIVFeIV cluster capable directly to the iron-sulfur center. Using advanced EPR spectroscopic techniques (see the Further Reading section), the EPR spectrum of the MnIIIFeIII form is centered at g ≈ 2 region (1.86, 1.92, 2.00). A similar observation of substrate/cofactor-induced EPR-silent activase (37). The fully reduced activase is proposed to contain an all-ferrous [4Fe-4S]0 cluster because it is a diamagnetic and EPR-inactive. When the activase is reduced by dithioate or a photochemical reductant, a typical low spin spectrum changes, for example, increased rhombicities and distinct line patterns may be observed (see the Further Reading section). In the presence of SAM, the photochemically reduced adenosyl radical is also proposed to be a key intermediate in pyruvate formate lyase (PFL) and anaerobic RNR enzymes in which it produces a stable g-acytyl radical for initiating catalysis. In PFL and RNR, the iron-sulfur cluster that cleaves SAM is located in an activase protein. The resting state of the activase contains a [4Fe-4S]3+/2 cluster, which is diamagnetic and EPR-silent. The activase is proposed to be a functional equivalent of the MnIVFeIII cluster by direct air exposure (Fig. 6). The fully reduced activase is proposed to contain an all-ferrous [4Fe-4S]3+ cluster, which is diamagnetic and EPR-silent. The activase is proposed to contain an all-ferrous [4Fe-4S]3+ cluster, which is diamagnetic and EPR-silent.
Concluding Remarks

EPR data on enzymes and mechanisms have been accumulating rapidly, and the knowledge learned from EPR-centered techniques has significantly contributed to the development of modern enzymology. In this article, the background and technique of EPR spectroscopy is introduced, and a few selected topics are used to illustrate the potential of its application in two areas of enzymology.

EPR spectroscopy has been a pivotal tool in the identification, quantification, and characterization of both cofactor-derived and protein-based radicals. With the assistance of EPR spectroscopy, several important enzymes are now known to be radical enzymes, including the well-studied cytochrome c peroxidase, galactose oxidase, photosystem II, prostaglandin H synthase, pyruvate formate lyase, ribonucleotide reductase, quinoox-containing enzymes, and coenzyme B12, or SAM-dependent superfamily of enzymes. Although as a terminology “radical enzymology” was only formally introduced in 2003 (11), it was recognized long before as a major area of enzymology. EPR-centered techniques will continue to be the primary tools in the future development of radical enzymology.

The oxidation state and electronic structure of protein-based paramagnetic metal ions can also be described in great detail by EPR spectroscopy, and the structural transitions in response to substrate-binding and the redox and environmental changes can be followed by EPR spectroscopy. Therefore, this technique provides an experimental handle in the studies of metalloenzymes.

To solve more complex chemical and biological problems, EPR spectroscopy has grown into a family of techniques. In addition to the conventional X-band continuous-wave EPR spectroscopy, ENDOR and ESEEM have become popular analytic tools (see the Further Reading section). PELDOR is an emerging technique, and its value in enzymology has received considerable attention (40, 41). EPR at a very high field (HF-EPR) is expected to characterize integer spin systems with large zero-field interactions, some of which are EPR silent at lower fields. Examples of where such an approach would be useful are Mn(III) in manganese enzymes, Fe(II) in hemoglobin, Fe(IV), Cof(I) in vitamin B12-binding enzymes, Ni(II), Mo(IV) in oxidases, and W(V) in dehydrogenases (42). The combination of pulse EPR and multifrequency EPR techniques seems to be the most promising use for enzymologists who are studying the dynamics and long-distance interactions in radical enzymes and paramagnetic metalloproteins. The development and successful application of these advanced EPR techniques will continue to play an important role in the future development of enzymology.

Electron Paramagnetic Resonance in Enzymology

Electron transfer

EPR spectroscopy can serve as an efficient tool for studying the delivery of electrons between biological systems. Nitrogenase, for example, consists of an iron protein and an iron-molybdenum protein. N₂-binding and reduction take place at the iron-molybdenum protein, which contains a 3Fe-9S-Mo-X-homocitrate cofactor (FeMo-co). During catalysis, FeMo-co acquires electrons one at a time from the Fe-protein. Using rapid freeze-quench EPR, Hoffman and Seefeldt et al. have trapped and characterized several reactive intermediates of the enzyme reaction (39). The relaxation properties of the intermediates have been measured by an innovative step-annealing approach, and the information obtained has helped to assign the structure of the observed intermediates with proposed structure. The direct outcome of this work is a significant step forward in understanding the nitrogenase catalytic mechanism. The step-annealing approach employed in the nitrogenase study includes rapidly warming a sample held at 77 K to 253 K by placement for a fixed time in a methanol bath held at that temperature, quench-cooling it back to 77 K, and then collecting a 2 K EPR spectrum. These procedures are based on Davydov and colleagues’ studies of the iron-oxygen intermediates that are directly generated in an EPR sample at 77 K by radiolytic cryoreduction (39).

The oxidation state and electronic structure of protein-based paramagnetic metal ions can also be described in great detail by EPR spectroscopy, and the structural transitions in response to substrate-binding and the redox and environmental changes can be followed by EPR spectroscopy. Therefore, this technique provides an experimental handle in the studies of metalloenzymes.

To solve more complex chemical and biological problems, EPR spectroscopy has grown into a family of techniques. In addition to the conventional X-band continuous-wave EPR spectroscopy, ENDOR and ESEEM have become popular analytic tools (see the Further Reading section). PELDOR is an emerging technique, and its value in enzymology has received considerable attention (40, 41). EPR at a very high field (HF-EPR) is expected to characterize integer spin systems with large zero-field interactions, some of which are EPR silent at lower fields. Examples of where such an approach would be useful are Mn(III) in manganese enzymes, Fe(II) in hemoglobin, Fe(IV), Cof(I) in vitamin B12-binding enzymes, Ni(II), Mo(IV) in oxidases, and W(V) in dehydrogenases (42). The combination of pulse EPR and multifrequency EPR techniques seems to be the most promising use for enzymologists who are studying the dynamics and long-distance interactions in radical enzymes and paramagnetic metalloproteins. The development and successful application of these advanced EPR techniques will continue to play an important role in the future development of enzymology.

NMR for Proteins
Biologists and chemists are increasingly turning to fluorescence to investigate proteins. Not only is fluorescence detection highly sensitive, but it can also report specific information about a range of properties of proteins. For example, fluorescence can be used to probe the environment of fluorescent molecules, interactions with other proteins, and the motions of proteins over time scales from picoseconds to seconds. This article surveys the properties of biologic fluorophores that can be used to study proteins and introduces the fluorescence techniques commonly applied to proteins, with an emphasis on the information generated. Techniques discussed include steady-state emission, time-resolved detection, fluorescence anisotropy or depolarization, energy transfer, fluorescence correlation spectroscopy, single-molecule spectroscopy, and fluorescence imaging.

Fluorescence is the basis for elegant and sensitive tools for studying proteins. Its applications range from detection of proteins at concentrations as low as single molecules to characterization of protein structure and dynamics. Since Gregorio Weber pioneered protein fluorescence studies in the 1950s (1), biologists and chemists have increasingly turned to fluorescence to probe the properties of proteins. Two fundamental reasons exist to use fluorescence. First, fluorescence is one of the most sensitive detection methods known. Second, fluorescence signals report a wealth of information on protein structure, dynamics, and interactions. This chapter contains a survey of fluorescence techniques with an emphasis on the information generated relevant to proteins. Additional surveys can be found listed in the Further Reading list. More focused review articles are referenced in the context of specific methods or techniques.

**Biologic Fluorophores**

Fluorescence measurements on proteins require both an appropriate fluorescence technique and the presence of a suitable fluorophore. The techniques used for the application of fluorescence to proteins are described later in this article. In this section, we briefly consider three classes of fluorophores that are used widely to study proteins: native fluorophores including fluorescent amino acids, extrinsic fluorescent labels, and autofluorescent proteins. Each has advantages for probing proteins and has distinct drawbacks: No perfect fluorophore exists for studying proteins.

**Native fluorescent amino acids**

The use of fluorophores intrinsic to the protein allows researchers to probe protein structure and dynamics without incorporating non-native fluorophores that could perturb the native structure of the protein. Proteins usually contain one or more fluorescent amino acids, which makes dynamic studies on the native protein feasible. Often, fluorescent amino acid residues can be introduced by site-directed mutation without altering protein structure significantly.

The three aromatic amino acids, tryptophan (Trp), tyrosine (Tyr), and phenylalanine (Phe), are the only native amino acids with useful fluorescence properties. Figure 1A shows their absorption and fluorescence spectra. Their fluorescence properties are summarized in Table 1. Note that the relative absorption coefficients increase in the order Phe < Tyr < Trp. The fluorescence quantum yields increase in the same order. The product of absorption coefficient and fluorescence quantum yield can be taken as a measure of the brightness of the fluorophore. By the standards of fluorescent dyes (see below), the brightness of all three amino acids is poor. Trp is the brightest of the three, and for proteins with a small number of Trp residues it may be possible to assign fluorescence decays to specific Trp residues. As a result, of the three fluorescent amino acids, Trp is by far the most widely exploited for its fluorescent properties. Fluorescence from Tyr is also detectable but may be masked by Trp fluorescence. Proteins often contain many Tyr residues, so it is often not possible to isolate the fluorescence from individual Tyr residues. Fluorescence from Phe is weak and not often used in fluorescence studies.
Fluorescence Techniques for Proteins

Figure 1  (a) Absorption and fluorescence spectra of fluorescent amino acids blocked with peptide bonds: N-acetyltryptophanamide (black), N-acetyltyrosinamide (green), and N-acetylphenylalaninamide (red) in aqueous solution. The absorption spectra (left) show the relative absorption strengths of the three amino acids. The fluorescence spectra (right) are normalized to the same peak intensity (see Table 1 for relative quantum yields). (b) Fluorescence emission spectra of the maleimide derivatives of four common fluorescent dyes: Alexa Fluor 488 (green), tetramethylrhodamine (yellow), Texas red (orange), and Cy 5 (red).

Although Trp fluorescence is the strongest of the three fluorescent amino acids, its fluorescence is also the most complex. The Trp fluorescence spectrum is highly sensitive to its environment. Trp residues buried in the protein tend to fluoresce at shorter wavelengths (λ<sub>max</sub> as low as 308 nm), whereas solvent-exposed Trp residues emit at longer wavelengths (λ<sub>max</sub> = 353 nm in water). The environmental sensitivity of λ<sub>max</sub> results from the large increase of the Trp dipole moment in the fluorescing excited state (denoted the 1<sub>La</sub> state). The environment surrounding Trp, including H-bonds and charged groups, can therefore tune the emission wavelength over a large spectral range (see reference 2). The fluorescence quantum yield of Trp is also highly sensitive to the environment, and depends on the distance and the orientation of the indole side chain of Trp relative to groups that quench Trp fluorescence, especially carbonyl groups of the peptide backbone. The fluorescence quantum yield of Trp is modulated further by the presence of two closely lying excited states, 1<sub>La</sub> and 1<sub>Lα</sub>. Several fine reviews of the fluorescence properties of Trp describe these properties in greater detail (see Further Reading). Although the fluorescence from Tyr residues is often less intense than the fluorescence from Trp residues, Tyr fluorescence is not complicated by the presence of two close-lying excited states, and Tyr emission spectra are much less sensitive to the
fluorescence in its reduced, NADH state) and flavin adenine dinucleotide (FAD). NADH is weakly fluorescent in water, but its fluorescence yield increases markedly on binding to a protein-binding site with an emission peak around 470 nm (3). FAD and flavin mononucleotide (FMN) are also fluorescent with an emission maximum around 520 nm, but fluorescence is quenched on binding to many flavoproteins (4).

Fluorescence labels
As described above, the intrinsic fluorophores that nature provides in proteins generally have rather low absorption coefficients and quantum yields. For many applications, brighter fluorescence probes are needed, and emission in the visible region is desirable. One way to meet these needs is by labeling with a fluorescent dye. A wide range of fluorescence probes is now available for this purpose (see Fig. 1b). A summary of the spectroscopic and photophysical properties of many fluorescence probes is available in References 5 and 6.

Extrinsic fluorophores have emerged as remarkable tools for studies of proteins in part because reactive derivatives are available to target labeling to specific functional groups in proteins. Derivatives (which include isothiocyanates, succinimidyl esters, and sulfonyl chlorides) are available to label amino groups such as lysine residues or the N-terminus of the protein. However, proteins may contain many lysine residues, which makes it problematic to label a specific site selectively. Thiol-reactive fluorescent probes (iodoacetamides and maleimides) offer more selectivity because they can be targeted specifically to cysteine (Cys) residues in proteins. Additional details about the chemistry of labeling functional groups in proteins are available from Molecular Probes (Invitrogen Corp., Eugene, OR) (5).

Often, the greatest challenge in applying fluorescence probes to proteins is the labeling procedure itself. Although the chemical conditions for effective labeling of amino groups and thiols are well established, selectively targeted labeling may require thorough characterization of the reactivities of functional groups. Proteins often have multiple Cys or Lys residues with varying reactivities toward thiol-reactive or amine-reactive probes, respectively. Under the proper conditions, it may be possible to label the most reactive site. Other strategies include site-directed mutagenesis to eliminate Cys residues from protein sites where labeling is undesired and to introduce a Cys residue at the desired location. More selective labeling motifs can also be introduced into proteins by site-directed mutagenesis. For example, a tetra-cysteine motif can be introduced and labeled with a fluorophore derivatized with biarsenical ligands (7).

Figure 2a illustrates the concepts of radiative and nonradiative decay, fluorescence quantum yield, and fluorescence decay. A molecule in an excited electronic state can relax by several channels. Molecules excited to a vibrational level in the excited state undergo vibrational relaxation (cooling, yellow arrows in Fig. 2a) to the lowest vibrational level of the excited state in a
Fluorescence Techniques for Proteins

Figure 2 (a) Jablonski diagram of photophysical processes related to light absorption and emission. One-photon (green arrows) or two-photon (red arrows) exciting a vibronic level in the excited S1 electronic state is followed by rapid vibrational relaxation in the excited state. Nonradiative relaxation of the excited state can occur by internal conversion to the ground state (blue arrow) or intersystem crossing to the triplet state T1 (gray arrow). Other processes that may deplete the excited state include photochemistry and energy transfer (light blue arrow). The excited state can also relax radiatively by emitting a photon (orange arrow). (b) Illustration of fluorescence generated by one-photon excitation (left) or two-photon excitation (right). The one-photon excitation probability is linear in light intensity, whereas the two-photon excitation probability is quadratic in light intensity and therefore occurs mostly in the focal region.

few picoseconds or less. Other nonradiative relaxation channels include internal conversion with rate constant $k_{ic}$ to generate another electronic state with the same electronic spin, or intersystem crossing with rate constant $k_{isc}$ to the triplet state T1. Other decay channels may include excited-state reactions such as electron transfer, proton transfer, or isomerization, with rate constants denoted $k_{pc}$ in Fig. 2a or electronic energy transfer to another molecule, $k_{fret}$. All processes compete kinetically with radiative decay from the excited state. Radiative decay has an intrinsic rate constant (denoted $k_r$) that can be calculated from the integrated absorption coefficient (11).

The total decay rate constant $k_f$ of the excited state is simply the sum of the rate constants for all processes that deplete the excited state:

$$k_f = k_r + k_{ic} + k_{isc} + k_{pc} + k_{fret} + \cdots$$  \hspace{1cm} (1)

where ... includes the rates of any other processes that deplete the excited state. The intensity of fluorescence is proportional to the population of excited states; therefore, after excitation the probability of fluorescence emission decays with the rate constant $k_f$. The inverse of this value is called the fluorescence lifetime $\tau_f$.

The fluorescence decay is then described by:

$$I(t) = I(0) \exp(-k_f t) = I(0) \exp(-t/\tau_f)$$  \hspace{1cm} (2)

The fraction of the decay rate that results in emission of a photon is the fluorescence quantum yield (or quantum efficiency) $\phi_f$:

$$\phi_f = \frac{k_r}{k_f}$$  \hspace{1cm} (3)

Note that if the radiative rate $k_r$ can be calculated, then the fluorescence decay rate and fluorescence lifetime follow from the fluorescence quantum yield $\phi_f$. Of course, the situation is often more complex. As will be described below, fluorescence decays for proteins often do not follow the single exponential decay model of Equation 2. The fluorescence quantum yield and Equation 3 then provide an average fluorescence lifetime.

Excitation sources

The simplest steady-state measurements of fluorescence properties such as the fluorescence emission spectrum or the steady-state anisotropy can be carried out in a standard fluorometer with excitation from a lamp source and a monochromator. Common lamp sources in commercial fluorometers include xenon lamps for excitation from the UV to the near-IR (250 nm to 1100 nm).

For many advanced fluorescence applications, the sample is excited with a laser. Lasers have several advantages over traditional lamp sources: 1) Laser beams often have low beam divergence and therefore are directed readily and focused onto a sample; 2) laser sources can generate narrow excitation bandwidths, which allows excitation of the fluorophore of interest or photoselection of a subset of fluorophores; and 3) through a technique called mode-locking, some lasers can generate extremely short pulses of light, which allows time resolution of protein dynamics on time scales from less than one picosecond ($10^{-12}$ s). The laser source selected for a given technique will depend on the wavelengths needed, the desired beam power, and, for time-resolved experiments, the required pulse width. The properties of some laser sources are summarized in Table 2.

Two-photon excitation

With intense laser pulses, new nonlinear optical phenomena are possible. The prime example is two-photon excitation (TPE). The peak power in a laser pulse from a Ti:sapphire laser (pulse width ~100 fs) can readily reach 10⁵ W or higher, with a focused intensity of 10¹⁴ W/cm². Under these conditions, excitation can occur with two photons that have half of the energy (twice the wavelength) of the corresponding one-photon transition (see Fig. 2a). The rate of TPE is given by:

\[
\frac{dN^*}{dt} = \delta(2) I^2 N^2 \cdot (hv)^2
\]

where \( N^* \) is the population of the excited states, \( N \) the population of ground states, \( I \) is the peak intensity of the laser pulse in W/cm², \( v \) is the optical frequency of the laser pulse, \( h \) is Planck’s constant, and \( \delta(2) \) is the two-photon cross section. The two-photon excitation probability also depends on the polarizations of the photons, but \( \delta(2) \) is usually given as an orientationally averaged value for linearly polarized light and an isotropic sample. The two-photon excitation spectra and cross sections have been described for fluorescence dyes (12), Trp (13), NADH and flavins (14), and GFP and other fluorescent proteins (15).

Fluorescence Techniques Applied to Proteins

Multiple parameters can be measured for fluorescence photons: count rate (or intensity), wavelength (\( \lambda \)), polarization (\( p \)), arrival time (\( t_a \)), time delay after excitation (\( t_d \)), and location (\( x_t \)) on an imaging detector. These parameters carry information about the fluorophore that includes the nature of its environment, its interactions with other molecules, and its motions. Fluorescence techniques that exploit each of these parameters are described below.
Steady-state fluorescence spectroscopy: intensity and wavelength

The most straightforward fluorescent technique is simply the measurement of the fluorescence intensity. Laser-induced fluorescence (LIF) is one of the most sensitive detection methods known. In LIF, the fluorescence intensity excited by a laser beam is used to quantify the amount of fluorophore present. When combined with a separation technique such as capillary electrophoresis, LIF is a powerful biologic analysis method. Detection limits can reach less than 100 femtomolar and potentially the single-molecule level (reviewed in Reference 17).

The fluorescence intensity resolved by wavelength constitutes the fluorescence spectrum. The wavelengths of fluorescence photons contain information about the environment of the fluorophore and the sample heterogeneity. For example, as described above, buried Trp residues tend to have blue-shifted emission bands ($\lambda_{\text{max}} < 330$ nm), whereas Trp residues partially or fully exposed to water have red-shifted emission bands ($\lambda_{\text{max}} > 340$ nm). Therefore, protein conformational changes or unfolding may be accompanied by shifts in the native fluorescence spectra. Fluorescence spectra can be measured on a standard fluorometer, which is available from many manufacturers.

Time-resolved fluorescence: time after excitation

In this section, we discuss methods that detect the time delay between excitation of a fluorophore and arrival of a fluorescence photon. The distribution of $t_i$ times constitutes the fluorescence decay profile of the fluorophore. The average time lag between the excitation event and the emission is the fluorescence lifetime $\tau$ of the fluorophore. The fluorescence decay contains information about dynamic processes that deplete the excited state (Fig. 2a). In time-resolved fluorescence experiments, the fluorescence decay is measured to gain information about these processes.

Often, experimentally measured fluorescence decays do not follow the simple single-exponential form predicted by Equation 2. In many cases, the fluorescence decays are better described by a multieponential decay:

$$I(t) = I(0) \sum_i a_i \exp(-t/\tau_i)$$  \hspace{1cm} (5)

or by a distribution of decay times

$$I(t) = I(0) \int_0^\infty a(\tau) \exp(-t/\tau) d\tau$$  \hspace{1cm} (6)

In Equation 5, $\tau_i$ is the decay time and $a_i$ is the relative amplitude for the $i$th decay component, and in Equation 6 $a(\tau)$ is the normalized distribution of decay times.

The observation of a nonsingle exponential fluorescence decay contains additional information about the nature of the system of fluorophores. Two general reasons exist for observation of nonsingle exponential decays. First, the sample may be heterogeneous, comprising different ground-state conformations or environments that have different intrinsic fluorescence lifetimes (Equation 5) or a distribution of lifetimes (Equation 6). Second, excited-state reactions may exist that are reversible (which allows return to the fluorescent state) or that generate a new fluorescent state that has a different decay rate.

A great deal of attention has been focused on the origin of nonsingle-exponential fluorescence decays in proteins. Some of the most intensely studied cases involve the fluorescence decays of the amino acids Trp and Tyr in proteins. Fluorescence decays for Trp in proteins are almost always multieponential. The origins of the nonsingle-exponential fluorescence decays continue to be debated. In proteins with multiple Trp residues, multieponential decay can be expected because of different environments and different decay times for each Trp. As with the emission wavelength, the fluorescence lifetime of a Trp residue is highly sensitive to its environment, notably the presence of quenching moieties (for example, histidine residues, disulfide bonds, or the carbonyl group of peptide bonds).

Even proteins that contain only a single Trp residue generally exhibit multieponential decays. Several hypotheses have been proposed to explain why. First, multiple conformational states may exist for the single Trp such as different rotameric configurations (orientations about the Trp $\chi_1$ or $\chi_2$ C-C bond) (18). Even in the absence of multiple rotamers, the electron-transfer quenching rate is extremely sensitive to the local environment, so a distribution of local microconformational states may cause a noneponential fluorescence decay. Other possible sources of noneponential fluorescence decay include the response of the protein and surrounding solvent to the change in dipole moment of Trp on excitation (“solvation”) (19).

Time-resolved fluorescence measurement

Two common methods exist for measuring of fluorescence decays in proteins: time-domain and frequency-domain measurements. Signals are processed by time-correlated single-photon counting (TCSPC) for time-domain measurements, or by phase fluorimetry for frequency-domain measurements. For higher time resolution, both time-domain and frequency-domain methods generally employ the same light sources and the same detectors. Although one or the other technique may have some advantages in certain applications, recent analysis showed that the two methods give essentially identical results for a series of fluorescence lifetime standards (20). More thorough treatments of TCSPC and frequency domain fluorometry are available in books cited in “Further Reading.”

TCSPC is illustrated in Fig. 3a. In addition to a mode-locked laser for pulsed excitation and a detector with high time resolution (usually a micro-channel plate photomultiplier tube capable of time-resolution of 20–30 ps), the required instrumentation includes constant-fraction discriminators to generate electrical pulses triggered by fluorescence photons and by the reference (the excitation pulse), a time-to-amplitude converter or other device to measure the time lag between reference and fluorescence counts, and a multichannel scaler to accumulate.

Figure 3
Time-resolved fluorescence techniques. (a) Time-correlated single-photon counting. The sample is excited with a short pulse of light. A fluorescence photon is detected by a microchannel-plate photomultiplier tube, which generates a voltage pulse. A portion of the excitation pulse is split off from the excitation beam and detected by a photodiode to generate a reference pulse. The time lag between excitation pulse and fluorescence photon is determined by a timer. After many counts are detected, the accumulated histogram of time lags gives the fluorescence decay convoluted with the instrument response function. (b) Illustration of the fluorescence response (solid red lines) to modulated excitation (dashed blue lines), simulated for a 1-ns fluorescence lifetime. At low modulation frequencies, the fluorescence response closely follows the modulation. High modulation frequencies generate a greater phase shift and demodulation of the fluorescence response. The phase shift and demodulation are analyzed as a function of modulation frequency to determine the fluorescence decay properties.

The histogram of lag times. Until recently, each device was a separate component. Now, it is possible to obtain the complete TCSPC electronic processing system on a single computer card. Manufacturers include Becker & Hickl (Berlin, Germany) and PicoQuant (Berlin, Germany).

In the frequency domain, fluorescence lifetime measurements are based on the phase shift and demodulation of a fluorescence signal with respect to a modulated excitation beam (21) (illustrated in Fig. 3b). For routine measurements with low time resolution, a fluorescence lamp or continuous laser source can be transmitted through an intensity modulator such as a Pockels’ cell. For high time-resolution, the modulation frequency achievable by this method is not high enough, and the method employs pulsed excitation, just as in TCSPC. The signal analysis consists in measurement of the fluorescence response at a range of frequencies (harmonics of the pulse repetition rate). The phase shift \( \phi \) and modulation depth \( m \) are given as a function of the modulation frequency \( f \) by (\( \omega = 2\pi f \)):

\[
\tan\phi(\omega) = \omega\tau_f \quad \text{and} \quad m(\omega) = \left(\frac{1}{1 + \omega^2\tau_f^2}\right)^{1/2}
\]

Accurate results require measurement of multiple modulation frequencies and fitting the resulting phase shifts and modulations to characterize the fluorescence decay. At low frequencies, the fluorescence signal follows closely the modulation of the excitation pulse. At high frequencies, the time lag between excitation produces a phase shift in the fluorescence signal, and the distribution of time lags over the fluorescence decay manifests itself as a decrease in modulation. The instrumentation required, in addition to the mode-locked laser source and detector, includes mixing and tuning electronics to detect the fluorescence response as a function of frequency.

Both TCSPC and frequency-domain fluorimetry are limited in time resolution by the response of available detectors, typically >25 ps. For cases in which higher time resolution is needed, fluorescence up-conversion can be used (22). This technique uses short laser pulses (usually sub-picosecond) both to excite the sample and to resolve the fluorescence decay. Fluorescence collected from the sample is directed through a material with nonlinear optical properties. A portion of the laser pulse is used to “gate” the fluorescence by sum frequency generation. The fluorescence is up-converted to the sum frequency only when the gate pulse is present in the nonlinear material. The up-converted signal is detected. The resolution of the experiment therefore depends only on the laser pulse widths and not on the response time of the detectors. As a result, fluorescence can be resolved on the 100-fs time scale. For a recent application of fluorescence up-conversion to proteins, see Reference 23.

Fluorescence anisotropy: polarization

Here, we discuss the polarization of fluorescence emission. The spatial orientations of emitting fluorophores determine the polarization of photons emitted. This relationship is the basis of fluorescence depolarization experiments as illustrated in Fig. 4a. When a sample of randomly oriented molecules (e.g., proteins...
Fluorescence Techniques for Proteins

Fluorescence anisotropy is generated by excitation of the sample with vertically polarized light, which excites molecules preferentially whose transition dipole is aligned with the polarization (red arrows), generating an anisotropic distribution of excited molecular orientations. The fluorescence emission is therefore preferentially polarized vertically. The fluorescence emission is anisotropic. As the fluorophores reorient, the fluorescence emission becomes depolarized, and the fluorescence anisotropy decays. Thus, the rate of fluorescence depolarization measures the rate of molecular reorientation, whether by rotational diffusion, domain motion, segmental reorientation, or local reorientational motion of the fluorophore.

Several parameters have been defined to describe fluorescence depolarization. One is the polarization, \( p \), given by:

\[
p = \frac{I_\parallel - I_\perp}{I_\parallel + 2I_\perp}
\]

Jablonski showed in 1960 that the fluorescence depolarization can be described naturally by another parameter, the fluorescence anisotropy, \( r \), defined by:

\[
r = \frac{I_\parallel - I_\perp}{I_\parallel + 2I_\perp}
\]

where \( r \) denotes the steady-state (time-averaged) anisotropy, \( I_\parallel \) is the fluorescence intensity with polarization parallel to the excitation polarization, and \( I_\perp \) is the fluorescence intensity with polarization perpendicular to the excitation polarization. Francis Perrin had derived an equation in 1926 that related the steady-state polarization \( p \) to the fluorescence lifetime. Cast in terms of the anisotropy, this equation takes on an especially simple form:

\[
r = r_0 \left( 1 + \frac{\tau_f}{\tau_r} \right)^{-1}
\]

where \( \tau_f \) is the fluorescent lifetime, \( \tau_r \) is the rotational correlation time (sometimes denoted \( \phi \)), and \( r_0 \) is the short-time limiting anisotropy. Equation 10 can be used to estimate rotational correlation times from steady-state fluorescence measurements.
One application of fluorescence anisotropy is in fluorescence polarization assays, in which steady-state anisotropy measurements are used to detect binding of ligands to proteins (24). Fluorescence polarizations assays are effective for cases in which a fluorescent ligand binds to a much larger object such as a protein. On binding to the protein, the fluorescent ligand experiences a marked increase in its rotational correlation time, which results in an increased steady-state anisotropy. The technique lends itself to high-throughput assays of ligand binding, which permits rapid screening of binding interactions and sensitive determination of binding affinities.

For time-resolved measurements, Equation 9 can be expressed in time-dependent form:

\[ r(t) = \frac{1}{\tau} \langle F(t) \rangle \cdot \langle F(t) \rangle - 1 \]  

(11)

where now the fluorescence intensity decays are measured as a function of time for parallel and perpendicular polarizations. The importance of Equation 11 lies in the relationship of the fluorescence anisotropy to the reorientation of the transition dipole moment:

\[ r(t) = \frac{1}{\frac{3}{2} d^2} \cdot \langle F(t) \rangle \cdot \langle F(t) \rangle - 1 \]  

(12)

where \( r(t) \) is the angle of reorientation of the emission transition dipole, and the brackets \( \langle \cdots \rangle \) denote the average over parallel absorption and emission transition dipole times at \( t = 0 \) (see Fig. 4b). The maximum value for the anisotropy, obtained for parallel absorption and emission transition dipole times, is 0.4, which corresponds to a rotation \( \gamma \) of 3 to 1.

The time dependence of the anisotropy \( r(t) \) depends on the underlying dynamics of reorientational motion. For rotational diffusion (tumbling) of a spherical object, the expected anisotropy decay is exponential with a rotational diffusion time given in the hydrodynamic limit by the Stokes-Einstein-Derjaguin equation. For nonspherical molecules, more complex time dependence may be detected. (For more on these topics, see the book by Cantor and Schimmel in Further Reading.)

Interesting applications of anisotropy decay for proteins often develop from tumbling of the protein as a whole, but from other reorientational degrees of freedom. These motions may include protein domain motions or segmental motions in proteins and peptides. The anisotropy decay in this case is non-single-exponential (see Fig. 4c) and takes the form:

\[ r(t) = r_0 \sum_i a_i \exp(-t/\tau_i) \]  

(13)

where \( a_i \) is the relative amplitude and \( \tau_i \) the correlation time of the \( i \)th rotational component. The slowest rotational correlation time is usually the global tumbling time of the protein. Faster rotational correlation times represent local motions. The amplitude \( a_i \) contains information about the orientational freedom available for the fast motion of the fluorophore (25).

Time-resolved anisotropy decays can be recorded by time-correlated single-photon counting. The fluorescence signals \( I_{\|}(t) \) and \( I_{\perp}(t) \) are both convolutions of the instrument response function (IRF) with the sample response and can be analyzed by nonlinear regression with iterative reconvolution of the fitting function with the IRF. In contrast, the anisotropy \( r(t) \), as calculated according to Equation 11 directly from the raw fluorescence signals, cannot be written as a convolution with an instrument function. For this reason, it is much more reliable to fit the signals \( I_{\|}(t) \) and \( I_{\perp}(t) \) directly rather than to fit \( r(t) \) to determine the anisotropy decay properties.

Fluorescence anisotropy decay can also be measured by frequency-domain methods. In this approach, the polarized fluorescence intensities \( I_{\|}(\omega) \) and \( I_{\perp}(\omega) \) are measured as a function of the modulation frequency of the polarized excitation beam. Even more information about frequency-domain anisotropy measurement and analysis can be found in the monograph by Lakowicz (see Further Reading).

Fluorescence correlation spectroscopy: photon arrival time

The arrival times of fluorescence photons contain information about correlations in fluorescence signals. Fluorescence correlation spectroscopy (FCS) (26) exploits these correlations to measure the magnitude and time scales of fluctuations in fluorescence. These fluctuations contain information about the dynamic time scales of the system and the concentration of fluorescing molecules. Correlations may span time ranges from nanoseconds to milliseconds, which extends the dynamic time window for fluorescence measurements far beyond what is achievable in fluorescence lifetime measurements. The autocorrelation function is calculated as:

\[ G(\tau) = \langle F(t) \cdot F(t + \tau) \rangle / \langle F(t)^2 \rangle \]  

(14)

where \( \langle \cdots \rangle \) is the fluctuation in the fluorescence intensity \( F(t) \) and \( \langle F(t)^2 \rangle \) here denotes the average over \( t \). The recorded autocorrelation functions are typically fit to a function that describes diffusion through a three-dimensional Gaussian observation volume with adjustable parameters, which include the diffusion time \( \tau_d \), the average number of molecules \( \langle N \rangle \) in the focal volume, and the focal volume dimensions \( r_z \).

\[ G(\tau) = \left( \frac{1}{\langle N \rangle} \right) \left( \frac{1}{1 + \frac{\tau}{\tau_d}} \right) \left( \frac{1}{1 + \left( \frac{\tau}{\tau_d} \right)^2 - \frac{\tau_z}{r_z}^2} \right) \]  

(15)

Because the magnitude of the correlation function in the short time limit is inversely proportional to the concentration of fluorophores, FCS can be used to follow changes in concentration. The diffusion time \( \tau_d \) yields the translational diffusion coefficient. If the fluorophore undergoes intramolecular dynamics or photophysical processes, then Equation 15 must be modified accordingly (27). A analysis of the autocorrelation with a modified fitting function can then provide dynamic information about these processes.
Reviews listed in Further Reading provide excellent introductions to FCS. Related techniques have been developed to detect other molecular properties. These properties include fluorescence cross-correlation spectroscopy (FCCS) (28) to detect codiffusing fluorophores and photon-counting histograms (PCH) (29), or fluorescence intensity distribution analysis (FIDA) (29) to distinguish fluorescent species according to their brightness.

Resonance energy transfer: molecular calipers

Förster resonance energy transfer (FRET) is a remarkable tool for detecting changes in the distance between two fluorophores. FRET is the nonradiative transfer of excitation energy from the excited state of one fluorophore (the donor) to another (the acceptor). It is sensitive to the separation between fluorophores on the scale of tens of Ångstroms, a distance range highly useful for proteins. The theory of dipole–dipole coupling between donor and acceptor (separated by distances that are large compared to the molecular sizes of the fluorophores) was developed by Theodor Förster. In this limit, the rate of energy transfer is given by:

$\kappa_{\text{FRET}} = \frac{1}{\tau_D} \left( \frac{R_0}{R} \right)^6$  \hspace{1cm} (16)

where $\tau_D$ is the lifetime of the donor when no acceptor is present, and $R_0$, known as the Förster radius, is the distance between fluorophores where the FRET rate is equal to the intrinsic donor decay rate (i.e., the efficiency of FRET is 50%). A detailed discussion of the theory and application of FRET to proteins can be found elsewhere in this volume.

Single-molecule fluorescence

The intrinsic high sensitivity of fluorescence detection is illustrated dramatically by the detection of fluorescence from single fluorophores. Many fluorescence techniques described above have been applied with single-molecule sensitivity. In heterogeneous samples, where a distribution of molecular properties exists (structure, dynamics, and environment), single-molecule measurements can map out the distribution, which yields information that is not readily available from bulk or ensemble-averaged measurements. Single-molecule detection sensitivity can also be applied fruitfully in cases where the copy number of molecules is low, for example in detection of proteins in the contents of single cells. Single-molecule detection is often carried out with a fluorescence microscope equipped with a sensitive detector such as an avalanche photodiode or a CCD camera. A detailed discussion about single-molecule measurements are available from several reviews (see Further Reading).

Imaging: location of emitted photons

Another area of rapid growth in application of the fluorescence techniques to proteins is in imaging of cells and tissues. Through use of an array detector such as a CCD camera with wide-field illumination or beam scanning with confocal detection, the spatial position of fluorophores can be recorded with a precision determined by the resolution of the microscope. (Single-particle tracking techniques can provide even greater precision by fitting the intensity profile of the emitted light (30).) A wide range of fluorescence techniques is now applied routinely to biologic imaging. These techniques include two-photon fluorescence microscopy, fluorescence recovery after photobleaching, fluorescence lifetime imaging, FRET imaging, and fluorescence anisotropy imaging. An introduction to topics within the broad area of fluorescence imaging techniques is available in many resources. See, for example the book by Pawley listed in Further Reading.

Förster Resonance Energy Transfer (FRET) for Proteins

Lambert K. Chao and Robert M. Clegg, Physics Department, University of Illinois-Urbana-Champaign, Urbana, Illinois
doi: 10.1002/9780470048672.wecb171

Förster Resonance Energy Transfer (FRET) is a spectroscopic technique applied throughout physics, chemistry, and biology to measure quantitatively the distance between selected locations on macromolecules and to determine the close association between interacting molecular components. Because FRET typically occurs over distances from 0.5 to 10 nm, it is especially useful for investigating many interesting biological molecular structures. It is also particularly valuable for following the dynamics and structural fluctuations of biological molecular systems. FRET can be applied in solution or under imaging conditions (such as in fluorescence microscopy, nanoscience, and even macroscopic imaging). In this article, we discuss the fundamentals of FRET. These principles apply to every FRET measurement. We present the basic rudiments and the relevant literature of FRET to provide the reader with the necessary background essential for understanding much of the past and modern literature. At the end of the article, we give a short discussion of several applications of FRET to proteins. The literature for FRET is vast, and many new applications are constantly being developed. We could not do justice to the many practitioners of FRET in such a short space, but armed with the background that is presented, we hope this basic information will help readers follow much of the literature and apply it in their own work.

The description of Förster Resonance Energy Transfer (FRET) in a form that is useful for quantitatively interpreting experimental results was first described in 1946 (1) and was later more quantitatively described by Förster in a series of publications (2–10). It has been popular and extensively used in biochemistry since the early 1950s. Many reviews have been published that cover not only the theory and analysis but also the application to protein structures. For the additional perusal of the reader, we list here some selected classic general overviews and discussions of the theory and analysis (11–52). These reviews contain many references to the literature that deal with specific topics, including proteins. In this article, we will concentrate on a discussion of the physical basis of the FRET mechanism and will present a few applications from the literature to determine macromolecular structures. The initial applications of FRET were by physicists and physical chemists. They dealt mainly with solution studies of freely diffusing molecular chromophores and with solid structures. But already in the early 1960s, the power of applying FRET to biological systems was realized: for instance, applications to proteins (16, 20, 23, 34) and to nucleic acids (53, 54). By this time, the theory had been fully developed and tested; however, the applications were hindered by the limitations of a choice of suitable chromophores that could be attached covalently to specific sites of the structures. Thus, many original applications were carried out using either intrinsic chromophores (tryptophan or tyrosine) or dyes that were known to bind noncovalently to protein or nucleic acid structure. Quantitative interpretations of the early experimental results were thereby complex because the placement of the dyes on the biological macromolecules were usually not well known. However, many ingenious analysis methods were developed to extract structural information from the data. The limitation of available chromophores pairs that can be used to investigate structures of proteins has been removed in the last 20 years; a very large number of available chromophores that can be used as extrinsic labels of proteins can now be purchased commercially. All the research areas in this review are being actively and vigorously pursued, and despite the fact that FRET has been used extensively for over 50 years, new methods of measurement and analysis as well as new areas of application are continually being developed. The literature is extensive and sometimes daunting to the newcomer to the FRET field. The
following is an introduction to the basics of FRET, which enables the reader to read the vast, continually expanding FRET literature. We especially emphasize the aspects of FRET that are critical for determining structural and kinetic information about proteins and the biological structures that incorporate proteins.

Examples Representing the Broad Applications of FRET and Proteins

The introduction of fluorescent proteins has been a great boon for use as FRET pairs that can be inserted into protein structures under genetic control. In vivo FRET studies have benefited greatly from the incorporation of the green fluorescent protein (GFP) gene into a host genome (53) to form protein hybrids. This method eliminates the external labeling of organic fluorescent dyes and allows labeling of specific proteins in vivo. Fluorescence lifetimes and photo-physical properties of fluorescent proteins have been characterized (56–65). It is easier to interpret time-resolved FRET studies quantitatively if the donor has only one fluorescence lifetime; although average lifetimes are often used. The original wild-type GFP and GFP variants exhibit complex (multiexponential) decays from their excited states (66, 67), which limit the reliability of lifetime measurements. Fluorescent proteins better suited for fluorescence lifetime imaging (FLI) and FLI-based FRET studies have been obtained by random and site-directed point mutations (63) for a concise informative review of the development of monomeric fluorescent proteins, see Reference 68).

Energy transfer is an integral part of photosynthetic systems (see review chapters in Govindjee et al., (69)). Excitation energy transfer lies at the heart of the phenomenon and its mechanisms (70). The fluorophore of interest is chlorophyll and a few other intrinsic chromophores. The fluorescence intensity and lifetime of plants are tightly coupled to 1) the competition between the rapid shuttling of the excitation energy by FRET, 2) the dissipation of the excitation energy by quenching mechanisms, and 3) the eventual irreversible transfer of the energy into the reaction center, where it initiates the electron transfer chain of photosynthesis (71, 72). As a matter of fact, photosynthesis was one of the initial motivations for developing the dipole-dipole mechanism of FRET (1, 73), and the role of FRET and its mechanism is still a very active research topic in photosynthesis (70, 74–77).

Single-molecule experiments in a microscope with the macromolecules of interest attached to a surface have made extensive use of FRET in the last several years (78–80). FRET allows one to directly observe conformational changes, and if the kinetics take place in the right time range (tens of microseconds to seconds), then the individual steps can be observed, and the kinetic rate constants can be determined. A nother method that has single-molecule resolution is fluctuation correlation spectroscopy (81, 82). Thereby FRET can be used to measure kinetics of protein conformational changes and noncovalent binding reactions as the macromolecule passes through diffraction limited focused laser light in a fluorescence microscope (83). This technique has been further developed to achieve picosecond time resolution, which allows fluorescence lifetime measurements to be made on the diffusing entities, and FRET to be determined from the lifetimes (60, 84, 85). Additional examples of the application of FRET to proteins are given at the end of the article, after discussing the physical basics of FRET.

What is the Basis for the FRET Phenomenon

Hetero-and homo-FRET

As the name implies, FRET involves the transfer of energy from a molecule in an electronically excited state (this molecule is called the donor) to another molecule (the acceptor) that is within a certain distance from the donor. The transfer of energy is brought about by a dipole-dipole interaction between the donor and acceptor. The acceptor is usually a different molecular species, but it can be the same as the donor. If the donor and acceptor are different molecular species, then the energy transfer is called hetero-FRET. If the donor and acceptor are the same, then it is called homo-FRET. For proteins, most applications in the literature use hetero-FRET to determine information about protein structures and conformational changes. In hetero-FRET, the fluorescence intensity of the donor decreases because a probability exists that the donor loses its excitation energy by transferring excitation energy to the acceptor, instead of fluorescing. If the acceptor can also fluoresce and energy transfer takes place, then emission from the acceptor can usually be observed. With true homo-FRET, the intensity of the fluorescence does not change; the energy is simply transferred from one identical molecule to the other, and the probability of emission remains the same. The only way to observe homo-FRET is to measure the decrease in fluorescence anisotropy (polarization). For measuring homo-FRET, the donor molecules are excited with polarized light, just as when measuring normal fluorescence anisotropy. Donor molecules oriented in a direction best suited for absorbing the polarized light are preferentially excited. Because the donor molecules are selectively excited according to their orientation relative to the excitation light polarization, their fluorescence emission will also be polarized preferentially in a direction related to the excitation light polarization. The extent of polarization depends on the rotational correlation time and time the molecules are in the excited state. If homo-FRET can take place, then those donor molecules excited by homo-FRET are not oriented solely relative to the excitation light, but they depend also on the relative orientation of the originally excited donor molecules and the molecules that accept the energy (as we will see in the general formula for energy transfer). This process will decrease the overall polarization of the sample. The measured anisotropy can then be used to interpret the extent of energy transfer.

The efficiency of FRET

The number of energy quanta transferred from excited donors to acceptors divided by the number of quanta initially absorbed...
by donors is called the efficiency of FRET. The maximum of this efficiency fraction is one. Whether energy transfer is more or less likely to occur in a particular situation will depend on what other paths are available for the excited donor molecule to give up its energy and how likely the donor will de-excite via these alternate paths. In other words, FRET is in direct kinetic competition with all other mechanisms of de-excitation of the donor. Therefore, for FRET to take place, the transfer must occur in the same time range, or faster, than all other de-excitation pathways (such as fluorescence emission, dynamic quenching, intersystem crossing to the triplet state, etc.). In practice, the actual transfer process is not measured directly, but is inferred by measuring its effect on other reaction pathways in kinetic competition with FRET. For example, the efficiency of FRET can be determined by comparing donor or acceptor fluorescence intensities in the presence and absence of FRET. This measurement can be done in steady-state or time-resolved experiments (25, 42, 45, 49, 86).

The fluorescence quantum yield of the donor cannot be zero. On the other hand, the acceptor does not have to fluoresce. Because energy is conserved, the transfer must be resonant; that is, the energy lost by the acceptor must equal the energy gained by the acceptor. The probability that the energy can be transferred depends strongly on the distance between the molecules (see Eq. 1). This dependence makes FRET particularly suited for measuring molecular distances and determining spatial proximities.

The distance dependence of FRET and $R_0$

For two isolated molecules (donor and acceptor), the rate of energy transfer $k_{ET}$ from the excited donor to the acceptor is proportional to the inverse sixth power of the distance between the two molecules $R$ and is equal to

$$k_{ET} = \frac{1}{\tau_D} \left( \frac{R_0}{R} \right)^6$$  \(\text{(1)}\)

where $\tau_D$ is the lifetime of the donor excited state in the absence of the acceptor; $R_0$ is the average distance between donor and acceptor molecules when the rate of transfer is equal to $1/\tau_D$. $R_0$ is often approximately 5 nm.

The rate of transfer shown in Equation 1 has an exceptionally strong $1/R^6$ distance dependence. As discussed above, the probability of energy transfer is in competition with all the other pathways of de-excitation. For instance, according to Equation 1, if the molecules are separated by less than about 0.5$R_0$, then the rate of transfer is greater than 65 $\times$ (1/$\tau_D$). Therefore, on the average, essentially all the excitation energy will be transferred from the donor to the acceptor. If the molecules are separated by 2$R_0$ or greater, then the rate of transfer is less than 0.015 $\times$ (1/$\tau_D$). Essentially, on the average, no energy will be transferred. Thus, as a rule of thumb, because of $R_0 \approx 5$ nm, FRET can only be used to determine distances less than 10 nm. For reasons that will be evident later, the lower limit is approximately 0.5 nm.

The constant $R_0$ is dependent on several parameters: 1) the relative orientation of the transition dipole moments of the two molecules (these dipoles are the spectroscopic transition dipoles), 2) the extent that the fluorescence spectrum of the donor overlaps with the absorption spectrum of the acceptor, and 3) the surrounding index of refraction. We will deal with each of these below (see Equation 8). Because many proteins have diameters less than 10 nm, this distance dependence explains the usefulness of FRET for determining distances inside proteins as well as between interacting proteins, which is the reason that the name “spectroscopic ruler” was coined for FRET (20). FRET is a convenient method for determining the distance between two locations on proteins, or for determining whether two proteins interact intimately with each other. Fluorescence instrumentation is available in many laboratories, and a plethora of dyes and a wide variety of fluorescent proteins are now readily available. Therefore, FRET is a viable option for most researchers. With care, FRET can yield valuable information concerning protein-protein interactions, interactions of proteins with other molecules, and protein conformational changes.

Quantitative expressions for measuring the efficiency of FRET

The efficiency of FRET is the fraction of times that an excited donor molecule will transfer its excitation energy to an acceptor. For instance, if the efficiency of transfer is 0.3, and if a molecule is excited 100 times, then on average it will transfer the excitation energy to the acceptor 30 times. A common way to express the efficiency is by means of the rate of energy transfer (Equation 1). After the donor has been excited from the ground state ($S_0$) into its first excited singlet state ($S_1$), the donor can exit the $S_1$ state by several pathways (see Fig. 1a).

As indicated in Fig. 1a, all pathways that lead away from the excited state of a chromophore (either to the ground state—or by some radiative or nonradiative process—or passage to the triplet state) are in direct kinetic competition with each other. FRET is one of these pathways. Each i-th pathway exists with a certain rate constant ($k_i$, in seconds$^{-1}$).

Figure 1b is a schematic that depicts the kinetic pathways. Because they are in direct competition, the probability of going by any single pathway (the efficiency of that pathway) is the ratio of the rate of that pathway divided by the sum of the rates of all the pathways.

The efficiency of energy transfer, Fig. 2a, can be expressed as

$$E_{FRET} = \frac{\# \text{ times FRET pathway is chosen}}{\text{total \# of times the molecule is excited}} = \frac{k_{FRET}}{\sum k_i}$$  \(\text{(2)}\)

where $k_{FRET}$ is the rate constant for FRET, and the $k_i$s are rate constants (with units of s$^{-1}$), and the only ones that are included in Equation 2 are those that emanate...
Forster Resonance Energy Transfer (FRET) for Proteins

Figure 1 - FRET and competing pathways. (a) A Perrin–Jablonski diagram shows common spectroscopic transitions for de-excitation of the donor fluorophore. Absorption of a photon excites the donor from the S0 to the S1 excited state, where it rapidly relaxes (typically in less than 1 ps) to the lowest vibrational level of the S1 state, which is known as internal conversion (IC). Internal conversion involves energy loss through vibrational interactions with the surroundings. The excited molecule is in a higher vibrational state of S1; thereby releasing heat to the surroundings, finally ending up in the lowest vibrational state of S1. The donor can then undergo de-excitation from the lowest vibrational level of the excited state to the S0 ground state through several pathways. The typical fluorescence lifetime (independent of the other pathways) is on order of 1–10 ns. Through spin–spin or spin–orbital interactions, the S1 state can undergo intersystem crossing (ISC) into the excited triplet state where it spends some time (typically 10–100 s, depending on the concentration of oxygen in the solution) before phosphorescence or conversion to the ground state by internal conversion takes place. The ground state of oxygen is a triplet, and it can easily react with the triplet state of the chromophore, producing reactive oxygen species (radicals) that can collide with the chromophore, destroying it (photolysis). (b) This panel shows a schematic of the various competing pathways for leaving the excited donor state, including quenching, photolysis, fluorescence, and phosphorescence, which compete with FRET. Dexter transfer involves energy transfer to the acceptor molecule by exchange of electrons (see text) when the electronic orbitals of the donor and acceptor overlap. By measuring the effect of FRET on one of the competing processes (e.g., donor fluorescence), one can measure the FRET efficiency. It is not necessary to measure fluorescence to determine FRET efficiency, but this technique is the normal way. It is also possible to measure the fluorescence intensity of the acceptor (if the acceptor can fluoresce) to detect and quantify FRET.

The lifetime of an excited molecule (in seconds) is the inverse of the sum of the kinetic rates (in s⁻¹) for all the pathways for exiting the excited state. Thus, in the absence of an acceptor, the lifetime is

$$\tau = \left( \sum_{i \neq \text{ET}} k_i \right)^{-1}$$  \hspace{1cm} (3)

And in the presence of an acceptor, the lifetime is

$$\tau_{\text{a}} = \left( \sum_{i \neq \text{ET}} k_i \right)^{-1}$$  \hspace{1cm} (4)

Therefore, the efficiency can also be given in terms of the measured fluorescence lifetimes in the presence and absence of an acceptor

$$E_{\text{FRET}} = \frac{1}{\tau_{\text{a}}} - \frac{1}{\tau} = \frac{1}{\tau_{\text{a}}} - \frac{1}{\tau_{\text{a}} + \tau} = \frac{1}{\tau_{\text{a}}} - \frac{1}{\tau_{\text{a}} - \tau_{\text{a}}}$$

Thus one can determine the efficiency of FRET by measuring the nanosecond fluorescence lifetime of the donor in the presence (A) and the absence (A⁻) of the acceptor. If one has the possibility of making this measurement, then it is a convenient, accurate, and robust way to measure the efficiency of FRET because the lifetimes can often be determined accurately, and not many corrections or experimental controls need to be made when calculating the efficiency.

Several ways exist to determine the efficiency by measuring steady-state fluorescence. It is easily observed by inspecting the first equality in Equation 2. The best way to acquire steady-state values of the fluorescence intensity is photon counting. We will not go into the way it is done with hardware and electronics (it is usually done automatically with modern instrumentation), but simply note that by using photon counting one can easily...
Förster Resonance Energy Transfer (FRET) for Proteins

Measure a correct value of the intensity at any wavelength by counting the number of photons emitted. If one does not count photons, then the light detector must be corrected for the sensitivity of the photomultiplier at different wavelengths. We can rewrite Equation 2 as

\[ E_{\text{FRET}} = \frac{\text{# times FRET pathway is chosen}}{\text{total # of times the molecule is excited}} = \frac{\#(\text{photons}_{\text{B,A}}) - \#(\text{photons}_{\text{B,A}})}{\#(\text{photons}_{\text{B,A}})} \]

\[ = 1 - \frac{\#(\text{photons}_{\text{B,A}})}{\#(\text{photons}_{\text{B,A}})} \]

\[ #(\text{photons}_{\text{B,A}}) \text{ means the number of photons emitted by the donor in the presence or absence of the acceptor, respectively. This "counting" quantification is very important when measuring the efficiency of FRET, because the quantities of interest in Equation 6 are the number of photons emitted and the number of photons absorbed, and not their energy. The experiment can be conducted either on an ensemble of molecules (where different donor molecules will be excited by each excitation event) or by repetitive experiments on a single molecule. Thus, the numerator of Equation 6 is just the number of photons that the donor emits in the absence of an acceptor minus the number of photons emitted in the presence of an acceptor. This difference is just the number of "quanta" that are transferred to the acceptor, which would have been emitted as fluorescence photons if the acceptor were not there. The denominator is then simply the number of photons emitted by the donor in the absence of an acceptor. Thus, when the acceptor is far away, the efficiency is zero. When the acceptor is very close to the donor, the efficiency becomes one. Note the exact parallel of Equation 6 to Equation 5 (i.e., \( E_{\text{FRET}} = 1 - \frac{\#(\text{photons}_{\text{B,A}})}{\#(\text{photons}_{\text{B,A}})} \)). This parallel relationship occurs because the lifetime of the donor emission becomes shorter when another pathway (for instance, \( k_{\text{on}} \)) opens up for an escape from the excited state. That is, the average time in the excited state becomes shorter. It reduces the number of photons emitted by the donor by transferring a certain number of energy quanta from the excited donor to the acceptor. Often one measures the intensity of fluorescence. The intensity is proportional to \( \#(\text{photons}) \text{ per second}. \) Then, provided the concentration of the donor is the same in both measurements, and the conditions of measurement remain identical, the efficiency is

\[ \frac{\text{#(photons)}_{\text{B,A}}}{\text{#(photons)}_{\text{B,A}}} = \frac{1}{1 - \frac{\text{#(photons)}_{\text{B,A}}}{\text{#(photons)}_{\text{B,A}}}} \]

\[ = 1 - \frac{\text{#(photons)}_{\text{B,A}}}{\text{#(photons)}_{\text{B,A}}} \]

\[ l_{\text{D,A}} \text{ is the measured fluorescence intensity of the donor in the presence and absence of the acceptor, which is measured under identical conditions and with the same donor concentration. If the concentration of the donor is not identical in both measurements, then it can usually be corrected simply by multiplying by the corresponding concentration ratio.}

Conditions for FRET and the Effect of the Transition Dipoles Orientations

The value of \( R_0 \) for a singular pair of D and A molecules is

\[ R_0 = \frac{9000 \ln(10) \phi_0}{N_A \lambda_0 \eta^2} \]

\[ \left[ \int_{\lambda_0}^{\infty} \frac{F(\lambda)}{\lambda^4} \lambda^4 \left( \frac{\pi n^2}{\lambda} \right)^4 \right] \]

where, \( \lambda \) is wave number (in cm\(^{-1}\) units), \( \phi_0 \) is the quantum yield of the donor, \( N_A \) is Avogadro’s number, \( n \) is the index of refraction pertaining to the transfer, \( \epsilon(\lambda) \) is the molar absorption coefficient of the acceptor (in units of cm\(^{-1}\)mol\(^{-1}\)), \( F(\lambda) \) is the fluorescence intensity of the measured fluorescence spectrum of the donor, and \( e^2 \) is an orientation factor that results from the inner product between the unit vector of the electric near field of the donor dipole and the unit vector of the absorption transition dipole of the acceptor (see the Orientation Factor section below). The ratio of integrals in the bracket has units of cm\(^3\)mol. Using the units given in the paragraph above, we have:

\[ R_0 = 8.79 \times 10^{-25} \Phi_0 \lambda_0 \frac{\pi}{2} \eta^2 \text{ cm}^6 \]
Forster Resonance Energy Transfer (FRET) for Proteins

**Figure 3** The electric field of the donor and the orientation factor. (a) The donor dipole \( p_D \) in the electric field \( E_D \) of the donor \( p_D \) and the donor dipole orientation \( \theta_D \) (the angle between \( p_D \) and \( r \)). (b) This schematic shows the donor and acceptor dipoles and illustrates the 
angles and radial vectors used in the definition of the orientation factor \( \nu^2 \). The coordinate system is chosen such that the \( p_D \) and \( E_D \) vectors are in the \( r \)-y plane, the \( p_A \) vector can be in any direction, and is not supposed to be in either the \( r \)-y or \( r \)-x planes. The dipole field is symmetrical about the azimuthal angle of the \( p_A \) vector.

### Distance dependence

For energy to be transferred from the donor to the acceptor, an interaction must occur between the two molecules, and the energy must be conserved (i.e., the energy lost by the donor equals that gained by the acceptor). Coulomb (charge-charge) interactions between the electron distributions in both molecules are responsible for the FRET interaction, and the energy transfer can be understood as an interaction between two classical oscillating dipoles. Actually, a classical derivation of the FRET equations (87, 26) results in the identical expression as a quantum mechanical derivation (3, 48). The electric field of an oscillating dipole is very large in the “near-field” region where the field can be described by a pure dipole field (Fig. 3a). A dipole field at some point in space a distance \( R \) from the center of the dipole is dependent on the angle relative to the dipole direction, and it varies with distance as \( 1/R^3 \). The interaction energy between the two dipoles therefore varies as \( 1/R^6 \). The interaction energy also depends on the relative orientations of the two dipoles and the orientation of each dipole to the separation vector between the two dipoles (see Figs. 3a and 3b). The dipole-dipole nature of the interaction explains the \( 1/R^6 \) dependence of the rate of energy transfer (Eq. 1).

### Overlap integral

It is important to realize that in this near-field zone of the dipoles (which extends maximally 10 nm for FRET) no photon exists; the lack of photons in the near-field zone is essentially because of the Heisenberg uncertainty principle of quantum mechanics (88). That is, the energy is transferred without the emission or absorption of a photon. Of course, the energy transferred from the donor must equal exactly the energy transferred to the acceptor. However, it turns out that the interaction between the two molecules in the near-field zone can be described as if the acceptor is bathed in an oscillating electric field of the near-field zone of the donor, \( E_D \) in Equation 10. This oscillating electric field (with a frequency equal to that of the fluorescence of the donor emission, \( F_D \) of Equation 8) is in the near-field zone of the donor where no photons exist and not in the far field zone where photons exist. The energy of such a Hertzian oscillating dipole is not emitted as photons until a distance of about one wavelength away from the donor. Energy is conserved during the transfer event; that is, the energy lost by the donor must equal the energy taken up by the acceptor. The change in the energy levels of the donor and the acceptor are the same energy levels that correspond to the spectroscopic transitions of the donor (the emission spectrum) and acceptor (the absorption spectrum). Therefore, to conserve energy, the emission (fluorescence) spectrum of the donor \( F_D \) must overlap with the excitation (absorption) spectrum \( \varepsilon_A \) of the acceptor (Fig. 2b). The more these spectra overlap, the stronger is the energy transfer; that is, a larger spectral overlap leads to a larger \( R_0 \). The \( F_D \) and \( \varepsilon_A \) spectra (Fig. 2b) are those of the separate donor and acceptor components. These spectra must be the appropriate spectra that correspond to the identical conditions as where the FRET measurements are made. Often the spectra can simply be taken from the literature that refers to the separate dyes. But often, the dyes physically interact with the proteins, which changes the dye’s absorption or emission spectra. The overlap integral involves the weighting function \( v^2 \) in addition to the emission spectrum of the donor and the absorption spectrum of the emitter (see Eq. 8). As mentioned above, although no photon is emitted or absorbed in the transfer process, the emission spectrum of the donor and the absorption spectrum of the acceptor are still involved in the overlap integral. This participation of the optical spectra is because FRET involves changes in the energy levels of D and A that are identical to those in normal absorption and emission events. An important condition for FRET to occur is that the interaction between the donor and acceptor is very weak, and the two molecular species retain their separate electronic and vibrational structures and energy levels. In FRET, the donor and acceptor are very weakly perturbed by dipole interactions, which is formally the same type and strength of interaction that describes the interaction of the chromophores with light. Therefore, the energy transitions, which can occur in the donor and acceptor molecules during FRET, are the same as their respective spectroscopic transitions when absorbing or emitting photons. This requirement for the conservation of energy, which is expressed by the overlap integral in the expression for \( R_0 \) (Eqs. 8 and 9), is also the reason for the word “resonance” in FRET. We emphasize once more: Although the emission and absorption spectra of the donor and acceptor are in the overlap integral, the FRET process does not involve the emission or the absorption of a “photon.”
The most difficult factor to control and usually the hardest to action of the donor electric field near-field zone of the donor (by studying the interaction of the acceptor dipole in the description of FRET) is also perfectly consistent with a quantum the near-field of the donor is not propagating, and the field diagonalizes from the oscillating electric field of the donor Hertzian dipole. And this field were equivalent to the oscillating electric field of the donor with the dipole moment of the acceptor. The equations for FRET have been derived classically (87, 26, 48) by assuming that the donor molecule is an oscillating point dipole [a Hertzian dipole (89)]. One assumes that the acceptor is located in the “near-field zone” (which extends much less than one wavelength of light of the corresponding frequency) of the oscillating dipole of the donor (Fig. 3). The acceptor absorbs the energy by interacting with the oscillating near field of the donor (the donor oscillates at the same optical frequency where the acceptor absorbs). The near field is not radiating (no transverse photon emission occurs in the near-field zone of a Hertzian dipole). And the electric field in the near field has both longitudinal and transverse components, in contrast to the far field zone, where the electric field has only transverse components. Nevertheless, the mechanism of absorption of energy by the acceptor from the oscillating electric field of the donor Hertzian dipole is identical to the mechanism of absorption of light of the same frequency. Therefore, the interaction of the “transition moment” of the acceptor with the electric field of the donor obeys the same rules as normal absorption of light by the acceptor (polarization dependence and all the spectral requirements for normal absorption). The rate of absorption is proportional to the square of the vector dot product of the acceptor transition dipole with the electric field of the donor, just as though this field were equivalent to the oscillating electric field of light impinging on the acceptor. However, the electric field in the near-field of the donor is not propagating, and the field direction is longitudinal as well as transverse vector components (propagating light photons has only vector components transverse to the direction of propagation). This electric field is a reflection of the fact that in the near-field zone no photon could even exist according to the uncertainty principle. This simple classical description (which results in the correct theoretical description of FRET) is also perfectly consistent with a quantum derivation.

The orientation factor can be best understood quantitatively by studying the interaction of the acceptor dipole in the near-field zone of the donor (Fig. 3a). The energy of interaction of the donor electric field $E_D$ and the acceptor dipole moment $\beta_A$ is $E_D \cdot \beta_A$. The rate of absorption is proportional to the square of this energy of interaction. Therefore, the rate of energy transfer is proportional to $(E_D \cdot \beta_A)^2$ (Eq. 11).

The field $E_D$ that surrounds an oscillating classical electric dipole $\beta_D$ is shown in Fig. 3a.

$$E_D = \frac{|\beta_D|}{r^2} \left(3 \cos \theta_D \cdot \hat{r} - \beta_D \right)$$

(10)

where $|\beta_D|$ is the time independent dipole strength, $r = |\vec{r}|$ is the distance from the point donor dipole (in FRET it is the distance from D to A), and $\hat{r}$ is the unit vector pointing from the donor dipole to the position $\vec{r}$, where the acceptor is located. $\theta_D$ is the polar angle between $\hat{r}$ and $\vec{r}$, and $\beta_D$ is a unit vector perpendicular to $\hat{r}$ that points in the direction of increasing $\theta_D$ (Fig. 3a). The caps designate unit vectors. Figure 3b shows the juxtaposition of two dipoles, and it defines the parameters used in the Equations 10, 11, and 12. As we said above, $k_{ET}$ in Equation 1 is proportional to $(E_D \cdot \beta_A)^2$, according to classical electrodynamics. We can write

$$k_{ET} \propto \left( E_D \cdot \beta_A \right)^2$$

(11)

where $k_{ET}^2$ has been defined as

$$k_{ET}^2 = \left[ 2 \cos \theta_D \cdot \hat{r} - \beta_D \cdot \sin \theta_D \cdot \hat{r} \cdot \beta_A \right]^2$$

(12)

The orientation factor $k_{ET}^2$ can have values between 0 and 4. We have given $k_{ET}^2$ in two different representations in Equation 12.

Thus, the rate of energy transfer depends on the square of the dipole product between the acceptor dipole (transition dipole) $\beta_A$ and the field $E_D$ of the donor dipole (transition dipole), $\beta_D$ (Eq. 11 and Fig. 3b). For any chosen locations and orientations of the donor and acceptor, the value of $k_{ET}^2$ involves the cosine of the angle between the unit vectors $\beta_D$ and $\beta_A$ (i.e., $\beta_D \cdot \beta_A$) as well as the cosine of the angles between $\hat{r}$ and $\beta_D$ (i.e., $\hat{r} \cdot \beta_D$) and between $\hat{r}$ and $\beta_A$ (i.e., $\hat{r} \cdot \beta_A$). Therefore, for any constant selected angle between the donor and acceptor dipoles (that is, constant $\beta_D \cdot \beta_A$, the value of $k_{ET}^2$ will depend on the position in space where the acceptor dipole is relative to the donor. The strength of the field of the donor molecule for any particular constant values of $\beta_D$, $\beta_A$, and $\beta_D \cdot \beta_A$ changes with the distance $|\vec{r}|$ as $1/|\vec{r}|$, that is, for any particular direction of $\vec{r}$ relative to $\beta_D$. As illustrated in Fig. 3a, for a particular angle between the orientations of the donor and acceptor dipoles $\beta_D \cdot \beta_A$.

---

WILEY ENCYCLOPEDIA OF CHEMICAL BIOLOGY © 2008, John Wiley & Sons, Inc.
the angle between the acceptor dipole and the electric field of the donor depends on the position in space of the acceptor. Also, for constant relative orientations of the donor and acceptor dipoles (constant $\hat{p}_D \cdot \hat{p}_A$), and for constant $\cos \theta_D \cdot \cos \theta_A$, $x^2$ is constant (Eq. 11 and 12). In this case, the rate of FRET is solely a function of the distance between the donor and acceptor. However, if only $\theta_D$ and $\theta_A$ are constant, then the distance dependence is more complicated than just the distance between the donor and acceptor. This intertwining relationship between the distance separating the donor and acceptor and the orientational dependence of $x^2$ illustrates the complexity of determining a value for $x^2$.

Because the orientations and spatial locations of the two chromophores may vary over the ensemble of molecules, and because they can also change during the time the donor is in the excited state, the measured effect of $x^2$ is usually an average over the appropriate spatial/temporal distributions. Whenever $E_D$ and the acceptor dipole moment $\hat{p}_A$ have parallel orientations, the rate of FRET is maximum for that placement in space for the acceptor relative to the donor. For $\hat{p}_A$ oriented parallel to $E_D$, the possible maximum values of $x^2$ are between 0 and 4; that is, the actual maximum value depends on the value of $\theta_A$ (see below). The minimum value of $x^2$ is zero for every position of the acceptor relative to the donor whenever $E_D$ and the acceptor dipole moment $\hat{p}_A$ are oriented perpendicular to each other.

The possible introduction of error in the estimation of the FRET efficiency from the orientation factor is often of concern when measuring FRET in proteins or between proteins. This uncertainty can occur because the actual distribution of dye orientations is often not known, or because the dyes do not rotate freely and rapidly relative to the fluorescence lifetime of the donor. If the donor and acceptor molecules undergo rotational or translational movements during the time the donor is in the excited state, or if an ensemble of different donor and acceptor orientations exist, then the value of $x^2$ (and of course the rate) will be averaged over the corresponding ensemble of configurations. Because $x^2$ can, in principle, range from 0 (e.g., acceptor absorption dipole parallel to the electric field of the donor) to 4 (e.g., end-to-end stacked parallel dipoles), the variation in the rate of FRET can be extensive because of such movements. This possible variation in $x^2$ becomes especially apparent when one notes that the measurement of the rate of transfer (or the efficiency) varies directly as $\kappa^2$ (90), and therefore directly with $x^2$ (see below). If the condition of very rapid (compared with the lifetime of the donor) rotational movements of both donor and acceptor is met, then $x^2$ is rigorously $2/3$, which arises from averaging over all possible orientations. If rapid re-orientation through all angles is not the case, then limitations on the degree of rotational freedom can have significant effects on the measured efficiency of energy transfer. However, as we discuss below, the assumption that $x^2 = 2/3$ is often a justified, and reasonable one to make (39, 48, 86).

It is worthwhile to consider a few simple examples to get a feeling for the values of $x^2$. If the two dipoles have orientations in space perpendicular to each other, and if the acceptor dipole is juxtaposed next to the donor, but in the direction perpendicular to the direction of the donor dipole, then $x^2 = 0$ (that is, because, $\theta_D = \pi/2$, so $\cos \theta_D = 0$, and $\theta_A = 0$). However, this example is only a special case where $x^2 = 0$. As was pointed out above, for any position in space of the acceptor molecule, $x^2$ will equal zero for all orientations of $\hat{p}_A$ where $E_D \cdot \hat{p}_A = 0$. And for most of these positions where $E_D \cdot \hat{p}_A = 0$, the donor and acceptor dipoles are not perpendicular to each other (see Fig. 3a). Conversely, if the donor and acceptor dipoles are perpendicular, then most locations of the acceptor relative to the donor will have $x^2 = 0$. This relationship is easiest to observe by looking at the second equality in Equation 12 or by examining Fig. 3a. Another simple example is when the dipoles are parallel ($\hat{p}_A \cdot \hat{p}_D = 1$). Then, if $\theta_D = 0$ and $\theta_A = 0$ (parallel dipoles, stacked on each other), then $x^2 = 4$. But when $\theta_D = \pi/2$ and $\theta_A = \pi/2$ (again parallel dipoles, but now next to each other), then $x^2 = 1$. In the latter case, $\hat{p}_A$ is parallel to $E_D$ but $\hat{p}_D = \hat{p}_A \cdot r = 0$, and the value of $x^2$ is four times smaller than when $\cos \theta_D = \cos \theta_A = 0$. These few examples demonstrate the complexity of the behavior of $x^2$. In Fig. 3a, we have indicated both the orientation of $\hat{p}_D$ and $E_D$, as well as the angle $\theta_A$ (where $\cos \theta_D = \hat{p}_A \cdot r$). More thorough discussions of $\kappa$ can be found in the literature (35, 48, 51).

Because fluctuations always exist in positions and angles of the D and A molecules, the actual value of $x^2$ is an ensemble average or a time average. The most commonly used average value is $x^2 = 2/3$. As already mentioned, this result is rigorously true if during the excited state lifetime of the donor the orientations of the donor and acceptor can each individually reorient fully in an independent random fashion. However, even when this condition is not met (for instance when the anisotropy of the dyes is not close to zero), it has been found that the approximation $x^2 = 2/3$ is often satisfactory (39, 42, 45, 51, 90). It is often discussed in the literature as though $x^2 = 2/3$ pertains only to the case of very rapidly rotating D and A molecules. This statement is not true, because depending on the placement of the dyes and their relative orientations, it is possible for $x^2 = 2/3$ at every location of the acceptor relative to the donor, even when the dyes cannot rotate at all. Also, many dyes used for FRET have more than a single transition dipole, which can be excited at the same wavelengths. Because different transition dipoles of a fluorophore are usually not parallel to each other (they are often perpendicular to each other), the presence of multiple transition dipoles leads again to an averaging of $x^2 = 2/3$. Finally, if one is interested in detecting a change in structure or extent of interaction (binding), then one may not be interested in exact estimates of $x^2$. For instance, when fluorescent proteins are used in FRET experiments, $x^2$ can become a very important variable, and averages are often not applicable. This situation occurs because the chromophores are fairly rigidly held in the fluorescent protein structure, and the fluorescent proteins may have specific interactions either with each other or with other components of the complex under study (91, 92).
higher indices of refraction in the molecular surroundings (the solvent). A high index of refraction—which is equal to the square root of the dielectric constant—means that the electrons in the molecules of the solvent are freer to respond to an electric field than for solvents with lower indices of refraction. The solvent is assumed not to absorb at the wavelengths in question, so the index of refraction is real (not a complex number). This screening from the response of the solvent molecules leads to a damping of the extent of the field, and therefore the two dipoles (donor and acceptor) must be closer together in a solvent with higher index of refraction to have the same strength of interaction as in a solvent with lower index of refraction. Note that the wavelengths are also shorter in a higher index of refraction; however, remember that FRET does not involve propagating light fields. The actual situation is somewhat more complex, and the reader is referred to an excellent discussion in the recent literature (93-95), which clears up common misconceptions as to the origin of the effect of the index of refraction for FRET. In addition, the index of refraction varies significantly over short distances in and on the surface of proteins (96); for very short distances, the concept of an index of refraction becomes suspect. However, usually an average value is chosen between 1.33 and 1.5, which correspond to values of water and crystals of polypeptides. The value chosen usually depends on whether the dyes are in direct contact with water or are inside the protein, where the dyes are removed from water. Detailed numerical methods (96, 76, 97, 70) can be used to take into account directly the interaction between charges if the protein structures are known and if the position and orientations of the chromophores are known, which extensive numerical calculations, whenever the structures are well known, avoid the use of an “effective” index of refraction.

Quantum yield of the donor

Equation 8 shows that \( R \) is dependent on the quantum yield of the donor \( \phi_D \). This dependence is not strong; \( R \propto \phi_D^{1/6} \). For instance, \( R(\phi_D = 0.1) / R(\phi_D = 0.01) \approx 0.7 \). Therefore, small changes in the quantum yield of the donor will not make large differences in the value of \( R \). Of course, if increasing \( \phi_D \) by a factor allows one to make accurate measurements of distances or to observe conformational changes, then the change can be significant. However, the range of distances observable by FRET are not a strong function of the quantum yield of the donor. However, small displacements in the horizontal placement of the efficiency curve of Fig. 2a can significantly increase or decrease the sensitivity of a FRET measurement. In some circumstances, it is advisable to choose a donor-acceptor pair that have a smaller \( R \) preferably in the range of the distance one is interested in measuring (see section below on “What is important, \( R \) or \( \phi_D \)?”). One can sometimes shorten \( R \) by simply adding a collisional dynamic quencher to the solution, which will lower the quantum yield of the donor in the absence of the acceptor, lowering \( \phi_D \), thereby adjusting \( R \) to lower values (90).

Transfer at very short distances

The Förster transfer mechanism (Eqs. 1, 8, and 10) is valid at all distances in the near-field region where the approximation of point dipoles is valid. At very small distances from the molecular dipoles, the finite extended distribution of the electrons make the point dipole approximation invalid (98, 99). In this case, the higher order terms such as quadrupoles and octapoles would have to be taken into account (14, 15). In addition, if no electric dipole interactions occur between the donor and acceptor (for symmetry conditions, making the transition dipole zero), then these electric quadrupole terms and interactions between the magnetic dipole and electric dipole terms have to be taken into account. The lack of electric dipole transitions is seldom the case, and the use of quadrupole terms has not yet been important for the interpretation of FRET in proteins. However, if the two participating dipoles are very close, then transfer by electron exchange [Dexter transfer (14, 15)] also presents a possible pathway for energy transfer. This type of energy transfer should not be referred to as FRET because it is a different mechanism than Förster Transfer and requires a partial overlap of the electronic orbitals of the donor and acceptor. The transfer probability drops off exponentially, following the exponential decrease in the overlap of the wave functions of the electronic orbitals. However, even in photosynthesis, where the chlorophylls are very close and oriented to maximize energy transfer, it has not been shown unequivocally whether Dexter transfer is an important pathway for energy transfer in the photosynthetic unit. Nevertheless, one should be aware of these other mechanisms of energy transfer.

Noncoherent energy transfer (FRET) or coherent transfer

Lately there has been increased interest in coherent transfer. Förster transfer assumes that interactions with the molecular surroundings, or the internal vibrations of the molecules, are sufficiently rapid so no correlation exists between the act of excitation of the donor and the act of transfer. In other words (to give an anthropomorphic analogy), during the time when FRET can take place the donor shows no memory of how, or when, it was excited. This lack of memory is attributed to the chaotic, randomizing effects take place in subpicosecond times, rapidly relaxing the initially excited molecule to the lowest vibrational state of the excited electronic state (before fluorescence emission or FRET). A similar process takes place after the energy is transferred to the acceptor; the original acceptor state immediately following the transfer is rapidly randomized so that the transfer is irreversible. Whenever this randomization occurs, energy transfer can be analyzed from a probability viewpoint (Förster transfer), as is the case in the derivation of the Equations 2-7, 8, and 11. That is, in Förster transfer we consider the probability per unit time for each pathway where the probabilities are independent of time and independent of each other. This probabilistic treatment of all the rates of deexcitation from the excited state for Förster transfer holds true whether the donor and acceptor are identical (homo-FRET) or different molecules (hetero-FRET); if
molecules (or atoms, with which most of these coherent transfer experiments have taken place) are completely isolated from the environment (such as in a vacuum at very low temperatures, e.g. well below 1 K), or if one is observing the fluorescence emission in the femtosecond time range at low temperatures (\(\sim 77 \, \text{K}\)), then it is possible to observe coherent transfer. Under the right conditions, the energy oscillates between different states (with the energy localized on different molecules or atoms) as a function of time; that is, the location of the excitation energy is not localized on just one chromophore independent of time. Instead, the energy is distributed between different chromophores and oscillates from one to the other. These oscillations can be observed in the time dependence of the fluorescence emission. Analogous oscillations in the transfer of energy between different interacting molecules in resonance (even without emission) were first described by Schrödinger (100). Until recently, it was not considered relevant for protein systems; however, lately these oscillations have been observed for photosynthetic systems at low temperatures (101, 102). How important these coherent oscillations are for the mechanism of photosynthesis at normal temperatures remains to be determined. But the effect has created much interest. The question is whether this coherent transfer, which is very rapid and can therefore transfer energy over large distances before the processes that lead to transfer becomes incoherent, plays a major role in the efficiency of photosynthesis.

What is Important: \(R_0^2\) or \(R_0\), and When?

Whether \(R_0^2\) or \(R_0\) are more important, may sound like a silly question; however, a subtle difference determines when one may be of more interest than the other. Usually, \(R_0\) is stressed. \(R_0\) is the distance where the rate of transfer is half the rate of de-excitation from the excited state (\(1/2\) in Eq. 1).

One usually tries to choose dye pairs (donor and acceptor) such that the expected range \(R_0\) is in the most sensitive part of the efficiency curve (Fig. 2a). Choosing appropriate donor and acceptor molecules can be done by trial and error, researching the literature, or determining the variable parameters in Equation 8 and calculating \(R_0\). The variable experimental parameters that define \(R_0\) are: \(|\text{D}|, \alpha, \kappa, F, n, x, \varepsilon\), and \(v_0\). To make calculations of \(R_0\), one usually chooses \(x^2 = 2/3\), and then corrects the \(x^2 = 2/3\)-calculated \(R_0\) by the appropriate factor if it is suspected that \(x^2 \neq 2/3\). Because \(R_0\) is proportional to the \(1/6\) power of \(|\text{D}|, \alpha, \kappa, F, n, x^2\), and \(v_0\), the value of \(R_0\) is not a strong function of these parameters; therefore, variations in their values do not change the value of \(R_0\) very much. As we pointed out above, \(R_0\) is proportional to the \(4/6\) power of the index of refraction, \(n\). So a fractional change in the index of refraction can have a more significant effect on \(R_0\). For instance, a 20% change in \(n\) will change \(R_0\) by only 3%. However, a 20% change in \(n\) will change \(R_0\) by 13%. So, all the variations in \(R_0\) are smaller than the corresponding variation in the parameter itself. Even if the parameters change by a factor of 2 (except for \(n\)), \(R_0\) will only change by 12%, which is the reason that the \(R_0\) of many dyes are in the same range. So, one might get the idea that variations in these parameters will be insignificant compared with the expected (or searched for) changes in distance.

However, the measured variation in the range of transfer (Eq. 1) is proportional to \(R_0^2\), which means that variations in these parameters could have a much more significant effect on the measured efficiency. If \(R\) is not approximately within \(R_0 \pm 0.5R_0\), then the measured efficiency (Eq. 2) will not depend on variations or changes in these parameters significantly (Fig. 2a), because the efficiency is within about 8% of the minimum or maximum value, and such small changes may be hard to measure. However, if one is in the range \(R \approx R_0 \pm 0.5R_0\), then the changes in any of the parameters \(|\text{D}|, \alpha, \kappa, F, n, x^2\) and \(v_0\) can lead to significant changes in the efficiency that could be confused with changes in \(R\). The sensitivity to such conformational changes (if the dyes are chosen with judicious values of \(R_0\)) is one of the valuable characteristics of FRET. This possibility should be carefully considered, especially whenever one is using FRET to measure changes in protein structure and wants to interpret the results as a change in \(R\) (see, for instance Reference 90). In any case, as is clear from looking at Equation 1, one achieves maximum efficiency for observing small changes in \(D\)—A distances when \(R\) is approximately equal to \(R_0\). The take-home message is that when choosing dyes for specific cases, it is worthwhile to consider carefully the choice of dyes, investigate their spectroscopic properties, and calculate the \(R_0\). It is not necessarily the best choice to select dye pairs that show the maximum values of \(R_0\).

Examples of FRET and Proteins

For over 50 years, FRET has been applied to protein and peptide structures (103, 104). It would be impossible to review even a small selection of the vast literature, and the following list of applications does not attempt to present details of the methodologies or the results. We will present just a few selected publications to give a flavor of the type of problems where FRET is applied, and from which the interested reader can obtain references.

FRET has been shown to acquire reliable estimates of protein and other macromolecular structures (27, 34, 53, 90, 103-108). Attention must be paid to the relative orientations of the transition dipoles of the donor and acceptor (28), but it has also been shown that for many biological systems, the approximations \(x^2 = 2/3\) is reasonable and gives correct distances despite relatively high fluorescence anisotropies of the donor and/or acceptor emissions (39, 109, 90). Reasons for this approximation have been discussed (48). Conformational changes based on singular positions of the donors and acceptors as well as donor-acceptor distributions can be observed in the nanosecond time range by measuring the fluorescence lifetimes of the donor or by following steady-state fluorescence of the donor or acceptor at longer times (110, 113-117). FRET is also very useful as the measurement basis of biochemical
The stoichiometry and formation of macromolecular assemblies and aggregated protein structures can often be quantitated by well-planned and correctly analyzed FRET measurements. A common problem in FRET studies can occur with the use of multi-donors and multi-acceptors. But analysis methods have been developed to take this problem into account, and it can also be an advantage when determining structures (125–127).

FRET has been widely used to determine the distribution of proteins in membranes and their interactions in two dimensional systems, as well to detect communication across membranes (128–137). The introduction of fluorescent proteins has been a great addition to the repertoire of FRET measurements of protein systems in solution and especially in fluorescence microscopy (138–141). Indeed, the number of applications of FRET in fluorescence microscopy have exploded in recent years, and novel analysis methods have also been developed in order to extract quantitative parameters from image data (142–146).

In bioluminescence resonance energy transfer (BRET), the excitation of the donor is carried out with a biological/chemical reaction instead of light excitation. It was discovered as a naturally occurring phenomenon (147). The photoprotein aequorin in Aequorea euryp挝es emits blue light when alone; however, when GFP and aequorin are associated in vivo, GFP accepts the energy from aequorin and emits green light. The use of bioluminescence as a donor in vitro was realized early (148), and it has undergone a renaissance because of the availability of the biological systems used for donor and acceptor excitation (149, 150). In general, the donor is replaced by luciferase, which becomes excited chemically in the presence of a substrate and can transfer its energy to an acceptor, which is usually (although not necessarily) a fluorescent protein (149, 150). BRET is very useful in microscopy and the background fluorescence is essentially zero. BRET has also been used in high-throughput screening (151).

Proteins are biological macromolecules whose structure and functions are essential to every biological process within cells. Protein phosphorylation is one of the most important post-translational modifications and it has a profound effect on protein function. Recently, concurrent advances in bioanalytical technologies and informatics enabled studies of proteins and phosphoproteins on a global scale. These large-scale approaches represent an integral component of systems biology, which is an area of scientific inquiry that focuses on a biological system as a whole. State-of-the art mass spectrometry is a key technology for global-scale protein and phosphoprotein analyses. Phosphorylated proteins from diverse biological systems can be probed with a combination of separation methods, tandem mass spectrometry, and bioinformatics, to reveal the identity of the phosphorylated protein and the exact localization of the site(s) of phosphorylation. Characterization of the phosphoproteomes in cells, tissues and biological fluids provides an excellent foundation on which to build new knowledge of living systems.

Proteins are the final products of gene expression, and while the genome provides the “blueprint” for the molecular components of a living cell, proteins are the essential molecules responsible for cellular structure and function. Decades of studies of proteins in a one-by-one fashion have generated a wealth of knowledge on proteins as individual parts of the cellular machinery. Recently, interrogation of proteins in biological systems on a global scale gave rise to a new area of scientific inquiry, termed proteomics. Proteomics focuses on the study of the proteome, which is defined as the array of proteins that are present in a cell, organ, or biological fluid at a specific time, under a specific set of conditions. The goals of proteomics are diverse and include elucidation of basic molecular mechanisms that regulate cell function in physiological and pathological state, discovery of novel targets for the development of improved drug treatments, discovery of biomarkers for early detection of a disease and for design of tailored therapies, and many other objectives.

From the analytical standpoint, large-scale, comprehensive analysis of proteins is an extremely challenging undertaking because of the enormous complexity of proteomes and their dynamic nature. In fact, the development of proteomics as a scientific discipline was made possible through the concurrent advances in separation sciences, mass spectrometry, and informatics. Mass spectrometry has been the essential technology that enabled interrogating proteins on a global scale, with a high degree of sensitivity and accuracy. The purpose of this chapter is to describe the basic principles of mass spectrometry in the context of proteomics. Specifically, the review focuses on the use of mass spectrometry for large-scale analysis of specific subsets of proteomes – the phosphoproteomes. The chapter includes discussion of the basics of gas-phase behavior of peptides and phosphopeptides, and shows the role of mass spectrometry as a component of a general analytical strategy for phosphoproteome analysis. Because of the diversity of the analytical platforms that are being used, this review is not intended as a comprehensive description of all approaches. Rather, this article includes an overview of selected methods, a sampling of relevant references, and an example of a mass spectrometry-based phosphoproteomics methodology used in the authors’ laboratories.
Biological Background

Proteins are high molecular weight organic molecules that are essential to every biological process within living systems. Proteins are structurally and functionally diverse. Some proteins are assembled in multi-unit complexes to form the cytoskeleton of cells or other mechanical structures, while others are enzymes that catalyze biochemical reactions, or they participate in signal transduction within a cell or in cell-to-cell communication. Post-translational modifications play a key role in regulatory cellular processes, and in particular, protein phosphorylation is central to most of the signaling events that ultimately determine the biological status of all eukaryotic cells. The intracellular regulation of protein phosphorylation within cells occurs via a very complex system of positive and negative feedbacks with the surrounding environment. Protein phosphorylation regulates critical protein functions such as protein-DNA, protein-RNA, and protein-protein interactions, enzyme activity, protein trafficking, protein intracellular localization, and protein degradation. Aberrations in protein phosphorylation can have deleterious consequences and have been linked to various diseases, including cancer. It is estimated that approximately 30% of all proteins in a mammalian cell are phosphorylated at any given time (1).

A proteome represents the complete repertoire of proteins present in a cell at any given time. The term phosphoproteome refers to a specific subset of the proteome that includes all the phosphorylated protein species. Phosphoproteomics focuses on the comprehensive characterization of phosphorylated proteins in biological systems, including identification of phosphorylated proteins, assignment of their exact sites of phosphorylation, and quantification of changes in protein phosphorylation. The expansion of proteomics and phosphoproteomics in recent years has been driven by technological developments. The greatest challenge for proteomics is the inherent complexity of cellular proteomes, which is due to the dynamic nature of the proteome, the large number and wide abundance range of cellular proteins, and their diverse physicochemical properties. It is recognized that the diversity and extent of proteome complexity cannot be solved by a single technology. Instead, the trend in proteomics is to develop an array of methodologies from which a method or a set of methods can be selected to tailor the analytical strategy to suit a specific study. Chromatography and electrophoresis are the central separation technologies for proteomics. High performance mass spectrometry in combination with bioinformatics tools are key components for protein identification and characterization.

Mass Spectrometry in Phosphoproteomics

Proteins are made of twenty “standard” amino acid residues joined together through peptide bonds. Each of the twenty amino acids has unique physico-chemical properties stemming from the size of the side chain, and the possible presence of an acidic or basic ionizable group. Protein phosphorylation most commonly occurs on serine, threonine, or tyrosine residues. The task to characterize phosphorylated proteins on a proteome-wide scale includes determination of protein identities and localization of the phosphorylated amino acid residues in these proteins. Mass spectrometry is the central technology for these tasks. Although there have been major advancements in the mass spectrometry analysis of intact proteins in proteomics (2), most approaches still focus on characterization of peptides and phosphopeptides from protein/peptide digestion of proteins. Therefore, the discussion in this section will concentrate on these strategies.

Mass spectrometry has several inherent characteristics that make it an excellent choice for peptide analysis. The technique is rapid, versatile, highly amenable to automation, and it requires low-to-mid femtomole sample quantities to yield reliable information about the amino acid sequence of a peptide. (The field of mass spectrometry is continuously moving towards improved detection limits, and cutting-edge instruments provide sensitivity in the attomolar range). For phosphoproteome analysis, the general analytical strategy (Fig. 1) includes isolation of the proteins from the biological system under study; protein or peptide fractionation and enrichment of phosphorylated protein/peptides; mass spectrometry measurement of specific attributes of phosphopeptides, including their mass and fragmentation patterns; searches of protein sequence databases to identify the proteins and to assign phosphorylation sites.

Protein extraction

The first step in the analysis of proteomes and phosphoproteomes involves extraction of proteins from the biological system under study; the objective is to solubilize the proteins and to prepare them for subsequent analysis. Obviously, this step is critical for the overall success of the analysis, and choice of

---

**Figure 1** Basic components of a general analytical strategy for phosphoproteome analysis.
methods should be tailored to the characteristics of the biological system and to the goals of the study. Depending on the biological system, protein extraction may involve disruption of cells, removal of contaminants such as salts (e.g., by dialysis or ultrafiltration), and/or overabundant proteins (e.g., by immunoadfinity columns). For phosphoproteomics, particular care must be taken to preserve phosphorylation of the proteins, i.e., to prevent the action of protein phosphatases. This is achieved by controlling the temperature of the sample and by addition of phosphatase inhibitors to the extraction buffer.

**Separation and enrichment**

Complexity of the analyte mixtures is a critical issue for phosphoproteome analysis. The challenge is to probe a specific subset of molecules (phosphopeptides) among an enormous number of other peptides: diverse physicochemical properties and low abundance of many phosphoprotein/phosphopeptides further contribute to the challenge. To address this issue, multidimensional fractionations of analyte mixtures, often in conjunction with phosphoprotein/phosphopeptide enrichment, are necessary prior to the mass spectrometry analysis itself. Fractionation of the original analyte mixture produces multiple mixtures, each with reduced complexity than the starting material. The necessity to analyze all the fractions decreases the overall throughput of the analytical platform but results in an improved coverage of the phosphoproteome. The fractionation steps can be performed at the protein level or at the peptide level, using electrophoretic and/or chromatographic methods. At the protein level, the traditional approach for proteome fractionation involves two-dimensional gel electrophoresis (2D-PAGE) that combines isoelectric focusing (IEF) in the first dimension and SDS-PAGE in the second dimension. For phosphoproteomics, specific stains or immunoblotting may be used to selectively visualize phosphorylated proteins in 2D gels. One-dimensional electrophoretic separations using IEF or SDS-PAGE provide protein fractions of moderate complexity. Alternatively, separations may be performed at the peptide level after proteolytic digestion of the entire proteome. In the context of phosphoproteomics, the most widely used methodology involves strong cation exchange chromatography (3, 4).

The electrophoretic or chromatographic separation methods are often combined with enrichment strategies to specifically enrich for phosphorylated species. This enrichment can be employed at the protein level, preceding protein fractionation, and/or at the peptide level following protein fractionation and digestion. Enrichment is accomplished by various types of affinity chromatography. Affinity chromatography methods may involve immunoadfinity using antibodies specific for phosphorylated amino acid residues in proteins or peptides (5), immobilized metal ion affinity chromatography (IMAC) (6) or metal oxide affinity chromatography (MOAC) (7). Some analytical platforms include esterification to reduce non-specific binding of non-phosphorylated peptides to the IMAC column (8). Chemical derivatization methods have also been developed that replace the phosphate group with a chemically different moiety, e.g., to introduce a tag that allows subsequent capture of the modified peptides (reviewed in ref 9).

**Mass spectrometry of peptides and phosphopeptides**

The basic goal of the mass spectrometry measurement in the context of peptide analysis in proteomics and phosphoproteomics is to determine specific attributes that are then used in subsequent database searches to provide: 1. the identity of the proteins present in the sample; 2. location of the sites of phosphorylation in these proteins. Both pieces of information are derived from the mass of the peptide and, most importantly, from the gas-phase dissociation patterns that are diagnostic of the peptide’s amino acid sequence and phosphosite location. The gas-phase dissociation patterns are obtained via tandem mass spectrometry (MS/MS). On a phosphoproteome-wide scale, the analysis includes measurement of the attributes for many thousands of individual peptides.

**Basics of gas-phase behavior of peptides**

Mass spectrometry deals with measurements of gas-phase ions. Therefore, the first step in peptide analysis by mass spectrometry is the conversion of the analytes into charged species in the gas phase. Peptides are relatively large, non-volatile biomolecules. In today’s world, the two ionization methods that are used in mass spectrometry of peptides and other biological macromolecules are matrix-assisted laser desorption/ionization (MALDI) and electrospray ionization (ESI). MALDI and ESI are based on different principles (10, 11); however, both methods ionize peptides via protonation in an acidic environment. MALDI produces mainly singly-protonated peptide ions, while in ESI protonation occurs on all available basic sites in the peptide, thus yielding multiply-charged species. For tryptic peptides, which possess an amino group at the N-terminus, a basic amino acid (arginine or lysine) at the C-terminus, and possible internal basic amino acid residues, doubly- and triply-charged peptide ions usually predominate. Multiple charging in ESI has important implications for subsequent dissociations of the (activated) peptide ions. The “mobile” proton originally localized on the N-terminus migrates along the peptide backbone by internal solvation, producing a heterogeneous population of peptide ions that have the same sequence but different sites of protonation (12, 13). This heterogeneity of protonation sites drives the dissociations of peptide ions in MS/MS that are discussed below.

Mass analysis determines the mass-to-charge ratio (m/z) of ions derived from the analyte. For peptide ions, two characteristis can be obtained. The first characteristic is the molecular weight of the peptide, which can be calculated from the measured m/z of the source-generated intact peptide ion (the so-called molecular ion). The second characteristic is structural information that is obtained via an MS/MS analysis. A n M S/MS experiment measures gas-phase dissociations of an activated molecular ion of the peptide to yield product-ion data that are diagnostic of the peptide sequence. The basic sequence of events in MS/MS includes: 1. mass selection of the peptide ion of interest (that is population of ions of a single m/z) as a so-called precursor ion; 2. activation of the precursor ion, most commonly through collisions with an inert gas, followed by dissociation of the activated precursor and formation of product ions; 3. mass
analysis of the product ions and recording of the MS/MS spectrum. The process of collisional activation and dissociation is termed collision-induced dissociation (CID). Depending on the instrument type, the MS/MS events can be separated in space (tandem-in-space) or in time (tandem-in-time).

In MS/MS, protonated peptide ions in the gas phase dissociate via cleavages along the peptide backbone; fragmentations can occur at any of the three types of bonds that make up the backbone of the peptide (Fig. 2). The nomenclature for peptide dissociations distinguishes six major series of sequence-determining product ions (14, 15). The N-terminal series encompass the a-, b-, and c-ions; and x-, y-, and z-ions. In addition to the six basic series, other types of product ions may also be observed (16) under certain conditions. The relative abundance of the different product ions depends on the amino acid sequence of the peptide, on the internal energy of the dissociating precursor ion, and on additional variables that affect the CID process (17). Under low-energy CID regime, used for example in ion trap mass spectrometers, the predominant types of product ions are the b-ions and y-ions that form by cleavages of the peptide bond. As shown in Fig. 2, adjacent (singly-charged) product ions from a series have a difference in mass that determines the amino acid present at that position of the peptide. For example, if the amino acid in position 3 of the tetrapeptide in Fig. 2 is a serine (R3=CH2OH), the mass difference between the y2 and y3 product ions will be 18 Da, corresponding to the mass of the serine residue -NH-CH(C2H5)OH-. Therefore, when an MS/MS spectrum of a peptide ion contains high quality data for one complete or several partial overlapping product ion series, then the sequence of the peptide can be deduced from the MS/MS data.

**Specifics of phosphopeptides**

Phosphorylated peptides are modified peptides and therefore most of the basic concepts discussed above also apply to mass spectrometry of phosphopeptides.

In terms of ionization, the majority of large-scale phosphoproteomics strategies utilize ESI. The difficulty to effectively analyze phosphopeptides by ESI-based approaches is often attributed, among other factors, to selective suppression of phosphorylated peptides in the presence of unmodified peptides, and to decreased ionization efficiencies of phosphopeptides relative to their non-phosphorylated counterparts. However, this notion has been challenged in a recent study [18] underscoring the complexity of the phenomena associated with analyses of highly complex peptide/phosphopeptide mixtures.

Modification by phosphorylation adds 80 Da to the mass of the corresponding peptide. The principles of gas-phase dissociations of protonated phosphopeptide ions into sequence-determining product ion series are analogous to those of non-phosphorylated peptides, with an additional issue that must be taken into consideration. Under CID conditions phosphorylated peptide ions undergo a facile neutral loss of H3PO4, corresponding to the loss of 98 Da. The mechanisms that underlie this dissociation behavior have been studied for phosphoserine-, phosphothreonine-, and phosphotyrosine-containing peptides (19, 20). The loss of phosphoric acid from the molecular ion produces a non-sequence-specific product ion (M + H)−. This product ion can serve as a marker ion, indicating the presence of a phosphorylated peptide. An example of an MS/MS spectrum of a phosphorylated peptide is shown in Fig. 3. This spectrum illustrates the typical fragmentation behavior of protonated phosphopeptide ions in ion trap MS/MS. The spectrum is dominated by the intense (M + 2H-H3PO4)2+ product ion; the spectrum further contains product ions of the y- and b- series that determine the amino acid sequence of the phosphopeptide and the location of the phosphorylation site. Often, the scenario is not so favorable. The loss of phosphoric acid dominates and not enough other product ions are observed for an unequivocal sequence determination. One way to remedy this unfavorable outcome is to perform an additional dissociation, an MS/MS/MS, where the primary product ion (M + H)− H3PO4)2+ is mass-selected and then dissociated via CID.

The LC-MS/MS experiment

This section discusses a typical mass spectrometry experiment used for phosphopeptide analysis. Typically, after peptide fractionation and enrichment, the peptide digest will contain phosphopeptides in mixture with nonphosphorylated peptides. This mixture will be of a high complexity. Commonly, the mass spectrometry measurement itself is preceded by a separation of this peptide digest by reversed-phase liquid chromatography, interfaced online to MS. This LC step, typically performed in nanoflow mode and using a shallow mobile phase gradient, will separate the peptides according to their hydrophobicities. The peptides eluting from the LC are ionized by nanoESI, and peptide mass and MS/MS data are measured.
Two issues have to be addressed. First, because of the complexity of the starting mixture, even after LC separation, multiple peptides will elute and therefore at any given time there will be more than one peptide ion present. Second, the characteristics, including the mass of the precursor ion that is needed to set the precursor selection in MS/MS are not known. These issues are dealt with through data-dependent acquisition mode, in which the mass spectrometer automatically cycles through a sequence of measurements of MS and MS/MS data. For peptide and phosphopeptide analysis, the instrument measures an MS spectrum to obtain masses of the analytes eluting from LC at that particular time. Based on the information from these MS data, subsequent MS/MS events are set – for example, 5 MS/MS measurements of 5 of the most intense ions from the MS spectrum, provided they are above a specified intensity threshold. The cycle is repeated many times during the LC-MS/MS analysis. To maximize information gained in the MS/MS steps, some strategies are incorporated such as a permanent exclusion from MS/MS of known contaminants throughout the entire analysis; temporary exclusion of peptides whose MS/MS have already been measured for the duration of the expected time that it takes for the peptide to elute from the LC column. These strategies that decrease redundancy and maximize the number of peptides surveyed in the analysis are particularly important for phosphopeptides that are frequently minor components in a peptide digest. In a typical LC-MS/MS analysis, a large number of MS and MS/MS spectra are acquired, for example >10,000 MS/MS spectra on state-of-the-art ion trap instruments.

Bioinformatics

In proteomics and phosphoproteomics applications, search programs are used that utilize minimally processed MS/MS data without the need for manual interpretation (21). Development of these programs, for example SEQUEST, that allow the integration of mass spectrometry data with database searching has been one of the enabling developments in proteomics. In SEQUEST-based searches, the experimentally measured peptide mass is used to locate in the database peptide sequences whose masses match the measured mass, and then experimental product ion patterns are compared to theoretical patterns for each candidate peptide, and a correlation score is calculated. The highest scoring peptide sequences are reported. For phosphopeptide characterization, the search considers possible addition of 80 Da to serine, threonine, and tyrosine residues. After completion of the search, it is imperative that the spectra and the database search outputs are inspected before an ultimate decision about the correctness of the match is reached. For phosphopeptides, this examination includes verification that the correct amino acid sequence was retrieved, and verification of the assignment of the phosphorylation site. Once the phosphopeptides are identified and their sites are characterized, additional bioinformatics resources are available for in silico analysis and functional integration. For example, with the program ScanSite (scansite.mit.edu), sequences of the identified proteins are searched to locate motifs that would suggest phosphorylation by a specific kinase or a phospho-specific binding interaction.
Information on protein phosphorylation is compiled in several databases, for example Phosphosite (www.phosphosite.org), Phosida (www.phosida.org), and others.

Additional approaches and current developments

Mass spectrometry-based phosphoproteomics is characterized by a great diversity of bioanalytical workflows and by continuous developments of new and improved strategies. Some of these new approaches are summarized in this section.

To address some of the issues associated with CID of phosphopeptides, new strategies for ion activation/dissociation have been introduced recently in the context of phosphoproteomics. In particular, electron transfer dissociation (ETD) is emerging as a promising new strategy for MS/MS-based phosphopeptide analysis (22, 23).

It should also be noted that besides the conventional product ion scanning, specialized MS/MS functions have been adopted for phosphopeptide analysis (9). These include precursor ion scanning for monitoring the precursors of the product ion (或许是9) in the negative mode, or precursors of the phosphotyrosine-specific immonium ion at m/z 216.043 in the positive mode.

Finally, quantitative information in phosphoproteomics may be obtained through the use of stable isotope labeling. Stable isotope labeling is a proven approach for mass spectrometry-based quantification. Recent examples of stable isotope labeling methods that have been successfully adapted for large-scale quantification of protein phosphorylation include the iTRAQ methodology that involves chemical tagging at the peptide level (24), and the Stable Isotope Labeling of Amino Acids in Culture (SILAC) methodology that involves metabolic labeling (4).

Chemical Tools and Techniques

The study that serves to illustrate a possible bioanalytical strategy for characterization of protein phosphorylation in a human pituitary tissue (25) is included. The analytical methodology involves in-gel IEF for protein separation, IMAC for enrichment of phosphopeptides after digestion, LC-MS/MS and database searches for phosphopeptide identification and localization of the phosphorylated amino acid residues.

The tissue sample is obtained from surgery or autopsy, and it must be frozen immediately to prevent protein degradation. Prior to analysis, the proteins including phosphoproteins are extracted via homogenization in the Trizol reagent that isolates proteins from RNA and DNA; a phosphatase inhibitor cocktail is added to minimize dephosphorylation. Proteins are obtained in the last step of the Trizol-based extraction in the form of a pellet that is then dissolved in a buffer suitable for isoelectric focusing. This buffer typically contains chaotropes such as urea and thiourea, CHAPS detergent, ampholytes that aid in the IEF, and dihydrothreitol as a reducing agent. IEF that is performed in a commercially available immobilized pH gradient (IPG) strip separates the proteins based on their charge. After IEF, the strip is divided into sections. Each section still contains multiple proteins but the complexity of these mixtures is greatly reduced compared to that of the initial mixture. The proteins in each section of the IPG strip are digested with trypsin to produce mixtures of peptides that include phosphorylated and non-phosphorylated peptides. IMAC is used to enrich for phosphorylated peptides. The steps in the IMAC procedure involve: 1. selective binding of the phosphopeptides via interaction of their phosphate groups with the immobilized metal ion (e.g., Ga+3) under carefully controlled acidic pH conditions; 2. washing of unbound and non-specifically bound material; 3. elution of phosphopeptides from the column under alkaline conditions. Following IMAC, desalting and volume reduction of the samples is performed with a C18 minicolumn, and the samples are analyzed by LC-MS/MS. The nano-LC setup includes a combined capillary column/spray needle packed with a C18 stationary phase. The i.d. of the column is 75 µm, the i.d. of the spray tip is 15 µm, and the flow-rate is on the order of 50-150 nl/min. Mobile phases typical for reversed-phase chromatography that are compatible with mass spectrometry are used, such as water/acetonitrile/formic acid or water/methanol/formic acid (26). Peptides and phosphopeptides eluting from the nano-LC are ionized by nanoelectrospray to produce multi-protonated ions in most cases (doubly or triply charged). MS and MS/MS spectra are acquired in the data-dependent mode. MS/MS/MS may be performed in non-data-dependent mode in a separate LC-MS/MS experiment. Alternatively, this step, where MS3 is triggered when a (M + nH-H3PO4)n product ion is present in the MS/MS spectrum, may be incorporated into data-dependent scanning (3). The set of data is used to search a protein sequence database such as SWISSPROT or NCBI (nr). The search parameters include modifications for C-terminal carboxylic acid residues that are added upon phosphorylation is expected to occur. The search yields lists of phosphopeptide matches with scores indicating the quality of the match. The matches are evaluated manually. This evaluation has two objectives: confirmation of the correct amino acid sequence of the phosphopeptide which establishes the presence of the phosphorylated form of the corresponding protein in the pituitary; and assignment of the exact phosphorylation site(s) in the peptide. This validation includes inspection of the MS/MS data and the scores. Finally, the phosphorylated proteins are put into context of current scientific knowledge, using databases such as Phosphosite that extract and compile published information on protein phosphorylation.

Membrane Protein Structure, Techniques to Study

Gavin King and Ann M. Dixon, University of Warwick, Coventry, United Kingdom
doi: 10.1002/9780470048672.wecb653

The biological importance of membrane proteins has been recognized worldwide for many years, but historically these proteins have proved difficult to characterize structurally because of a variety of experimental challenges. Recently, technological advances across several disciplines have prompted considerable progress in three-dimensional structure determination of membrane proteins. This review describes the state-of-the-art methods that have successfully produced high-resolution membrane protein structures to date. Most notably, X-ray crystallography will be discussed, as this technique has made by far the largest contribution to our current knowledge of membrane protein structure. This is followed by discussion of nuclear magnetic resonance spectroscopy and cryo-electron microscopy, both techniques that have also been successful in producing high-resolution structures for membrane proteins, albeit to a lesser degree than X-ray crystallography. Finally, we will discuss atomic force microscopy. Although this technique cannot be used for atomic level structural determination, it offers distinct advantages for investigation of membrane protein oligomerization, dynamics, and large-scale conformational changes. Recent notable membrane protein structures are included throughout to illustrate progress in the field as well as the strengths and weaknesses of each method.

Structural, biophysical, and biochemical studies of membrane proteins have revealed the importance of this class of proteins in fundamental biological processes such as the import and export of nutrients and waste into and out of cells, cell division, and signaling, to name a few. With approximately one third of sequenced genomes encoding integral membrane and membrane-associated proteins, and two thirds of all drugs in development targeting membrane proteins, their importance is now well accepted. However, three-dimensional (3-D) structures of the majority of known membrane proteins still elude us. Of the 47,000 protein structures deposited in the Protein Data Bank (PDB), only about 1% are for membrane proteins. Solving the structures of these proteins has proved to be highly challenging, and it still represents the leading edge of protein structural biology. The slow progress is caused, in part, by difficulties in protein production and purification (especially for eukaryotic membrane proteins) and in part by experimental difficulties encountered because of their large size and the requirement for detergent/lipid solubilization. Despite these obstacles, significant advancement has been made over the past decade. Careful production of membrane proteins and major breakthroughs in instrumentation have yielded stunning results for several classes of membrane proteins, including channels, pores, and receptors. The resulting structural data have given us an insight into the architecture of both simple and complex membrane proteins as well as their function [for an excellent summary of known structures, see http://blanco.biomol.uci.edu/MembraneProteins_xtal.html]. In this review, we will cover the four most successful and commonly used experimental methods for determination of membrane protein structures, namely X-ray crystallography, nuclear magnetic resonance spectroscopy, electron microscopy, and atomic force microscopy, with particular emphasis on recent advances. We note that molecular dynamics simulations have also contributed significantly to our current understanding of membrane protein structure, and closely accompany the above.
Membrane Protein Structures by X-Ray Crystallography

X-ray crystallography is by far the most successful method for solving structures, having provided approximately 80% of the membrane protein structures currently held in the PDB. The first membrane protein structure solved by X-ray crystallography (XRC) was that of the photoreaction center from Rhodopseudomonas viridis, originally solved at 3 Å resolution in 1985 (1). Since that time, XRC has been applied to a wide variety of membrane protein families. This technique typically produces 3-D structural data with resolution ranging from 1.5 to 3.5 Å, making it the highest resolution technique currently available for structure determination.

XRC determines the precise arrangement of atoms within a crystal by analyzing the scattering (diffraction) of X-rays by electrons to produce an electron density map. The rate-limiting step in structure determination by XRC is the production of well-ordered 3-D crystals, which has proved to be highly challenging as illustrated by the scarcity of membrane protein structures. Obtaining sufficient quantities of highly purified protein for numerous crystallization trials is often difficult, as membrane proteins can be toxic to heterologous hosts. Recent advances in automation and miniaturization have greatly reduced the quantity required, currently enabling investigators to test up to 100,000 conditions in parallel per day using less than 300 mg of protein (2). Despite these advances, however, crystallization remains a "trial-and-error" process, involving numerous variables and exacerbated for membrane proteins by the need for solubilizing agents such as detergents, which can greatly destabilize protein folds and shield crystal contacts.

The size and quality of the crystals greatly impacts the resolution of XRC (X-ray crystallography) and, therefore, is of utmost importance. The X-ray source also plays a key role in the quality of XRC data. Traditional X-ray sources can suffer from poor spatial coherence and low beam strength. For these reasons, synchrotron sources are now commonly used to collect data. A synchrotron source produces high-energy X-rays that more effectively penetrate the crystal to interact with atoms in the protein. The X-ray beam from a synchrotron source is more coherent, has a higher concentration, and can be accurately focused on very small targets.

3-D crystallization of membrane proteins

The first, and often most difficult, step in XRC is the production of 3-D crystals of purified protein. It is important to emphasize the importance of protein purity for successful crystallization because, although it is true that a nonhomogenous mixture may crystallize, it has been noted by some researchers that difficulties in crystallizing a protein may be negated by further purification. Crystallography of membrane proteins is a complicated process, and various approaches have been used, including vapor diffusion, microdialysis, batch crystallization and the recently developed lipid-phase methods. Detailed information on membrane protein crystallization can be found in several excellent reviews in the "Further Reading" section. The general principle of protein crystallization involves the supersaturation of a protein solution. The addition of precipitating agents such as salts, organic solvents, or polymers triggers the crystallization process.

Detergents play a vital role in the crystallization of membrane proteins. However, as mentioned, they can also have a destabilizing effect on the protein. For successful crystallization, the detergent micelles must be accommodated in the crystal lattice with minimum effect on the formation of crystal contacts. The choice of detergent and its associated properties (polarity of head group, aliphatic chain length, size) must be explored for each protein (3). Generally, charged detergents should be avoided because of the risk of repulsion between protein-detergent complexes. The length of aliphatic chains should be balanced between the need to cover the protein’s hydrophobic surfaces and the need to have as low a detergent volume as possible to maximize protein-protein contacts. The phase behavior of detergents and lipids is also a pertinent consideration. Phase separation from a micellar phase (detergent-rich) toward a nonmiscible phase (detergent-poor) can occur at high-detergent and precipitant concentrations. These phase boundaries have been exploited to enhance crystallization of membrane proteins (4). The use of additives such as small amphiphiles (e.g., heptane-triol, LDAO) can also enhance crystallization by reducing the volume of detergent in the protein-detergent complex, leading to increased numbers of crystal contacts (5). However, the overriding problem with the use of detergents is the increase in the number of variables that need to be optimized in crystallization trials, which is already considerable. Coupled with the use of additives, this presents a huge number of possibilities. The absence of a general set of rules to guide detergent/additive choice is currently a significant problem for crystallization, and it increases the timescale for each structure.

A significant landmark in membrane protein crystallization has been the development of lipidic cubic phase technology (6). This technically challenging approach is capable of producing crystals that diffract beyond 2 Å while providing an environment resembling that of a natural membrane. Lipidic cubic phases are gel-like materials into which the protein is embedded. Crystallization is then initiated by the addition of precipitants. If successful, the resulting crystals contain ordered layers of protein-lipid sheets, with contacts formed within and between the sheets. Lipidic cubic phases have been successfully used to crystallize several membrane proteins, including archeal seven transmembrane proteins (6, 7). Co-crystallization with antibody fragments (Fv fragments of Fab domains) has also been used to enhance membrane protein crystallization (8, 9). The fragments form bridges between protein-detergent complexes, thus increasing the number of protein-protein contacts. Using this method, crystallization was achieved for the cytochrome bc1 complex (8), the KcsA potassium channel (10), and more recently the human β3 adrenergic receptor (Fig. 3A) (11-13). A caveat to this approach is that antibody production must be
Membrane Protein Structure, Techniques to Study

The process of crystallization is still largely a process of trial and error, but in an attempt to formulate general rules, the cumulative experiences of X-ray crystallographers are being compiled into online databases such as the Marseille Protein Crystallography Database (14) and the Biological Macromolecule Crystallography Database (15). These and similar databases will provide useful starting points in crystallization trials and may greatly accelerate the process.

Collection of X-ray diffraction data

A detailed examination of the crystallographic method is beyond the scope of this article. Sources of more detailed information can be found in the “Further Reading” section. The general method of XRC involves five steps: 1) crystallization of purified protein (discussed above); 2) measurement of crystal diffraction; 3) phase determination; 4) phase and electron density calculations; 5) model building. Once crystals are formed, they are exposed to X-rays and diffraction data are collected. Exposure to X-rays can damage the crystals, and this can be reduced by freezing the crystal under a nitrogen stream at 100 K. This approach is not always favorable for membrane proteins as crystal contacts can be quite weak and, therefore, highly sensitive to temperature. Cooling can further destabilize the crystal by causing the detergents to undergo phase transitions that perturb crystal contacts. For these reasons, cooling may be limited to 4°C, which often proves sufficient to collect diffraction data. Smaller crystals are more amenable to freezing but often yield poor-quality data, being best suited for use with synchrotron beams (16). After a collection of diffraction data, phase determination is commonly carried out for soluble proteins using the method of molecular replacement. This method is less useful for membrane proteins because of the lack of known structures. A related method for phase determination is the “heavy-atom” method, which involves soaking crystals in heavy-atom solutions. Unfortunately, this method is also not as effective for membrane proteins because of the reduced binding of heavy atoms, which is a direct result of the decrease in hydrophilic surfaces, lack of accessibility, and nonspecific interactions of hydrophobic heavy-atom compounds with detergents. An alternative approach to the phase problem involves multi-wavelength anomalous diffraction phasing using selenomethionine (17). Diffraction and phasing data are used to create an electron-density map and to build a preliminary model. The model is further refined by multiple rounds of energy minimization and manual manipulations. Finally, simulated annealing is performed to produce the final structure of the protein.

Recent notable structures

Human β-2 adrenergic receptor

In 2007, this structure was solved to a resolution of 2.4 Å (11) (Fig. 3a), and it represents the first structure of a ligand-activated G-protein-coupled receptor. Crystallization was achieved using the antibody co crystallization approach. This work revealed structural features not seen before in this protein family, including cholesterol-mediated intermolecular associations and an extracellular loop containing a helix.

Sodium-potassium pump

The structure of the sodium-potassium pump was solved in 2007 to a resolution of 3.5 Å (Fig. 3b), in complex with two bound rubidium ions (13). Structures were also solved for other members of the P-type ATPase family (18, 19) around the same time revealing the structural similarity between family members as well as the conformational changes that occur during function.

Acid-sensing ion channel

This high-resolution structure (1.9 Å) solved in 2007 was the first structure of an acid-sensing ion channel (19). It belongs to the degenerin/epithelial sodium channel family of ion channels, which play essential roles in diverse biological processes such as mechanotransduction and ion homeostasis. The structure (Fig. 3c) revealed the trimeric state of the protein channel as well as a possible mechanism for activation, involving long-range conformational changes triggered by proton binding.

Membrane Protein Nuclear Magnetic Resonance Spectroscopy

Solution-state nuclear magnetic resonance (NMR) spectroscopy has also proved very useful in membrane protein structure determination, particularly for smaller proteins. Like XRC, solution NMR requires the use of high concentrations of protein as well as solubilizing agents like detergents, and therefore, it requires a similar level of optimization. However, when optimal conditions are achieved, NMR provides high-resolution structural data and has the added advantage of providing information on function, dynamics, topology, and interactions of the protein with the membrane, lipids, and other proteins. NMR determines the arrangement of atoms in a protein by exploiting the quantum magnetic property that certain atomic nuclei will align their magnetic moment with an external magnetic field. Perturbation of B₀ by a second perpendicular magnetic field leads to a response of the atomic nuclei that is detected as the NMR signal. NMR signals provide information on both short- and long-range interatomic distances that are used with simulated annealing methods to determine the 3-D structure of a protein. The lifetime of the NMR signal is related to the size of the protein, with signals for large, slowly tumbling proteins relax very rapidly. This relaxation leads to severe broadening of the signals, and it places a practical limit on the size of proteins that can be analyzed. Thus far, solution-state NMR has yielded the global fold of an 82-kDa soluble protein (20); however, for membrane proteins, the practical limit is around 40 kDa, making it most useful for proteins or individual domains. NMR studies of several membrane proteins have been carried out in the solid-state (in lipid bilayers), and this will be discussed briefly in the next section. However, a larger number of membrane proteins has been studied in solution, and this will be the main focus here.
Membrane Protein Structure, Techniques to Study

Figure 1  Ribbon representations of three membrane protein structures determined using X-ray crystallography. (a) The human β2 adrenergic receptor was crystallized using the technique of antibody co-crystallization (11) (PDB ID: 2R4R). The structures of the receptor (i) and the antibodies (ii) are shown. (b) The structure of the sodium-potassium pump (12) (PDB ID: 3B8E) is shown, indicating the three subunits of the protein. (c) The structure of the acid-sensing ion channel 1 at low pH (13) (PDB ID: 2QTS), which is composed of three chains (i, ii, and iii) that assemble to form a trimer.

Solid-state NMR

Solid-state NMR will only be considered in brief because of the limited number of novel membrane protein structures produced. For comprehensive reviews of this technique, the reader is referred to the “Further Reading” section. Around 17 structures (mainly small peptides) solved by solid-state NMR have been deposited in the PDB, with the first being gramicidin A in 1997 (21) and the most recent being the backbone structure of Influenza A M2 proton channel transmembrane domain (22). Solid-state NMR differs from the solution-state in that the molecule under investigation is static or slowly tumbling, resulting in broad NMR peaks with low resolution and sensitivity. This fundamental problem has been tackled by development of MAS (magic-angle spinning) (23) and REDOR (rotational echo double resonance) (24) experiments. Advantageously, solid-state NMR methods enable membrane proteins to be studied in lipid bilayers resembling native membranes; a disadvantage is that proton detection is challenging, with most studies focusing on isotopically labeled samples.

Membrane protein samples for solution-state NMR

Three-dimensional structure determination by NMR requires complete assignment of spectral peaks (or resonances), and the success of this process is highly dependent on sample preparation. Similarly to XRC, obtaining purified protein is a rate-limiting step in NMR structure determination. Resolution and sensitivity can be increased through isotopic labeling of proteins with 15N and 13C, either by expression in labeled media or by incorporation of labels during synthesis. Once a labeled protein has been obtained, solution conditions (e.g., temperature, pH, and ionic strength) must be optimized for NMR. For membrane proteins, this also involves selection of a solubilizing agent, which can solubilize the protein at a sufficiently high concentration for NMR (typically ~1 mM), produce high-resolution spectra, and maintain the protein in its native conformation. Detailed protocols for protein and sample preparation can be found in the “Further Reading” section.

NMR data collection and structure determination

Once a suitable membrane protein sample is prepared, spectral assignments are made. A assignment is another rate-limiting step in NMR structure determination, and it has greatly benefitted

Dodecylphosphocholine (DPC) micelles were employed to determine the structure of OmpA (25) (PDB ID: 1G90) (b) Bicelles, composed of lipid/detergent mixtures, have been used recently to solve the structure of the Bnip3 transmembrane domain dimer (26) (PDB ID: 2J5D) (c) Synthetic lipid bilayers closely approximate the natural environment of membrane proteins and have been used with solid-state NMR to determine the structure of the fd bacteriophage ph2 coat protein (27) (PDB ID: 1MZT). (d) Amphipols are amphiphilic polymers consisting of a hydrophilic backbone onto which numerous hydrophobic chains are attached that can coat the hydrophobic region of membrane proteins. (e) Nanodisks are self-assembling structures composed of a phospholipid bilayer disk encircled by an engineered membrane scaffold protein. (f) Lipid cubic phases are primarily used in X-ray crystallography studies but recently have shown promise for use in NMR studies as well. (g) NMR structure of the phospholamban pentamer (PDB ID: 1ZLL), looking down on the central cavity. (h) Side view of the phospholamban pentamer shown in (g) overlaid with a refined version of the structure published in 2006 (PDB ID: 2HYN).

From the development of the TROSY (transverse relaxation optimized spectroscopy) triple resonance experiments, which improve spectral resolution and sensitivity (36). Although TROSY experiments will not be covered in detail here, briefly these experiments reduce relaxation of NMR signals at high magnetic field strengths, thus increasing the molecular mass of proteins that can be studied to ~50 kDa. Additional benefits can be realized by using TROSY in conjunction with a selectively deuterated protein and deuterium decoupling, acting to further reduce broadening of signals (37). TROSY experiments have been used successfully to assign the resonances of both β-barrel (25, 38) and α-helical membrane proteins (39).

After completion of the spectral assignment, NMR-derived short- and long-range distances can be determined by measurement of nuclear Overhauser enhancements (or NOEs). An NOE is an interaction between a pair of atoms ≤5.0 Å apart, and the intensity of the NOE can be related to the distance (r) separating the pair. The use of NOEs can be problematic for helical proteins as they tend to have few long-range NOEs. The use of methyl protonation can increase the number of NOEs; however, because of the poor chemical shift dispersion of methyl groups in helical membrane proteins, this approach is generally ineffective. An alternative is the use of residual dipolar couplings (RDCs) to obtain long-range distances. RDCs are derived from the difference in coupling constants in an aligned and unaligned state, providing information on the orientation of internuclear vectors relative to the external magnetic field (40). Several methods have been developed to produce weak alignment of membrane proteins, thus enabling the measurement of RDCs. Polyacrylamide gels can be used for small-to-medium proteins to produce an anisotropic environment where protein orientations are limited, resulting in weak alignment (40).
Membrane Protein Structures, Techniques to Study

DNA nanotubes are also a promising alignment method with the added advantage that they are resistant to detergent and do not reduce achievable protein concentrations (41). Alignment can also be achieved by incorporation of paramagnetic lanthanide ions into diamagnetic proteins (42). Once aligned samples are prepared, RDCs are accurately measured using a set of TROSY-based experiments (43). Importantly for helical proteins, a plot of backbone amide RDCs versus residue number produces a wave pattern with a periodicity of 3.6 residues per cycle for helical regions, allowing detection of helical secondary structure and the tilt of the helix relative to the magnetic field (44). The use of RDCs for structure refinement has been demonstrated for several membrane proteins, including OmpA (45), Vpu (46), and MreF (47).

Finally, NMR-derived distance information as well as information about dihedral angles (obtained from chemical shifts) is incorporated into structure calculations performed using molecular dynamics and simulated annealing programs such as CNS (48) and XPLOR-NIH (49) to calculate the protein structure.

Recent notable structures

Mistic

Despite its uncertain status as a membrane protein, the structure of Mistic from Bacillus subtilis determined in detergent micelles highlights a promising approach to solving the 3-D structure of multispanning helical membrane proteins by solution-state NMR (50). Backbone and side-chain assignment was achieved by partial deuteration and full 13C/15N labeling of the protein. The conformation of its four u-helices was determined using 13C chemical shift-derived angle restraints, NOEs, and hydrogen bond restraints. Importantly, 497 long-range restraints from 5 paramagnetic spin labels and 29 long-range NOEs allowed the fold of the protein to be determined.

Outer membrane protein a (OmpA)

In 2001, the structure of the transmembrane domain of OmpA (Fig. 2a) was solved in DPC micelles, and it represented the largest membrane protein structure (19 kDa) to have been solved by NMR at that time (25). TROSY triple-resonance experiments enabled a large number of the residues to be assigned for the deuterated protein. Relatively limited structure restraints (NOEs, dihedral angles, interstrand hydrogen bonds) revealed an eight-stranded β barrel structure for the transmembrane domain of this ion channel that was very similar to the existing X-ray structure.

Phospholamban pentamer

Phospholamban is a homopentameric membrane protein involved in muscle contraction through regulation of the calcium pump in cardiac muscle cells. The structure of the unphosphorylated protein solved in DPC micelles reveals a symmetric pentamer of phospholamban monomers (Fig. 2b) stabilized by leucine/isoleucine zipper motifs along the transmembrane domains (51). Notably, another structure was produced for phospholamban (Fig. 2h) that used a variant of the traditional simulated annealing and molecular dynamics protocol that reduced the chances of entrapment in local minima (52).

Membrane Protein Structures by Electron Microscopy

Electron microscopy (EM) has also made major contributions to the field of membrane protein structure determination, and could potentially lead the field before long. This technique provides major advantages in that the structural features of membrane proteins can be measured in their native membranes or reconstituted lipid bilayers, and not in detergents as required by (and which often limits the success of) XRC and solution NMR techniques. Although electron microscopy has historically produced lower resolution structures than XRC and NMR, recent improvements in instrumentation and sample preparation have produced data with resolution that rivals even the best X-ray structures (53).

The first reported 3-D model of a membrane protein was obtained using EM. This ground-breaking work was reported by Henderson and Unwin in 1975, who analyzed two-dimensional (2-D) crystals of bacteriorhodopsin within the purple membrane to produce a density map with 7Å resolution and a structural model of the protein (54). This data provided our first view of the architecture of a membrane protein, revealing key features such as membrane spanning u-helices. Fifteen years and many instrumental and methodological improvements later, a model of bacteriorhodopsin at atomic resolution was reported, marking the first structure solved by electron microscopy (55). Since that time, structures of important membrane protein classes, including pores (53, 56), receptors (57–59), channels (60, 61), transporters (62), and enzymes (63), have been solved using EM.

EM can provide structural information for a protein at a variety of different resolutions depending on the microscope used, the method of staining, and the condition of the sample. State-of-the-art electron microscopes can provide resolution of up to a few angstroms for good quality samples. In order to obtain high-resolution structural information from EM, one important factor is the electron source. Electrons emitted from a heated metal cathode suffer from poor spatial coherence and yield only a small amount of signal at high resolution. An alternative electron source that is rapidly gaining widespread use, the field emission gun (FEG), produces a much more coherent electron beam by limited heating in combination with an electric field. Certainly most of the current high-resolution EM structures have been acquired using an EM equipped with an FEG.

Another important factor in obtaining high-resolution data is the minimization of radiation damage to the sample. Radiation damage results from exposure of the protein sample to the electron beam as it is being imaged, and it greatly limits the resolution of the data. This loss of resolution is one of the primary reasons that XRC has had more success in obtaining structural data for proteins sensitive to radiation. One method that greatly reduces radiation damage and represents a major milestone in the field is electron cryomicroscopy (cryo-EM), in which samples are prepared in a frozen hydrated state and imaging takes place at liquid nitrogen or liquid helium temperatures under high vacuum. Cryo-EM is now the method of choice for the freezing and imaging of biological macromolecules.
Preparation of samples for cryo-EM analyses

In order to produce 3-D reconstructions of membrane protein structures effectively, cryo-EM is most successful for samples present as single particles or in 2-D crystals (as opposed to the 3-D crystals used in XRC). Single-particle cryo-EM is used primarily for large proteins and complexes that do not form crystals (64). In this approach, images are obtained for particles fixed to a carbon-film surface and coated in a layer of heavy metal salts, a process called negative staining, that acts to protect the sample from beam damage and improve image contrast, or particles suspended within a layer of vitreous ice (cryo-EM). These images are then averaged after alignment of the various particle orientations.

Although single-particle EM has been most successfully and routinely used for soluble proteins, structural information for several membrane proteins including the nandine receptor ion channel (58), the L-type Ca\(^{2+}\) channel (61), the voltage-gated K\(^{-}\) channel (60), and the inositol (1,4,5)-triphosphate receptor (65) has also been obtained using this method. However, single-particle EM has thus far resulted in low-resolution structural information, typically yielding data with resolutions in the range. A further disadvantage of single-particle cryo-EM is the lower limit for molecular weight, which is currently approximately 250 kDa. This limit results from the need to distinguish between individual particles and molecules in the surrounding medium, and it is unlikely to change in the future (66).

The highest resolution cryo-EM data has thus far been obtained for proteins present in 2-D crystals (a technique known as electron crystallography). This technique measures the structural features of membrane proteins reconstituted into 2-D crystals in the presence of lipid bilayers. In contrast to the 3-D crystals used in XRC, in which proteins are solubilized in detergent micelles that can disrupt crystal formation and reduce crystal quality, formation of 2-D crystals forces the membrane proteins to pack within a lipid bilayer, thus restoring their native environment. A further advantage of 2-D crystallization is that it requires very small amounts of protein (as opposed to NMR, which requires milligram quantities).

As with the growth of 3-D crystals, the growth of 2-D crystals is often the most difficult step in cryo-EM analysis of a membrane protein. Two-dimensional crystallization of membrane proteins can be achieved by mixing the protein with detergent and lipids, and then slowly decreasing the detergent concentration (e.g., by dialysis). Two-dimensional crystals can also be formed by vesicle fusion, addition of crystallizing agents, addition of detergents to reduce the lipid-protein ratio, or adsorption onto lipid monolayers (for a review of 2-D crystallization techniques, see the “Further Reading” section). Because the fundamental mechanisms of 2-D crystal formation are thus far very poorly understood, extensive screening of suitable lipids and lipid-protein ratios is required (67) to obtain a high-quality crystal. However, in some cases, membrane proteins that have proved very resistant to 3-D crystal formation have readily formed 2-D crystals in lipid membranes.

Two types of 2-D crystal have been analyzed by cryo-EM: sheet-like (planar) crystals and tubular crystals. Planar crystals are tilted in the electron beam in order to obtain different projection maps of the crystal at a variety of angles. Maps collected at different angles are then averaged together to produce a 3-D reconstruction (68). However, the planar crystal cannot be tilted through all angles in the microscope (for example, a sample rotated through 90° would then be parallel to the electron beam) and typically can only be rotated through 70°–75°. The resulting resolution is, therefore, spatially heterogeneous and appears to have what is known as a “missing cone” of data. Alternatively, membrane proteins can also crystallize into tubular crystals where, in a single crystal “tube” one can potentially see all orientations of a protein without the need to tilt the crystal. Tubular crystals overcome the “missing cone” of information and provide resolution that is equal in all directions (59).

Collection of cryo-EM data

High-resolution cryo-EM data can be collected in two forms: electron images (69) or as electron diffraction patterns. Cryo-EM images contain information on both amplitude and phase, which can be analyzed after Fourier transformation. The quality of the amplitude data can be improved if combined with electron diffraction data, which contains only amplitude information. In this way, EM overcomes one of the main difficulties in XRC. In XRC, only diffraction patterns are obtained. X-rays cannot be used to form an image of the crystal; therefore, the phase information is lost. In contrast, electron microscopes contain electron lenses that can capture phase information.

Structure determination and other applications of cryo-EM

A 3-D structure is determined by fitting an atomic model to a 3-D density map at a given resolution. This map is determined by analyzing EM images and electron diffraction patterns. Because the membrane protein is embedded within a lipid bilayer, 2-D crystals more closely resemble its native environment than 3-D crystals do. The protein Aquaporin 1 (AQP1) embedded in a 2-D crystal was shown to maintain its biological activity (70). Because they are more likely to adopt their native fold in a lipid bilayer, 2-D crystals are thought to provide more biologically relevant structural information about protein-protein and protein-lipid interactions. This is illustrated by the 3-D structure of the transporter protein EmrE, which has been solved by both XRC (71) and cryo-EM (62). Comparison of the two structures reveals important differences between the structure of EmrE in a 2-D crystal (formed in detergent) and its structure in a 2-D crystal (embedded in a bilayer) that result from the presence of lipids.
Membrane Protein Structure, Techniques to Study

conformational changes of a protein over time, thus yielding critical insight into function. In these time-resolved studies, conformational changes are induced in the protein (by changing pH, adding ligand, etc.) and then trapped by freezing the crystal. Freezing can take place at several time points after induction of a conformational change to produce a series of structures that describe a reaction pathway. Time-resolved studies have been performed to investigate the photocycle of bacteriorhodopsin (72), the gate-opening mechanism of the acetylcholine receptor (57), and more recently, the pH-dependent mechanism for a Na\(^+\)/H\(^+\) antiporter (73).

**Recent notable structures**

**Aquaporin-0**
The structure of this water-selective membrane pore protein (Fig. 3a and 3b) represents the highest resolution structure obtained from electron crystallography to date (53). Data were obtained for Aquaporin-0 in double-layered 2-D crystals, and its staggering 1.9-Å resolution clearly reveals water molecules within the pore. The data also reveal associated lipids, allowing key protein-lipid interactions to be modeled.

**Aquaporin-4**
This 3.6-Å structure of Aquaporin-4 (Fig. 3c) was determined by electron crystallography of double-layered 2-D crystals (56). Features in the structure show that Aquaporin-4 can form membrane junctions, and they suggest for the first time its role in cell adhesion. This structure is of additional interest in that it is the first structure of a multispanning mammalian membrane protein obtained by purely recombinant methods.

**Glutathione transferase-1**
At 3.2 Å, the resolution of this recent structure also rivals that obtained in XRC (63). This structure provides a strong insight into the function of the protein, and it reveals key differences between the glutathione binding site of this membrane-spanning enzyme and that of its soluble counterparts.

**Imaging Membrane Proteins by AFM**
The 2-D crystals of membrane proteins discussed in the above section can also be analyzed using atomic force microscopy (AFM) (74). Although it is a low-resolution technique restricted to surface contouring, and as such cannot provide atomic level structural information, AFM has developed into a powerful tool for investigation of oligomerization, dynamics, and large-scale conformational changes. AFM also provides several advantages over EM. As mentioned, high-resolution EM analyses require coating of the sample, low temperatures, and high vacuum. In contrast, AFM images (or topographs) can be obtained under physiological conditions allowing investigation of structure and conformational changes involved in function (e.g., gating of channels). AFM is also the only imaging technique that can collect data on liquid samples, and it is therefore able to provide, in addition to images of 2-D crystals, images of membrane bilayers in an aqueous environment.

AFM was first used to analyze a membrane protein in 1990, when images were collected on hydrated purple membranes (75). In these images, the global arrangement of bacteriorhodopsin molecules was observed for the first time at near-physiological conditions (75). The resolution of AFM images has improved steadily over the past 20 years, and now the technique is regularly used to observe individual proteins and macromolecular assemblies in both 2-D crystals (74–78) and in native membranes (75, 81, 82). From AFM images, information has been obtained for a wide variety of membrane proteins, including Class A G-protein-coupled receptors (81), pumps (78, 83), channels (76), enzymes (84), and pores (80). Larger protein complexes, such as the light harvesting complexes I and II, have also been studied in both 2-D crystals (79) and in their native membranes (82).

Currently, the resolution of AFM is lower than that of NMR, XRD, or cryo-EM. The highest resolution AFM data thus far has been collected on samples in 2-D crystals, producing structural data with resolutions between 9 and 14 Å (77–80). In general terms, AFM works by raster scanning (scanning line by line) a very sharp tip attached to a flexible cantilever over a sample
Membrane Protein Structure, Techniques to Study

in order to produce a contour map of its surface. In order to
maximize resolution, vertical fluctuations of the tip must be
minimized. This is achieved using a self-regulating feedback
system (or servo system), which keeps the cantilever deflection
approximately constant by making small adjustments in the
vertical displacement of the sample. A 2-D crystal provides
an ideal sample for AFM as it is hard and flat, with the protein
embedded in a densely packed array, thus restricting any lateral
or vertical movement of the protein. Another prerequisite for
high-resolution data is minimal interaction between the tip and
the sample, and this is greatly influenced by the size and the
geometry (or sharpness) of the tip. The tip geometry is most
commonly an inverted pyramid. Depending on its sharpness, as
the tip moves across a surface, structures may interact with both
the end of the tip as well as the sides of the tip. Any interactions
with the sides of the tip will cause a broadening of the signal,
thus reducing the lateral resolution of the image. This effect,
also known as tip convolution, is most noticeable on surfaces
with considerable height differences. Most of the tips used on
high-resolution instruments are now commercially fabricated,
with the best tips having a radius of curvature of >5 nm.

Structure determination and other
applications of AFM

As mentioned, individual membrane proteins and complexes
in 2-D crystals and in densely packed, noncrystalline arrays can
be imaged by AFM at sub-nanometer resolution (76–80, 84).
This makes AFM ideally suited to provide information on the
conformation and oligomeric state of membrane proteins in their
native membranes. One very nice example of this is the study of
rhodopsin in its native membrane (81). AFM was used to image
native disk membranes in aqueous solutions, and revealed the
organization of rhodopsin into dimers and higher oligomers.
By imaging membranes in aqueous solutions, AFM also allows
us to observe conformational changes of biomolecules as they
function.

Because deflections of the cantilever can be detected in the
10-50 pN range, making single-molecule force measurements
possible, AFM can also be used to study protein folding. In
these studies, the AFM tip is displaced toward the sample until a
protein is attached by contact adhesion, the tip is then retracted.
Force versus distance curves are recorded before and after
adhesion in order to determine the forces involved in unfolding
or “unzipping” the protein. In addition to the force versus
distance curves, images can also be acquired before and after
an unfolding event to observe the effects on the surrounding
environment (85).

Recent structural studies

KirBac3.1

AFM is a powerful method of providing information on larger scale structure, especially when combined with higher resolution structural data. This fact is beautifully illustrated in the investigation of the KirBac3.1 potassium channel (76). AFM imaging of KirBac3.1 embedded in a lipid bilayer has revealed the tetrameric assembly of the protein (Fig. 4a and 4c) as well as large conformational changes upon ligand binding (Fig. 4b and 4d), thus providing insight into the gating mechanism of this channel.

F0F1-ATP synthase

The F0F1-ATP synthase is responsible for synthesizing ATP in many organisms. This enzyme is composed of two rotary motors (F0 and F1) connected by a central stem, and the stoichiometry of these two motors is of critical importance to energy conversion. F0F1-ATP synthases are very large, making them unsuitable for study by NMR or X-ray crystallography. However, AFM is ideally suited to such applications and has been used to determine the oligomeric states of the F0 and F1 motors in several species of bacteria and plants to shed new light on how the enzymes function (84, 86, 87).

Summary

The aim of this review has been to summarize the key tech-
niques currently used for determination of membrane protein
structures. Thus far, XRC has produced the largest number of
membrane protein structures, and it has achieved the highest resolu-
tion of any other technique. However, this technique still re-
quires a high-quality crystal, which is currently the rate-limiting
step in the process. Steady progress in our understanding of
crystal growth and the development of new crystalization meth-
ods show great potential for future studies. NMR has proved to
be a valuable technique for the study of small membrane pro-
teins and individual domains of larger proteins. In addition to
3D structural information, NMR can also provide information
on dynamics and lipid binding. NMR also has the advan-
tage that it does not require crystals, which are difficult and
time-consuming to produce, and instead uses a large range of
membrane mimetics and solubilizing agents. The major limi-
tations of NMR remain the upper limit on protein size and
difficulties in resolving resonances for assignment purposes.

Continued developments in instrumentation, experimental meth-
ods, and improved membrane mimetics will greatly advance the
field. EM has also made a large impact on our knowledge of
membrane proteins and promises to equal or surpass the more
static structural methods of XRC and NMR. Because of recent
new developments in technology, cryo-EM has caught up with
XRC and NMR in terms of resolution and is well positioned to
lead the field in the future. Both EM and AFM offer the unique
advantage that membrane proteins can be studied in synthetic
lipid bilayers as well as their native membranes, producing more
biologically relevant structural data. Furthermore, these methods
allow study of conformational changes over time, in response to
such events as lipid binding or unfolding. However, the most
exciting prospect for future studies of membrane proteins comes
when data from all these methods are used in concert, alongside
molecular dynamics simulations, to describe the structures and
functions of these essential proteins.

doi: 10.1002/9780470048672.wecb394

Solution NMR methods for determining three-dimensional, atomic resolution structures and dynamic properties of biologic macromolecules are well established. Currently, an ever-increasing number of experimentally solved protein NMR structures is available and contributes to our understanding of biology. The development of novel NMR approaches, labeling techniques, and calculational algorithms allows the study of larger and more complex systems. Here I summarize the basic NMR approaches, discuss labeling and assignment strategies, and provide examples for their uses.

Introduction

Understanding protein function relies on studying protein structures at the atomic level. Among the various techniques that can be applied to investigate proteins, only two have provided many high-resolution structures: single-crystal X-ray diffraction and nuclear magnetic resonance (NMR) spectroscopy. Currently, the Protein Data Bank (PDB) contains 36,329 crystal and 5757 NMR protein structures, with 1685 and 134 complexes determined by X-ray or NMR, respectively. Although X-ray crystallography has contributed protein structures since the 1950s, with NMR only reaching this stage in the 1980s, the number and size of macromolecular structures that have been investigated by NMR has increased dramatically over the past 20 years (1). Thus, NMR now is firmly established as a methodology that has moved beyond its initial applications in analytical chemistry into the structural biology field.

In the early years, the development of a wide range of two-dimensional (2-D) NMR experiments (using 1H as the active nuclei) culminated in the determination of three-dimensional (3-D) structures of several small proteins (2, 3). Under favorable circumstances, 2-D NMR techniques can be applied successfully to the structure determination of proteins up to ∼100 residues (4, 5). Beyond 100 residues (∼10 kDa), however, 2-D methods tend to fail, principally because of the spectral complexity that cannot be resolved in two dimensions. In the late 1980s and early 1990s, a series of major advances took place, and the introduction of three- and four-dimensional (4-D) experiments that use 13C and 15N nuclei significantly extended the attainable spectral resolution (see 6, 7, for reviews). The combination of multidimensional with heteronuclear methodologies also alleviated problems associated with large linewidths, mainly because they exploit heteronuclear couplings that are large compared with homonuclear proton couplings. (Note that with increasing molecular mass, a molecule tumbles slower in solution, resulting in increased linewidth; consequently, the efficiency of magnetization transfer through bonds decreases dramatically, rendering 1H through-bond correlation experiments unsuitable for large systems.) Following these spectroscopic advances, further progress occurred with the introduction of residual-dipolar-coupling (RDC)-based methodologies, transverse relaxation-optimized spectroscopy (TROSY) experiments, and specialized isotopic labeling schemes. Exploiting all the recent developments, it is possible now to determine the structures of proteins in the 50 kDa range at a resolution comparable with ∼2 Å resolution crystal structures. The upper application limit for the current NMR methodology probably is around 50–60 kDa. The largest single-chain proteins solved to date to high resolution comprise 240–260 residues with molecular masses of 25–30 kDa (8–14). The largest overall protein structures solved to date are multimers (15–17) or protein complexes (14, 18, 19). In addition, beyond the elucidation of three-dimensional structures, investigations of even large systems are possible (20–23). These studies include the identification of secondary structures, the mapping of intermolecular binding sites, and the study of conformational changes. Determinations of the relative orientation of domains or proteins within multiprotein complexes based on RDCs are feasible, and dynamical characterizations of very large biomolecular complexes can be carried out.

In addition to methodological advances in protein NMR that make structure determination of small systems routine and of large systems possible, the availability of commercial high-field spectrometers equipped with cryogenic probes has played a major role as well. Currently, spectrometers used for biomolecular NMR employ magnets that range in field strength from 14.1 T (600 MHz) to 22.3 T (950 MHz). The improved resolution and increased sensitivity afforded by these state-of-the-art instruments allows the detection of small signals, in particular NOEc: permits measurements on low solubility proteins; and aids in the investigation of large molecular weight complexes.
General Strategy

The power of NMR over other spectroscopic techniques results from the fact that every NMR active nucleus gives rise to an individual resonance in the spectrum that can be resolved by using multidimensional (i.e., 2-D, 3-D, or 4-D) techniques.

To measure distances between hydrogen atoms via NOEs, the corresponding resonances have to be identified unambiguously. Thus, each resonance has to be assigned to a unique atom in a specific monomer unit (amino acid for proteins) in the macro-molecule. This assignment is achieved via a combination of through-bond and through-space correlations. Subsequent identification of NOE through-space interactions yield the principal experimental parameters—distance constraints—that are used for NMR structure calculations.

The principles of structure determination by NMR thus can be summarized as follows: 1) sequential resonance assignment, 2) torsion angle determination and stereospecific assignment at chiral centers using three-bond scalar couplings combined, where appropriate, with intraresidue and sequential interresidue NOE data, 3) identification of through-space NOE connectivities between protons separated by less than 5 Å, 4) determination of orientational constraints extracted from ratios of heteronuclear relaxation (T_r/T_s) or residual dipolar couplings (RDCs), and 5) calculation of 3-D structures on the basis of all the above experimental NMR restraints by using one or more of several computational algorithms (24).

Sequential Resonance Assignment

Conventional sequential resonance assignment has been applied to proteins up to about 100 residues, albeit with considerable effort. It relies on 2-D homonuclear 1H–1H through-bond correlation experiments to identify amino acid spin systems. These spin systems are linked via 2-D 1H–1H NOE experiments that identify through-space (5 Å) sequential connectivities of the type Cα(i)–HN(i) + 1, Cα(i)–HN(i) + 2, and Cα(i)–HN(i) + 3 along the backbone (25). Cα and Cβ represent main chain and side chain carbons, respectively; i represents the reference amino acid residue, with i + 1 indicating the next residue in the chain. As stated earlier, for larger proteins the spectral complexity is such that 2-D experiments no longer suffice, and it is essential to increase the spectral resolution by increasing the dimensionality of the spectra (26).

In some cases, it is still possible to apply the same sequential assignment strategy based solely on through-bond correlations that involve well-defined heteronuclear one-bond (1JCα, 1JNα, 1JNCO, 1JCαCO, and 1JCC) and two-bond (1JNC, 1JCC) scalar couplings along the polypeptide chain (17, 28). Figure 1 illustrates the magnetization transfer paths in four types of experiments. Pulsed-field gradient methodologies (29, 30) reduced the required measuring times and it became possible to acquire only a few scans per increment without introducing artifacts. This allows each 3-D experiment to be recorded in as little as a few hours. In most cases, however, signal-to-noise requirements necessitate 24 hours of measuring time. For proteins larger than ~25 kDa, the assignment of the backbone and side chain carbons is facilitated by using a sample in which the non-exchangeable (carbon-attached) protons are deuterated (see also below). Perdeuteration results in narrower lines caused by a substantial increase in the relaxation times of carbon and proton spins in the proximity of the substituted deuterons. The approximately six-fold lower gyromagnetic ratio of deuterons relative to protons accounts for this phenomenon. Thus, for example, in the case of a 30 kDa protein, the average transverse relaxation time (T2) for the backbone amides is increased from ~13 ms in the protonated sample to ~28 ms in the perdeuterated sample (8).

In addition to perdeuteration, it is possible to narrow the linewidths significantly via the so-called transverse relaxation-optimized spectroscopy (TROSY). In these experiments, transverse relaxation is suppressed by the use of destructive interference between dipole–dipole coupling and chemical shift anisotropy (31). The TROSY sequence can be incorporated into numerous multi-dimensional experiments, and its effectiveness increases with increasing field strength up to an optimal value. For example, for a 150 kDa protein at a spectrometer frequency of 750 MHz, the residual linewidths of the 13C and NH resonances in a TROSY experiment will be ~10 Hz and ~45 Hz.
respectively, in a protonated sample, and -5 Hz and 15 Hz, respec-
tively, in a perdeuterated sample. TROSY is not limited to 1H, 1H-correlation experiments only; it also can be applied to aromatic 13C, 1H spin systems (32), methyl groups (either 13CH3 or 13CH2D), and methylene (13CH2) groups (33). The successful applications to very large protein complexes with molecular masses of up to 800 kDa (33, 68) render 13C, 1H-correlation experiments as important alternatives to the 15N, 1H ones. In particular, such carbon ex-
periments are ideally suited to study protein dynamics because methyl groups are appealing probes that are distributed uni-
formly throughout the protein structure (34). TROSY, in conjunction with appropriate levels of perdeuter-
amination, removes one major impediment to extending the NMR method to larger proteins, namely broad lines that arise from slow molecular tumbling. However, it still is essential to assign all the side chain resonances, a task that becomes problematic for perdeuterated systems where protons have been replaced by deuterons and are therefore of low abundance, although as-
signments of the side chains carbons are easy. Through-space NOE interactions between protons provide the main source of geometric information and protons are necessary to calculate structures. Through-bond HCHC-correlated and total correlated spectr-
troscopy experiments can be employed for proteins up to 25 kDa to transfer magnetization from protons to carbon through 
neighboring carbons and back to protons. For proteins larger than 25 kDa, however, the sensitivity of these two experiments is markedly reduced as the 13C linewidths approach the value of the 1JCC coupling (1-30-35 Hz). An alternative, power-
ful strategy is to rely on through-space correlations between adjacent carbon atoms (i.e., 13C-13C NOE) (35). In contrast to through-bond correlations, the efficiency of transfer of the 13CC, 13CC NOE increases with both increasing molecular weight and increasing field strength. This increase has been exploited in a suite of 13C heteronuclear direct detection experiments that are suitable for sequential protein backbone assignment (36).

Torsion Angles and Side Chain Rotamers

Coupling constant data allow the extraction of torsion angle restraints given their simple geometric, Karplus-type (37) rela-
tionships. For small molecules, the coupling constants can be measured directly from the in-phase or antiphase splitting of a particular resonance in the 1-D or 2-D spectrum. For large sys-
tems for which the individual linewidths exceed the coupling, it becomes difficult to extract accurate couplings in this manner. As an alternative, exclusive correlated spectroscopy (ECOSY) ex-
periments are employed to generate reduced cross-peak mul-
tiplets (38). Although this permits one to measure accurate couplings, the sensitivity of ECOSY experiments, unfortunately, is quite low. In addition, the usefulness of such experiments is curtailed by the fact that the couplings in multi-dimensional experiments have to be measured in the indirectly detected fre-
quency dimensions and hence are influenced by any limitation in digital resolution. To overcome these shortcomings, a series of highly sensitive quantitative J correlation experiments have been developed (39). In some of these experiments, the coupling is obtained from the ratio of cross-peak to diagonal-peak inten-
sities, and in others, it is obtained from the ratio of the cross 
peaks obtained in two separate experiments (with the coupling active and inactive) that are recorded in an interleaved manner. The most precise coupling values are obtained from experi-
ments that allow their extraction from the difference of two 
large multiple quantum splittings (40, 41). Particularly useful couplings are 3JC, 3JHC, 3JHH, and 3JCH, which are related to the back-
bone torsion angle φ, the 3JC, 3JCH, 3JHH, 3JHH, and 3JCH, couplings, which report on the χ1 side chain torsion angle, and the 3JCH, 3JHH, couplings, which are linked to the χ2 and χ3 side chain torsion angles of leucine, isoleucine, and methionine. For smaller proteins, it is often possible to obtain stereospecific assignments of χ-methylene protons on the basis of a qualita-
tive interpretation of the homonuclear 3JCH coupling constants 
and the intraresidue NOE data that involve the NH, CαH, and 
CαH protons (35). A more rigorous approach, which also per-
mits one to obtain χ, φ, backbone, and χ1 side chain torsion angle restraints, involves the application of a conformational grid search in φ, φ, χ1 space on the basis of the homonu-
clear 3JHH, and 3JCH coupling constants (which are related to χ1 and χ3, respectively) and the intra- and sequential intraresidue NOEs that involve the NH, CαH, and CαH protons (42, 43). This information can be supplemented and often supplant ed by measuring heteronuclear couplings using quantitative J correla-
tion spectroscopy. For larger proteins, the most useful couplings in this regard are the 3JC, 3JHH, and 3JCH, couplings that involve the aromatic, methyl, associated and methylene C atoms. These couplings suffice to derive the associated χ1 side chain rotamer. An alternative method that uses cross-correlated relaxation al-
lo ws one to measure angles between bond vectors directly and 
thus does not rely on coupling constants. It defines the back-
bone torsion angle φ, either by measuring the dipole-dipole cross-correlated relaxation of double-quantum and zero-
quantum coherences that involve the intraresidue dipolar 
field of the 1H-N(1) and 13C-H(1) bond vectors (44) or by measuring the cross-correlated relaxation between 
13C-H(2) dipolar interaction and 13C(carbonyl) chemical shift 
anisotropy (45).

NOE Assignment in Proteins

For the purposes of spectral assignment, the complement of 3-D heteronuclear experiments outlined above is sufficient in most cases. However, because of spectral overlap, greater increases in resolution are required for reliable identification of NOE through-space interactions, even for medium-size proteins. This increase is achieved by extending the dimensionality to four di-

dmensions (6). In this manner, each 1H-1H NOE interaction is specifed by four chemical shifts, the two proton frequencies of the atoms that give rise to the NOE and the resonance frequen-
cies of the heavy atoms to which they are attached (Fig. 2). The number of NOE interactions present in each 2-D plane of a 4-D
NMR for Proteins

Figure 2  Schematic illustration of 2-, 3-, and 4-D heteronuclear-edited NOE spectroscopy.

\[ 1^{13}C/^{15}N, \quad 1^{13}C/^{13}C, \quad \text{or} \quad 1^{15}N/^{15}N-\text{separated NOE spectrum is relatively small compared with a homonuclear proton 2-D NOESY spectrum. This yields an inherently high-resolution 4-D spectrum, despite low digitization. Indeed, it has been born out after more than a decade that both good sensitivity and resolution for proteins up to 400 residues can be achieved using this methodology. Once complete 1H, 1^{15}N, and 1^{13}C assignments are obtained, analysis of the 4-D 1^{15}N/^{13}C, 1^{13}C/^{13}C, and 1^{15}N/^{15}N-separated NOE spectra permits the assignment of numerous NOE interactions in a relatively straightforward manner. The first successful application of these methods to the structure determination of a protein greater than 15 kDa occurred in the early 1990s with the determination of the solution structure of interleukin-1, a protein of 18 kDa and 153 residues (46). Equivalent methodology now is used routinely for medium-size proteins.

For proteins larger than 30 kDa, it is not always possible to obtain complete side chain proton assignments, either because of spectral overlap or the lack of through-bond connectivities caused by large linewidths. In such cases, selective or defined deuteration (see below) is extremely helpful. One of the simplest approaches is to use a sample of a perdeuterated protein in which only the amides are protonated by back-exchange with water. Recording a 4-D 1^{15}N/1^{15}N-separated NOE spectrum (47) allows one to obtain NOEs with exceptional sensitivity because many spin-diffusion pathways are removed and long mixing times can be employed. In addition, labeling strategies in which the amides and methyl groups are protonated, while all other groups are deuterated, have become very popular and can aid in structure determination (48, 49). Such labeling regimes retain the advantage of deuteration in triple resonance assignment experiments while ensuring the presence of a reasonable number of protons in strategic locations for the purpose of NOE detection and structure determination. Indeed, model calculations have shown that it is possible to obtain low-resolution global folds on the basis of NH–NH, NH–methyl, and methyl–methyl distances alone (50). A striking example of a successful fold determination obtained with the tools described above is that of the 723-residue protein Malate Synthase G (51).

Protein Complexes

The concept of heteronuclear, multidimensional spectroscopy outlined above can be extended and modified for applications to protein complexes. To that end, complexes are prepared so that one component is labeled with 15N and 1^{13}C and the other one is unlabeled (i.e., one partner remains at natural isotopic abundance). Provided that one constituent in the complex (e.g., a peptide, an oligonucleotide, a drug, or other ligand) presents a relatively simple spectrum that can be assigned by 2-D methods, the most convenient strategy for dealing with such protein complexes involves using a 1^{15}N- and/or 1^{13}C-labeled protein and an unlabeled ligand. It then is possible to use a combination of heteronuclear filtering and editing to design experiments in which correlations that involve only protein resonances, only ligand resonances, or only through-space interactions between ligand and protein are observed (52). These experiments have been employed successfully in several laboratories and for a wide range of systems, including protein–drug, protein–peptide, and protein–nucleic acid complexes.

For protein complexes or multimeric proteins, additional, specifically tailored labeling schemes can be used to facilitate the identification of intermolecular NOEs. Note that multimeric proteins can be viewed as protein complexes between identical subunits. For such complexes, 1:1 mixtures of 1^{13}C/1^{15}N/1^{1}H, 1^{15}N/1^{13}C/1^{1}H, 1^{13}C/1^{15}N/1^{1}H, and 1^{15}N/1^{13}C/1^{1}H-labeled proteins enable one to record high sensitivity 2-D, 3-D, and 4-D experiments to observe specifically NOEs.
between 1) protons attached to $^{13}$C or $^{15}$N and protons attached to $^{12}$C or $^{14}$N, 2) $^{13}$C-attached and $^{15}$N-attached protons, and 3) $^{15}$N-attached protons and protons attached to $^{12}$C or $^{14}$N. In this manner, correlations that are specific for intermolecular contacts can be identified unambiguously from either side of the interface by employing two complex samples with alternating labeled partners. An example of strips from a 3-D $^{13}$C-edited, $^{12}$C/14N-filtered NOE spectrum and a depiction of the responsible contacts in the final structure of the protein–protein complex are illustrated in Fig. 3.

### Additional Structural Restraints

The traditional interproton distance and torsion angle restraints that initially allowed three-dimensional structure determination of proteins can be supplemented by several other NMR observables. These observables include three-bond coupling constants (related to torsion angles), amide deuterium isotope effects on $^{13}$C$_\alpha$ shifts (related to the backbone $\psi$ angle (53)), $^{13}$C secondary chemical shifts (related to the backbone $\phi$ and $\psi$ angles), and $^1$H chemical shifts (influenced by short-range ring current effects from aromatic groups, magnetic anisotropy of C=O and C–N bonds, and electric field effects that arise from charged groups). These parameters are easily measured and therefore represent a useful source of additional information. Indeed, it was found that the agreement between observed and calculated values for these various parameters was frequently better for high-resolution X-ray structures than for the corresponding high-resolution NMR structures that were determined without these restraints. Inclusion of such additional NMR restraints has little impact on the precision of NMR structures but clearly improves their accuracy.

Greater improvements in the quality of structures generated from NMR data can be obtained by using a conformational database potential derived from dihedral angle relationships in databases of high-resolution protein crystal structures (54, 55). The rationale for including such “packing” potentials stems from uncertainties in the description of the nonbonded contacts, which present a key limiting factor in the attainable accuracy of protein NMR structures. The nonbonded interaction terms currently used in most algorithms have poor discriminatory power between high- and low-probability local conformations. It therefore seems reasonable to bias sampling during simulated annealing refinement to conformations with dihedral angles close to those that are known to be physically possible and energetically favorable. In this manner, the variability in the structures is primarily a function of the experimental restraints rather than an artifact of a poor nonbonded interaction model. Therefore, this procedure does not compromise the agreement with the experimental restraints, and deviations from idealized covalent geometry remain within experimental error.

### Orientational Restraints

Structure determination by NMR traditionally has relied exclusively on restraints whose information content is entirely...
local and restricted to atoms close in space. Specifically, NOE-derived short (~5 Å) interproton distance restraints, supplemented by coupling constants, 1H secondary shifts, and 1H long-range shifts are used. The success of the NOE-centered NMR methodology is based on the fact that short interproton distances highly restrict the conformational space of the molecule. However, numerous cases exist in which restraints that define long-range order would be highly desirable or necessary. In particular, the relative positioning of structural elements that do not have many short interproton distance restraints is critical for the accurate determination of the molecular structure.

Anisotropy should be greater than an order of magnitude. This typically means that the diffusion anisotropy should be greater than 34 m3/molecule, which is about 6 · 10−12 m3/molecule. For molecules in isotropic solution, this typically means that the magnetic susceptibility anisotropy should be greater than 0.2 Hz make the potential routine use of dipolar couplings for biomolecular structure determinations. Sufficiently high degrees of alignment are achieved in this manner, resulting in one-bond dipolar couplings of 5–40 Hz that are easily detectable by simply measuring the splittings in 2D- and 3D-coupled HSQC spectra. Additional experiments for extracting other types of RDCs and the development of more media that allow tuning the degree of molecular alignment followed suit. Limitations with respect to the long-term stability of the original DMPC/DHPC phospholipid-based liquid crystal phases prompted the replacement of the diacyl phospholipids by non-hydratable dialky analogs (64). Other alternative alignment media include quasi-ternary systems of surfactant/salt/alcohol, which are known to form Helfrich lamellar phases (65, 66), as well as lyotropic liquid crystals formed by alkyl-poly (ethylene glycol)/alcohol mixtures in water (67). Importantly, suspensions of charged, rod-shaped viruses and filamentous phages (68, 69) have proven very robust and popular over the last few years. Indeed, more than half of the NMR structures in the PDB that are solved to date with RDCs were aligned in colloidal phase solutions. Methodologies that do not involve any liquid crystalline media but rather exploit the anisotropy of strained polymeric gels also are employed increasingly. Vertical (70) or radial compression of polycrylamide gels (72) are introduced into the gel matrix simply by diffusion. Such gels are extremely stable and inert and even allow the study of proteins under denaturing conditions.

Several important reasons exist for having different alignment media available. First, not every medium is compatible with the properties of the protein or systems under investigation. Proteins that interact with membranes are clearly not compatible with phospholipid-based media, and very flexible or partially folded proteins have a tendency to strongly interact with bicelles. Likewise, negatively charged molecules, such as nucleic acids, tend to bind to positively charged lamellae, whereas positively charged proteins potentially can interact with negatively charged phosphate groups at neutral pH values. This interaction can result in an increase in the electrostatic component of the alignment, causing large linewidths or a collapse of the liquid crystalline phase. Second, because the alignment tensors in two different alignment media will exhibit different correlations, changing the alignment medium commonly results in different orientations of the solute molecule with respect to the magnetic field. The presence of different orientations is an important property that resolves the degeneracies in the orientation of a given interatomic vector in the relationship between dipolar coupling and intermolecular vector orientation. A RDC measured in a given alignment medium positions the vector between the two coupled partners on one of the two possible, oppositely oriented cones on a unit sphere. If the alignment tensor in the second medium has a different orientation relative to the molecular frame of the molecule, the same vector now will reside on two different cones. Thus, the true orientation of this particular interatomic vector will lie at the intersections between the two cones. Therefore, RDCs measured in several independent media allow one to define uniquely the associated vector orientations.
Naturally, using heteronuclear T\textsubscript{J}/T\textsubscript{J} ratios or RDCs in NMR structure determination and refinement assumes that internal motions are negligible. The magnitude of RDCs depends on the generalized order parameter S for internal motions of the interatomic vector (72), thus different contributions have to be considered, at least in principle. In practice, however, it has been found satisfactory to assume a uniform S value for all those residues for which heteronuclear relaxation measurements indicate a well-ordered conformation, as evidenced by experimental S\textsuperscript{2} values of 0.7–0.9 (corresponding to S values of 0.85–0.86), rather than to use individual, residue-specific S values. Therefore, dipolar coupling constraints for residues that experience either slow conformational exchange or low order parameters (S\textsuperscript{2} < 0.6) need to be excluded from the data set used for structure determination.

A key aspect in the use of either \textsuperscript{15}N/T\textsubscript{J}/T\textsubscript{J} ratios or RDCs for structure refinement is the need to determine the magnitude (D\textsubscript{0}) of the anisotropy and rhombicity (R) of the diffusion or the alignment tensor. These quantities can be obtained by examining the distribution of the measured \textsuperscript{15}N/T\textsubscript{J}/T\textsubscript{J} ratios (73, 74) from the powder pattern appearance of their distribution. Alternatively, a maximum-likelihood method for extracting D\textsubscript{0} and R (75), singular value decomposition for calculation of the Saupe order matrix (76), or prediction of the alignment tensor based on the shape of the solute molecule by using an obstruction model (77) can be employed.

**TROSY**

As discussed above, spectral overlap of resonances can be overcome to a certain degree by increasing the dimensionality of the spectra and by employing isotope-labeling approaches. However, limitations imposed by transverse relaxation pose a severe technical challenge, and deuteration alone cannot extend the application range of solution NMR to beyond ~60 kDa. For very large systems, TROSY methods (31) alleviate linewidths challenges. Such experiments work best with deuterated proteins that carry protonated amide groups or selectively protonated methyl groups.

Transverse relaxation increases proportionally with molecular mass because of the slower tumbling or decreased rotational correlation time \(\tau_2\). This increase leads to a broadening and a loss of signal intensity. T\textsubscript{J} for the amide nitrogen is dominated by dipole-dipole (DD) relaxation between \textsuperscript{1}H and \textsuperscript{15}N spins and by the chemical shift anisotropy (CSA) of each individual spin. A fluctuating, time-dependent magnetic field, B\textsuperscript{CSA}(t), is induced by CSA and modulated by Brownian motion. Similarly, DD relaxation induces a motion-dependent magnetic field that, together with CSA, perturbs the local magnetic field of the \textsuperscript{15}N spin and causes transverse relaxation and line broadening of the cross peak. Although the B\textsuperscript{CSA}(t) field is proportional to the overall B\textsubscript{0} magnetic field strength, B\textsuperscript{CSA}(t) is independent of B\textsubscript{0}, but its sign depends on whether the two spins \textsuperscript{1}H and \textsuperscript{15}N are parallel or antiparallel. Because B\textsuperscript{CSA}(t) and B\textsuperscript{DD}(t) both influence the relaxation of the \textsuperscript{15}N spin with the same angular and time dependence, the two fields either add or subtract. For one multiplet coherence, B\textsuperscript{DD}(t) opposes B\textsuperscript{CSA}(t), resulting in a narrow linewidth, whereas the other multiplet coherence relaxes fast because B\textsuperscript{CSA}(t) and B\textsuperscript{DD}(t) are additive, causing broad lines. The TROSY experiment aims for optimal compensation of B\textsuperscript{CSA}(t) with B\textsuperscript{DD}(t) by increasing B\textsubscript{0}; even if the optimal field strength of 1 GHz is not quite attainable yet, excellent compensation already is observed at 700 MHz. Technically, transverse relaxation optimization is achieved by eliminating the inversion (decoupling) of the scalar coupled \textsuperscript{1}H spin during \textsuperscript{15}N evolution and by eliminating the inversion (decoupling) of \textsuperscript{1}H during \textsuperscript{15}N acquisition. Alternatively, the scalar coupled \textsuperscript{13}N spin can also be eliminated during polarization transfer in so-called \textsuperscript{13}N, \textsuperscript{1}H CRIP-T (cross-correlated relaxation induced polarization transfer)-TROSY experiments (78). Basically, in all TROSY experiments, favorable (sharp) multiplet components are selected by varying schemes along the evolution (\textsuperscript{15}N or \textsuperscript{13}C) and acquisition (\textsuperscript{1}H) dimensions.

**Specific Labeling Approaches**

Isotope labeling methodologies have played pivotal roles in solution NMR studies of proteins from the earliest days. In many cases, labeling has greatly improved the quality of spectra by both reducing the number of resonances and by concomitantly narrowing linewidths. A ready 40 years ago, deuteration was used to eliminate the complexity of the one-dimensional \textsuperscript{1}H spectra of proteins by growth in D\textsubscript{2}O media, supplemented either with uniformly or selectively protonated amino acids. This process allowed monitoring the remaining resonances and helped to identify conformational changes that occurred during ligand binding (79, 80). Selective amino acid protonation in otherwise deuterated proteins or vice versa has been used regularly for spectral simplification and residue type assignment over the years (see Reference 81 for a review). Random fractional deuteration improves the quality of homonuclear proton 2-D spectra by removing contributions to proton linewidths from proton-proton dipolar relaxation and \textsuperscript{1}H-\textsuperscript{1}H scalar couplings. The decrease in sensitivity that results from the loss of protons is largely offset by a reduction in peak linewidths at deuteration levels of 50–75%. Superior spectral quality also ensues in many heteronuclear experiments for highly deuterated proteins, first noted in a \textsuperscript{13}C, \textsuperscript{15}N HSQC spectra of larger proteins (81). Deuteration in the context of triple-resonance spectroscopy first was employed for correlating sequential amides in a 4-D HN(COCA)NH experiment (82), followed by a suite of triple-resonance experiments for backbone assignments (83). The larger the protein, the more deuteration is necessary. Unfortunately, this comes at the cost of reducing the number of protons available for NOE-based interproton distance restraints.

A different technique used for incorporating isotopically labeled peptide segments within a protein sequence is based on protein splicing (84, 85). In this manner, signals of selected N- or C-terminal regions along a peptide chain can be made NMR observable. However, very few applications of segmentally labeled protein have been reported to date in structural NMR, and more robust methodologies along these lines are needed.

An extremely powerful labeling strategy was introduced by R. Rosen et al. (86) who developed a method that produces high
levels of deuterium at all positions in a protein with the exception of a select set of methyl groups. This approach relies on the fact that pyruvate is the metabolic precursor of Ala, Val, Leu, and the methyls (12 only). Therefore, the methyls of pyruvate can be used as the sole carbon source in D₂O-based minimal medium. Unfortunately, the presence of methyl isotopomers is a drawback both in terms of resolution and sensitivity. Therefore, an alternative approach was devised in which bacteria are grown in a highly deuterated, glucose-containing, medium supplemented with amino acid precursors and amino acids that have useful patterns of protonation and deuteriation (87). Despite the benefits of deuterium substitution that causes reduced heteronuclear transverse relaxation rates, associated deuterium isotope shifts for 1H and 13C resonances are unfortunate drawbacks. Fortunately, given the additivity and only weak structural dependence of deuteron isotope effects, chemical shift assignments between fully protonated and perdeuterated molecules can fairly easily be transferred. (88). This is not the case for partially deuterated systems because the presence of multiple deuterium-containing isotopomers at each site can complicate the spectra significantly. Although spin gymnastics has been applied to this problem, the best solution at present seems to be the elimination of all but CH₃ isotopomers during protein expression (87).

As an alternative to expression with defined precursors, Kainocho et al. (89) developed an elegant cell-free translation system for assembling proteins from synthetic stereoisotope-labeled amino acids. In this so-called SAIL (stereo-array isotope labeling) approach, each 13C(1H)₂ unit is replaced stereospecifically with 13C(2H)₃ and each 13C(1H)₃ unit is replaced stereospecifically with 12C(1H)₃. In addition, redundant methyl groups are converted to 12C(1H)₃, and six-membered aromatic rings are labeled with alternating 12C(2H)₂ and 13C(1H)₂ moieties. This labeling pattern preserves through-bond correlations for backbone, side chain assignments, yields sharper lines by decreasing long-range couplings and dipolar relaxation pathways, simplifies the coupling patterns for the easy extraction of 3J couplings and yields unambiguous stereo-specific assignments. As an additional bonus, the methyl and methylene labeling patterns make the analysis of side chain relaxation measurements more straightforward. The SAIL approach is particularly useful for high-throughput protein structure determination in structural genomics, where automated resonance assignments based on a limited number of proton shifts feed into automated structure determination algorithms.

Quality and Validation of NMR Protein Structures

The traditional representation of NMR structures as ensembles frequently provokes the question about the overall quality of NMR structures, compared to that of X-ray structures. Although this contribution is not focused on the algorithms used for NMR protein structure determination (see Reference 90 for a review) and their influences on the resulting ensembles of structures, it maybe instructive to briefly comment on this question. The validation of structures typically involves two aspects: 1) how well do the structures agree with the experimental data and 2) how do the structures compare with statistics derived from a reference database of high-quality protein structures in terms of standard geometric values (e.g., PROCHECK (91) and WHAT IF (92)). The latter aspect is common to both X-ray and NMR structures. With respect to experimental data, the main quality indicator for a crystal structure is the free R-factor that quantitatively measures the agreement between the observed and the calculated reflections. An equivalent NOE R-factor is problematic because NOEs generally are implemented in a qualitative manner and direct refinement against NOEs is not commonly used. Therefore, it is important for NMR structures to use a large set of experimental restraints and ensure that no violations of these restraints are present in the final ensemble of structures. In addition to the quality of the experimental input data, the energy function used in the final refinement step also influences the quality of protein NMR structures. Currently, the best quality indicator for NMR structures is an R-factor for NOE couplings (93). The dipolar R-factor expresses the ratio of the observed rms difference between measured and calculated values with that expected for a totally random distribution of vectors. In this manner a quantitative and readily interpretable measure of the agreement between measured and calculated dipolar couplings is obtained. R (dipolar) is readily amenable to complete crossvalidation, an important consideration in assessing quality.

Conclusions and Outlook

The development of highly sensitive multidimensional heteronuclear NMR experiments at high fields in conjunction with specifically tailored labeling approaches has propelled the field of protein structure determination by NMR towards larger molecular weight ranges. At present, proteins and protein complexes up to 50–60 kDa are amenable to detailed structural analysis in solution. In addition, although not covered in this review, NMR offers a unique means of probing molecular motions on the picosecond to the second time scales (94). Despite these advances, it needs to be stressed that several key requirements have to be satisfied to permit a successful structure determination of larger proteins and protein complexes by NMR. The system in hand must be soluble and should not aggregate up to concentrations of about 0.3–0.5 mM; it must be stable at room temperature (or at least ~10°C) for considerable periods of time; it should not exhibit significant conformational heterogeneity that may manifest itself in extensive line broadening; and finally, it must be amenable to the various labeling methodologies. Currently, still only relatively few examples exist in the literature of single chain proteins in the 30–50 kDa range whose structures have been solved by NMR. Likewise, only a handful of protein-DNA, protein-peptide complexes, and protein oligomers have been determined to date using these methods. One can anticipate, however, that over the next few years many more high-resolution NMR structures of proteins and protein complexes will become available. In addition, methods for studying large protein complexes are still being developed, and questions related to dynamics, binding, and conformational (allosteric) changes can be probed (95). There is no doubt that
NMR as a methodology has come a long way and will continue to provide structural and dynamical answers for biologic questions that are complementary to those obtainable by X-ray crystallography.

One goal of chemical biology is to document and understand the macromolecular interactions that take place in the cell. In this review, we discuss the classic yeast two-hybrid method (and its derivatives) and how this method continues to provide insight into the number of protein–protein partnerships in a cell. In turn, these platforms have been adapted to explore a variety of interactions, such as those between proteins and small molecules. These systems collectively are called three-hybrid assays, and they provide new opportunities for the discovery of potential binding pairs. However, two- and three-hybrid assays also have significant disadvantages, such as incomplete coverage and high rates of false positives. With these issues in mind, we discuss emerging ways of minimizing the impact of these limitations using microarrays and mass spectrometry. Finally, chemical probes related to the three-hybrid concept are going beyond observation and providing active, rational control over individual protein–protein contacts. In these systems, bifunctional compounds are used to homo- or heterodimerize target proteins reversibly, thus altering their colocalization. By purposefully controlling protein–protein contacts, these chemical dimerization methods have progressed beyond observation and towards synthetic manipulation of protein function.
The two-hybrid method is robust and lends itself well to automation; thus, high-throughput applications of the two-hybrid approach have become increasingly common over the last decade. These projects encompass two phases: an initial phase of reagent development and a subsequent phase of high-throughput, two-hybrid screening. Methods for recombination-based cloning (4) and increased experience with large-scale cloning projects have enabled the generation of many successful bait and prey collections in numerous organisms (5-11). Subsequent high-throughput screening procedures typically employ array and pooling strategies driven by simple robotics (Fig. 1a).

In one approach, haploid yeast carrying bait and prey constructs, respectively, are mated to generate a diploid strain with both bait and prey for analysis of protein-protein interaction. This screen can be accomplished either by arraying the haploid strains before mating (generating an interaction "matrix") or by using bait/prey libraries (6, 7). The efficiency of these methods is improved by pooling; small pools of baits and preys are tested first, and individual interactions are subsequently confirmed through analysis of a particular pair (12-14).

Although the two-hybrid approach has clearly proven to be a powerful tool for biological discovery, it is not without its caveats. For example, some genuine interactions may be missed in a two-hybrid screen because a given protein may not be expressed properly as a binding domain- and/or activation domain-fusion (15); also, certain interactions may be too weak to be detected by two-hybrid methods, although the minimum affinity threshold for detection has been difficult to determine. Moreover, the two-hybrid method is prone to identifying false-positive interactions, and many possible sources of these artifacts exist (16). For example, a given protein pair may interact by yeast two-hybrid analysis but be precluded from interacting in vivo because of the distinct subcellular localizations of the two proteins (i.e., one protein may be nuclear, whereas the other may be cytoplasmic). In the two-hybrid method, both putative interacting proteins are forced to the nucleus by virtue of nuclear localization signals incorporated in the chimeras, which yields an artificial colocalization and correspondingly artificial potential for interaction. In general, this situation exemplifies a class of false-positive results by two-hybrid analysis, wherein the two hybrid-associated proteins possess the potential to interact in vivo but are restricted from doing so in their cellular context. A reflection of the yeast two-hybrid assay itself are also evident, which results in observed transcriptional activity independent of protein-protein interaction. This additional class of false-positive results is exemplified by bait/prey proteins that are capable of activating reporter transcription in the absence of a second hybrid (15).

Figure 1 The classic yeast two-hybrid method and derivatives. (a) Schematic diagram of the yeast two-hybrid approach, describing an interaction between protein X and protein Y. Protein X is fused to a transcription factor DNA-binding domain (the "bait" construct), and protein Y is fused to a transcription factor activation domain (the "prey" construct). (b) High-throughput applications of the yeast two-hybrid method use mating of haploid strains carrying bait and prey, respectively. The resulting diploid strain serves as a host for a reporter Gene expression. (c) In one approach, haploid yeast carrying bait and prey constructs, respectively, are mated to generate a diploid strain with both bait and prey for analysis of protein-protein interaction. This screen can be accomplished either by arraying the haploid strains before mating (generating an interaction "matrix") or by using bait/prey libraries (6, 7). The efficiency of these methods is improved by pooling; small pools of baits and preys are tested first, and individual interactions are subsequently confirmed through analysis of a particular pair (12-14). Although the two-hybrid approach has clearly proven to be a powerful tool for biological discovery, it is not without its caveats. For example, some genuine interactions may be missed in a two-hybrid screen because a given protein may not be expressed properly as a binding domain- and/or activation domain-fusion (15); also, certain interactions may be too weak to be detected by two-hybrid methods, although the minimum affinity threshold for detection has been difficult to determine. More significantly, the two-hybrid method is prone to identifying false-positive interactions, and many possible sources of these artifacts exist (16). For example, a given protein pair may interact by yeast two-hybrid analysis but be precluded from interacting in vivo because of the distinct subcellular localizations of the two proteins (i.e., one protein may be nuclear, whereas the other may be cytoplasmic). In the two-hybrid method, both putative interacting proteins are forced to the nucleus by virtue of nuclear localization signals incorporated in the chimeras, which yields an artificial colocalization and correspondingly artificial potential for interaction. In general, this situation exemplifies a class of false-positive results by two-hybrid analysis, wherein the two hybrid-associated proteins possess the potential to interact in vivo but are restricted from doing so in their cellular context. A reflection of the yeast two-hybrid assay itself are also evident, which results in observed transcriptional activity independent of protein-protein interaction. This additional class of false-positive results is exemplified by bait/prey proteins that are capable of activating reporter transcription in the absence of a second hybrid (15).
Two-hybrid data validation

Considering the caveats indicated above, yeast two-hybrid methods are often coupled with secondary, high-confidence assays to define a truer interaction data set. Toward this end, Li et al. (8) undertook a large-scale yeast two-hybrid analysis of protein–protein interactions in Caernarvon’s elegans and used co-affinity purification assays to validate 143 putative interactions. Co-immunoprecipitation provides a high-confidence measure of protein interaction; however, the approach is labor intensive and presents a greater challenge for automation. Other related approaches have also been employed to verify protein interactions that are suggested by two-hybrid studies. For example, Tong et al. (17) integrated results from two-hybrid analysis with protein interaction data sets derived from phage display experiments to yield a subset of high-confidence interactions associated with Sk3 domain-containing proteins in the budding yeast. Protein localization data have also proven useful in identifying biologically relevant interactions within large two-hybrid data sets because interacting proteins should localize within the same subcellular compartment (18). Collectively, these and other approaches (see the section titled “Combining Two- and Three-Hybrid Screens with Other Technologies”) offer significant promise toward the construction of high-confidence protein interaction maps on a genome-wide scale.

Reverse two-hybrid approaches

The classic two-hybrid method has been modified over time to yield a variety of derivative approaches that offer complementary data. For example, the “reverse” two-hybrid method was developed to identify drugs, mutations, and/or proteins capable of disrupting a known interaction (Fig 3c). Briefly, the reverse two-hybrid approach employs a reporter gene that encodes a counter-selectable marker (e.g., the yeast gene URA3) (19). The URA3 gene product is required for growth on medium lacking uracil; however, this product is toxic to yeast cells grown on medium containing 5-fluoroorotic acid (5-FOA). By the reverse two-hybrid method, dissociation or inhibition of a hybrid interaction results in loss of URA3 expression, which permits cell growth in the presence of 5-FOA. Similar loss-of-interaction detection schemes have been devised using the Escherichia coli tet repressor (tetR) as a reporter (20). Expression of tetR represses expression from a second reporter containing an upstream tetR-binding site and, conversely, disruption of the interaction restores expression from this reporter. Although the affinity requirements and dynamic range of these methods have yet to be fully described, they have proven useful in proof-of-principle studies.

Membrane-associated two-hybrid systems

In the classic two-hybrid system, protein interaction is assayed in the nucleus, a subcellular environment for the detection of many protein–protein interactions—particularly those involving membrane proteins. As an alternative to nuclear two-hybrid assays, several groups have developed membrane-associated two-hybrid systems that use signaling components, such as Ras (21). The membrane-associated Ras protein binds and hydrolyzes GTP, alternating between an active GDP-bound form and an inactive GDP-bound state. These states are modulated by GTase-activating proteins that promote GTP hydrolysis and guanine nucleotide exchange factors (GEFs) that stimulate GDP release/GTP uptake. Aronheim et al. (22, 23) used Ras signaling as the basis for a two-hybrid system, substituting the human GEF Hsos for the native yeast RAS GEF, Cdc25p, in yeast cells carrying a mutant allele of cdc25. Using a hybrid consisting of a target protein fused to Hsos and a second putatively interacting protein localized to the cell membrane by a myristylation tag, protein–protein interaction recruits Hsos to the cell membrane, activating Ras, which, in turn, promotes cell survival and growth.

Takoff and colleagues (24) presented an extension of this system for the identification of proteins binding 3-phosphoinositide second messengers, PtdIns(3,4)P2 and PtdIns(3,4,5)P3, in vivo. In this system, the putative PtdIns(3,4)P2/PtdIns(3,4,5)P3 binding protein (or specifically just its predicted pleckstrin homology, PH, domain) is fused to constitutively activated GTβ-bound Ras. This hybrid protein is coexpressed with phosphatidylinositol 3-kinase (PI3K), which generates the 3-phosphoinositides in a temperature-sensitive Ras mutant. Binding of the target protein’s PH domain to the 3-phosphoinositides draws the hybrid protein to the cell membrane where the activated Ras substitutes for the nonfunctional mutant, which enables cell growth. Medici and colleagues (25) developed an additional membrane-based two-hybrid assay with bait and prey constructs consisting of the yeast G protein α subunit Gpa1p and the α-factor receptor Ste2p. By this approach, interaction between a Gpa1p chimera and Ste2p hybrid drives a signaling cascade that permits cell growth in a gap1 mutant background.

Imaging protein–protein interactions in live cells

In contrast to the classic yeast two-hybrid method and its close derivatives, chimeric protein–protein interactions may also be assessed in many organisms using readouts easily visualized in live cells. For example, Sanjiv Gambhir’s group developed a modified mammalian two-hybrid system using the Gal4p-DNA-binding domain, herpes simplex virus VP16 activation domain, inducible promoters, and the firefly luciferase gene as a reporter (26). In a proof-of-principle study, the helix-loop-helix proteins Id and MyoD were shown to interact, which results in luciferase activity visualized by standard methods of bioluminescence imaging in cell culture and in 293 T cells implanted in mice (26).

Protein–protein interactions may also be detected in living cells using hybrids that consist of fluorescent proteins capable of undergoing fluorescence resonance energy transfer (FRET). FRET refers to an exchange of energy occurring between two fluorescent molecules, with fluorons satisfying the following two criteria: 1) The emission spectrum of one fluorophore (the donor) must overlap with the excitation spectrum of the second fluorophore (the acceptor), and 2) the fluorors must be within approximately 10 nm of each other (reviewed in Reference 27).

(b) Detection of protein–protein interaction between X and Y by BRET using the Renilla luciferase (Rluc) as a bioluminescent donor and GFP as a fluorescent acceptor. The substrate for Rluc is deep blue coelenterazine. Constructs not drawn to scale.

If these requirements are met, the donor fluorophore (e.g., cyan fluorescent protein, CFP) can transfer the resonance energy of its excited state to the acceptor (e.g., yellow fluorescent protein, YFP), which causes it to fluoresce (Fig. 2a). The efficiency of this energy transfer depends on the inverse sixth power of the distance between donor and acceptor; therefore, the detection of FRET is a sensitive measure of the mutual proximity of two fluoros. Thus, FRET can be used to detect protein–protein interactions with high confidence and is amenable to implementation on a fairly large scale, using YFP- and CFP-chimeras. Recently, Müller et al. (28) used FRET to identify core proteins of the yeast spindle pole body, thus highlighting the applicability of this approach toward defining a target subset of protein–protein interactions.

Along similar lines, bioluminescence resonance energy transfer (BRET) also presents a technology for the detection of protein–protein interactions based on energy transfer between two proteins in close spatial proximity. As presented by De and Gambhir (29), BRET can be implemented using the Renilla luciferase (Rluc) as a bioluminescent donor and mutant green fluorescent protein (GFP) as a fluorescent acceptor (Fig. 2b). Proteins predicted to interact are fused to luciferase and GFP; interaction between the Rluc and GFP chimeras results in excitation of GFP by resonance energy transfer from the reaction of Rluc with its substrate, deep blue coelenterazine. De and Gambhir used this approach to detect Id–MyoD and FKBP12FRAP interactions in both cultured cells and in deeper tissues of mice with implanted cells overexpressing the fusion constructs (29).

Although FRET- and BRET-based technologies offer many advantages associated with the ability to image protein interactions in live cells, both approaches are substantially limited by the spatial constraints of energy transfer. Many genuine protein interactions may be missed in FRET/BRET approaches because donor and acceptor are not brought in sufficiently close proximity for resonance energy transfer by target protein dimerization (27). The false-negative rate associated with these technologies is, therefore, presumed to be high. Conversely, however, these approaches are prone to a very low rate of false-positive results, and detected interactions can be considered genuine with few exceptions.

Split-reporter strategies

Since the mid-1990s, numerous studies have advanced clever alternatives to transcription factor-based two-hybrid methods through technologies that use various split-reporter systems (30). In particular, Johnson and Varshavsky (31) developed an interesting split-protein sensor of protein interactions using the small protein ubiquitin (Ub). Ubiquitin is a 76-amino acid protein best characterized for its role in protein degradation: Covalent attachment of Ub to a target protein marks that protein for degradation by the 26 S proteosome (32, 33). In eukaryotes, newly formed Ub fusions are cleaved by site-specific proteases after the last Ub residue at the Ub–target protein junction, provided that the Ub protein is properly folded. The Varshavsky group took advantage of this fact, splitting Ub into amino- and carboxy-terminal halves and fusing each to one of two putatively interacting membrane proteins (Fig. 3a). The amino-terminal Ub fragment was modified additionally by the introduction of a point mutation that decreased its affinity for the carboxy-terminal Ub fragment. This carboxy-terminal fragment was fused to a transcription factor, which provided a convenient readout for this system. During target protein interaction, the amino- and carboxy-terminal Ub fragments are brought into close proximity, which drives partial reassociation of Ub. This reconstituted Ub is recognized by its proteases, which results in...
cleavage and release of the transcription factor; protein interaction thus can be monitored by the activity of reporter genes (e.g., H15 and lacZ) recognized by the released transcription factor. This split-Ub system has been used successfully in several studies in organisms ranging from yeast to humans (34, 35) and, in fact, was used recently to isolate proteins interacting with human Bap31 and Erb3 (36). This method has also been applied to membrane proteins (37).

The Blau group has presented an alternative protein fragment complementation approach for detecting protein-protein interactions using the well-studied reporter β-galactosidase (β-gal) (38). The lacZ gene is known to exhibit intracistronic complementation, wherein pairs of inactive β-gal deletion mutants are capable of complementing each other in trans, assembling to yield an active enzyme. To use β-gal fragments as the basis for a protein interaction system, Rossi et al. (38) selected β-gal mutants (ΔN and ΔC) with low affinity for each other and fused each mutant to one of two target proteins. Target protein interaction drives the formation of active β-gal, which provides a convenient and quantitative monitor of protein dimerization. Recently, Wehman et al. (39) have modified this system, using a truncated low-affinity ω-peptide that weakly complements the ω fragment, such that recognition between the two fragments in the absence of forced dimerization is insufficient to maintain a complemented enzyme. Accordingly, reversible interactions can be monitored by this method, and the activity of the enzyme is directly related to the local concentration of the enzyme fragments. This approach has been used successfully as an assay of nuclear import/export (39) and as a monitor of G-protein-coupled receptor internalization (40). As with other ω-gal readout systems, this complementation approach allows for convenient signal visualization, which offers a method for the direct assessment of protein interaction in the context of native cell compartments and environments. The Michnick group has also developed an elegant split-reporter system, based on reconstitution of dihydrofolate reductase (DHFR) (41). In this system, cell survival requires functional DHFR; thus, a successful protein-protein interaction can be identified readily by selection. This system has been applied to the identification of peptide sequences that bind the Ras-binding domain of Raf (42).

The β-gal luciferase enzyme has also served as the basis of an informative protein fragment complementation approach for detecting protein-protein interactions in cells and living animals (43). By this method, amino- and carboxy-terminal fragments of luciferase are fused to target proteins of interest, such that protein-protein interaction reconstitutes active luciferase (Fig. 3c). Luker et al. have used this approach to investigate STAT1 activity and yielded data suggesting that STAT1 proteins homodimerize in the absence of ligand-induced phosphorylation (43). In addition to the firefly enzyme, Renilla luciferase has also been used, for example, to explore protein kinase A interactions (44). These luciferase complementation imaging strategies share several advantages of the systems described above and, in particular, provide near real-time detection of protein-protein interactions in intact cells and living animals. Tom Keppola’s group has developed a distinct and powerful variation on split-protein detection strategies, by using fragments of a fluorescent protein as part of a technique termed bimolecular fluorescence complementation (BIFC) (45). In this method, nonfluorescent fragments of enhanced yellow fluorescent protein are fused to putatively interacting target proteins; protein interaction brings these fragments into close proximity, which results in detectable yellow fluorescence (Fig. 3d).

**Figure 3** Protein fragment complementation strategies. (a) Schematic representation of the split-ubiquitin yeast two-hybrid system. The amino-terminal fragment of ubiquitin is designated “Nub;” and the carboxy-terminal fragment is designated “Cub.” Interaction of proteins contains a deletion of residues 11–41. Fragments not drawn to scale. (c) Firefly luciferase complementation by protein-protein interaction results in fluorescence at 545 nm. Again, fragments are not drawn to scale. (d) Bimolecular fluorescence complementation using split mutants of YFP, as applied in mammalian cells, results in fluorescence at 545 nm. Again, fragments are not drawn to scale.
For genuine in vivo interaction partners, the BiFC approach is typically quite successful, although the fluorescence intensity produced by target protein dimerization is routinely less than 10% of levels generated by intact yellow fluorescent protein (45). To date, BiFC has been used to identify interactions among many types of proteins in numerous cell types and organisms (reviewed in Reference 46) and provides a method not only to identify protein interactions but also to define the subcellular localization of protein complexes in living cells (47). The BiFC approach is amenable to many additional applications (47); however, it is not without its limitations. Specifically, the fluorescent protein fragments in a BiFC system associate irreversibly under some conditions and exhibit an intrinsic affinity for each other in the absence of target protein interaction, which limits both the sensitivity and scope of BiFC-based studies. Nonetheless, the approach holds significant potential as a generally applicable means of imaging protein interactions and complexes in single live cells, with future promise for even broader applications in a wide range of organisms.

Three-Hybrid Screens

The classic three-hybrid screen

Although the two-hybrid is an effective option for protein–protein interactions, this platform is not suitable for other types of macromolecular contacts, such as those involving small molecules or nucleic acids. The three-hybrid screen was developed specifically to address this need; for reviews see References 48–50. The third component in these systems is a small molecule or RNA that serves as the “bait” (Fig. 4). A general feature of three-hybrid “baits” is that they have two distinct, nonoverlapping domains; the anchoring end has a well-characterized binding partner, whereas the other side is used to query a collection of potential “preys.” For example, the first compound used in a three-hybrid was composed of a dexamethasone (Dex) anchor attached to FK506 (2). Dex has high affinity for the glucocorticoid receptor (GR), and, therefore, it is bound to the promoter via its tight association with this well-characterized binding partner, whereas the other side is used to query a collection of potential ligands.

References 48–50. The third component in these systems is a small molecule or RNA that serves as the “bait” (Fig. 4). A general feature of three-hybrid “baits” is that they have two distinct, nonoverlapping domains; the anchoring end has a well-characterized binding partner, whereas the other side is used to query a collection of potential “preys.” For example, the first compound used in a three-hybrid was composed of a dexamethasone (Dex) anchor attached to FK506 (2). Dex has high affinity for the glucocorticoid receptor (GR), and, therefore, it is bound to the promoter via its tight association with this well-characterized binding partner, whereas the other side is used to query a collection of potential ligands.

Although the two-hybrid is an effective option for protein–protein interactions, this platform is not suitable for other types of macromolecular contacts, such as those involving small molecules or nucleic acids. The three-hybrid screen was developed specifically to address this need; for reviews see References 48–50. The third component in these systems is a small molecule or RNA that serves as the “bait” (Fig. 4). A general feature of three-hybrid “baits” is that they have two distinct, nonoverlapping domains; the anchoring end has a well-characterized binding partner, whereas the other side is used to query a collection of potential “preys.” For example, the first compound used in a three-hybrid was composed of a dexamethasone (Dex) anchor attached to FK506 (2). Dex has high affinity for the glucocorticoid receptor (GR), and, therefore, it is bound to the promoter via its tight association with this well-characterized binding partner, whereas the other side is used to query a collection of potential ligands.
with a LexA–GR fusion (Fig. 4a). The query end of this divergent compound recruits a transcriptional activator that is fused to FK506-binding protein (FKBP). The reporter gene is typically a selection marker, such as LEU2, or a directly detectable signal, such as fluorescence or luminescence. Thus, this relatively straightforward adaptation of the two-hybrid platform has the potential to identify binding partners for a variety of macromolecules.

Features of the three-hybrid

Several recent studies have examined the strengths and limitations of the three-hybrid. For example, this system has been successfully adapted for use in yeast (51) and bacteria (52). In addition, extensive analyses of the kinetic and affinity requirements have been reported (53, 54). These studies have revealed that, although the dynamic range is small (\( \sim 1 \) order of magnitude), the three-hybrid signal is dependent on the association strength of the interaction, with a minimal \( K_D \) of \( \sim 50 \) nM (55). This in-depth work has helped refine our understanding of the key interactions, and, through these studies and others (48), the features of three-hybrid screens that influence the signal have begun to be revealed.

Target identification for small molecules

In forward chemical genetics, a system is treated with a collection of compounds and a candidate molecule that produces the desired phenotype identified (56–58). One main challenge in this field is that each new chemical probe requires follow-up studies to identify its cellular protein target (59). Accordingly, one primary use of the three-hybrid system is to find these targets. However, the challenge is that the molecule of interest must be covalently coupled to the anchoring compound without a loss of binding affinity (Fig. 4a). One of the most extensive synthetic studies was reported by the Verdine group, in which they generated a library of 320 tetrahydrooxazepines attached to an analog of FK506 on solid phase (60). This study validates that large collections of bifunctional ligands are possible, but, in practice, only a few query molecules have been screened. For example, the Kley group used a three-hybrid approach, coupled with affinity chromatography and in vitro kinase assays, to identify CDK1, CDK2, and other kinases as the protein targets of the kinase inhibitors, purvalanol B, roscovitine, and indeno[1,2-c]pyrazole, IP-1 (51).

Reverse three-hybrid

The downside to the three-hybrid as a target validation tool is that a suitable attachment point must be found on the query molecule. Oftentimes, selection of an appropriate site requires structure-activity relationship (SAR) studies to avoid damaging the compound’s binding affinity. Moreover, each chemical entity requires individual synthetic effort because the properties of

![Figure 5](image-url)
the linker can have important effects on the efficiency of the system (51, 54). One way to avoid the need for synthetic manipulation of the query molecule is to conduct a reverse three-hybrid screen. Similar to the reverse two-hybrid discussed above, a library of compounds is applied to a two- or three-hybrid reporter (Fig. 4f), and if the molecule interrupts the reconstituted complex, the reporter is deactivated. In one example, this approach was used to identify inhibitors of the helicase-prime interaction in Bacillus stearothermophilus (61). A related system involves expression of potential binding proteins in the presence of an intact three-hybrid contact (Fig. 5e) (62). These reverse three-hybrid systems do not require extensive synthetic manipulations and are ideal for those examples in which little SAR is available or no suitable attachment point is found.

**Screens for enzymatic activity and enzyme inhibitors**

The Cornish group has reported new variations of the three-hybrid, which all involve an enzyme as a necessary fourth component (Fig. 5b). In their first report, they developed a way to study cephalosporinase activity in yeast; they installed a cephalosporinase-sensitive site within a Dex–MtX conjugate such that the enzymatic activity would cleave the bifunctional component (63). Later variations of this platform have been used to evolve glycosynthase activity (64). Briefly, formation of a glycosidic link between detached sugar analogs reconstituted the bifunctional "bait" that subsequently activated the DHFR–GR-based LEU2 selection marker (Fig. 5g). Using this method, they evolved a glycosynthase with fivefold better enzymatic activity. Related methods have been used to study phosphorylation-dependent protein–protein contacts (65, 66), which demonstrates the versatility of this approach. These systems all take advantage of the signal-amplifying properties and high sensitivity of three-hybrids to monitor enzyme-dependent interactions in living systems.

**RNA–RNA interactions and RNA-binding proteins**

A rather adaptation of the three-hybrid replaces the bifunctional small molecule with an RNA molecule (first described by SenGupta et al. in 1996 (67) and reviewed more thoroughly by Jaeger et al. (68)). The bifunctional RNA is composed of two distinct domains: one part has a well-characterized affinity for an RNA-binding protein (typically MS2 coat protein or Hiv-1 Rev-MtX), whereas the query RNA is used to pan for possible "preys" (Fig. 4b). This system has been used to verify aptamer interactions (69) and to identify RNA–RNA interactions (70); also it has been used successfully to characterize over 20 RNA-binding proteins (68). Additionally, this method has been quite successful in revealing the key interacting residues in known RNA-binding proteins, including p53, HIV Tat, FBF-1, and histone hairpin binding protein (HHP). By random or directed mutagenesis (68, 71-74). Like other three-hybrid systems, the kinetics and binding constants are important for the efficiency of this system (75). As evident by the more than 60 published reports of successful three-hybrid screens (68), this method has proven to be a powerful addition to the arsenal of molecular and chemical biologists.

**Membrane-associated three-hybrid screens**

As mentioned above, advantages are gained by screening in non-nuclear compartments, but adapting the two- and three-hybrid technologies for different reporter strategies can be challenging. The Kley group has developed a system that they call MA SPIT as one solution (76). In this system, erythropoietin receptor is expressed as a fusion with DHFR in mammalian cells, and methotrexate-coupled bait molecules are used to recruit the prey (Fig. 5c). This membrane-proximal juxtaposition triggers Jak2-mediated phosphorylation of STAT3 and activation of a downstream reporter. This system was used to identify a family of ephrin receptor tyrosine kinases as targets of the inhibitor, PD173955 (76). Although this system is relatively complex, it represents an important advance because it allows screening in the cytosol and opens the possibility of finding contacts in their native subcellular environment.

**Combining Two- and Three-Hybrid Screens with Other Technologies**

Both two- and three-hybrid screens are limited by technical problems, such as high false-positive rates and incomplete coverage. This last problem is best illustrated by comparing the hits in otherwise identical screens. Parrish et al. compared the hits from three screens of 24,000 protein–protein interactions (~54% of the estimated total) in Drosophila and found remarkably little overlap (only 2 gene common to all three, and only 61 shared by at least 2 experiments) (77). Similar trends were seen in human two-hybrid systems, and, together, these findings strongly suggest that the coverage of possible interactions is incomplete (77). Insufficient data prevents similar comparisons in three-hybrid systems, but it is presumed that similar problems will be encountered. Minimizing the impact of these limitations might be best achieved by coupling two- and three-hybrid screens with other methods. Specifically, recent advances in mass spectrometry and microarrays are being used to investigate and confirm protein–protein interactions. High-throughput mass spectrometry is being used to both identify protein–protein contacts and to investigate these interactions on a proteome-wide scale (78-80). Thus, any interactions identified by two- or three-hybrid screens might be confirmed by this means. Finally, advances in microarray profiling offer promise to those screening for novel protein–protein or protein–ligand interactions. In these techniques, potential binding partners are labeled (e.g., with fluorescence or other reporter) and passed over patterned proteins, small molecules, or carbohydrates arrayed on a chip. After removing nonspecifically adsorbed material, the remaining "hits" represent interacting pairs. Technical advances over the past 10 years have positioned mass spectrometry and microarrays as viable tools for performing large-scale protein interaction...
Chemical Dimerization: Three-Hybrids for Conditional Regulation of Protein Function

Chemical inducers of dimerization

Although two- and three-hybrid screens are useful ways to identify new protein–protein and protein–drug contacts, the next set of questions require one to control these interactions rationally and to confirm their importance in a biological process. Toward this goal, the chemical dimerization systems developed in the mid-1990s by Crabtree and Schrieber are ideal tools (89–93). In these systems, a chemical inducer of dimerization (CID) is used to force the conditional homo- or hetero-dimerization of two proteins (for more in-depth reviews of these systems, see References 94–97). The target proteins are expressed as fusions with known drug binding domains such that addition of the bifunctional molecule causes their tight association (Fig. 6a). Although other pairs have been used (98–102), the most common systems are the homodimerization of FKBP by dimers of FK506 and the heterodimerization of FKBP with the FK506-rapamycin binding (FRB) domain by analogs of rapamycin. The shared feature of these CIDs is that they have two nonoverlapping domains; thus, they can bridge two proteins. A further common property of these systems is that they are reversible; thus, they offer the opportunity to regulate protein function conditionally. Whereas two- and three-hybrid screens are used to identify binding partners, CID systems are typically used to test whether protein colocalization is necessary and sufficient to instigate a biological response.

CIDs are used in many biological applications

Chemical dimerization has been remarkably successful at addressing previously inaccessible biological questions (Fig. 6a). For example, recent studies have explored the mechanisms of complex pathways, such as chromatin disassembly (103) and learning and memory (104). In addition, this method has proven quite adept in studies aimed at understanding signaling through the T-cell receptor (89), vasopressin receptor (105), GTPases (110), and phosphoinositides (111, 112). Similarly, this procedure has been used to gain regulatory control over important cellular processes, such as apoptosis (113, 114), preRNA splicing (115), translation initiation (116), glycosylation (64, 117), pathogen recognition (118, 119), and secretion (120, 121). This list of applications is necessarily brief, because greater than 300 manuscripts have been published across numerous scientific areas using CID systems (http://www.ariad.com/wt/page/ktb_references). This expansive literature illustrates the widespread acceptance of this method in the scientific community. In addition, this breadth makes a comprehensive overview of the area difficult, and the interested reader is encouraged to pursue several excellent reviews (49, 93–97, 122).

Inhibition of protein–protein interactions

A recent use of CIDs is to inhibit protein–protein interactions. One reason that this class of interactions has been difficult to block is that they typically involve a large and complex surface (123). Therefore, typical drug-like molecules are often too small to block these contacts effectively. This problem is particularly evident in amyloid formation, in which high-affinity protein–protein interactions lead to formation of cytotoxic, oligomeric structures (124). To alleviate this problem, we used a bifunctional CID that binds tightly to amyloid on one end and to FKBP on the other (Fig. 6b) (125). Recruitment of FKBP to the amyloid interface blocked the interaction 40-fold better than “regular” inhibitors (125, 126). These studies established that CIDs could be used in unconventional ways to engage biological systems and achieve desired outcomes.

Conditional protein stability

The chemical dimerization platform has been adapted for several other new applications. One approach is to recruit the target protein to the proteolytic machinery using CID-directed engagement leads to proteosomal degradation and concurrent, conditional removal of its function (127, 128). In another approach, an intrinsically unstable FRB tag is added to the target, which causes degradation of the entire chimera (Fig. 6c) (129–131). More than 5 kcal/mol of folding energy is rescued by CID-mediated recruitment of FKBP (130), and, thus, this method can be used in cultured cells, mice, and Xenopus laevis to regulate protein function conditionally (129, 130, 132). This method has proven useful in studies of developmental processes; in one recent example, unstable FRB fusions were used to learn that the kinase GSK3β is required for midline fusion during two brief times in mouse gestation (133). An improved version of this method has also been reported recently by the Wandless group; in these systems, stability of the tag can be controlled without the need for a recruited protein partner (134, 135). The Wandless group found that unstable FKBP proteins can be attached to a variety of targets and that a modified rapamycin analog, termed Shield-1, is sufficient to recover the stability of the chimeras. This simplified system has been applied to study falcipain function in Plasmodium falciparum (126) and the phenotypes of essential genes in Toxoplasma gondii (137). The goal of these technologies is to regulate protein function at the posttranscriptional level. By targeting this stage of a protein’s lifetime, one avoids the lengthy transcriptional and translational process to generate more rapid conditional systems. In practice, these systems typically display changes in protein levels over 1 or more hours.
Figure 6  Chemical dimerization. (a) The general components of homo- and hetero-dimerization systems are shown schematically. The binding proteins (X and Y) expressed as chimeras with the targets and these fusions are brought into proximity by the bifunctional small molecule. A variety of molecules have been used as the chemical inducer of dimerization (CID; see text for details). (b) CID-based approach to inhibiting difficult protein–protein contacts; a readily available cellular protein, FKBP, is used to preclude amyloid formation stably. (c) Inducible stabilization. Three variations on the CID system involve the conditional stabilization or destabilization of one protein target. A representative system is shown; an unstable domain leads to degradation of the target, but recruitment of the binding partner recovers protein levels and function. (d) Conditional protein mislocalization is shown schematically, with the example of nuclear import used to illustrate the general components. Reconstitution of a target with an NLS favors temporary nuclear uptake, whereas removal of the small molecule reverses this process.

Conditional control over subcellular localization

Although some biological processes occur over hours, other questions may require more rapid regulation. Conditional protein mislocalization offers fast kinetics and, thus, may be suitable for these specific situations. In these systems, a CID is used to append a subcellular address signal reversibly to the protein of interest (Fig. 6d) (138, 139). Because a protein’s function is often linked to its position within the cell (e.g., a transcription factor cannot be active in the cytoplasm), this system offers rapid and selective control.

Conclusions and future directions

Chemical dimerization and three-hybrid systems are being applied to numerous different biological systems, in a variety of organisms, and in a growing number of technological variations. Likewise, the classic two-hybrid is being reimagined in new ways, such as fragment complementation. At the same time, improvements in parallel technologies, such as high-content microscopy screening, mass spectrometry, and microarray profiling, have offered new opportunities. Together, this suite of methods is being used to study and control macromolecular contacts. As chemical biologists continue to develop, refine, and reimage two- and three-hybrid techniques, more insights will be made.

Computational Approaches in Drug Discovery and Development

Honglin Li, Mingyue Zheng, Xiaomin Luo, Weiliang Zhu and Hualiang Jiang, Shanghai Institute of Materia Medica, Chinese Academy of Sciences, Shanghai, China

doi: 10.1002/9780470048672.wecb098

Recently, computational approaches have been considerably appreciated in drug discovery and development. Their applications span almost all stages in the discovery and development pipeline, from target identification to lead discovery, from lead optimization to preclinical or clinical trials. In conjunction with medicinal chemistry, molecular and cell biology, and biophysical methods as well, computational approaches will continuously play important roles in drug discovery. Several new technologies and strategies of computational drug discovery associated with target identification, new chemical entity discovery, and lead optimization will be the focus of this review.

Drug research and development (R & D) is a comprehensive, expensive, and time-consuming enterprise, and it is full of risk throughout the process (1). Numerous new technologies have been developed and applied in drug R & D to shorten the research cycle and to reduce the expenses. Among them, computational approaches have revolutionized the pipeline of discovery and development (2). In the last 40 years, computational technologies for drug R & D have evolved very quickly, especially in recent decades with the unprecedented development of biology, biomedicine, and computer capabilities. In the post-genomic era, because of the dramatic increase of small-molecule and biomacromolecule information, computational tools have been applied in almost every stage of drug R & D which has greatly changed the strategy and pipeline for drug discovery (2). Computational approaches span almost all stages in discovery and development pipeline, from target identification to lead discovery, from lead optimization to preclinical or clinical trials (see Fig. 1). In this review article, we highlight some recent advances of computational technologies for drug discovery and development; emphases are put on computational tools for target identification, lead discovery, and ADME/T (absorption, distribution, metabolism, excretion, and toxicity) prediction.

Target Identification

Target identification and validation is the first key stage in the drug-discovery pipeline (see Fig. 1). By 2000, only about 300 drug targets had been reported (3, 4). The completion of human genome project and numerous pathogen genomes unveils that there are 30,000 to 40,000 genes and at least the same number of proteins; many of these proteins are potential targets for drug discovery. However, identification and validation of druggable targets from thousands of candidate macromolecules is still a challenging task (5).

Numerous technologies for identifying targets have been developed recently. Experimental approaches such as genomic and proteomic techniques are the major tools for target identification (6, 7). However, these methods have been proved inefficient in target discovery because they are laborious and time consuming. In addition, it is extremely difficult to get relatively clear information related to drug targets from enormous information produced by genomics, expression profiling, and proteomics (5). As complementarities to the experimental methods, a series of computational (in silico) tools have also been developed for target identification in recent two decades (6, 8-12). In general, they can be categorized into sequence-based approach and structure-based approach. Sequence-based approach contributes to the processes of the target identification by providing functional information about target candidates and positioning information to biological networks. Such methods include sequence alignment for gene selection, prioritization of protein families, gene and protein annotation, and expression data analysis for microarray or gene chip. Here, we only introduce a special structure-based method for target identification—reverse docking.

Molecular docking has been a promising approach in lead discovery (2, 13) (also see discussion below). Reverse docking,
Deformylase (PDF) is a target for anti-H. pylori drugs. PDF is a potential target for screening new anti-H. pylori agents. In a similar approach, Paul et al. (15) successfully recovered the corresponding targets of four unrelated drugs with reverse docking method.

The advantage of reverse docking is obvious, in addition to identifying target candidates for active compounds, it is also possible to identify potential targets responsible for toxicity and/or side effects of a drug under the hypothesis that the target database contains all the possible targets (20). However, reverse docking still has certain limitations. The major one is that the protein entries in the proteins structure databases like PDB are not enough for covering all the protein information of disease related genomes. The second one is that this approach has not considered the flexibility of proteins during docking simulation. These two aspects will produce false negatives. Another limitation is that the scoring function for reverse docking is not accurate enough, which will produce false positives (16). One tendency to overcome these shortages is to develop new docking program including protein flexibility and accurate scoring function. Another tendency is to integrate sequence-based and structure-based approaches together.
Lead Discovery

Computational approaches for lead discovery are more mature than those for target identification. Some methods such as virtual screening and library design have become promising tools for lead discovery and optimization (2, 13). Here, we introduce two computational techniques, virtual screening, and focused combinatorial library design.

Virtual screening

The drugs developed in the past 100 years are found to interact with approximately 500 targets; in the same period, about 20,000,000 organic compounds including natural products have been synthesized or isolated. Moreover, the genomic and functional genomic projects have produced additional 1500 druggable targets for drug intervention to control human diseases (21). Therefore, it is believable that a large number of new drugs, at least many leads or hits, hide in the existing chemical databases, which contain the pharmacophore elements and may conform to the pharmacophore feature is constructed by structure-activity relationship analysis on a series of active compounds (26) or is deduced from the X-ray crystal structure of a ligand-receptor complex (27). Taking this 3-D–pharmacophore feature as a query structure, 3-D database search can be performed to select the molecules among a large number of candidate molecules likely to be active against a chosen biological receptor (23). Therefore, how to dig out this source is a hard task. Collecting all the existing compounds and screening them randomly against all the potential targets one by one are extremely impractical, because it is intolerably expensive and time consuming. However, virtual screening shows a potential to satisfy this requirement. Indeed, virtual screening has been involved into the pipeline of drug discovery as a practical tool (22).

In essence, virtual screening is designed for searching large-scale hypothetical databases of chemical structures or virtual libraries by using computational analysis for selecting a limited number of candidate molecules likely to be active against a known biological receptor (23). Therefore, virtual screening is a logical extension of 3-D pharmacophore-based database searching (PBDS) (24) or molecular docking (25), which is capable of automatically evaluating very large databases of compounds.

Two strategies have been used in virtual screening (see Fig. 3); 1) using PBDS to identify potential hits from the databases, mostly in the cases that 3-D structures of the targets are unknown and 2) using molecular docking approach to rank the databases if the 3-D structures of the targets are available.

Normally, these two approaches are used concurrently or sequentially, because the former can filter out the compounds quickly and the latter can evaluate the ligand-receptor binding more accurately.

For the pharmacophore-based screening, a 3-D-pharmacophore feature is constructed by structure-activity relationship analysis on a series of active compounds (26) or is deduced from the X-ray crystal structure of a ligand-receptor complex (27). Taking this 3-D–pharmacophore feature as a query structure, 3-D database search can be performed to select the molecules from the available chemical databases, which contain the pharmacophore elements and may conform to the pharmacophore geometric constraints. Then the selected compounds are obtained either from commercial sources or from organic synthesis for the real pharmacologic assays (see Fig. 3).

Docking-based virtual screening (DBVS) requires the structural information of both receptors and compounds. The general procedure of DBVS includes five steps: receptor modeling (virtual screening mode construction), compound database generation, computer screening, hit molecules postprocessing, and experimental bioassay. The core step of virtual screening is docking and scoring. Docking is a process to place each molecule from a 3-D small-molecule database into the binding site of a receptor protein, optimize the relative orientation and conformation for a ligand interacting with a protein, and select molecules from the database that may bind to the protein tightly. Billions of possible conformations can be created for a flexible ligand even with a few freedom degrees in the rotation space alone; current optimization algorithms cannot sample exhaustively for all conformations and orientations, needless to say to account for the flexibility of protein with thousands of degrees of freedom. Therefore, instead of searching exhaustively in the search space, an optimization algorithm should sample the solutions effectively and rapidly close to the global optimum (28). Basically, the optimization algorithms employed widely by molecular docking program can be divided into three categories: numerical optimization methods, random or stochastic methods, and hybrid optimization methods. Essentially, there are three types of scoring functions (29), which

\[
\text{IC}_{50} \text{ values)
\]

\[
\text{IC}_{50} \text{ values)
\]
include force-field based scoring functions, empirical scoring functions, and knowledge-based scoring functions. However, no single scoring function can perform satisfactorily for every system because many physical phenomena determining molecular recognition were not fully accounted for, such as entropic or solvent effects (13). Since Kuntz et al. (30) published the first docking algorithm DOCK in 1982, more than 20 docking programs have been developed in recent two decades. Of the existing docking programs, DOCK, FlexX, AutoDock, and GOLD are most frequently used, other programs such as Glide, ICM, and Surfex have been applied successfully in virtual screening. However, many limitations and challenges still exist for molecular docking, such as accurate prediction of the binding conformation and affinity, protein flexibility, entropy, and solvent effects. Without doubt, the molecular docking process is still a complex and challenging project of computational chemistry and biology (25, 31).

Virtual screening has discovered numerous active compounds and leads, more than 50 compounds have entered into clinical trials, and some have been approved as drugs (2). Virtual screening enriched the hit rate (defined as the quotient in percentage of the number of active compounds at a particular concentration divided by the number of all compounds experimentally tested) by about 100-fold to 1000-fold over random screening (22, 32). Additionally, virtual screening provides an alternative way in firstly finding new leads of some targets, whereas the techniques for high-throughput screening remain in development (e.g. potassium ion (K⁺) channels). By using docking-based virtual screening in conjunction with electrophysiological assay, we discovered 10 new blockers of the eukaryotic Shaker K⁺ channels, 4 natural product blockers (33), and 6 synthetic compounds (34).

**Focused combinatorial library design**

What big pharma and medicinal chemists are seeking is new chemical entities (NCEs), which can be strictly protected by compound patents. Nevertheless, all hits discovered by screening the existing compounds databases can only find the new medical usages for the existing compounds or old drugs. At least two kinds of computational approaches are available for NCE discovery: de novo drug design (35, 36) and combinatorial library design (37). The de novo drug design does not start from a database of complete molecules but aims at building a complete molecule from molecular bricks (“building blocks”) to fill the binding sites of target molecule chemically. The complete chemical entries could be constructed through linking the “building blocks” together, or by growing from an “embryo” molecule with the guidance of evaluation of binding affinity. The “building blocks” could be either atoms or fragments (functional groups or small molecules). However, using atoms as “building blocks” is thought to be inefficient, which is seldom used currently. In the fragment-linking approach, the binding site is mapped to identify the possible anchor points for functional groups. Then, these groups are linked together to form a complete molecule. In the sequential-growing approach, the molecule grows in the binding site controlled by an appropriate search algorithm, which evaluates each growing possibility with a scoring function. Different from docking-based virtual screening, fragment-based de novo design can perform sampling in whole compound space, which can obtain novel structures that are not limited in available databases. Nevertheless, the quality of a growing step strongly depends on previous steps. Any step chemically growing wrongly would lead to an unacceptable result. For the fragment linking approach, it remains a
demonstrated the efficiency of the strategy for focused library design and screening. In addition, the novel chemical entities reported in this study could be leads for discovering new therapies against the CypA pathway.

ADME/T Optimization

It has widely been appreciated that ADME/T should be involved in the early stage of drug discovery (lead discovery) in parallel with efficacy screening (40, 41). Many high-throughput technologies for ADME/T evaluation have been developed, and the accumulated data make it possible to construct models for predicting the ADME/T properties of compounds before structural modifications. These computational models may reduce the redesign-synthesize-test cycles. Hereinafter, we will show how computational approaches predict and model the most relevant pharmacokinetic, metabolic and toxicity endpoints, which thereby accelerate the pace of new drug development.

Prediction of intestinal absorption

Absorption of drugs from the gastrointestinal tract is a complex process that can be influenced by not only physicochemical and physiological factors but also by formulation factors. Some published models and commercially available computer programs have been developed for predicting the intestinal absorption. Among them, physiologically based approaches are of particular interest because the human physiological environment and the processes involved in drug absorption are simulated.

Mixing tank models describe the intestine as one or more well-mixed tanks, in which dissolved and solid forms of drug have a uniform concentration and are transferred between the mixing tanks by first-order transit kinetics. This model has been implemented in commercial program Intellipharm PK (http://www.intellipharm.com) and OraSpotter (http://www.akosgmbh.de). Tube models assume the intestine to be a cylindrical tube with or without changing radius, which includes the mass balance models and the models used in PK-Map and PK-Sim (http://www.bayertechnology.com). In the mass balance model, the difference between the mass flows in and out of the tube represents the mass absorbed per time unit, and it is proportional to the permeability and the concentration of the drug in the intestines. In models of PK-Map and PK-Sim, a transit function was introduced and the intestinal permeability coefficient can be calculated solely by the lipophilicity and molecular weight of the investigated compound.

Yu et al. (42) developed an absorption and transit (CAT) model, which formed a basis of many models and commercially available computer programs, such as GITA (GI-Transit Absorption), iDEA (http://www.akosgmbh.de) and GastroPlus (http://www.simulations-plus.com). iDEA uses an absorption model proposed by Grass et al. (43), and GastroPlus uses the ACAT (advanced compartmental absorption and transit) model developed by Agoram et al. (44). Parrott et al. (45) compared these two commercial programs both in their ability to predict fraction absorbed for a set of 28 drugs and in terms of the functionality offered. The results suggested that iDEA may perform better with measured input data, whereas GastroPlus presents a...
more sophisticated user interface, which shows strengths in its ability to integrate additional data.

**Prediction of blood–brain barrier (BBB) permeability**

The blood–brain barrier (BBB) is a physiological barrier in the circulatory system that restrains substances from entering into the central nervous system (CNS). The orally administered drugs that target receptors and enzymes in the CNS must cross the BBB to produce desired therapeutic effects. At the same time, the peripherally acting agents should not cross it to avoid the side effects (46). To date, various methods that have been applied for model generation include the traditional statistical approaches and state-of-art machine-learning techniques.

Generally, current BBB models have shown acceptable capabilities depending on the approaches used and particularly the type and the size of the dataset under investigation. Some insights into the molecular properties that determine the brain permeation have also been gained. However, most current in silico modeling of BBB permeability start with the assumption that most drugs are transported across the BBB by passive diffusion. Absence of data regarding active transport or P-glycoprotein (P-gp) efflux limits the development of accurate and reliable BBB models that can more closely mimic the in vivo situation. Recently, Adeno et al. (47) reported their studies based on a large heterogeneous dataset (~1700 compounds) including 91 P-gp substrates. Likewise, Garg and Verma (48) took the active transport of the molecules into consideration in the form of their probabilities of becoming a substrate to P-gp, and their results indicated that the P-gp indeed plays a role in BBB permeability for some molecules.

**Prediction of CYP-mediated metabolism**

The human cytochromes P450 (CYP450) constitute a large family of heme enzymes. In drug development, the CYP-mediated metabolism is of particular interest because it may profoundly affect the initial bioavailability, desired activity, and safety profile of compounds. A great variety of in silico modeling approaches have been applied to CYP enzymes. Connections and integrations between the “ligand-based,” “protein-based,” and “ligand-protein interaction–based” groups of methods have been extensively described in the review of Graaf et al. (49). Apart from this methodological categorization, current in silico models mainly address the following three aspects of metabolism: CYP inhibition, isoform specificity, and site of CYP-mediated metabolism.

Inhibition of CYP enzymes is unwanted because of the risk of severe side effects caused by drug–drug interactions. A novel Line-Walking Recursive Partitioning method was presented that uses only nine chemical properties of the shape, polarizability, and charge of the molecule to classify a compound as a 3A4, 2C9, or 2D6 inhibitor (50). Recently, Jensen et al. (51) constructed Gaussian kernel weighted k-NN models to predict CYP2D6 and CYP3A4 inhibition, resulting in classification models with over 80% of overall accuracy.

CYP isoform specificity predicts the subtype responsible for the main route of metabolism. This type of study started from the work by Manga et al. (52), in which the isoform specificity for CYP3A4, CYP2D6, and CYP2C9 substrates was investigated. Terfloth et al. (53) reported a similar study on the same dataset using ligand-based methods, and the accuracy of prediction was improved substantially.

The site of metabolism (SOM) refers to the place in a molecule where the metabolic reaction occurs, which is usually a starting point in metabolic pathway investigation. Recently, Sheridan et al. (54) reported a study addressing the SOM mediated by CYP3A4, CYP2C9, and CYP2D6. In this study, pure QSAR-model was constructed with only substructure and physical property descriptors. The cross-validated accuracies range from 72% to 77% for the investigated datasets, which are significantly higher than that of earlier models and seem to be comparable with the results from MetaSite (http://www.moldiscovery.com), which is a more mechanism-based method of predicting SOM.
Prediction of toxicity

At present, a variety of toxicological tests needs to be conducted by the drug regulatory authorities for safety assessment. Computational techniques are fast and cheap alternatives to biochemical as they require neither experimental materials nor physically available compounds. Some examples of available computer programs that predict toxicity are Deductive Estimation on Risk from Existing Knowledge (http://www.thesalolimited.org), Multi-Purpose Computer Automated Structure Evaluation (http://www. molsoft.com), and Toxicity Prediction by Computer Assisted Technology (current DIS TOPKAT, http://accelrys.com/products/discovery-studio/toxicology). Recently, developments in artificial intelligence research and the improvement of computational resources have led to efficient data-mining methods that can automatically extract structure toxicity relations (STRs) from toxicity databases with structurally diverse compounds. Helma et al. (55) described some general procedures used for generating QSTR models from experimental data. Here, we briefly present a study made to model the mutagenic probability (56).

Mutagenity is the ability of a compound to cause mutations in DNA, which is one of the toxicological liabilities closely evaluated in drug discovery and their toxic mechanisms have been relatively well understood. In the development of QSTR models, it is essential to select the structural or chemical properties most relevant to the endpoint of interest. For mutagenicity, we designed a molecular electrophilicity vector (MEV) to depict the electrophilicity of chemicals, which is a major cause of chemical/DNA interaction. A model for the classification of a chemical compound into either mutagen or nonmutagen was then obtained by a support vector machine together with a F-score based feature selection. For model construction, the SVM-c-MEV method shows its superior efficiency in the data fitting, with a concordance rate of 91.86%. For validation, a prediction accuracy of 84.80% for the external test set was yielded, which is close to the experimental reproducibility of the Salmonella assay. The F-score based feature weighting analyses highlight the important role of atomic partial charges in describing the noncovalent intermolecular interactions with DNA, which is usually a hard part in the mutagenicity prediction.

The Future

The technological progress of computational chemistry and biology brought a paradigm change to both pharma and research institutes. Computational tools have been considerably appreciated in drug discovery and development, which play increasingly important roles in target identification, lead discovery, and ADME/T prediction. In the future, in addition to improving individual existing computational techniques, such as perfection of the accuracy and effectiveness of virtual screening, one major tendency is to integrate computational chemistry and biology together with chemoinformatics and bioinformatics. This research is leading to a new topic known as pharmacoinformatics, which will impact the pharmaceutical development process and increase the success rate of development candidates (57).

Another tendency is to use more accurate computational approaches, such as molecular dynamics simulation, to design specific inhibitors or activators against the pathway of target protein folding (58). By using this strategy, Broglio et al. (59) obtained inhibitors that may block HIV-1 protease monomer to fold into its native structure, which causes the inhibitors not to create resistance. Similarly, by targeting the C-terminal β-sheet region of an Aβ intermediate structure extracted from molecular dynamics simulations of Aβ conformational transition (60), we obtained a new inhibitor that abolishes Aβ fibrillation using virtual screening in conjunction with thioflavin T fluorescence assay and atomic force microscopy determination (61).

After the completion of the human genome and numerous pathogen genomes, efforts are underway to understand the role of gene products in biological pathways and human diseases and to exploit their functions for the sake of discovering new drug targets (62). Small and cell-permeable chemical ligands are used increasingly in genomics approaches to understand the global functions of genome and proteome. This approach is referred to as chemical biology (or chemogenomics) (63). Another emerging field is computational systems biology to model or simulate intracellular and intercellular events using data gathered from genomic, proteomic, or metabolomic experiments (64). This field highly impacts drug discovery and development.

Lead Optimization in Drug Discovery
Pharmacokinetics of Drug Candidates, Determination of

Ronald E. White, Schering-Plough Research Institute, Kenilworth, New Jersey

doi: 10.1002/9780470048672.wecb644

Pharmacokinetics is a mathematically based discipline that describes the time course of uptake, distribution, and elimination of a drug in an organism. This article explains the physiologic basis and clinical interpretation of the various pharmacokinetic parameters, such as half-life, clearance, and oral bioavailability. Because of the central importance of pharmacokinetics to the clinical use of drugs, the determination of pharmacokinetics is required at several points in the research and development cycle of new drug candidates. The rationale and methods of determination are discussed.

The therapeutic effectiveness of drugs generally can be related to the concentrations achieved at the physiologic site of action and to the length of time that effective concentrations are maintained (1, p. 1). For instance, molecules of an antibiotic must reach the site of infection (e.g., inner ear, lung, or bladder) to interact with the molecular target (typically an enzyme) in the infecting bacteria. Similarly, cough suppression or relief of clinical depression may require a medicine to penetrate the blood-brain barrier to access molecular targets (typically pharmacologic receptors) in the central nervous system. Therefore, an assessment of the effectiveness of the therapy partly depends on our ability to monitor concentrations of the drug in these organs. However, because often it is not feasible to measure intraorgan concentrations of drugs directly, we usually measure blood concentrations and then infer the corresponding tissue concentrations by using predetermined relationships for the particular drug and organ in question. In practice, we establish the blood concentration that corresponds to the actual tissue concentration necessary for therapeutic effectiveness for each clinical drug, which allows us to discuss therapy in terms of blood concentrations only without reference to tissue levels. A useful clinical drug must exhibit several practical characteristics (2):

- **Efficacy**: the intrinsic ability of the compound to produce a desired pharmacologic effect.
- **Availability**: the ability of the compound to reach the target organ.
- **Safety**: the sufficient selectivity at the therapeutic dose so that undesirable pharmacologic actions are acceptably mild.
- **Persistence**: the sufficient residence time in the body to allow a clinically useful duration of action, usually expressed as the plasma elimination half-life.

Pharmacokinetics (PK) is a mathematically based scientific discipline that describes the time course of uptake, distribution, and elimination of a drug in an organism. A central goal of PK is to determine the length of time that target pharmaceutical receptors are exposed to pharmacologically effective concentrations of the drug molecules. Therefore, PK is of the utmost importance in understanding drug action, especially the duration of action, optimal dose size, individual variation in response, interactions between drugs, and developed resistance or tolerance to drugs.

**Clinical Pharmacokinetics**

The following discussion addresses only small-molecule drugs, chemical compounds with molecular weights less than 1,000 Daltons. Large-molecule drugs (biologics) such as vaccines, cytokines, antibodies, and genes also can be studied by the methods of pharmacokinetics, but they are distributed and cleared in fundamentally different ways than small molecules. (3, 4).

**Dose and administration**

Dose refers to the amount of the drug to be administered to the patient and may be expressed in several ways. The most common form is the amount (expressed in milligrams) taken in an oral formulation such as a tablet, capsule, or syrup. Often, the formulation is provided by the manufacturer in several dose strengths, such as 10, 25, and 50 mg. Some medicines are delivered by a parenteral route such as inhalation, topical, subcutaneous, or intravenous to deliver the medicine more directly to the target organ, to control the rate of delivery, or to substitute for when oral dosing is impractical. Depending on the rate of elimination of the drug from the body, additional doses are administered at intervals to maintain adequate therapeutic.
blood levels. Because the presence of food in the gastrointestinal tract may affect the absorption of some drugs, the patient may be instructed to take the drug either with or between meals. Thus, a dosing regimen must be designed to achieve a particular concentration over a particular interval or time of day in relation to meals, such as a 10-mg tablet taken once a day after dinner.

**Meaning and interpretation of pharmacokinetic parameters**

Plasma, the fluid component of blood left after the separation of cells, commonly is used for pharmacokinetic determinations. Figure 1 illustrates the time course of drug concentrations in plasma following either an intravenous (iv) or an oral (po) dose of a hypothetical drug. In the case of the iv bolus dose, the drug is delivered completely to the bloodstream essentially instantaneously and then concentrations immediately begin to decline as the drug distributes within and is eliminated from the body (see the dashed curve in Fig. 1). The solid curve shows the drug concentration profile for the same dose given orally. In this case, because the drug first must be absorbed from the gastrointestinal tract to reach the blood, concentrations initially rise (absorption phase); however, when the rate of absorption equals the rate of elimination, the input and output processes reach a balance and the peak concentration (Cmax) is seen. Thereafter, when absorption is complete and only the elimination process is left, the elimination phase is reached and concentrations decline as the body acts to remove the drug.

During the absorption phase, the plasma concentration attains the minimum therapeutic threshold accompanied by onset of the efficacious effect. A desirable medicine has a large window between the efficacious concentration and a concentration that produces undesirable side effects (adverse event threshold). As concentrations fall after Cmax, the duration of effect is determined by the time above the therapeutic threshold. Thus, the illustrated drug loses effect after about 12 hours and requires a second dose by that time.

**Figure 1** Plasma concentration time profiles for a single 42-mg dose of a hypothetical drug with a half-life of 8 hours, Vd 42 liters, and oral bioavailability of 80%. Dashed curve: intravenous bolus dose. Solid curve: oral dose. Dotted horizontal lines represent plasma concentrations required for efficacy (green) and for the onset of adverse events (red).
A successful dosing regimen will keep $C_{\min}$ accumulation index of these two is called the time points (Fig. 4 trapezoids formed between successive measured concentration to approach the adverse event threshold.

state (Cave plasma concentrations over a single dosing interval at steady state (Fig. 3 each successive dose (Fig. 3). The time-weighted average of plasma concentrations over a single dosing interval at steady state ($C_{\text{SS}}$, SS) is higher than that on the first dose, and the ratio of these two is called the Accumulation Index (R) (1, p. 87). A successful dosing regimen will keep $C_{\text{SS}}$, SS well above the therapeutic threshold at all times while never allowing $C_{\text{SS}}$, SS to approach the adverse event threshold.

$AUC$ is a measure of the total exposure of the body to the drug and can be estimated as the sum of the areas of a series of trapezoids formed between successive measured concentration time points (Fig. 4 and Equation 1) (1, p. 469). Because a drug may not necessarily be completely absorbed or may undergo presystemic metabolism or other elimination during the absorption process, the related parameter $F$ indicates the fraction of an orally administered dose that actually reaches the systemic circulation. As a practical matter, $F$, which usually is expressed as a percentage, is calculated as the ratio of the $AUC$ measured from an oral dose to the $AUC$ from an equivalent intravenous dose that is delivered completely to the bloodstream (Equation 2) (1, p. 42). Because two different drugs generally have different $C_{\text{max}}$, values, bioavailabilities, and half-lives, the observed exposures (i.e., $AUC$s) will be different even though equal doses of the drugs may have been given.

$AUC = \sum_{i=1}^{n} \frac{1}{2} (C_i + C_{i-1}) \times (t_i - t_{i-1})$ (1)

$F = \frac{AUC_{\text{oral}}}{AUC_{\text{iv}}}$ (2)

$V_d$ measures the volume of plasma in which the drug appears to be dissolved and is calculated by dividing the amount of drug in the body by the observed concentration in plasma at that time (Equation 3) (1, p. 20). For a drug that is confined to the plasma compartment, $V_d$ is the volume of plasma in the body (ca. 3 liters (L) in humans) (6). A drug that freely passes into and out of the cells of tissues will have a $V_d$ value of about 42 L (i.e., nominal total body water for an adult human) (6). However, many drugs show $V_d$ values that are much greater than 42 L, which cannot correspond to any physiologic compartment. In these cases, the drug must be sequestered significantly outside of the plasma compartment into organs and tissues. For this reason, $V_d$ sometimes is called the apparent volume of distribution. Because it is difficult to know at any moment the exact amount of drug in the body because of continuous elimination, we usually cannot apply Equation 3 directly to determine $V_d$ and we must use an indirect method (see below).

$V_d = \frac{\text{amount \ in \ plasma}}{C_{\text{plasma}}}$ (3)

Finally, $CL$ describes how quickly the drug is eliminated completely from plasma or blood and has the units of volume per unit time. $CL$ is calculated easily from the plasma $AUC$ observed for a given dose (Equation 4) (1, p. 37). For an intravenous dose $F = 1$, Equation 4 simplifies to $CL = \text{Dose/AUC}_{\text{iv}}$. For an oral dose, if the bioavailability is not known, then the $Dose/AUC$ calculation yields $CL/F$ rather than the true clearance.

$CL = \frac{\text{Dose}_{\text{oral}}}{\text{AUC}_{\text{oral}}}$ $F = \frac{\text{Dose}_{\text{iv}}}{\text{AUC}_{\text{iv}}}$ (4)

$CL$ is a useful working concept because it is related to the passage of drug-containing blood through a clearance organ such as liver or kidney. A drug that is cleared only by the liver (by liver metabolism, for instance) can be cleared only as fast as blood flows to the liver. This mass transport limitation is expressed in Equation 5 (1, p. 166), where $Q$ is the total blood flow to the liver (about 1.4 L per minute (min)) (1, p. 138), $CL_{\text{int}}$ is the intrinsic ability of the liver to clear the drug if blood flow were not a limitation, and $f_l$ is the fraction of the drug not bound to proteins in plasma (7). We can see from Equation 5 that in the two extreme cases, $CL$ is equal to...
elimination, instance, for a drug that has both hepatic and renal routes of clearance is the sum of the individual organ clearances. For clearance is that it is additive. In other words, the total systemic from urine back into blood. A final useful characteristic of concentration time profile is treated descriptively by the method of noncompartmental analysis, persistence in the body is described by a new parameter, mean residence time (MAT, the average time that an drug molecule resides in the body) rather than terminal elimination half-life. For many drugs, MRT is a better indicator of the clinically effective duration. The difference between MRT values for oral and intravenous doses gives a descriptor of the rate of intestinal absorption called the mean absorption time (MAT). Noncompartmental analysis also defines a new volume parameter, \( V_{\text{ss}} \), the volume of distribution at steady state, which is useful for calculations of plasma levels after multiple dosing or during intravenous infusion. A second descriptor of volume, \( V_{\text{s}} \), represents the volume of distribution during the terminal elimination phase and is calculated exactly the same as \( V_{\text{ss}} \) in the one-compartment model (see Equation 6). \( V_{\text{s}} \) usually is different from \( V_{\text{ss}} \) and seldom is used in clinical dosing regimen considerations.

**Role of PK in the Drug Discovery and Development Process**

**Discovery**

Basic research elucidates the complex biochemical events that comprise a biologic process, such as the regulation of blood glucose, and identifies key control points that are mediated by enzymes or receptors. Most drugs exert their pharmacologic action by modulating the activity of one of these enzymes or receptors within cells of the abnormally functioning organ. So, the next step in the drug discovery process is lead generation, the design or discovery of a small molecule that will bind to the molecular target to modulate its activity. Once a lead has been generated, medicinal chemists typically synthesize thousands of analogs by systematically varying the structure to create a compound that has been optimized with respect to potency and selectivity toward the molecular target. PK characteristics, and

---

**Equations**

1. When \( CL_{\text{int}} \) is small compared with \( Q \), and \( CL \) is equal to \( Q \) when \( CL_{\text{int}} \) is large compared with \( Q \):

   \[
   CL = \frac{Q \times f_u \times CL_{\text{int}}}{Q + f_u \times CL_{\text{int}}} \tag{5}
   \]

2. Similarly, renal clearance is limited ultimately by kidney blood flow (ca. 1,100 mL/min) (1, p. 138). Clearance by kidneys comprises three processes: glomerular filtration, the rate at which the kidneys filter plasma (ca. 120 mL/min) (1, p. 169); direct secretion of drugs into urine; and reabsorption of drugs from urine back into blood. A final useful characteristic of clearance is that it is additive. In other words, the total systemic clearance is the sum of the individual organ clearances. For instance, for a drug that has both hepatic and renal routes of elimination, \( CL_{\text{tot}} = CL_h + CL_r \). Such a drug still can be cleared, albeit more slowly, in patients with either liver or kidney failure.

   For an ideal, so-called one-compartment drug (i.e., one that is in rapid equilibrium with all tissues), the parameters half-life, clearance, and volume of distribution are interrelated by Equation 6 (1, p. 24). Because half-life and clearance can be determined independently, it is possible to calculate \( V_{\text{ss}} \):

   \[
   CL = \frac{Q \times f_u \times CL_{\text{int}}}{Q + f_u \times CL_{\text{int}}} \times 0.693 \times V_{\text{ss}} \tag{6}
   \]

   As mentioned above, many drugs do not conform to the simple one-compartment model. These cases may require a two- or three-compartment model characterized by a bi- or tri-exponential decline (8). Alternatively, a simpler, commonly used approach is noncompartmental analysis, in which the concentration time profile is treated descriptively by the method of statistical moments (9). Whereas CL has exactly the same definition in noncompartmental analysis, persistence in the body is described by a new parameter, mean residence time (MAT, the average time that a drug molecule resides in the body) rather than terminal elimination half-life. For many drugs, MRT is a better indicator of the clinically effective duration. The difference between MRT values for oral and intravenous doses gives a descriptor of the rate of intestinal absorption called the mean absorption time (MAT). Noncompartmental analysis also defines a new volume parameter, \( V_{\text{ss}} \), the volume of distribution at steady state, which is useful for calculations of plasma levels after multiple dosing or during intravenous infusion. A second descriptor of volume, \( V_{\text{s}} \), represents the volume of distribution during the terminal elimination phase and is calculated exactly the same as \( V_{\text{ss}} \) in the one-compartment model (see Equation 6). \( V_{\text{s}} \) usually is different from \( V_{\text{ss}} \) and seldom is used in clinical dosing regimen considerations.

---

**Figure 4**

Estimation of the total AUC for an oral dose of the drug by use of the Trapezoidal Rule. Vertical lines from measured concentration time points define a family of trapezoids, the sum of the areas of these trapezoids approximates the area under the curve. The area beyond the last time point (24 hour) is estimated by multiplying the last measured concentration by the factor \( 0.693 \times T_{1/2} \). Area (24-hour) = \( C_{\text{final}} \times T_{1/2} \).
safety. This compound then is designated as a clinical candidate, and it enters the development process (10).

Given the importance of PK in the clinical use of drugs, a suitable human PK profile is an important criterion in the selection from many discovery compounds of a single candidate for advancement to clinical development. Therefore, contemporary drug discovery screening of compounds includes pharmacologic potency, selectivity, and PK properties in the acceptable range for the medical indication (11). Because drug discovery normally takes place before the clinical phase, the human PK characteristics of a drug candidate must be inferred from in vitro animal models or from various human-derived in vitro systems (12).

**PK screening**

**In vitro studies**

Because clearance at the whole-body level often is determined by metabolism at the cellular level, it is possible to use a variety of human-derived in vitro systems to determine rates of metabolism. These systems include pure human enzymes (such as cytochrome P450 enzymes) (13) and human liver subcellular fractions (microsomes) (14). However, with enzymes and subcellular fractions, some information is lost because the whole-cell integration of subcellular processes has been disrupted. The use of cultured human hepatocytes retains the whole-cell integration at the expense of greater experimental complexity (15). Each system provides a different window on the metabolic processes, is relatively easy to use, and can be obtained from commercial sources. Rates and pathways of metabolism may be compared with a series of discovery candidates to identify those with the greatest relative metabolic stability or with a benchmark compound of known human PK characteristics to provide a more absolute estimate of hepatic metabolic clearance.

**In vivo studies**

PK studies in typical laboratory animals (typically mice, rats, dogs, or monkeys) are useful because they directly determine the various PK parameters discussed above, which affords an understanding of the whole-body characteristics of absorption, distribution, metabolism, and elimination. Because these translate with some fidelity to humans, animal PK commonly is used to assess the PK acceptability of discovery compounds. Unfortunately, these studies tend to be too slow to permit rapid evaluation of dozens or hundreds of discovery compounds. Therefore, two modifications have been introduced that provide the PK acceptability of discovery compounds. First, if the compound was cleared mainly by hepatic metabolism in the animal species tested and if human hepatocytes in vitro suggest the same will be true in humans, then the measured hepatocyte clearance may be used in a process called in vitro/in vivo scaling (20, pp. 207–228) to provide an estimate of the human intrinsic clearance. The application of Equation 5 then gives an estimate of the human systemic clearance. Second, the animal PK parameters of CL and Vd can be subjected to allometric scaling (20, pp. 207–228) whereby the PK parameter is related to a measurable allometric variable such as body mass, body surface area, heart rate, and so forth (21) by fitting these parameter-variable pairs for several species to an empirical power equation of the form

\[ \text{PK parameter} = \alpha \times \text{(allometric variable)}^\beta \]  

where \( \alpha \) and \( \beta \) are adjustable constants. A common application is to scale CL according to body mass.

\[ \text{CL} = \alpha \times \text{(Body Mass)}^\beta \]  

Both CL and Vd from the animal PK studies may be scaled allometrically to provide the estimates of human CL and Vd needed to project the human half-life. In addition to calculating the half-life, one also can estimate the human therapeutic dose if the blood levels that correspond to efficacy in a relevant animal pharmacologic model have been measured. The AUC measured in the animal model can be equated with the AUC needed for efficacy in humans, and then the application of Equation 4 with the estimated human CL gives an estimated human dose.

For drugs intended for oral administration, the bioavailability \( F \) often is assumed to lie in the range between the lowest and highest values observed in the animal species tested. These projected human PK parameters need not be extremely accurate to be useful for planning.

**Preclinical development**

Before a new chemical entity can be tested in humans, its safety in various in vitro and in vivo pharmacologic and toxicity tests is
must be assessed (22). This assessment includes an administration of high doses to animals (typically mice or rats and larger animals such as dogs or monkeys) and in vitro tests of genotoxic potential (such as the Ames test). PK, normally will be determined in the animal species to be used for safety testing to assess the relationship between the oral dose and the exposure for dose selection and to select time points for the monitoring of exposure during the safety studies. In parallel with the safety testing, a large-scale chemical synthetic process must be developed to produce clinical supplies of the drug candidate to enable clinical trials. Finally, a clinical formulation must be devised to allow adequate and reproducible exposure in the clinical trials, and animal PK studies are helpful in the selection process. These studies usually examine Cmax, Tmax, and AUC for several possible formulations to allow matching to the desired clinical delivery profile. Data from the discovery and preclinical activities form the basis of a petition to government health authorities for permission to begin testing in humans. Once this dossier, called the Investigational New Drug Application (IND) in the United States, is approved, clinical trials may proceed (23). Information about the IND and other regulatory guidelines and documentation is available through the web link to the United States Food and Drug Administration at the end of this article.

**Clinical development**

Clinical trials are divided formally into four distinct but temporarily overlapping phases, defined by the objectives of each phase (24). Phase I tests the safety and tolerability of the drug candidate in normal healthy volunteer subjects. An important goal is to determine the maximum dose that may be safely given to establish the dose–exposure relationship and also the half-life. Phase II investigates whether the candidate modulates the pharmacologic target in ten to twenty patients (Phase IIb) using PK parameters, which are needed to plan the next phases. Phase IIc tests the drug in much larger groups of patients to establish the comprehensive clinical profile of the candidate, including confirming the therapeutic benefit with adequate statistics and investigating the variation of therapeutic response and the safety in various severities of the disease and in special populations such as ethnic groups or comorbidities. Phase IV usually occurs after the drug has been approved and is on the market and involves testing even larger populations for longer periods of time and testing against additional disease indications.

**Phase I**

Human PK is determined for the first time in Phase I, initially as a series of single doses escalated through several dose levels to establish the dose-exposure relationship and also the half-life. Because an oral dose may have an extended period of absorption, it is not possible to get the true clearance or volume of distribution from an oral dose; a confounding with bioavailability may occur. Furthermore, sometimes absorption is slower than elimination and a phenomenon known as “flip-flop kinetics” occurs in which the observed half-life really is a reflection of absorption and not elimination. Thus, when feasible, an intravenous dose is given to allow absolute oral bioavailability and the true values of total clearance, renal clearance, volume of distribution, and half-life to be determined. Administration of an intravenous dose requires the development of a sterile solution formulation and acute intravenous animal safety studies and may not be possible always with poorly soluble drugs.

The next step is multiple dosing at several dose levels within the range determined to be safe from the single-dose study. In addition to more investigation of clinical safety, the main PK purpose of multiple dosing is to establish how many doses are required to reach steady state and what steady state Cmax and AUC values are reached. A well-behaved drug will reach steady state in about five doses (see Fig. 3), and a general rule is that if doses are given at intervals of one half-life, then the steady state Cmax will be about twice that following a single dose (25, p. 123). Dosing more frequently than the half-life results in a more than twofold accumulation, and dosing less frequently than the half-life results in a less than twofold accumulation. The average plasma level to be expected at steady state can be calculated by Equation 9 where \( r \) is the dosing interval (1, p. 80),

\[
C_{\text{ave, ss}} = \frac{F \times \text{Dose}}{C \times r}
\]  

or can be determined from a numerical simulation using the Principle of Superposition (25, pp. 451-457). Importantly, a significant deviation of the accumulation index R-value from that predicted by the single-dose PK indicates a time-dependent alteration of clearance. For example, continuing exposure of the body to some drugs causes an adaptive response called autoinduction in which drug-metabolizing enzymes are upregulated to allow the body to eliminate the drug more rapidly (26). Such a drug would then show an R-value of less than one, which means that subsequent doses would lead to lower Cmax and AUC values. It is possible for autoinduction to be so severe that the drug becomes ineffective after a few doses. The opposite situation, although it is rare, also can occur; that is, R values can be much larger than expected, which means that when multiple dosing, the body becomes less able to clear the drug and plasma levels continue to rise. Greater–than–expected accumulation usually indicates some form of toxicity, such as organ toxicity or irreversible inhibition of clearance enzymes. The cytochrome P450 enzyme designated CYP3A4 is especially susceptible to irreversible inhibition (27), so the discovery process usually includes a screen for this type of behavior to prevent such compounds from reaching the clinic. Again, this type of nonideal PK behavior could be enough to cause the drug candidate to be clinically unusable.

An additional Phase I PK studies include the determination of the effect of food on orally administered drugs (28), formulation testing (29), detection of circulating metabolites of the drug (30), and checking for PK interactions between coadministered drugs (31). The most common form of drug-drug PK interaction is the competition of the two drugs for the same clearance mechanism, especially the CYP-P450 family of drug-metabolizing enzymes, which results in a limitation on which drugs ultimately
can be used clinically with the new agent (32). All clinical PK studies rely on some method of quantification of drug levels in blood or plasma, and the major bioanalytic technique in use today for this purpose is liquid chromatography coupled to tandem mass spectrometry (LC-MS/MS) (33, 34). Current technology permits the determination of picogram-per-mL levels of a drug in the presence of many interfering substances, with sample-to-sample cycle times less than 2 minutes. Because of individual biologic variability and inevitable experimental error, the measured drug concentrations at each time point will show variation among a group of subjects, which results in the need to express derived pharmacokinetic parameters as a mean value with an associated coefficient of variation (1, p. 203).

In addition to the conventional first-in-human approach described above, another available approach allows rapid access to the clinic to answer specific questions addressable by a single dose in humans. The U.S. Food and Drug Administration allows a sponsor to proceed to limited clinical dosing with an Exploratory IND (35), which has more moderate requirements than the standard IND. Determination of human PK is the most common use of the new approach, which can be thought of as an extension of the discovery process to check human PK before the decision is made to commit full development resources to pursue the conventional IND. One option within the Exploratory IND is microdosing, which has even lower requirements (36, 37). A microdose is defined as no more than 1/100 of the expected therapeutic dose but not exceeding 100 micrograms. The advantages of a microdose are that minimal safety testing is required because only minute quantities of the drug candidate are administered and that large-scale chemical synthesis can be postponed until acceptable clinical PK is confirmed.

**Phase II**

Although the main goal of Phase II clinical trials is the determination of efficacy toward the disease indication, PK is a fundamental part of this determination because to understand the clinical use of the new drug candidate, it is necessary to determine the temporal relationship between the plasma levels and the pharmacodynamics of the beneficial effect (PK/PD). A secondary PK goal in Phase II is to determine if the disease state affects the PK of the candidate drug compared with the PK observed in healthy subjects.

During the dose range-finding portion of Phase II, several doses are assessed for efficacy in patients with the disease to be treated. The PK sampling at these doses is critical because it allows the construction of a pharmacokinetic/pharmacodynamic (PK/PD) model whereby the observed drug concentrations are used to predict the effect of the drug (20, pp. 189-205, 38). The simplest PK/PD model is the direct or E\textsubscript{max} model in which a direct relationship exists between the concentration and the effect; changes in plasma levels are reflected immediately in the pharmacologic response. Often, however, as concentrations increase, eventually the pharmacologic responses reach a peak or nadir and greater increases in concentration result in only a small change in effect. Ideally, the drug candidate is safe enough to dose to the maximal effect. However, it is more common to strike a balance between the magnitude of response and the incidence of adverse side effects. Some drugs follow a more complex PK/PD relationship called the indirect model in which the pharmacologic response temporally lags behind changes in plasma levels (hysteresis). In this model, the response seen from a particular plasma concentration in the declining phase of the PK curve may be much greater than it was for the same plasma concentration during the rising phase of the curve. Hysteresis occurs when the initial stimulus of the drug binding to the receptor is uncoupled in time to the observed clinical response because a biologic cascade of several biochemical or physiologic events must occur for the clinical response to become manifest. After it is determined which type of relationship applies, a theoretical PK/PD model can be fit to the concentration-response data, which thereby generates a quantitative understanding of the action of the drug and the ability to predict the response to be expected in any situation.

With the availability of a PK/PD model, clinical trial simulation (39, 40) can be performed to explore alternative dosing regimens and to help achieve the optimal design of the Phase III program. The inputs for simulation include the number of patients to be tested, the duration of the testing, the potential clinical end points, and most importantly, the dose(s) to be tested. With Monte Carlo methods to simulate the variability in PK and response observed in Phases I and II, hundreds of computer simulations are conducted for each design and dose level to estimate the statistical probability of a successful outcome (i.e., one that meets predetermined end points of efficacy and safety). The goal is to find a design and dose that balances a high likelihood of a successful trial with a low incidence of adverse events. Ideally, this simulation activity is done in collaboration with government health authorities to minimize the approval time for the Phase III design and the chance of a failed Phase III study (41).

**Phase III**

In Phase III, large-scale trials are mounted with the goal of showing statistically significant benefit against either placebo or, more usually, standard-of-care therapy. The use of many patients affords the opportunity to create a Population PK model for the drug, which is a statistical means to account for individual variation in PK by means of clinically measurable covariates such as age, gender, race, ethnicity, body weight, kidney function, and so forth (42). In this way, the PK characteristics of a particular patient can be estimated before dosing, which allows a rational means to select the dose most likely to prevent good benefit while minimizing risk. After Phase III is complete, the sponsor of the drug candidate may submit an application (called the New Drug Application in the United States) for approval to government health authorities of all countries in which marketing is desired (43).

**Summary**

Pharmacokinetics studies the relationships for a given drug between blood concentrations, uptake, distribution, elimination, pharmacologic effect, and time. Because drugs that require large doses must be dosed frequently, cannot be dosed orally, must be timed in relation to food intake or have strong interactions...
with other drugs, may have issues of patient compliance, variable response, or toxicity, the pharmacokinetic aspects of the behavior of a drug are critical to its successful clinical use. Accordingly, the scientists who design drugs must use preclinical pharmacokinetic screening methods to maximize the likelihood that a drug candidate is acceptable pharmacokinetically. Correspondingly, the researchers who test the drug in clinical trials must ensure that all aspects of pharmacokinetic behavior have been characterized thoroughly before submitting the drug for approval to regulatory authorities.
