In contrast to most receptors, most ligand-free steroid receptors are not membrane bound. They can be cytoplasmic or nuclear, depending on the receptor and the time scale. At a given instant, ERs are mostly nuclear, like the nuclear receptors. For the other receptors, the amount of nuclear localization is PR > MR > AR and GR. However, the dynamic picture is that receptors are “shuttling” back and forth across the nuclear membrane (53).
Proteins associated with unactivated receptors

All steroid-free receptors are associated with other proteins regardless of their whole cell localization. Detailed experiments with PRs and GRs have uncovered the workings of a complex of five proteins (hsps90, hsp70, Hop, hsp40, and p23), often called chaperone proteins, which participate in the assembly of newly synthesized receptors to the form capable of binding steroid (reviewed in Reference 55). Although hsp90 is required for the "maturation" of receptors, it does not seem to be required for the de novo folding of proteins (56). This "maturation" consists of both promoting cleft opening (to allow high affinity steroid binding) and to limit excessive cleft opening (to prevent receptors from being targeted for degradation) (57). The final assembled complex retains hsp90 and p23 along with one of four tetratricopeptide repeat (TPR) proteins: three immunophilins (FKBP51, FKBP52, and Cyp40) or protein phosphatase 5 (PP5). This heterogeneity of ligand-free receptors theoretically could lead to a diversity of biologic responses but that has not yet been documented. Intriguingly, it seems that chaperone proteins such as p23 and hsp90 may also facilitate the disassembly of receptor-containing transcriptional complexes (58, 59). The nuclear receptor RXR is a ubiquitous heterodimerizing partner of other nuclear receptors. The only receptor LBDs exist (see below for DBD structures), and they seem that chaperone proteins such as p23 and hsp90 may also facilitate the disassembly of receptor-containing transcriptional complexes (58, 59). The nuclear receptor RXR is a ubiquitous heterodimerizing partner of other nuclear receptors. The only receptor was defined before it was possible to examine receptor binding to the promoter regions of endogenous genes. This definition may need revision because it is now clear

Steroid-induced changes in receptor structure

The first biochemical evidence that steroid binding modifies receptor structure was that protease digestion produced different sized fragments (61). The ability of this simple technique to discriminate between agonist and antagonist ligands has met with limited success (62, 63 vs. 64, 65). Hydrogen/deuterium exchange mass spectroscopy has been used to distinguish between agonist and antagonist binding (66). Nuclear magnetic resonance permits a more thorough examination of receptor structure, and especially protein motion, but the current methods of signal acquisition limit the size of molecules studied to ~50 kDa. However, new techniques may be able to increase the size limitations to include intact steroid receptors (67).

X-ray structures of receptors

X-ray crystallography provides the most complete structural data of proteins. Unfortunately, no X-ray structure of an intact receptor is yet available. Numerous structure determinations of receptor LBDs exist (see below for DBD structures), and they all show the same basic feature of an "α-helical sandwich" composed of 12 α-helices and 2 β-sheets (Fig. 4) (68, 69), although the number of α-helices (10-13) and β-sheets (2-4) can vary across the entire family of steroid/nuclear receptors. Significant differences were noted between agonist- and antagonist-bound receptors because of induced-fit changes in protein structure, but they are not yet predictable (70) because small changes in ligand-binding position can yield much larger effects on receptor structure (71).

The first X-ray structures of ligand-free and ligand-bound receptors were not of the same receptor. Nevertheless, they suggested an attractive model in which the C-terminal helix (helix 12) was triggered (like a "mousetrap") to close over the ligand-binding pocket upon steroid binding (68). The generality of this model is unclear, though, because no repositioning of helix 12 was observed in ligand-free and ligand-bound forms of two nuclear receptors [PPARγ (72) and PXR (73)] and because residues C-terminal of helix 12 seem to be important for steroid binding to PRs (74), GRs (65), and ARs (75). An alternative path for ligand binding to and dissociation from thyroid receptors (a nuclear receptor) has been proposed to occur through an opening caused by a proline that creates a kink in helix 3 (76). Again, this may not be general as all steroid receptors are lacking the comparable proline residue (68). Thus, multiple binding mechanisms with attending conformational changes may exist.

Nuclear Binding of Receptors

Activation

Regardless of whether the initially formed receptor-steroid complex is cytoplasmic or nuclear, a still poorly understood process called activation (or transformation) converts the complex into a species with increased affinity for DNA and for nucleic. The term "activation" was defined before it was possible to examine receptor binding to the promoter regions of endogenous genes. This definition may need revision because it is now clear...
that ligand-free steroid receptors can bind to the HREs of regulated genes, albeit with little observable transcriptional activity (77, 78, 79). This finding should be contrasted with the promoter binding of ligand-free nuclear receptors, which usually decrease gene transcription. In all cases, however, agonist steroid binding initiates events that alter gene transcription. A activation of DNA binding is affected by heat, salt, dilution, ATP, RNAse, and high pH (80), and it is blocked by the salts of molybdate, vanadate, and tungstate (81). It is also accompanied by the loss and/or increased rate of dissociation of many associated non-receptor proteins (57). This step is not microscopically reversible, but unactivated GR and PR can be regenerated in an ATP-dependent, reticulocyte lysate system (reviewed in Reference 55).

Nuclear translocation and DNA binding

The only way into the nucleus is through the nuclear pores. The entry of all molecules larger than \( \approx 60 \text{kDa} \), including all steroid receptors, is mediated by two nuclear translocation sequences in the hinge region and LBD of the receptors and proceeds via a two-step process. The first step, binding to nuclear pores, is followed by active transport of the receptor through the pores (82). Once in the nucleus, the activated receptor–steroid complexes readily bind to naked DNA, both biologically active sequences (or HREs) and nonspecific DNA. Whether receptors bind to DNA as monomers or preformed dimers is still debated. Recent studies with progesterone receptors (83) and other DNA-binding proteins (84) suggest that preexisting dimers dissociate and bind to DNA cooperatively as monomers. Nonspecific DNA binding is thought to be important both for buffering the binding to HREs and for facilitating the search of the HREs within the cellular genome (85). Each receptor binds to an HRE either as a homodimer or as a heterodimer with a closely related receptor (e.g., PR-AR-P-R (86); ER\( \alpha \)-ER\( \beta \)(87); and GR\( \alpha \)/GR\( \beta \) heterodimers (88)). In contrast with the nuclear receptors, no functional heterodimer of RXR with a steroid receptor has been reported. The HRE has the features of an inverted palindrome of six nucleotides on each side of a 3-nucleotide spacer. Considerable variation in HRE sequence is tolerated by GRs (89) and PRs (90), and maximal gene induction can be achieved with suboptimal in vitro DNA binding sequences. Surprisingly, ARs, GRs, Mxs, and PRs, but not ERs, can all recognize many of the same HRE sequences. The HRE sequence recognized by ERs is much closer to that of the nuclear receptors (4). The binding of ARs, GRs, Mxs, and PRs to the same HRE would cause much of the specificity that is gained by having separate receptors for each steroid to be lost. Among the many mechanisms that may restore specificity are differential responses of cofactor association with receptors (90) and effects of flanking and spacer DNA (91, 92).

All HREs have the properties of an enhancer in that their activity to induce gene transcription is position and orientation independent. HREs are commonly found within the 2-kb upstream of the promoter of regulated genes but can be much further upstream (93, 94) and even downstream (95) of the start of transcription. Those genes that are repressed by steroid receptors usually do not contain the same HRE sequences (96) because the receptors are often bound to another protein that directly contacts other DNA sequences (97, 98) but see (99).

Gene repression can also occur by preventing other factors from binding to their regulatory sites in responsive genes (100, 101).

X-ray structures of DNA-bound receptors

Almost all X-ray structures to date are of the DBD complexed with DNA. They all display several common features, including a dimerization of the DNA-bound DBDs, which is consistent with the highly conserved amino acid sequence of the DBDs, including two "zinc fingers," each of which contains four cysteine residues that complex one Zn\(^{2+}\) ion (Fig. 5). The right-hand "knuckle" of the first zinc finger, or p-box, contains part of the recognition helix for DNA binding and contacts the major groove of the HRE double helical sequence. The recognition helix is dominated by three amino acids of the p-box: GS--V for AR, GR, MR, and PR and EG--A for ER. The identical sequence in AR, GR, MR, and PR explains why they all can bind to the same HREs. The sequence in ER is very similar to the EG--G of the nuclear receptors. Interestingly, despite the critical role of these residues in determining the specificity of DNA binding, only one amino acid contacts the DNA of the HRE (4, 102). The first X-ray structure of a steroid receptor DBD, including the C-terminal extension (CTE) of the DBD, is that for PR. This structure shows that, like the nuclear receptors (4), additional contacts are made by the CTE in the minor groove flanking the PRE sequence, thus extending the size of the PR binding site (92).

Receptor binding to chromatin

Most DNA in cells is not present as naked DNA, waiting for receptors to bind. Instead, a large assortment of proteins decorates the DNA to give chromosomal DNA. The most abundant proteins are the histones, which form nucleosomes and obscure many of the intrinsic binding sites of proteins. In this manner, most regions of the genome are rendered transcriptionally inactive. In many cases, chromatin architecture greatly reduces the basal level of gene expression and steroids increase the efficiency of transcription by altering chromatin structure. In other cases, often where the basal transcription levels are much higher, there is less need for chromatin remodeling, and the fold-increases in gene induction are correspondingly less (103). In several GR-regulated genes, the nucleosomes in the region of the HREs are phased so that the HRE sequence is facing away from the center of the nucleosome and is accessible to activated receptor–steroid complexes (104).

After a receptor binds to the HRE, a host of other factors are thought to be recruited (78). One group of proteins is involved in chromatin remodeling. These proteins fall into two subgroups: species like pCAF and CARM1, which have kinase, acetylase, or methylase activity and covalently modify histones (reviewed in Reference 105), and ATP-dependent complexes, such as SWI/SNF and NURD (reviewed in References 106 and 107; see also the article on Chromatin Remodeling). Elegant real-time, whole-cell fluorescence studies indicate that GR binding to chromosomal GREs is much more rapid; transient, and readily exchangeable than previously suspected (33). These results suggest that GR presence is not needed to perpetuate the initial activating signal. This process could occur by cofactors (e.g., CBP/p300 and CARM1) covalently modifying histories...
to facilitate transcription initiation, with subsequent rounds occurring in the absence of the initially bound receptor-steroid complex. A iteratively, the entire cycle of receptor binding and regulated gene transcription could be rapid (108).

Control of transcription—induction vs. repression

Regardless of whether the receptor is mediating gene induction or repression, the same two domains are involved. These domains, called activation function (AF) 1 and 2, are located in the N- and C-terminal regions of the receptor, respectively. The N-terminal AF1 domain is usually the most active and displays intrinsic transcriptional activity independent of the rest of the receptor protein. No canonical activation sequences, such as acidic blobs, glutamine-rich regions, and amphipathic helices (109), have been identified in the steroid receptors. In fact, the AF1 domain, and the N-terminal half of steroid receptors, is generally unstructured but is induced to fold into a more regular structure both when exposed to helix-stabilizing environments (110, 111) and upon interacting with other transcription cofactors (112). The AF2 domain commonly has much less intrinsic activity and is comprised of helices 3, 4, 5, and 12. These helices form a hydrophobic pocket that binds coactivators, such as the p160 coactivators SRC-1, TIF2/GRIP1, and AIB1/pCIP/ACTR/RAC3/TRAM1 (Fig. 4), and corepressors, such as NCoR and SMRT. Coactivator binding is mediated by α-helical structures with the sequence LxxL, where L is leucine and x is any amino acid. Corepressor binding to an overlapping, but not identical, region of the receptor involves a related sequence of LxxL/IxxxxL/L (123). This sequence, and region of corepressors, was initially defined from interactions with nuclear receptors but has been confirmed for the steroid receptors (114, 115). However, not all LxxL or LxxL/IxxxxL/L sequences in coactivators or corepressors (or other molecules) are sufficient for binding to receptors as adjacent residues also make contributions (116, 117). Given the partial overlap of the binding sites, it is not surprising that the association of coactivators and corepressors to a given receptor-steroid complex displays competitive inhibition in a manner that is controlled, at least in part, by the ratio of coactivators to corepressors (114, 118, 119). These receptor-associated cofactors are then thought to recruit a burgeoning array of additional factors, although probably not at the same time (78, 120, 121; see also the articles on Transcriptional Control and on Activators and Repressors of Transcription). The mechanism of action of most of these factors remains poorly understood.

Steroid hormones both increase and decrease the levels of gene expression to give induction and repression, respectively. However, it is not yet clear whether all HRE-bound receptor-agonist complexes are transcriptionally active (77). A major unanswered question is how superficially similar steps can cause opposite responses. As described, the HREs for gene induction and repression are different. Repression is often achieved via receptors that are tethered to a different DNA-bound protein (97, 98) but see (99) as opposed to the
receptor binding directly to DNA, as observed in induction. Tethering is not per se contraindicated for gene induction, as observed by the ability of GR sequences fused to the GAL4 DBD to bind via the GAL4-DBD to a GAL4 upstream activating sequence and still give gene induction that is augmented by added coactivators (31, 122). Also, the coactivators TIF2 and STAMP still augment the activity of GR-agonist complexes in both GR-mediated induction and repression (123). Hence, the ability of the same receptor-agonist steroid complex to cause increased or decreased gene expression implicates the importance of other processes such as DNA-induced conformational changes (124, 125) and the ability of nearby DNA-bound factors to influence the recruitment of and/or interaction with additional cofactors (93, 92, 99).

The opposite effect of agonist steroids in induction versus repression also causes some confusion regarding the role of coactivators and corepressors. In the absence of precise mechanistic data, we currently must rely on phenomenological descriptions. The original definition of a coactivator was a factor that increases the activity of an agonist steroid (126). Accordingly, a protein that is labeled a coactivator because it increases steroid-regulated induction would be expected to enhance steroid-mediated repression and afford less gene expression (123). Therefore, the apparently opposing effects of a coactivator during induction and repression simply reflect the opposite and currently unknown actions of the agonist steroid. Virtually all studies of gene induction involve averages from populations of cells, which led to the assumption that all cells respond equally to the same concentration of steroid. However, starting with the demonstration that two daughter cells can display drastically different levels of response to a common steroid concentration (127), it has become increasingly clear that transcription versus receptor binding to the gene was recently described in a real-time, single-cell study of the binding of green fluorescent, protein-labeled GRs to an integrated 200-copy tandem array of a reporter gene under the control of the mouse mammary tumor virus promoter (129).

Modulation of the parameters of receptor-mediated gene expression

Two distinctive parameters for gene induction (or repression) are the total activity (equivalent to V_{max} in enzyme kinetics) and the steroid concentration required for half-maximal activity, or EC_{50}. Most factors represented in the current model of steroid hormone action (e.g., Fig. 2) were identified on the basis of their ability to increase, or decrease, the total transcriptional activity (reviewed in References 113 and 130). The determinants of the EC_{50} have usually not been considered, partially because it has long been considered to be controlled predominantly by the affinity of steroid binding to receptor (131). However, this prediction that all genes regulated by a given steroid hormone will be induced (or repressed) with the same EC_{50}, in contrast, it is well known that EC_{50}s of multiple genes induced by the same receptor-steroid complex are not the same, even within the same cell (132, 133 and reviewed in Reference 134). Furthermore, the EC_{50} for gene repression is often much lower than for gene induction (reviewed in References 119 and 135). The circulating concentrations of steroids (e.g., cortisol ≈ 0.4 µM, estradiol ≈ 0.1 nM, or progesterone ≈ 5 nM) are in the region of half-maximal induction of many regulated genes. Consequently, genes with different EC_{50}s will display different extents of response to the single circulating concentration of each steroid that is present at any one time. In many instances, the levels of steroid change, such as for glucocorticoids during the normal 24-hr cycle and during stress or for estrogens and progestins during the female menstrual cycle and pregnancy. Under these conditions, the transcriptional levels of those genes with EC_{50}s near the average of the initial and final steroid concentration will be altered more than the levels of other genes.

Antiestrogens are widely used in endocrine therapies to block the action of endogenous steroids, such as androgen-dependent prostate cancer and estrogen-dependent breast cancer. A very important parameter under these conditions is the amount of residual agonist activity, or partial agonist activity, of the antagonist. The expectation from the general model of steroid action that the amount of partial agonist activity of an antagonist will be the same with all responsive genes has not been experimentally verified. Instead, as above with the EC_{50}, it was found that the amount of partial agonist activity usually varies with the gene (136, 137). Indeed, for reasons that are not understood, there seems to be an inverse correlation between these two parameters. Thus, for receptor-mediated induction of a given gene, the partial agonist activity of an antagonist invariably increases when the EC_{50} of an agonist decreases and vice versa (reviewed in References 119 and 135). It was then realized that these gene-specific differences in partial agonist activity were desirable and offered a theoretical means of blocking only those genes responsible for the undesired pathology while retaining nearly normal levels of other regulated genes. A prime example is the ability of the antiestrogen raloxifene to block estrogen actions in breast cancer but not in bone (138). In recognition of the importance of having the amount of partial agonist activity of a steroid vary in a gene- and cell-specific manner, the term “selective receptor modulator” (SRM) is increasingly used instead of antagonist (139, 140). Thus, antiestrogens are often referred to as SERMs (selective estrogen receptor modulators) and so forth.

Elucidating the mechanisms driving these changes in EC_{50}s for gene induction, and in partial agonist activity of antiestrogens or SRMs, may greatly expand the available therapeutic targets for treatment of a variety of human pathologies. Initial progress has been made with the findings that these changes can be reproduced by varying the concentration of steroid, receptor, coactivator, compresor, and other transcriptional cofactors such as CBP, pCAF, UbCB9, (reviewed in References 119 and 135) and a new protein STAMP (123). The physiologic relevance of these fluctuations is strengthened by the report that the levels of GR mRNA display circadian rhythms in several mouse tissues (141). The EC_{50} for glucocorticoid killing of thymocytes was lowered 10-fold in transgenic mice containing a 2-fold increase in GR gene dosage (142). Also, increasing the concentration of ER{alpha} 10-fold in human breast cancer cells increases the percentage of those genes that are induced by ER{alpha} from 22%
Much has been learned in the last 40 years since steroid hormone receptors were found to act via soluble intracellular proteins. This progress has been made under the guise of different labels, each of which is appropriately a discipline of chemical biology. First, better, longer lasting, and more specific steroids were prepared by chemists. Next, biochemists and biologists uncovered the basic steps by which steroid hormones affect the functioning of many cells and tissues of organisms. Biochemists and molecular endocrinologists discovered that the steroid receptors were a small subgroup of a much larger superfamily of related proteins that share many of the same features when inducing or repressing gene transcription. Molecular biologists have uncovered numerous additional factors that participate in steroid receptor regulation of gene transcription. Molecular physiologists are currently using powerful new techniques to determine the extent to which those mechanisms observed in isolated cell systems are employed in intact organisms for endogenous genes. System biologists are constructing mathematical models incorporating the burgeoning number of relevant factors in an effort to predict the effects of changing one or more components of the system. Eventually, clinicians will employ this wealth of information to correct selectively numerous pathologic conditions of the endocrine system. It is now clear that the specifics of steroid hormone action vary with the gene being regulated. The challenge ahead will be to gather sufficient gene-specific information to limit the effects of steroids to selected target genes and tissues, thereby increasing the desired therapeutic outcomes while reducing the number of unwanted responses.

Disassembly and deinduction: turning off steroid hormone action

Many steroid-regulated genes are only transiently induced or repressed, which is especially true for GR- and MR-responsive genes as the concentration of the activating hormone varies daily. Thus, cells need to be able to turn off steroid-controlled responses reasonably rapidly. Regrettably, very little research has been focused in this direction and even less is known. Interestingly, the chaperone proteins p23 and hsp90, which are required for the proper assembly of functional receptors (see above), may also promote the disassembly of the receptor transcriptional complex (58, 59 vs. 143). Over the last few years, evidence has emerged that the proteolysis of transcription factors and the 26S proteasome seem to be linked to active tran-
scription (77, 143, 144). More recent results, however, suggest that the role of the proteasome may be independent of proteol-
ysis (145). Furthermore, the proteasome inhibitor MG132 has been reported to both increase and decrease gene transcription (106). Additional work is clearly required to determine the gene-

Catalytic Modes in Natural Ribozymes

Michael E. Harris, Center for RNA Molecular Biology, and Vernon E. Anderson, Department of Biochemistry, Case Western Reserve University School of Medicine, Cleveland, Ohio

doi: 10.1002/790407048672.wexc640

In nature, RNA transmits genetic information, and it catalyzes reactions that are universal in biology. The reactions of phosphorus and carbon esters that are catalyzed by natural ribozymes occur with specific geometries and are susceptible to both acid and base catalysis as well as catalysis that involves metal ions. High-resolution structures of a few ribozymes implicate the involvement of individual nucleotides in performing these catalytic strategies. Detailed biochemical tests of the mechanisms of these ribozymes provide evidence for the involvement of nucleobase functional groups in acid/base catalysis, yet debate continues concerning their precise roles in proton transfer. Complementary structural and biochemical support has been gained for the involvement of specific RNA functional groups in positioning metal ions for catalysis. Still, only a few systems have been probed in sufficient depth to infer mechanistic detail and to achieve a complete chemical description of how ribozyme active sites enact specific catalytic strategies remains a key goal.

RNA Catalysis Is Ubiquitous in Biology

RNA holds a unique position in living systems because it can both convey genetic information as well as act as an enzyme to accomplish catalysis (1–3). RNAs that promote catalysis are called ribozymes, and the examples discovered thus far in nature catalyze addition/displacement reactions that involve phosphoesters and carbon esters with rate enhancements approaching that of enzymes (4). Now appreciated as a fundamental aspect of terrestrial biology, the existence of ribozymes was a milestone recognized by the Nobel Prize in Chemistry to Cech and Altman in 1986 (5, 6). The discovery of RNA catalysis was important not only because it broadened our understanding of biologic catalysis, but also because it suggests a central role for RNA in the development of self-replicating systems that are believed to underlie the evolution of cells and ultimately all of biology (7).

The known ribozymes in biology may be divided into three different classes defined by differences in structural complexity as well as by the chemical reactions they catalyze (Fig. 1): Small ribozymes cleave an RNA phosphodiester backbone by catalyzing the intramolecular attack of a ribose 2'-OH on the adjacent 3'-5' phosphodiester, which generates characteristic 5'-hydroxyl and 2',3'-cyclic phosphate products. In biology, small ribozymes are involved in replication of RNA viruses and are found in the 3' untranslated regions of genes where they are involved in gene regulation (8–11). Large ribozymes also catalyze addition/displacement reactions of phosphodiester bonds, but activate oxygen nucleophiles that include 2' and 3' ribose hydroxyls, or water for intermolecular nucleophilic attack displacing the 3' O. A new 2'5' or 2'3' phosphodiester is generated or, if the nucleophile is in water (or rather its lyate ion hydroxide), the RNA chain is cleaved producing 5' monophosphate and 2', 3' cis-diol termini. Large ribozymes include two classes of self-splicing introns (termed Group I and Group II), which catalyze two successive, site-specific transesterification reactions, and P RNA, the catalytic subunit of the RNA processing endonuclease, ribonuclease P (12–14). The peptidyl transferase active site of ribosomal RNA, which is responsible for the synthesis of all proteins in the cell, comprises a third class (15). The RNA active site within the large ribosomal subunit RNA catalyzes attack of a primary amine on the carbon ester linkage between amino acid and 3'-OH of tRNA, which results in formation of a peptide bond and free 3'-OH.

By analogy with protein enzymes and precepts of transition state theory, ribozyme catalysis should involve an array of interactions between RNA functional groups and the reacting groups of the substrate that lower the free energy of the reaction and provide a driving force for chemical conversion. Detailed biochemical tests of the mechanisms of these ribozymes provide evidence for the involvement of nucleobase functional groups in acid/base catalysis, yet debate continues concerning their precise roles in proton transfer. Complementary structural and biochemical support has been gained for the involvement of specific RNA functional groups in positioning metal ions for catalysis. Still, only a few systems have been probed in sufficient depth to infer mechanistic detail and to achieve a complete chemical description of how ribozyme active sites enact specific catalytic strategies remains a key goal.
Catalytic Modes in Natural Ribozymes

Figure 1  General chemical mechanism of addition/displacement reactions at RNA phosphodiesters and amino acid esters catalyzed by ribozymes in biology. (a) Intramolecular hydrolysis of RNA via attack of an adjacent 2'-OH catalyzed by small ribozymes. The action of acid and base in leaving group protonation and nucleophile deprotonation are indicated in gray. Catalytic interactions with the nonbridging oxygens that result in protonation of a phosphorane intermediate or by stabilization of a negatively charged phosphorane-like transition state is also indicated. (b) Intermolecular phosphoryl transfer catalyzed by large ribozymes. In the reactions of large ribozymes, the nucleophile (R1) is a ribose 2'- or 3' hydroxyl or a water molecule. Interactions that result in acid/base or electrostatic catalysis are indicated as in part A. (c) Amidolysis of an amino acid ester that results in peptide bond formation catalyzed by the peptidyl transferase active site of the ribosome. The R1 and R2 groups represent the 2'-OH groups of the aminoacyl-tRNAs in the ribosomal A-site and P-site, respectively. Similar catalytic interactions involved in facilitating proton transfer and charge stabilization are indicated. Note that the net proton transfer from the nucleophile to the leaving group could be mediated potentially by a single functional group.

Reactions Catalyzed by Natural Ribozymes

Reactions of phosphodiesters

RNA phosphodiester bonds are cleaved under both basic and acidic conditions in reactions that involve intramolecular displacement of the 5'-G by attack of the adjacent 2'-O, giving 2',3'-cyclic phosphates (Fig. 1). Under acidic conditions, the 2',3'-cyclic phosphates can isomerize to form 2',5'-cyclic phosphates (See Reference 16 and references therein). A lack of nucleophiles on a tetrahedral phosphate enter gives a pentacoordinated species, the structure of which is a trigonal bipyramid that has two apical and three equatorial ligands. Nucleophiles may enter and leave the intermediate transition state only through apical positions, but the pentacoordinated phosphorane may be sufficiently stable to allow ligand reorganization by a pseudorotation. In acid-catalyzed hydrolysis, a phosphorane intermediate...
forms, which is sufficiently stable to pseudorotate while the base-catalyzed reaction is thought to be concerted. Rates of phosphodiester addition/displacement reactions in solution are sensitive to both nucleophile and leaving group pKₐ. Bronsted analyses support a concerted mechanism for the base-catalyzed reaction in which significant charge on both positions exists in the transition state. For attack of an adjacent ribose hydroxyl, a change in the degree of sensitivity occurs with leaving groups with pKₐ > 12, which supports a change in the mechanism that involves formation of a phosphorane intermediate as the leaving group becomes less reactive (17). Kinetic isotope effects on the nonbridging and leaving group oxygens, as well as solvent deuterium isotope effects, have been measured for the hydrolysis of phosphate diesters with nitrophenol and nitrobenzyl leaving groups (18, 19). The observation of measurable nucleophile and leaving group KIEs for base-catalyzed nitrophenol ester hydrolysis demonstrate a concerted mechanism and indicate equilibrium deprotonation of the nucleophile prior to nucleophilic attack. For the acid-catalyzed reaction of less reactive nitrobenzyl esters, leaving group KIE analysis are consistent with a pre-equilibrium proton transfer to the ester oxygen atom, followed by rate-limiting P–O bond fission (20). Thus, enzyme active site interactions will facilitate proton transfer to and from the leaving group and nucleophile and will influence their reactivity provide powerful catalytic strategies.

In addition to acids and bases, metal ions and their complexes also catalyze phosphoryl transfer reactions in solution, which provides a model for possible mechanisms in enzyme catalysis (e.g., References 21–24). Metal ion coordination lowers the pKₐ of the interacting alcohol, which reduces its nucleophilicity but increases correspondingly the concentration of the lyate ion at neutral pH. Because both phosphodiester reactions are sensitive to the pKₐ of the nucleophile and leaving group, metal coordination at these positions can accelerate the reaction. Sensitivities of phosphoryl transfer reactions to ionic strength indicate that significant electrostatic repulsion occurs between anionic nucleophiles and the negatively charged phosphoryl center. Thus, metal ion interactions that offset this repulsion or interact more favorably with the negatively charged transition state relative to the ground state can provide catalysis as well. Additionally, as outlined above, these reactions occur with specific ionic geometries for the nucleophile and leaving group. Because they can coordinate multiple electronegative ligands, divalent metal ions can also promote catalysis by simultaneous interactions with the nonbridging phosphate oxygens and the nucleophile to offset the free energy costs of decrease in entropy in the transition state. Such additional catalysis beyond effects on pKₐ and ionic strength have been referred to as induced intramolecularity (23).

Transpeptidation–aminolysis of a carbon ester

The transpeptidation reaction catalyzed by the ribosome involves nucleophilic attack of an amine on a carbon ester with subsequent displacement of the alcohol (Fig 3c). Isotope exchange from water into the substrate ester during aqueous ester hydrolysis provided evidence for exchange between the carbonyl oxygen and water, which implicates the formation of a tetrahedral intermediate (e.g., Reference 25). A minolyses of esters in solution can be general base- or general acid-catalyzed; however, a break in the pH-rate profile at lower pH exists, which suggests a change in the rate-limiting step. Extensive analysis of pH and substituent effects show that with most esters, nucleophilic attack to form the intermediate is rapid and reversible, and the rate-determining step at high pH is proton transfer within the intermediate or its breakdown. For very fast reactions, evidence exists for a change to rate-determining formation of the intermediate (e.g., References 26 and 27).

Nucleophilic attack on carbon esters also shows dependence on both nucleophile and leaving group pKₐ, and structure reactivity studies support a stepwise mechanism in which a tetrahedral intermediate forms and is more stable for esters with poor leaving groups like the 3′-ribose OH of aminkyl-RNA esters used by the ribosome (28). The transition state for formation of the intermediate is believed to be neutral with a zwitterionic character. The transfer of a proton from nucleophile to carbonyl oxygen or the leaving group oxygen is proposed to be the rate-determining step. Isotope effects on the nucleophile, esterified carbon, and ester oxygen provide strong support for a stepwise mechanism for attack of oxygen and nitrogen nucleophiles on nitrophenyl esters (29). Thus, like phosphodiester reactions, specific reaction geometry is dictated and facilitation of this geometry, as well as of proton transfer from the nucleophile to carbonyl oxygen, or the leaving group oxygen can provide catalysis.

The Potential for Catalysis by Ribozymes

The potential for RNA to act as a catalyst is dictated by its structure as a linear polymer of the four common ribonucleotides. Like DNA, RNA can form double stranded, antiparallel helices via traditional Watson-Crick base pairing. However, the backbone of nucleic acids is highly flexible and RNA can form complex tertiary structures that often involve non-Watson-Crick base pairing to create active site crevices for catalysis. The phosphodiester backbone is charged negatively and interacts electrostatically as well as direct coordination with solution divalent cations. Ribose, purines, and pyrimidine bases contain both H-bond donors and acceptors that help stabilize higher-order structures and provide for substrate positioning, as well as participate in active site interactions. The potential for general acid/base catalysis is constrained by the available functional groups that can participate in proton transfer. The pKₐs of RNA nucleobases are 3.5 and 4.2 for A and C, and 9.2 for G and U and the ribose 2′OH has a pKₐ of ~12 (Fig 2a). As outlined below, metal ions can be bound tightly by RNA and such hydrated Mg(2⁺) ions have pKₐ of ~10. Thus, at neutral pH, A and C would be good acids, but at a low concentration relative to the unprotonated form. Althoug G and U could serve as bases, they exist predominantly in their protonated forms. Conversely, A and C could act as bases
Catalytic Modes in Natural Ribozymes

Figure 2

Ionizable functional groups in RNA. The base and acid forms of the nucleobase and ribose pKa values that are nearest to neutral are shown. The pKa of a water that forms an inner sphere coordination interaction with Mg(2+) is also shown. Because they are predominantly unprotonated, but ther low pKa, they provide less driving force for proton transfer at neutral pH. Similarly, G and U have protons to donate, but have high pKa. However, large pKa shifts to increase the concentration of the active protonation state of amino acid functional groups often are observed in protein enzymes (30), and no a priori reason seems to exist why RNA would not be prone to similar pKa perturbations. Indeed, nucleobases with altered pKa have been observed in model RNAs (31), and coupling structure formation has been highlighted as a means to provide the driving force for pKa shifting in RNA (32, 33). Furthermore, the sensitivity to pKa will depend on the Bronsted value for that reaction, which can lessen the impact of nonoptimal pKa as on reaction rate (34). Similarly, general acid/base catalysis will always occur when a large change occurs in the pKa of the reacting group, and when the pKa of the catalyst is intermediate between the initial and the final pKa values of the substrate group (35). For example, the pKa of the 2'-OH nucleophile undergoes a very large change in pH a, from a value of 12 for the substrate 2'-OH to a value of 0 for protonation of the product ester. Thus, nucleobase functional groups with pKa as considered nonoptimal (pKa 3–4 or 9.2) are between these values and can nonetheless provide significant general acid/base catalysis.

Like protein enzymes, an understanding of the involvement of ionized functional groups can be gained by analyzing the effects of changes in pH on rate. Much of the detailed analysis of RNA catalysis has involved analysis of mechanistic detail from such dependencies. Typically, functional groups that are active in their protonated state (acids) as well as in their unprotonated states (bases) are invoked. However, the same pH-rate profile can be observed for different mechanisms (Fig. 3). For example, a reaction that is catalyzed by both acid and base displays a bell-shaped rate dependence on pH with two apparent pKa as for the acid and base. However, switching the pKa as of these species does not change the observed data. This kinetic ambiguity (36) has a very large impact on mechanistic interpretations of structure-function relationships in catalytic RNAs (34, 36). Indeed, the presence of multiple titratable groups and/or the presence of specific acid/base catalysis adds even more ambiguity with respect to identification of mechanisms that can develop observed pH-rate behavior. Nonetheless, kinetic data

Figure 3

Idealized pH dependence of a ribozyme reaction. Ideal pH-species plots and pH-kin plots profiles according to a kinetic model for general acid/base catalysis. The solid lines depict a mechanism in which the species with the lower pKa (pKa,1) acts as the general base (shown by blue lines), and the species with the higher pKa (pKa,2) acts as the general acid (shown by red lines). The black line indicates the observed pH dependence of the reaction rate. The dotted lines simulate a mechanism in which the catalytic role of the species with pKa,1 and pKa,2 have been switched. Adapted from References 34 and 35.
provide a direct functional read-out and necessarily must be accom-
modated by models of ribozyme mechanism. An ongoing challenge, as described below, is in defining specific experi-
mental tests to assign catalytic roles to individual active site inter-
actions.

Metal ions can promote phosphoryl and carbonyl reactions in 
solution in several ways and are a common feature of protein 
enzyme active sites. Like acid/base catalysis, information on the 
importance of metal ions to catalysis often has been gained by 
analyzing the dependence of activity on metal ion concentra-
tion and identity. However, the dependence of RNA catalysis on 
Mg(2+) concentrations can be complex. Importantly, metal 
ions make large contributions to RNA folding and promote 
activity because of stabilization of the active RNA conformation 
(37, 38). Thus, the observed concentration dependence of the 
ribozyme reaction may (or may not) represent a direct role in 
catalysis (Fig. 4). For example, metal ions may bind to the 
folded RNA conformation at the active site with high affinity. At concentrations of ions that are saturated for folding, 
the observed metal ion dependence will reflect ion binding to 
the active site. In contrast, if ion binding at a site or sites that 
stabilizes folding occurs at a lower affinity, then the observed 
dependence of the reaction on metal ion concentration will 
represent necessarily the binding to the structural, but 
nonetheless activating, site.

Additionally, RNA–metal ion interactions take two thermo-
dynamically important forms: 1) diffuse binding in which the 
ions interact electrostatically with the negatively charged phos-
phodiesters backbone and 2) site-specific binding in which metal 
hydrate makes inner sphere or direct H-bond contact with an 
RNA functional group (39). Although diffuse ion interactions 
may weaken contact, they are numerous and overall have a high 
thermodynamic contribution to folding and to apparent catalytic 
activity. Also, site-bound interactions are fundamentally impor-
tant, but may only occur at certain steps in the ribozyme mech-
anism, or be linked indirectly to catalysis by stabilization of 
structure. The difficulty in characterizing these interactions bio-
chemically is described picturesquely as equivalent to searching 
for them amid the “sea” of other RNA–metal ion interactions.

Accordingly, titration experiments are difficult to interpret in 
terms of specific metal ion binding sites, and development of 
structural and biochemical probes for functional metal ion in-
teractions has been a considerable focus of ribozyme research.

**Evidence for Acid/Base Catalysis in the Hepatitis Delta Virus 
Ribozyme Active Site**

The hepatitis delta virus (HDV) ribozyme is a member of the 
class of small ribozymes and functions as a self-cleaving RNA 
sequence critical to the replication of the virus’ RNA genome 
(1, 8, 40). HDV ribozymes are proposed to employ several 
catalytic strategies that include an important example of general 
acid/base catalysis that involves a specific cytosine residue in 
the active site. Indeed, a milestone in our understanding of 
RNA catalysis was the observation that HDV and other small 
ribozymes could function in the absence of divalent metal 
ion cofactors, provided that high (molar) concentrations of 
monovalent ions are present (41, 42). These high monovalent 
ion concentrations are believed to stabilize the active RNA 
conformation, which implies that the primary role of divalent 
metal ions is in structural stabilization (42).

An additional insight into HDV ribozyme active site inter-
actions came from the determination of the structure of the 
ribozyme including the 3′ cleavage product. The 5′-OH termi-
nus of this product is located in a cleft formed by the intersection 
of conserved helical elements. Within this cleft, the 5′-OH is 
sufficient proximity to form a hydrogen bond with the N3 
of C75 (C76 in the antigenomic version of the ribozyme). If 
C75 becomes protonated, it could act as a general acid to affect 
rate of cleavage (43) (Fig. 5). Participation of titrat-
able groups in the HDV reaction is indicated by a bell-shaped 
pH-rate profile that reveals two groups with apparent pKa val-
ues. ~6.5 and 9 (44). However, in the absence of divalent metal 
ions, the pH dependence reversed, with the rate of cleavage in-
creasing with lowering of pH (42, 45, 46), which indicates that 
a metal ion hydrate could perform as a general base. Although 
deletion of C75/C76, or mutation to G or U, reduces cleavage 
adynamic activity drastically (45, 47) a C76A mutation retains signif-
icant activity but displays an altered apparent pKa for the pH 
dependence of the self-cleavage reaction (44, 45). Functional 
group modification experiments with C analogs with altered 
N3 pK as demonstrated the importance of C75 ionization in the 
HDV cis-cleavage reaction. Inhibition of ribozyme function also 
occur at C75 with a C analog that lacks the N4 amino group, 
which implicates the exocyclic amine in critical interactions.

**Catalytic Modes in Natural Ribozymes**

**Evidence for involvement of a cytosine 
nucleobase in proton transfer**

The hepatitis delta virus (HDV) ribozyme is a member of the 
class of small ribozymes and functions as a self-cleaving RNA 
sequence critical to the replication of the virus’ RNA genome 
(1, 8, 40). HDV ribozymes are proposed to employ several 
catalytic strategies that include an important example of general 
adcid/base catalysis that involves a specific cytosine residue in 
the active site. Indeed, a milestone in our understanding of 
RNA catalysis was the observation that HDV and other small 
ribozymes could function in the absence of divalent metal 
ion cofactors, provided that high (molar) concentrations of 
monovalent ions are present (41, 42). These high monovalent 
ion concentrations are believed to stabilize the active RNA 
conformation, which implies that the primary role of divalent 
metal ions is in structural stabilization (42).

An additional insight into HDV ribozyme active site inter-
actions came from the determination of the structure of the 
ribozyme including the 3′ cleavage product. The 5′-OH termi-
nus of this product is located in a cleft formed by the intersection 
of conserved helical elements. Within this cleft, the 5′-OH is 
sufficient proximity to form a hydrogen bond with the N3 
of C75 (C76 in the antigenomic version of the ribozyme). If 
C75 becomes protonated, it could act as a general acid to affect 
rate of cleavage (43) (Fig. 5). Participation of titrat-
able groups in the HDV reaction is indicated by a bell-shaped 
pH-rate profile that reveals two groups with apparent pKa val-
ues. ~6.5 and 9 (44). However, in the absence of divalent metal 
ions, the pH dependence reversed, with the rate of cleavage in-
creasing with lowering of pH (42, 45, 46), which indicates that 
a metal ion hydrate could perform as a general base. Although 
deletion of C75/C76, or mutation to G or U, reduces cleavage 
adynamic activity drastically (45, 47) a C76A mutation retains signif-
icant activity but displays an altered apparent pKa for the pH 
dependence of the self-cleavage reaction (44, 45). Functional 
group modification experiments with C analogs with altered 
N3 pK as demonstrated the importance of C75 ionization in the 
HDV cis-cleavage reaction. Inhibition of ribozyme function also 
occur at C75 with a C analog that lacks the N4 amino group, 
which implicates the exocyclic amine in critical interactions.
Figure 5  Proposed acid/base catalytic interactions in the HDV ribozyme active site. The cleavage site for the HDV ribozyme is shown with the nucleotide 5′ to the site of bond cleavage shown in red and the nucleotide 3′ to that site shown in blue. Two proposed mechanisms for the function of the C75 cytosine nucleobase and a hydrated active site metal ion are shown in which C75 acts as either an acid (left) or base (right) as described in the text.

in the active site (48). These data develop a model of general acid/base catalysis, with C75 potentially acting as the acid as indicated by the ribozyme–product structure and a hydrated divalent metal ion as the general base.

Remarkably, addition of exogenous cytosine or certain nucleobase and imidazole analogs can rescue partially the activity of the nearly inactive C75U mutant ribozyme (44, 49). Structure-function studies of the rescuing analogs provided additional insight into mechanism. The pH-rate profiles for the rescued reactions were bell shaped with one pKa attributed to ionization of the exogenous base. When a second potential ionizable nucleobase (C41) was removed, one leg of the bell-shaped curve was eliminated (50). The purported ionizable base, C41, is distant from the active site but may enhance cleavage rates through structural stabilization. The rescue of cleavage activity in the C75 deletion mutant, and by analogy the native ribozyme, can be explained by a model in which three ionizable groups exist (8, 34). These include: 1) the 2′OH group nucleophile (or a general-base catalyst with a relatively high pKa that acts at the 2′OH group, 2) a C75 or an analogous rescuing buffer that acts as a proton donor, and 3) a nucleobase (C41) associated with structure formation.

Thus, the role of C75 seems to act as a general acid in its protonated form. The most likely candidate based on the product complex and on the chemistry of phosphodiesters would be protonation of the 5′OH leaving group. Recently, Das and Piccirilli (51) provided strong evidence for this model using a chemically modified "activated" RNA substrate in which the 5′OH leaving group is replaced by sulfur, which has a lower pKa and thus is a better leaving group. The activated 5′S substrate specifically suppressed the effects of C75 mutation and modifications that alter its pKa, consistent with it providing general acid catalysis, which mediates proton transfer to the leaving group through a protonated N3-imino nitrogen. However, this model for C75 function is distinct from that derived from crystallographic studies of precursor forms of the genomic ribozyme in which catalysis is blocked by the C75U mutation, chelation of divalent metal ions, or 2′-deoxy substitution of the 2′-OH nucleophile (52). Importantly, these structures reveal electron density for a divalent cation coordinated to the 5′-O, whereas the position of the N3 of U75 is equidistant from the 2′O and the 5′O. Comparison of the precursor and product structures reveals differences in the active site structure after cleavage. Interpretation of these differences in terms of the catalytic mechanism suggests that a conformational change occurs and results in dissociation of the catalytic metal ion. Thus, although strong evidence exists that the C75 nucleobase functions in acid/base catalysis, likely in its protonated form, the specific transition state interaction is still of considerable interest as is the interplay of catalysis and metal ion binding.

Other small ribozymes

The HDV ribozyme, however, is only one example of the class of small ribozymes that catalyze self-cleavage, which includes the hammerhead, hairpin, V5, and glmS riboswitch ribozymes (1, 2). Like the mechanistic detail described above, crystal structures have been solved for several modified versions of these ribozymes, and the structures thus derived provide candidate
nucleobases that could act as acid/base catalysis. Biochemical tests of these interactions in the transition state have been made in several cases to support the involvement of nucleobases in proton transfer. Nonetheless, the same limitations with respect to kinetic ambiguity limit the detail with which specific active site mechanisms can be articulated. Riboswitches are a newly described class of self-cleaving RNA in which the catalytic activity is linked directly to regulation of gene expression (53, 54). The glmS ribozyme is a self-cleaving RNA that occurs in the 5' untranslated region of the mRNAs of the gene that encodes glucosamine-6-phosphate (GlcN6P) synthase in some Gram-positive bacteria and also acts to regulate gene expression in an analogous fashion. Self-cleavage represents gene expression when this ribozyme is activated by binding of GlcN6P (55). Recent structural and biochemical studies result in a model for this RNA in which it binds its activator such that the amine group of GlcN6P is in position to interact with the reactive phosphate potentially to provide nucleophilic activation. Such coenzyme usage raises the potential for an expanded catalytic repertoire for ribozymes. Yet, obtaining a complete description of the transition state interactions for the glmS and other small ribozymes continues to present structural biologists, theoreticians, and experimentalists with significant challenges.

Analysis of Divalent Metal Ion Interactions in the Group I Self-Splicing Intron Active Site
Structural and biochemical evidence for catalytic metal ion interactions

Group I (GI) introns are large ribozymes that function as self-splicing introns that catalyze two successive phosphorothioate reactions using a single conserved active site (4, 12). In the first reaction, the 3'-O of a G cofactor attacks the phosphodiester bond at the 5' splicing site; the 3'-OH of the last exon nucleotide is the leaving group. In the second reaction, the 3'-O product from the first reaction attacks the 3' splice site that generates the spliced exons; the 3'-O of the last intron nucleotide (termed ωG) is the leaving group. Note that the 3'-O leaving group in the first step is the nucleophile for the second step, and the interactions with the leaving group in the second step will replicate interactions involved in nucleophilic activation in the first step (Fig. 6) (56). Recent crystal structures of a ribozyme intermediate formed after the first splicing step show that the substrate is in a highly constrained conformation with complete reversal of strand direction at the 3' splice site (57, 58). A network of hydrogen bonding interactions positions the 3'-OH of the 5' exon proximal to the scissile phosphate, and the geometry is that expected for intrinsic nucleophilic attack. With respect to active site interactions with the nucleophile/leaving group oxygens, most attention has focused on divalent metal ion interactions, and now strong evidence exists that nucleophilic activation at both 3'-O nucleophiles involves direct coordination to active site Mg(2+).

The GI ribozyme reaction depends on the presence of divalent metal ions, but as indicated above, the binding of these ions plays multiple roles that include folding and enhancing substrate binding affinities (59). The rate of the chemical step is Mg(2+) dependent, but these data do not distinguish between direct or indirect roles, or a combination of both. As indicated above, distinguishing active site metal ions from what has been referred to as the "sea" of other functionally important metal ion interactions presents a considerable challenge. For the GI ribozyme and other catalytic RNAs, site-specific evidence for active site metal interactions comes primarily from analyses of thiophilic metal ion rescue of phosphorothioate and other substrate modifications (e.g., References 60 and 61). These analyses rely on the fact that substitution of a substrate phosphate for the phosphorothioate weakens the affinity of coordinated Mg(2+) ions.

Figure 6 Proposed divalent metal ion coordination interactions involved in metal ion catalysis by the GI intron ribozyme active site. The coordination interactions determined by substrate Ph and 3'-amino modification and quantitative metal rescue are depicted on the left. The individual interacting functional groups are shown in red. The observed metal ions (green spheres) in the crystal structure of the GI ribozyme active site is shown on the right and the metal ligands identified by functional studies are shown as red spheres. Adapted from Reference 56.

Adapted from Reference 56.
substantially such that catalysis is inhibited by several orders of magnitude. Because softer metal ions such as Mn(2+) and Cd(2+) coordinate more readily to sulfur, if inclusion of these ions in the reaction rescues activity, then a direct coordination interaction at the substituted position is likely. By comparing quantitative analyses of the concentration dependence of the metal ion rescue for different substrate modifications, a network of different metal ion coordination reactions has been revealed. The model developed from a series of elegant biochemical studies of this kind combined with a wealth of additional structure-function and kinetic data can be summarized as follows: Metal ions coordinate to both the 3'-oxygen leaving group and to the 3'-oxygen on the G nucleophile in the first step (MA and MB, respectively), and a third metal ion interacts with the 2'-hydroxyl of the G nucleophile (MC). Two metal ions (MA and MC) also contact the pro-SP oxygen of the scissile phosphate. Extension of this analysis to encompass phosphate oxygens within the intron itself provide evidence that these metal ions are positioned by coordination interactions with nonbridging oxygens that constitute, in part, the active site of the ribozyme (12, 61, 62).

Recently, high-resolution structures of the ribozyme, which includes one that contains the 2'-OH of the substrate G, a key metal ion ligand, have been reported that provide the most consistent model to date of active site interactions that include metal ion coordination to the functional groups identified biocchemically. In the most complete structure, two metals coordinate to nonbridging oxygens in the intron and substrate that include all biochemically identified interactions (56, 63). One Mg(2+) ion makes inner sphere contacts with both the 2'-O and the 3'-O nucleophile leaving group of the G cofactor. One obvious difference in this model is that one metal ion makes the contacts attributed to metal ions MB and MC in the model derived biocchemically. A through differences in the electrostatic environment of the active site because of different functional group modifications may complicate interpretation of the biochemical analyses, the remarkably high degree of correspondence between the structural and functional analyses provide the most detailed account to date for ribozyme active site metal ion interactions.

Other large ribozymes

The presence of active site metal ion interactions seems to be a general feature of the class of large ribozymes that catalyze phosphoryl transfer. Both Group I intron and RNase P RNA ribozymes that catalyze transesterification and phosphodiester bond hydrolysis, respectively, are thought to use metal ion catalysis as well. Although ample evidence exists for higher order structure that provides specificity via positioning the reactive phosphate, high-resolution structure of other examples of this class are limiting currently. Information that concerns active site structures comes largely from kinetic analysis of substrate modifications including the kinds of PS rescue experiments described above. Both GI1 and P RNA are modeled to have two metal ions coordinated to the pro-RP oxygen of the reactive phosphate and to the nucleophile and leaving group oxygens. However, the number and the position of coordinated metals and their ribozyme contacts are yet to be described fully. Under reaction conditions that favor the chemical step, both ribozymes react with rates consistent with general base catalysis but whether these ribozymes, like their smaller counterparts, employ functional groups in proton transfer remains unknown.

Substrate Positioning and Substrate Assisted Catalysis in the Peptidyl Transferase Center of the Ribosome

A landmark achievement in our understanding of biology has been the elucidation of the structure of ribosomes and their complexes with substrates, cofactors, and inhibitors (15). In addition to providing a wealth of functional insights, the structures showed that the peptidyl transferase active site involves RNA functional groups exclusively (64). Comparisons with model reactions indicate that the ribosome active site provides ~100-fold catalysis that is promoted significantly by positioning the reactive groups for catalysis. However, mechanistic studies have been providing evidence both for and against the involvement of active site functional groups in additional catalytic interactions (65, 66). Indeed, the extent to which the ribosome employs catalytic interactions with the amine nucleophile and the oxygenation of the tetrahedral intermediate has framed several important studies that concern ribozyme mechanism (67).

Structures of the large subunit with low-molecular weight substrates and products bound are highly suggestive regarding peptidyl transferase active site interactions (64, 67-69). Three groups exist in the neighborhood of the reactive amino group that could conceivably interact to assist in positioning and deprotonation of the nucleophile. These include the 2'-OH of A76 at the 3' end of the P-site bound peptidyl tRNA itself, the N3, and the 2'-OH of A2451 (Escherichia coli) of the large subunit tRNA. Replacement of the 2'-OH group of A76 in the P-site bound tRNA with 2'-H or 2'-F resulted in a dramatic decrease in the rate of peptide bond formation but did not affect ground state substrate binding (70, 71). Combined with the structural perspective, a role in nucleophilic activation is proposed; however, the precise role of this substrate residue in assisting catalysis is not resolved entirely. Site-specific incorporation of nucleoside analogs into 23S RNA of thermus aquaticus 50 S subunits (72) provided evidence that the ribose 2'-OH of A2451 is also important for catalytic function. Also, mutation of A2451 reduces the rate of the chemical step of peptide bond formation by ~100-fold (73, 74).

Using puromycin as an A-site substrate, the rate of the peptidyl transferase reaction is strongly pH-dependent, and pH-rate profiles suggest two ionizing groups with apparent pKa values of 7.5 and 6.9 (75). The second pKa of 6.9 has been attributed to the amine nucleophile of the puromycin substrate. In the single-protonated state in which the ribosomal group with pKa 7.5 is protonated whereas that with pKa 6.9 is deprotonated, the reaction is 100-fold faster compared with the uncatalyzed reaction. Protonation of a ribosomal group with pKa 7.5 thus seems to contribute a factor of ~100 to the observed rate that is...
Catalytic Modes in Natural Ribozymes

Figure 7. General chemical scheme for peptidyl transfer by the ribosome. The scheme shows nucleophilic attack by the amine group of the amino acid (with side chain R2) esterified to the tRNA in the ribosomal A site (right) on the ester linkage of the aminoacyl tRNA (with amino acid chain R1). The 2′OH of the peptidyl tRNA participates in the reaction and seems to transfer a proton to the 3′O leaving group, either directly or potentially via a solvent bridge. Adapted from Reference 76.

likely to be caused by additional catalytic interactions. Kinetic analysis of a A2451U mutant showed that the pH dependence caused by the ribosomal ionizing group was eliminated, which is consistent with a direct role of A2451 in catalysis (75). Thus, the peptidyl transferase active site clearly makes contacts that position the aminoacyl and peptidyl tRNA termini in the appropriate geometry for nucleophilic attack. In addition to substrate-assisted catalysis by the adjacent tRNA 2′OH, the ribosome active site also provides a network of noncovalent interactions that assists in providing additional rate enhancement (Fig. 7) (76).

Conclusions

All enzymes are constrained necessarily by the intrinsic chemistry of the reactions that they catalyze and the availability of functional groups for interfacing with this chemistry. As transesterification of phosphodiesters and carbon esters involves proton transfer, acid/base catalysis is a fundamental strategy for which strong support now exists for ribozymes. Yet, a continuing challenge is “following the protons” to and from active site functional groups and the substrate. Similarly, it is accepted widely that metal ions are involved directly in phosphotransfer reactions catalyzed by large ribozymes, but the site and number of active site metal ion interactions and their precise contribution to rate enhancement is still the subject of intense interest. Confronting these challenges and developing new technical and intellectual tools for understanding RNA catalysis represents a significant focus of the current investigations of ribozyme chemistry.

Acknowledgments

We thank Drs. Eric Christian, Michael Been, and Scott Silverman for helpful discussions regarding to the concepts discussed in this article. We are grateful particularly to Drs. Scott Strobel, Donald Burke, and Phil Bevilacqua for review and insightful comments on the manuscript. We are indebted to the community of enzymologists who investigate RNA catalysis and whose foundational work is alluded to, but not referenced explicitly, because of limitations of space and scope of this article.

Nucleic acids are highly reactive macromolecules that can undergo a variety of chemical changes that may be deleterious to their function. In particular, deoxyribonucleic acid (DNA) undergoes multiple spontaneous chemical changes and is reactive with reactive oxygen species generated during oxidative metabolism and with naturally occurring chemicals, ultraviolet radiation, and a myriad of environmental chemicals. This review highlights many of these chemical changes.

Biologic Background

The fact that nucleic acids are highly reactive and are thus subject to frequent chemical change, i.e., DNA damage, necessitated the evolutionary selection of multiple cellular protective mechanisms in order to sustain life. These mechanisms include multiple ones designed to (1) dispose of free radicals, (2) restore the normal chemistry and nucleotide sequence of damaged DNA (DNA repair), and (3) tolerate persistent DNA damage that threatens the viability of cells as a result of arrested DNA replication or transcription, or because of high levels of mutation. This review is largely restricted to a consideration of chemical alterations of the nitrogenous bases, the informational elements of DNA. However, consideration is also given to the formation of strand breaks in DNA. The article does not consider interactions of nucleic acids with synthetic compounds, of which a very large number is known to react with both DNA and RNA. Nor do we consider the mispairings of bases that arise from the occasional errors associated with normal DNA replication. Finally, we do not address chemical alterations in RNA, since most of the RNA in cells turns over rapidly and the biological significance (if any) of RNA damage is apparently limited. The nature and mechanism of the numerous biologic responses that cells can mount to cope with the consequences of DNA damage is also beyond the scope of this limited review. We refer interested readers to a recent comprehensive textbook on these topics and to numerous references quoted therein (1).

Spontaneous Alterations in DNA Chemistry

Tautomeric shifts

All of the bases commonly found in DNA (adenine (A), cytosine (C), guanine (G), and thymine (T)) can undergo spontaneous, pH-dependent chemical changes called tautomeric shifts (2). The base T normally exists in the keto form (C=O) in the C-4 position, but it can occasionally exist in the rare enol form (C–OH) (Fig. 1). Under such circumstances it can anomalously pair with G in the usual keto state. Conversely, the C-6 position of G in the rare enol form can pair with T in the usual keto form (Fig. 1). The same is true of the N-6 position of A, usually in the amino form (NH2), switching to the imino form (NH) tautomer; in which case, it can mispair with cytosine in the amino form (Fig. 1). Reciprocally C can mispair with A when the C-4 position switches to the rare imino form (Fig. 1).
Chemical Damage to Nucleic Acids

Figure 1  Anomalous base pairing involving rare tautomeric forms of the bases in DNA. When either T or G are in the rare enol form, they can pair. Similarly, when A or C are in the rare imino form, they can pair. (Reproduced from Reference 1 with permission.)

Tautomerism in the bases commands interesting prominence in the history of the elaboration of the structure of DNA by James Watson and Francis Crick. When in the early 1950s Watson was attempting to identify structurally compatible base pairing schemes using simple two-dimensional cardboard models of the bases, he inadvertently deployed the rare tautomeric states until the chemist Jerry Donahue pointed out this error to him.

The tautomeric forms I had copied out of Davidson's book were, in Jerry's opinion, incorrectly assigned. My immediate retort that several other texts also pictured guanine and thymine in the enol form cut no ice with Jerry. Happily he let out that for years organic chemists had been arbitrarily favoring particular tautomeric forms over their alternatives on only the flimsiest of grounds (3).

Spontaneous Deamination of Nitrogenous Bases in DNA

The common DNA bases A, C, and G, as well as the less common base 5-methylC, are endowed with exocyclic amino groups. These bases can be spontaneously lost as a function of the ambient pH and/or temperature (deamination), thus altering their ability to correctly pair with other bases (4).

Spontaneous Deamination of Nitrogenous Bases in DNA

The common DNA bases A, C, and G, as well as the less common base 5-methylC, are endowed with exocyclic amino groups. These bases can be spontaneously lost as a function of the ambient pH and/or temperature (deamination), thus altering their ability to correctly pair with other bases (4).

Deamination of cytosine (C) to generate uracil (U) in DNA

Perhaps the most extensively studied example of spontaneous deamination, certainly in terms of its biologic outcome, is that of C to yield uracil (U) in DNA (Table 1). U, which is chemically identical to T except for the methyl group in the C-5 position of the latter, most often pairs with A, resulting in permanent G:C → A:T transition mutations during subsequent rounds of DNA

replication (5). Additionally, the presence of U instead of T in the promoter regions of coding genes may affect the binding of regulatory proteins, thereby altering gene expression (1).

The chemistry of C deamination has been extensively studied (6, 7). It has been suggested that at neutral pH hydroxyl ions can directly attack the C-4 position of C (Fig. 2), especially in single-stranded DNA. An alternative explanation offered is an addition-elimination reaction during which dihydrocytosine is generated as an intermediate. This reaction may involve the formation of dihydrocytosine and dihydrouracil as intermediates (Fig. 2).

Cytosine in DNA is stable, with an estimated half-life of about 200 years (4). This value derives for a calculated rate constant for cytosine deamination in single-stranded DNA of ~2 × 10^-10/s based on the direct measurement of deamination in nucleotides and polynucleotides in vitro at various temperatures and pH (8). Evaluating the biologic significance of these values is problematic because they derive from in vitro measurements using single-stranded polynucleotides, whereas in living cells, most DNA is, of course, in the duplex configuration and the rate of spontaneous deamination of cytosine in duplex DNA in vitro is believed to be ~1% of that in single-stranded DNA (8). However, limited regions of single-stranded DNA are transiently generated in the course of various DNA metabolic transactions, in particular replication, transcription, and recombination. Additonally, considerable evidence exists that duplex DNA undergoes spontaneous localized denaturation, or "breathing," that could further promote this process (9). (On the other hand, single-stranded DNA can interact with specific DNA-binding proteins that may protect these regions of the genome from chemical change.)

The literature documents various situations in which C deamination is enhanced. These situations include the presence of C in cyclobutane pyrimidine dimers (a form of DNA damage caused by exposure to UV radiation; see later discussion) or in mispairings with other bases or with alkylated bases (1). Cytosine deamination is also promoted in the presence of nitrous acid, a reaction that although not considered in this review, has lent much to our understanding of possible chemical mechanisms of spontaneous deamination (1). While considering the presence of U in DNA, it is relevant to point out that this base can also arise in DNA by its misincorporation (instead of T) during normal DNA replication as a consequence of the existence of a small pool of dUTP (1). Not unexpectedly, perturbations that increase the pool size of dUTP relative to that of TTP promote this misincorporation (1). However, the biologic consequences of A:U "mispairs" in DNA are limited because such base pairs have the same coding potential as A:T pairs (1).

Essentially all life forms studied are endowed with enzymes that recognize and remove U from DNA. These enzymes, called uracil-DNA glycosylases (UDGAs), are historically noteworthy because their discovery identified a new class of DNA repair enzymes that collectively embrace many more substrates than uracil in DNA. The several DNA glycosylases that selectively remove uracil from DNA comprise a superfamil of proteins that are represented in all life forms (1).
Chemical Damage to Nucleic Acids

Figure 2  Plausible chemical mechanisms for the base-mediated deamination of cytosine. Top: Deamination resulting from 1,4-addition. Bottom: Deamination resulting from 1,2-addition. In both cases, only the cytosine ring is shown subsequent to hydroxide addition.

Deamination of 5-methylcytosine

Cytosine that is methylated at the 5 position (5-methylC) is naturally encountered in the genomes of some organisms, both prokaryotic and eukaryotic (10) (Table 1). It has been estimated that the rate of deamination of 5-methylC is significantly faster than that of C in single-stranded polynucleotides, and that it could account for as much as 10% of the spontaneous deamination events in the genome of mammalian cells under physiologic conditions (4). Since deamination of 5-methylC generates T in DNA, this spontaneous reaction is considered to be an important source of T:G mispairs that can lead to G:C → A:T transition mutations, especially in CpG-rich promoter regions of many genes, so-called CpG islands (1).

For many years it was considered that T:G mispairs generated by the deamination of 5-methylC would not be repaired by mismatch repair mechanisms because of the intuitive notion that conventional mismatch repair would not distinguish T in T:G base pairs from that in normal T:A base pairs, potentially leading to wholesale loss of TMP from DNA. However, the discovery of DNA glycosylases as a general class of base excision repair enzymes led to the detection of a DNA glycosylase that specifically recognizes T in T:G mispairs (1). Additionally, some bacteria are endowed with a specialized form of mismatch repair that distinguishes between T:G and T:A base pairs (1).

Deamination of adenine and guanine

The deamination of A and G in DNA to hypoxanthine and xanthine, respectively, transpires at rates about 50-fold less than that of C (9). The biologic significance of such deamination reactions is also overshadowed by data indicating that they transpire about 10,000 times less frequently than their complete loss from the genome during spontaneous depurination (see later discussion).

Spontaneous Loss of Bases from DNA (Depurination and Depyrimidination)

The spontaneous loss of bases from DNA after hydrolysis of the N-glycosyl bond linking them to the sugar-phosphate backbone is a frequent source of spontaneous DNA damage, with potentially important biologic consequences (1) (Table 1). It is estimated that the genome of the average mammalian cell sustains the loss of about 10,000 purines a day, generating many apurinic/apyrimidinic (AP) sites (9). AP sites are very unstable, often leading to hydrolysis of the sugar-phosphate backbone and the formation of strand breaks (1, 4, 9).

The kinetics of base loss has been extensively studied in vitro using polynucleotide substrates incubated at varying pH and temperatures. Such studies indicate that G is lost from DNA about 1.5 times more rapidly than A (11). Extrapolation of Arrhenius plots generated by direct measurements at varying temperatures yields a rate constant for the depurination of duplex DNA of $k = 3 \times 10^{-11}$/s at physiologic ionic strength and temperature (11). This result translates to the loss of $\sim 1$ purine/E. coli genome equivalent. However, thermophilic bacteria that thrive at high temperatures and often at very acidic pH may sustain the loss of several hundreds of purines each generation absent specific biologic mechanisms to offset this loss. As just mentioned, mammalian cells may sustain the loss of $\sim 10,000$ purines/day. The chemistry of depurination at acidic pH is believed to involve protonation of bases followed by elimination of the base in an S$_{N}$2-like process that probably involves a ribose-derived oxonium ion (Fig. 3). Pyrimidines are spontaneously lost from polynucleotides at about 1/20th the rate of the loss of purines, but this process may translate into the loss of hundreds of pyrimidines during each mammalian cell cycle (12).
Chemical Damage to Nucleic Acids

Figure 3  Plausible chemical mechanism for acid-catalyzed depurination and subsequent base-mediated strand cleavage, shown in the context of an A–T base pair. Only the adenine-containing segment of the molecule is shown subsequent to the initial reaction. The depurination reaction proceeds through an oxonium ion intermediate (top right) that is quenched by water. The resultant hemiacetal exists in equilibrium with the open-chain aldehyde, thus making the 2′-hydrogen relatively acidic and facilitating base-catalyzed elimination that leads to strand cleavage.

The deoxyribose residues that are generated at sites of base loss in DNA exist in equilibrium between the closed furanose form and the open aldehyde form (13) (Fig. 3). The 3′ phosphodiester bonds associated with the latter are labile and are readily hydrolyzed by β-elimination during which the pentose carbon to the aldehyde is activated at alkaline pH and at increased temperatures (13). The same reaction proceeds at a reduced rate at neutral pH, at physiologic pH and temperature, a site of base loss in DNA has an estimated average lifetime of ∼400 h (14).

Spontaneous Oxidative Damage to DNA

Products of oxygen breakdown, such as superoxide radicals, hydroxyl radicals (the most reactive oxygen radical known to chemistry) and hydrogen peroxide, collectively referred to as reactive oxygen species (ROS) (15, 16), are continuously generated as byproducts of mitochondrial respiration in all aerobic organisms, as well as from lipid peroxidation and from the metabolic activity of phagocytic cells. ROS can also be generated when cells are exposed to various exogenous agents, notably ionizing radiation and numerous chemicals (especially redox-cycling drugs) (1). ROS are highly reactive with DNA, as well as with proteins and lipids. Indeed, the so-called oxygen paradox points out that although oxygen is fundamental to aerobic life forms, ROS pose what is perhaps the most pervasive natural threat to the integrity of both the nuclear and the mitochondrial genomes of cells (15). Numerous disease states (in particular cancer) as well as the process of aging have been implicated as consequences of oxidative damage to DNA (1).

To cope with this fundamental problem, cells have evolved a myriad of defense mechanisms designed to both reduce the burden of free ROS and to repair damage generated in DNA by ROS (1). The former defense mechanisms primarily comprise multiple cellular antioxidants; antioxidant enzymes such as superoxide dismutase, glutathione peroxidase, and catalase (strategically located in or near the mitochondrial membrane), as well as naturally occurring antioxidants such as vitamins A, E, and C; glutathione and thioredoxin. Cellular oxidative stress, a state characterized by (but not limited to) extensive oxidative damage to DNA, results when levels of ROS exceed these various antioxidant defense mechanisms. The following discussion focuses on the chemistry and to a lesser extent the functional consequences of oxidative base damage to DNA. Details of the repair of such damage and of the regulation of various antioxidant enzymes are reviewed elsewhere (1).

Reactive oxygen species (ROS)

Molecular oxygen (dioxygen \(O_2\)) exists in a triplet ground state and hence is relatively unreactive with the singlet state of biologic molecules. But the unpaired orbitals of dioxygen can sequentially accommodate single electrons, yielding superoxide radicals \(\cdot O_2^-\), hydrogen peroxide \(H_2O_2\), hydroxyl radicals \(\cdot OH\), and singlet oxygen \(\cdot O_2\).
Chemical Damage to Nucleic Acids

I. OH, and water as shown in the following equation (15, 17):

\[ (e^-\cdot e^-) + (2H^+) \rightarrow H_2O_2 \rightarrow OH + H_2O \]

The parameters that most significantly influence the potential of ROS to interact with and damage DNA are their reactivity, their half-life, and their diffusibility in cells. Being highly reactive, OH can readily oxidize organic molecules. However, their extreme reactivity dictates a high probability that they will rapidly encounter a reactive cellular component other than DNA. Thus, they have limited diffusibility, and OH generated directly from leaky mitochondrial respiration is probably not a major source of DNA damage.

The generation of OH in the very close proximity required for its interaction with DNA is believed to transpire by the Fenton reaction (1), first described around the turn of the nineteenth century by Henry John Horstman Fenton, who discovered that hydrogen peroxide is a much more potent oxidant in the presence of various metals, notably the ferrous ion (FeI) than in their absence. Subsequently, Fritz Haber and coworkers proposed that the potent oxidant generated during the Fenton reaction is in fact OH, produced according to the following reaction (18):

\[ Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH + H_2O \]

Even trace concentrations of iron support a robust Fenton reaction if reducing agents such as NADH (17), ascorbate (19), or superoxide are available to recycle FeII to the active FeIII form. Although the Fenton reaction typically involves FeII, it is also supported in the presence of other transitional metals such as copper.

Like hydrogen peroxide, the free superoxide radical (O2-) is not highly reactive. However, this chemical moiety can readily generate H2O2, especially in the presence of the enzyme superoxide dismutase, by the reaction:

\[ 2O_2^- + 2H^+ \rightarrow O_2 + H_2O_2 \]

Superoxides can also reduce and liberate FeII from fenton, or liberate FeIII from iron-sulfur clusters (17, 20), thereby generating free iron that facilitates the formation of highly reactive oxygen species from H2O2 and O2- by way of the Fenton reaction.

Hydroxyl radicals can abstract electrons from residues of organic macromolecules (RH) by the following general reaction:

\[ RH + OH \rightarrow RH + H_2O \]

This reaction can initiate chain reactions that may generate DNA damage at considerable distances from the initial chemical event (21). Peroxidation of unsaturated lipids initiated by reactive free radicals such as OH represents a prominent example of such a chain reaction. The phospholipids of all membranes contain high concentrations of polyunsaturated fatty acids, and chain reactions involving hundreds of phospholipids can react in each oxidation event (22). The initial products of such fatty acid oxidation are lipid hydroperoxides, but these are relatively short-lived; they are either reduced by glutathione peroxidases to unreactive fatty acid alcohols or they react with metals to produce products such as epoxides and aldehydes, which are themselves reactive.

The major aldehyde products of lipid peroxidation are malondialdehyde and 4-hydroxyxynonenal (Table 1, Fig. 4). Malondialdehyde can react with DNA to generate adducts at the bases A, C, and G. The mutagenic adduct M1G (pyrimido[1,2-a]purine-10(9)H)one has been detected at levels as high as 1 adduct per 109 nucleotides in human tissues. M1G is a reactive electrophile that can undergo further modification, leading to cross-linking of an adducted DNA strand to the opposite strand, or to some protein (22). Exocyclic etheno adducts can also arise from lipid peroxidation, possibly by reaction of an epoxide of 4-hydroxyxynonanal with A, C, or G in DNA.

In addition to oxidants that are generated by the Fenton reaction, superoxide radicals (O2-) readily react with nitric oxide (NO), generating peroxynitrite anion (ONOO-) in the following reaction:

\[ NO + O_2^- \rightarrow ONOO^- \]

The protonated form of peroxynitrite anion, peroxynitrous acid, is highly reactive with biologic molecules. Hence, the production of nitric oxide from nitric oxide synthase (a complex enzyme containing several cofactors, and a heme group that is part of the catalytic site), which catalyzes the formation of NO from oxygen and arginine, can render cellular components such as DNA susceptible to superoxide-mediated damage (1).

DNA damage by ROS

Hydroxyl radicals can add to the DNA bases or abstract hydroxyl atoms, generating multiple types of DNA damage. The C4-C5 double bond of the pyrimidines C and T is particularly sensitive to attack by hydroxyl radicals, generating a large spectrum of oxidized pyrimidines, notably thymine glycol, urea residues, 5-OHdU, 5-OHdC, and hydantoin (Fig. 5).

Tables 1 and 2. Similarly, interaction of hydroxyl radicals with the purines A and G generates multiple purine oxidative products. The altered base 7,8-dihydro-8-oxo-guanine (23, 24), sometimes referred to as 8-oxoguanine (8-oxOG), is a biologically important form of base damage caused by oxygen free radicals (1) (Table 1). When present in DNA, this residue readily assumes a conformation that can base pair with A, resulting in transcription mutations after DNA replication (25).

Oxidative damage to the nitrogenous bases in DNA is readily generated during the handling of this biologic macromolecule under standard laboratory conditions. Despite the extensive use of antioxidants during the isolation and handling of DNA, this problem has seriously complicated accurate measurements of basal steady-state levels of oxidative damage in cells, especially with the advent of sensitive techniques for its measurement, and early estimates reported in the literature should not be relied on (1).

WILEY ENCYCLOPEDIA OF CHEMICAL BIOLOGY © 2008, John Wiley & Sons, Inc.
Figure 4. (a) Malonaldehyde is a major product of lipid peroxidation that is reactive with A, G, and C in DNA. (b) 4-Hydroxy-2-nonenal, another major product of lipid peroxidation, can generate exocyclic etheno adducts of A, C, and G in DNA. (Reproduced from Reference 1 with permission.)

Treatment of DNA with hydrogen peroxide or other free radical-generating systems (such as xanthine/xanthine oxidase) can also result in the formation of an imidazole ring-opened derivative of guanine, designated 2,6-diamino-4-hydroxy-5-formamidopyrimidine (FaPy) (26). This lesion is prominent among the forms of base damage induced by H$_2$O$_2$. Both this reaction and that for the analogous lesion in A proceed through a carbinolamine-type intermediate.

Close to 100 products of DNA base damage caused by ROS have been identified (27), usually by treating bases, nucleosides,
Chemical Damage to Nucleic Acids

Figure 5 Some of the many products of oxidation of the bases in DNA.

-or oligonucleotides in vitro with strong oxidants or ionizing radiation (27). It has been estimated that endogenous ROS may result in as many as 200,000 base lesions/day in the genome of the average mammalian cell (1).

Hydrogen abstraction typically affects the deoxyribose sugar units, leading to fragmentation of the sugars, base loss, and strand breaks with a terminal sugar residue fragment (28). Such breaks most often affect single polynucleotide chains of the DNA duplex. In contrast, ionizing radiation, which also generates ROS (1) typically produces clusters of hydroxyl radicals that can cause double-strand breaks. There is an extensive literature on ionizing radiation damage to DNA. This topic is not included in this review because absent unshielded travel in space, organisms are not typically exposed to ionizing radiation. Furthermore, as just noted, many types of DNA damage caused by ionizing radiation are identical to those generated during oxidative stress.

Anaerobic, or hypoxic, cells are resistant to the deleterious effects of ionizing radiation. Ionizing radiation, such as that used in radiotherapy, kills cells by producing DNA damage, particularly DNA double-strand breaks. This damage results from ionizations in the DNA or in water molecules very close to the DNA that produce a radical on the DNA (DNA•).

This radical then enters into a competition for oxidization primarily by oxygen (which fixes, or makes permanent, the damage), or reduction primarily by –SH-containing compounds that can restore the DNA to its original form. Thus, DNA damage, including single- and double-strand breaks, is less in anaerobic cells. This effect of oxygen in sensitizing cells to radiation is quantitated as the ratio of dose in the absence of oxygen to dose in the presence of oxygen needed to obtain the same surviving fraction of cells. For mammalian cells, this ratio is usually 2.5–3.0. The oxygen partial pressure that produces sensitivity midway between the oxic and the anaerobic responses is approximately 3 mm Hg. Clinical trials, particularly with head and neck cancers, have demonstrated that the more hypoxic tumors are more radioresistant than the less hypoxic tumors.

How cells cope with ROS

As mentioned, cells can survive the large amounts of ROS generated during normal cellular metabolism both by directly inactivating ROS by a variety of reactions, and by repairing oxidative damage to DNA. With regard to the former category

of cellular defenses, the following have been most extensively studied.

1. Superoxide dismutase (SOD) enzymes that eliminate superoxide by the reaction:

   \[ 2O_2^- + 2H^+ \rightarrow H_2O_2 + O_2 \]

   The several SODs in mammalian cells constitute a major form of protection against ROS. Since superoxide dismutase generates H₂O₂, its detoxifying effect primarily results from preventing the accumulation of free Fe²⁺ and the production of peroxynitrite.

2. Removal of hydrogen peroxide by catalase in the reaction:

   \[ 2H_2O_2 \rightarrow 2H_2O + O_2 \]

   In mammalian cells, catalase is largely contained in peroxisomes and does not seem to be nearly as biologically important as SOD (137).

3. The reduction of hydrogen peroxide by organic reductants (RH) such as glutathione, ascorbate, and cytochrome c:

   \[ H_2O_2 + 2RH \rightarrow 2H_2O + 2ROH \]

4. Yet another mode of defense against oxidant stress in mammalian cells is by transcriptional induction of heme oxygenase, which acts to generate heme metabolites with anti-oxidant properties (29).

Other Types of Spontaneous Damage to DNA

Spontaneous alkylation of DNA

Alkylating agents are electrophilic compounds that react efficiently with nucleophilic centers in organic macromolecules, including DNA (1). Alkylating agents can be highly toxic to cells and are widely used in the treatment of cancer primarily for this reason. Alkylating agents can be either monofunctional or bifunctional. The former have a single reactive group that reacts covalently with one of the many nucleophilic centers in DNA. Bifunctional agents have two reactive groups, so each molecule can potentially react with two sites in DNA, generating crosslinks. Numerous potential reaction sites for alkylation have been identified in all four nitrogenous bases, but not all of them have equal reactivity. The sites of reaction in DNA for many monofunctional alkylating agents include the following: in A, N1, N3, N6, and N7; in G, N1, N2, N3, N7, and N9; in C, N4, N6, and N7; and in T, N1, N3, N6, and N7.
0\textsuperscript{2}; in C, N3, N\textsuperscript{4}, and O\textsuperscript{2}; and in T, N3, O\textsuperscript{2}, and O\textsuperscript{4}. The ring nitrogens of the bases are in general more nucleophilic than the oxygens, with the N7 position of guanine and the N3 position of adenine being the most reactive (1). Alkylation of oxygen in phosphodiester linkages results in the formation of phosphotriesters (1).

Cells are endowed with several distinct enzyme-catalyzed mechanisms that specifically effect the repair of various alkylated bases (1). The alkylating agents used experimentally to generate the multiple substrates attacked by these enzymes are, in the main, not naturally occurring. However, it is intuitively compelling that these enzymes must have evolved to cope with spontaneous forms of alkylation damage to DNA (Table 1). Support for the notion of spontaneous alkylation damage to DNA comes from several studies.

1. Some microorganisms are endowed with a particular methyltransferase activity that catalyzes the methylation of halide ions (31), thereby naturally generating methyl chloride (MeCl\textsubscript{1}), a mutagenic alkylating agent that can react with various atoms in the nitrogenous bases. Large amounts of methyl chloride are also naturally generated during the burning of biomass (32), and reactive methyl radicals can arise by the irradiation or oxidation of methyl compounds such as methylhydrizine (33).

2. Some antibiotics are alkylating agents. A prominent example is streptozotocin, an antibiotic produced by the soil bacterium Streptomyces achronogenum. This compound is a 2-deoxy-1-glucose derivative of the potent alkylating agent methylnitrosourea (MNU), among naturally occurring chemical in this category, steroids are becoming increasingly recognized as a source of spontaneous DNA damage. Steroids are derived from cholesterol,

Spontaneous DNA–DNA and DNA–Protein Crosslinks

The covalent interaction of a chemical with bases on both strands of the DNA duplex can result in the formation of interstrand DNA crosslinks. Such lesions can interfere with the separation of the two polynucleotide chains that is required during various DNA metabolic transactions, especially replication and transcription. The biologic consequences of DNA crosslinking have been mainly investigated using synthetic bifunctional chemicals such as bifunctional alkylating agents (nitrogen and sulfur mustards are notable examples). However, several possible endogenous sources of interstrand crosslinks have been identified. For example, dietary nitrites can be converted to nitrous acid under the acidic conditions in the stomach. Nitrous acid generates interstrand crosslinks preferentially between the exocyclic N\textsuperscript{2} amino groups of guanine at CG sequences (36), and it has been estimated that a DNA interstrand crosslink may result for every four deaminations generated by nitrous acid (1). Aldehydes constitute another potential source of interstrand crosslinks in cells. Acetaldehyde, a product of normal cellular glycolysis, can cause DNA interstrand crosslinks (1). Malon-dialdehyde (another aldehyde) can be generated as products of lipid peroxidation.

DNA–protein crosslinks can constitute another source of spontaneous DNA damage, although one that has not been as extensively studied as the types of DNA damage already discussed. Nonetheless, aldehydes have been shown to cross-link histones and other DNA-bound proteins to polynucleotides. Cerulein and related aldehydes can also be endogenously generated by oxidative degradation of unsaturated lipids. Guanine adducts of acrolein, crotonaldehyde, and trans-4-hydroxynonenal can form crosslinks with peptides (37). This reaction is mediated by a Schiff base linkage between a ring-opened aldehyde moiety and the N-terminal \(\alpha\)-amine of the peptide (37).

Relatively unreactive chemicals can be metabolically activated to forms that are highly reactive with DNA.

A variety of relatively nonpolar compounds can undergo metabolic activation that is effected by specific metabolizing enzymes (38). The biologic function of these enzymes is to convert potentially toxic, lipid-soluble nonpolar chemicals to more reactive water-soluble and thus excretable forms, frequently esters (38). However, many of these more reactive water-soluble compounds can interact with nucleophilic centers in DNA (38), generating various types of base adducts. A series of membrane-bound proteins endowed with mono-oxygenase activities have been extensively characterized as components of these detoxification systems. These heme-containing proteins strongly absorb light at \(\sim 450\) nm and in combination with one or more membrane-bound flavoprotein reductases are often referred to as the cytochrome P-450 system (1).

A mong naturally occurring chemical in this category, steroids are becoming increasingly recognized as a source of spontaneous DNA damage. Steroids are derived from cholesterol,
which is converted to 17-hydroxyprogesterone by a series of specific oxidation-reduction reactions. Additional such reactions generate the adrenal cortical steroids, as well as the sex hormones estrogen, progesterone, and testosterone. Estrogens, including the natural hormones estradiol and estrone, can be hydroxylated at several positions by cytochrome P-450 enzymes. Hydroxylation at the 4 position to generate catechol estrogens is particularly important with regard to DNA damage. In cells, 4-hydroxylated catechol oxides are oxidized to semiquinones and then to DNA-reactive quinones. These quinone intermediates react at the 3- and 7-positions of the purine bases in DNA, creating unstable bulky adducts that are readily depurinated. The catechol estrogen metabolites have the potential to produce the full spectrum of oxidative DNA damage discussed above.

Although not widespread, aflatoxins, among the most potent liver carcinogens known, represent another example of DNA-damaging agents that have their origin as products of natural metabolism. Aflatoxins are toxins produced by the fungi Aspergillus flavus and Aspergillus parasiticus. Contamination of cereal grains such as rice, peanuts, and corn by these fungi can result in human and animal exposure (39). Chemically, the aflatoxins consist of a difurofuran ring system fused to a substituted coumarin moiety, with a methoxy group on the benzene ring (39). Among the aflatoxins of fungal origin, aflatoxin B1 is the most potent. Aflatoxin B1 can enter cells by passive diffusion and is metabolically converted by mixed function oxygenases of the cytochrome P-450 system, generating aflatoxin B1-8,9-epoxide as a major product (39). G residues in double-stranded DNA are preferentially attacked by this reactive electrophilic epoxide (1). The major product is an N7 adduct on G (8,9-dihydro-8-(N7-guanyl)-9-hydroxyaflatoxin B1) (40). The positively charged imidazole ring weakens the glycosyl bond, promoting depurination and subsequent sites of base loss. Mildly alkaline conditions can result in the formation of formamidopyrimidine derivatives containing an opened imidazole ring, which is a reaction that has also been identified in vivo (39).

**DNA Damage Caused by Natural Environmental Agents**

**Ultraviolet radiation from the Sun**

UV radiation from the Sun is a ubiquitous and important source of DNA damage that contributes to the high incidence of skin cancer in exposed individuals. The UV radiation spectrum has been arbitrarily divided into the UV-A component (wavelengths 320–400 nm), the UV-B component (wavelengths 295–320 nm), and the UV-C component (wavelengths 100–295 nm). Penetration of the atmospheric ozone layer is weak for wavelengths below 300 nm. Thus, solar UV radiation primarily comprises the UV-A and UV-B components. However, experimental studies typically involve the use of UV-C radiation from germicidal lamps with a sharp emission maximum at 254 nm. Since this wavelength is very close to the absorption maximum of DNA (260 nm) and is inefficiently absorbed by proteins, UV-C radiation-induced damage is relatively specific for DNA (1).

**Major photoproducts in DNA**

When cells are exposed to UV-C radiation, the quantitatively most abundant form of DNA base damage involves saturation of the pyrimidine 5,6-double bonds, resulting in covalent linkages between adjacent pyrimidines through a four-membered ring structure (1) (Fig. 6). This lesion is called the cyclobutane pyrimidine dimer (CPD). CPD can exist in cis-syn, cis-anti, trans-syn, or trans-anti configurations, but in double-stranded B-form DNA, they exist predominantly in the cis-syn form (1). However, trans-syn dimers are generated to some extent, mainly in denatured DNA (1), and can be detected in single-stranded regions and in duplex DNA with special conformations, such as the junctions between B-DNA and Z-DNA (1).

The thermodynamic and spectroscopic properties of short segments of duplex DNA containing a single CPD indicate that cis-syn CPD can be accommodated in the double helical structure of B-DNA such that hydrogen bonding with the opposite A residues is possible (41). The crystal structure of...
UV light is one in which the C6 position of a 5′-oligonucleotides (1). Although Watson-Crick base pairing can occur at the 3′ T in a CPD, base pairing of the 5′ T with A is severely weakened because one hydrogen bond cannot be made. CPD are extraordinarily stable to extremes of pH and temperature and to total acid hydrolysis of DNA. They can thus be readily resolved from thymine in such hydrolysates by a variety of chromatographic techniques, and quantitated (1).

The formation of CPD during irradiation of DNA is a reversible process that can be represented by the following reaction:

\[ \text{Py} + \text{Py (DNA)} \rightleftharpoons \text{Py}_{\text{add}} + \text{Py (DNA)} \]

This reaction reaches photochromic equilibrium when the thymine-containing CPD content (T \( \rightarrow \) T, T \( \rightarrow \) C, and C \( \rightarrow \) T dimers) reaches ~7% of the total thymine content of DNA (1). This steady state reflects a dynamic equilibrium in which the rate of CPD formation (which is pseudo-zero order, to good approximation) and that of CPD reversal (which is first order in dimer content) are equal (1). The yield of T \( \rightarrow \) T CPD is highest, whereas that of C \( \rightarrow \) C CPD is lowest (1). CPD are not randomly distributed in DNA. Numerous studies at the DNA sequence level have shown that their yields depend on DNA sequence context. In general, the equilibrium level of CPD is higher for TT sites flanked on both sides by A compared with such sites flanked on the 5′ side by A and on the 3′ side by G or C (1).

A another major form of damage generated in DNA by UV light is one in which the C6 position of a 5′ pyrimidine is covalently linked to the C4 position of the 3′ adjacent pyrimidine (Fig. 6). These lesions (which are readily detected by their lability in alkali conditions at 80-100°C (43)) are called pyrimidine-pyrimidine (6-4) adducts, or simply (6-4) photoproducts (6-4PP). The pyrimidine planes in (6-4PP) are almost perpendicular. Hence, they result in prominent distortions of the double-helical structure of DNA. (6-4PP) can involve adjacent TC, CC, or (less often) TT sequences. Their formation at CT sequences is infrequent. Cytosine methylation at the C5 position inhibits the formation of (6-4PP) (44). The yield of (6-4PP) is proportional to the incident UV fluence in the range 100-500 J/m² and continues to increase after exposure to several thousand J/m² (1). In UV-C-irradiated DNA, the ratio of CPD (6-4PP) is ~3:1 (1).

**Minor photoproducts in DNA**

Exposure of DNA to UV radiation also generates oxidative base damage. In particular, thymine glycol (5,6-dihydroxy-5,6-dihydrothymine) can be generated by saturation of the 5,6-double bond of some pyrimidines. Under anhydrous conditions, the so-called "spore photoproduct" or 5,6-dihydro-5-(a-thyminyl)-thymine, another type of dimeric pyrimidine photoproduct, can be generated by addition of a methyl group of a thymine to the C5 position of a neighboring thymine. The formation of this major photoproduct in UV-irradiated bacterial spores of B. subtilis (1) is dependent on the configuration of the DNA, being generated more readily in DNA in the compacted A-form (1). Consequently, the spore photoproduct is readily formed in dry DNA films and in DNA solutions containing high concentrations of ethanol (1).

Another type of chemical reaction involving a pyrimidine base is the addition of a molecule of water across the 5,6 double bond of C to yield a 5,6-dihydro-6-hydroxy derivative and yield the cytosine hydrate. The quantum yield for the formation of cytosine hydrates in UV-irradiated DNA is greater in single-stranded than in duplex-DNA (45). Hydrates of cytosine, deoxycytidine, CMP, or dCMP are unstable, readily reverting to the parent form by dehydration (45). However, their half-life is dramatically increased in DNA, and cytosine hydrate may be the major nondimer C photoproduct. Cytosine hydrate can undergo deamination and dehydration to yield uracil (1). The hydrate of 5-methylcytosine may undergo deamination to yield 5-thymine hydrate, which can convert to thymine upon dehydrogenation (1).

A photoproduct called 8,8-adeno dehydrodimer is observed after irradiation of poly(dA). This lesion involves a single 8,8 bond linking the imidazole rings (46). Another uncharacterized lesion involving adenosine has been reported after UV irradiation of simian virus 40 DNA (1). The lesion is alkali-labile and occurs at ACA sequences. Other photoninduced lesions involving purines have been identified (47). The fact that they are recognized by DNA repair enzymes suggests that they are physiologically significant. In general, the generation of purine photoproducts lesions is enhanced if they are flanked by two or more contiguous pyrimidines on their 5′ side (1).

**DNA crosslinks and strand breaks**

UV radiation can result in the cross-linking of DNA to proteins (DNA–DNA crosslinks) have also been observed, mainly when DNA is irradiated in the dry state, in an extremely densely packed condition (such as in the heads of salmon sperm), or in other special conformations (1). The spore photoproduct, formed in UV-irradiated dry DNA as described above, can arise not only between adjacent pyrimidines in the same chain but as a reaction between pyrimidines in different DNA chains (1).

Irradiation of DNA with very high doses of UV-C light can also result in breakage of the polynucleotide chain (1). However, the amount of UV radiation required to reduce the molecular weight of Streptococcus pneumoniae DNA by 50% is about 100 times that required to reduce the transforming activity of the streptococmycin resistance marker of that organism to the same extent (1). No chain breaks are detected in phage T7 DNA exposed to doses of UV radiation that inactivate almost 100% of the phage population (1). Thus, no conclusive evidence shows that the direct formation of DNA strand breaks by UV-C radiation is of biologic consequence. The frequency of strand breaks and DNA-protein crosslinks is dramatically increased by irradiation at longer wavelengths (1). In cells, most strand breaks observed after UV-irradiation are caused by biologic processing, either from interruption or breakdown of stalled
DNA replication forks, or as intermediates in the repair of photoproducts.

Conclusions

As discussed, much is known regarding the chemical reactivity of DNA and how these transformations lead to mutation. As discussed, much is known regarding the chemical reactivity of DNA and how these transformations lead to mutation. However, important challenges remain. For example, most of the estimates regarding the rates of DNA damaging processes are derived from simple model studies using oligonucleotides.

Do these rates reflect the reality of what occurs in the context of chromatin? These questions are challenging and new technologies will be required to address them. Although not covered in detail in this review, there is much to be done to increase our understanding of the enzymatic mechanisms employed by repair proteins to undo the damage brought about by everyday life. Thus, we anticipate that the field of DNA damage and repair will continue to fascinate both chemists and biologists for some time to come.

DNA Transposable elements are segments of DNA capable of moving from one locus in a genome to another, or from one genome to another, using mechanisms that do not depend on large regions of sequence homology between the TE and the target DNA site. Their effects were observed first in plants in the middle of the twentieth century (1), and they were characterized at the molecular and mechanistic levels, largely in bacteria, in the last three decades (2). With the birth of whole genome sequencing, a growing recognition has occurred of the ubiquity of TEs, of their diversity, and of importance in shaping both eukaryote and prokaryote genomes and in influencing genome function. In some cases, their numbers are so high that it is tempting to consider that, together with bacteriophages, plasmids, and mobile introns, they form part of a genomic “ecosystem.” In the prokaryotes alone, nearly 2000 different insertion sequences (ISs; the simplest form of autonomous TEs) have been identified (IS-finder: www-is.biotoul.fr). TEs have been classified in various ways (see http://bioinformatics.org/wikiposon/doku.php). For example, in eukaryotes, a major division can be drawn between those elements that transpose via an RNA intermediate (Class I: retroviruses, retrotransposons) and those that transpose via a DNA intermediate (Class II: DNA transposons). Nevertheless, perhaps the most pertinent classification, for the purposes of this article, that deals exclusively with DNA transposons is based on the reaction mechanisms that they have adopted for their movement (3). These reactions involve cleavage of the DNA at the ends of the TE in the donor DNA molecule and transfer of these ends into a target DNA. They are catalyzed by a TE-encoded enzyme, the transposase. In the special case of retroviruses, the (DNA) provirus is liberated from its donor site not by DNA cleavages but by transcription to generate an RNA copy. During the viral lifecycle, this provirus is subsequently reverse-transcribed into a double-strand DNA genomic copy. This copy is then processed by an enzyme that resembles a transposase, the retroviral integrase or IN, which also assures subsequent integration into the host genome. Currently, the following five types of DNA transposase have been recognized: the DDE enzymes (most are identified so far) (3, 4); the tyrosine transposases (related to tyrosine site-specific recombinases of the phage λ Int family) (2); the S-transposases (related to serine site-specific recombinases of the γδ resolvase family) (2); the Y2-transposases (related to Rep proteins involved in rolling circle replication and to Relaxases, which are involved in conjugative gene transfer in bacteria) (5); and, finally, the Y1-transposases (also related to Rep and Relaxase proteins). The Y1-transposases were discovered only a few years ago (6–8), and it seems likely that other types of enzyme will be identified in the future. Each class of enzymes catalyzes a distinct chemistry that we describe below.

DDE Transposases and Integrases

The DDE enzymes are named for their characteristic triad of acidic amino acids (aspartate and glutamate). These enzymes bind in a sequence-specific way to the ends of the TE that generally carry terminal inverted repeat sequences and include the transposase recognition sequence. The simplest TEs, such as bacterial ISs, tend to carry only single transposase-binding sites at each end, whereas other more complex transposable elements...
may carry arrays of such binding sites. These arrays may be arranged in different patterns at each end and provide a means for distinguishing one end from the other. This arrangement could be involved, for example, in regulating transposon gene expression or in forming an asymmetric synaptic complex. It could lead to end-specific ordered cleavages or strand transfers that would determine the order of events that lead to integration.

Many DDE transposases carry a DNA sequence-specific binding domain in their N-terminal regions and at least one domain involved in multimerization. Generally, the catalytic domain is located in the C-terminal part of the protein. The DDE domain is by far the most studied and best understood binding domain in their N-terminal regions and at least one that would determine the order of events that lead to integration. The acidic pocket coordinates two Mg²⁺ ions jointly between DNA and RNA. Phosphodiester backbone by water. With the appropriate DNA substrate, the target phosphate can be shown to undergo stereochemical inversion in the course of the reaction, which implies a direct single-step, in-line nucleophilic attack (17). It is important to note that no covalent enzyme-DNA intermediate is formed during catalysis by DDE enzymes.

The acidic pocket coordinates two Mg²⁺ ions jointly between the nucleic acid substrate and the catalytic acidic residues of the enzyme (Fig. 1). This idea was based on the proposition of Staats (the two-ion model), which concerns the reaction chemistry of exonuclease activity of DNA polymerase (16). This coordination enhances nucleophilic attack of the nucleic acid phospho-sugar backbone and guarantees substrate recognition and catalytic specificity (16).
Despite their diversity, DDE transposases catalyze only two chemical reactions: cleavage and strand transfer (Fig. 1a and 1b). These reactions involve single-strand DNA cleavages. DDE enzymes do not catalyze double-strand cleavage. The cleavage reaction occurs at both ends of the TE, generally using H2O as the nucleophile, to generate 3′-OH ends (19, 20) (Fig. 1a). In the retroviral integrase (IN) proteins, this reaction is known as processing. For several transposons, this reaction is a major regulatory checkpoint because, in these cases, cleavage does not occur on isolated TE ends but requires prior formation of a transposase complex that involves both ends. In several systems, it has been shown that complex assembly evolves through several steps and becomes increasingly stable during this process. This evolution reflects the highly organized architecture of the complex, known as the transpososome (21).

A dynamic model of the catalytic reactions that lead to strand cleavage has been proposed based on structural considerations (22). A summary is thought to involve coordinate binding of transposase, its DNA substrate(s), and two divalent metal ions. On transposase DNA binding, the two metal ions (H and T for hydrolysis and transfer, respectively; Fig. 1a) find their appropriate positions in the active site and are poised for catalysis. Metal ion H orients and activates the water molecule (depicted as −OH) for nucleophilic attack. Metal ions T (which
is coordinated with an irregular geometry) and H then move closer to each other. The target phosphorus atom adopts a pentavalent transition state (Fig. 1a2), which is then converted into product as the metal ions move back and away from each other (presumably by charge repulsion between T and H). The resulting 5′-phosphate and 3′-OH then dissociate (Fig. 1a3).

In the case of nucleases, the reaction terminates at this step. For transposase, however, the liberated 3′-OH of the transposon end is then used as a nucleophile in a second reaction: trans-esterification. In this reaction, the 3′-OH attacks the target DNA, which results in strand transfer or joining of the transposon strand to its target strand. The detailed picture of the DDE cleavage reaction (Fig. 1a) might also be extended to the strand transfer reaction (Fig. 1b). The nucleophile of this reaction would now be the 3′-OH group from the preceding cleavage reaction, which would be coordinated by the T cation (Fig. 1b1). Therefore, the trans-estearification reaction is comparable to that of cleavage but, here, the in-line nucleophilic attack transfers the free 3′-OH end of the transposon in the target DNA (red in Fig. 1b), which creates a transposon-target joint.

Although all transposons with a DDE transposase (“DDE transposons”) use this type of chemistry, a large diversity exists in the overall transposition mechanism. As explained above, DDE transposases catalyze only single-strand cleavage and transfer of the 3′-OH transposon ends (the transferred strand). However, to liberate the transposable element from donor DNA, the transposase must deal with the second DNA strand (also called the nontransferred strand (3, 24). A subclassification of DDE transposases is based on the mechanisms used to manage this.

In the well-characterized bacterial IS4 family (which includes IS50 and IS10), it is the liberated 3′-OH of the transferred strand that is used to attack and to cleave the second strand. This generates a hairpin intermediate (Fig. 1c), in which transferred and nontransferred strands are joined, and both DNA strands that flank the ends are removed. Hairpin formation involves a considerable torsion of the DNA, which is aided by extrusion of a subterminal thymine residue from the DNA helix—a flipped-out T (25). This formation has been studied in detail for both IS10 and IS50 and requires a specific group of aromatic residues within the DDE domain. These residues are conserved within the family (26), and they serve to initiate and to stabilize this sequence-specific distortion (27). A second round of cleavage then removes the interstrand hairpin that regenerates the initial 3′-OH, which is used subsequently in the final strand transfer reaction.

This type of second strand management is found in eukaryotic transposable elements, such as the HAT group (28), and in V(D)J immunoglobulin-gene rearrangements (2) (Fig. 1d). In these cases, however, hairpin formation occurs on the equivalent of the transposon flanks rather than on the transposon itself. In the case of V(D)J, no specific subterminal T exists, and in the case of the HAT transposons, the hairpin is formed on the transposon flank and can vary between different HAT copies. Thus, hairpin formation in these cases occurs on sequences that are not necessarily conserved, and it seems unlikely that it involves a specific flipped-out T residue.

For the widely dispersed Tc-Mariner transposon group, the transposase first cleaves within the 5′ end of the transposon—the nontransferred strand. This activity resembles the nuclelease activity (see above) that simply terminates at the cleavage step and does not take in charge the strand transfer step. Moreover, unlike transposition reactions, this cleavage does not require formation of a synaptic complex (29). The transferred strand is cleaved at the very tip of the TE. The fact that the nontransferred strand is cleaved within the transposon results in retention of the few TE-specific bases in the donor molecule after TE excision.

After rescaling and repair, the donor backbone retains several additional base pairs derived from the TE (called a scar) that marks the passage of the transposon (2).

Interestingly, transposon Tn7 behaves in a similar way but, in this case, the 5′ endonuclease activity is supplied by a separate enzyme whose structure resembles that of a type II restriction enzyme (30), and cleavage occurs clearly at the transposon tip rather than within the TE. Transposition of Tn7, like most bacterial elements, does not leave a scar. In both the Tc-Mariner transposon group and the Tn7 family of transposons, the transposase then cleaves and transfers the 3′ end in a true DDE transposition reaction (Fig. 1e). Finally, cases exist in which the second strand is not processed at all. These include bacteriophage Mu and the Tn3, IS1, IS30, and IS256 families. Here, replication is involved intimately in the transposition process itself. In a first step, the transposase cleaves and transfers a transposon end to a target DNA. For phage Mu and Tn3, both transposon ends are transferred directly into target DNA that links both donor and target molecules at each of the transposon ends (2) whereas for IS2 (3), IS30 and IS256 family members, the 3′OH of one transposon end attacks the opposite end. In both cases, a branched structure is generated around which a replication fork is then assembled to resolve this structure (Fig. 1f). In the case of Mu and Tn3, strand transfer is followed by replication and leads to duplication of the transposon. In the case of IS1, IS30, and IS256 family members, replication leads directly to formation of a transposon circle intermediate and regenerates the original donor locus. The transposon circles, which carry abutted transposon ends, are highly recombinogenic transposition intermediates. They then undergo insertion readily into a suitable target DNA in a reaction that involves concomitant transposon-catalyzed cleavage and concerted transfer of both ends (31).

The Tyrosine and Serine Transposases

Although the reactions catalyzed by the 5- and Y-site-specific recombinases are well characterized, little is known about the biochemistry of their cousins, the Y- and S-transposases. These transposases are thought to catalyze strand breakage and transfer as do their site-specific recombinase relatives. Neither of these requires divalent metal ions for catalysis. Although these transposases show site-specificity for the ends of the donor transposon, they seem more flexible than classic site-specific
recombinases in the DNA target sequences they recognize and use as the partner during integration. Strand cleavage catalyzed by the Y- and S-recombinase enzymes occurs using a tyrosine or serine hydroxyl group, respectively. This generates a phospho-
roline or phosphoserine intermediate. The Y-recombinases form a 3'-phosphoryl residue bond, whereas the S-recombinases create a 5'-phosphosphate bond. Various host accessory proteins are required in these reactions to generate protein-DNA complexes with the correct architecture for catalysis.

The Y2-Rep and Relaxase proteins are less well understood, and the Y2 IS151 transposase is proving to be difficult to work with. Again, it is assumed largely that the Y2 enzyme behaves the same as the related plasmid and phage Rep and plasmid Relaxase proteins. The mechanism of the final group, the Y1 transposases, is now relatively well understood.

S-recombinases

Cleavage and strand transfer are mediated by successive tran-
esterification reactions within a synaptic complex that includes the two partner DNA sequences (called core sequences) bound by a recombinase tetramer. In the transposases, the DNA se-
quences would be the transposon ends. The nucleophile hydro-

droxyl of the catalytic serine residues initiate recombina-

tion by attacking specific phosphodiester bonds (the scissile phosphates) of the DNA backbone (Fig. 2a). Cleavage re-

sults in covalent attachment of the proteins to the 5' ends of the cleaved DNA strands and production of 3'-OH free ends. Cleavage (Fig. 2a) and strand transfer (Fig. 2b) is mediated by successive trans-
esterification reactions within a synaptic complex that includes the two partner DNA sequences (called core sequences) bound by a recombinase tetramer. In the transposases, the DNA sequences would be the transposon ends. The nucleophile hydroxyl of the catalytic serine residues initiate recombination by attacking specific phosphodiester bonds (the scissile phosphates) of the DNA backbone (Fig. 2a). Cleavage results in covalent attachment of the proteins to the 5' ends of the cleaved DNA strands and production of 3'-OH free ends. The first cleavage and/or strand exchange allows the reaction to proceed to the second pair of strand exchanges that occurs at the other end of the central region of the core site (Fig. 2b). Exchange of the second pair of strands is separated temporally and spatially from the first. This exchange, together with the inverted polarity of cleavage, represents the major differences to S-recombinase driven catalysis.

Y transposases are heterogeneous. They share the capacity to be transferred by a conjugative mechanism from cell to cell and are referred to as conjugative transposons (CTns) (2). Oftentimes, they carry antibiotic resistance determinants (usually the tetM gene) and are important vectors for disseminating this antibiotic resistance. Some are self transferable (e.g., Tn916 from Streptococci and Tn525 from Enterococci), whereas others are mobilized by functions provided in trans by other elements such as conjugative plasmids or other CTns (e.g., the NUS elements from Bacteroides spp.). They can have a very broad host range and seem to contribute significantly to gene transfer in complex bacterial populations.

Y2-transposases

These enzymes are members of a family of nucleases (34) known as the HUH superfamily because they include a con-
served histidine-hydrophobic-histidine motif that provides two of three ligands to an essential divalent metal ion cofactor. Gen-
erally, these enzymes are monomeric. Members include proteins that initiate conjugative plasmid transfer from cell to cell or catalyze rolling circle replication (RCR) in certain bacteriophages and plasmids. Prokaryotic members include the IS11 family and the newly identified ISCR group (35), whereas eukaryotic members include the helitrons (22).

The similarity between RCR and rolling circle transposition (RCT) is underlined by the fact that the “left end” of IS1 resembles a rolling circle replication origin—the structured region that is recognized and undergoes single-strand-specific cleavage to initiate replication. The enzymes carry five conserved blocks of amino acids, one of which includes a pair of tyrosine residues involved in catalysis. The best-characterized reactions that use Y2 enzymes are those involved in plasmid replication (e.g., pK174). They use two active site tyrosines and cleave the DNA by releasing the 3'-OH and 5'-phosphotyrosyl bond during cleavage.
Figure 2 Proposed mechanism of Y- and S-transposases. (a) The S-transposases. Proteins are shown in yellow and transposon ends in green. This figure is based on the known mechanism of serine site-specific recombinases. The serine nucleophiles are indicated (S) as are the 5′-OH liberated on formation of the phosphotyrosine bonds. (b) Synapsis and attack by the tyrosine. The top right and bottom left subunits are active for cleavage. (b2) Cleavage liberates the 3′-OH, which then attacks the phosphotyrosine bond on the opposite (horizontal as drawn) subunit to reveal the DNA strand in a first strand transfer step. (b3) The first strand transfer product. (b4) Second strand cleavage. The top left and bottom right transposase subunits are activated and cleave the opposite strands. (b5) Second strand transfer results in formation of a transposon joint and a donor backbone from which the transposon has been deleted. (b6) The Y-transposases. Proteins are shown in yellow and transposon ends in green. This figure is based on the known mechanism of tyrosine site-specific recombinases. The tyrosine nucleophiles are indicated (Y) as are the 5′-OH. (c) Synapsis and attack by the serine nucleophile. (c2) Rotation of the substrates (large arrow). (c3) Realignment and 3′-OH attack of the phosphoserine bonds. (a4) Resealing the broken strands generates a transposon circle and a reclosed donor backbone from which the transposon has been deleted. (c) The Y1 transposases. The left and right transposase subunits are activated and cleave the opposite strands. (c4) Excision of IS generates a transposon circle and a reclosed donor backbone from which the transposon has been deleted. (c5) Single stranded cleavage and transfer results in formation of a transposon joint and a donor backbone from which the transposon has been deleted as a transposon circle. (c) The Y1 transposases. The left and right transposase ends are shown in red and blue, respectively. (c1) Diagram that shows the potential secondary structures at the left and right ends. (2) TnpA binding and cleavage. The top strand is recognized by TnpA (yellow ellipses) that catalyzes cleavage via a 5′-phosphotyrosine linkage (black arrow). This cartoon shows that the covalent bond is formed at the 5′ end of the left end and at the 3′ end of donor flank at the right end. (c3) Cleavage is then followed by exchange between the left and right ends to generate a Right End–Left End transposon joint and to liberate a single strand transposon circle. (c4) Excision of IS and closure of the flanking backbone would leave a deletion bubble in the bottom strand. (c5, c6) Replication of the donor plasmid (arrow) would generate a copy of the original donor plasmid with an intact, double strand IS copy (c6), and a copy of the plasmid devoid of the IS (c5).
The RCT mechanism confers several interesting features on the IS91 family members. These elements do not carry terminal inverted repeats nor do they generate target site duplications as do the DDE transposons. IS91 itself inserts with a specific orientation at the 3' end of a conserved tetrancleotide sequence (5'CTTG3' or 5'GTTC3'), which is probably involved in transposition initiation and termination and also required for additional efficient transposition. Deletion of the downstream ("right") end results in "one-ended" transposition in which different lengths of vector DNA neighboring the deletion accompany the element to its new target site. These terminata with a 5'CTTG3' or 5'GTTC3' tetrancleotide located in the vector (2).

Y1-transposases

These enzymes were identified and characterized more recently (3). They are also part of the HUH superfamily of nucleases but currently characterized members have only one catalytic tyrosine and form obligatory dimers in both the bacteria and the archaebacteria (37). IS608 does not possess terminal IRs. The left (LE) and right ends (RE) include palindromic repeats, which form DNA hairpins located at some distance from the cleavage sites. The cleavage site at the left end is 19b upstream from the 5' end of the flanking donor DNA at RE (Fig. 2c1). IS608 insertion occurs 3' to a tetrancleotide TTAC contained in the flanking DNA, which abuts LE (38) directly (Fig. 2c2). Moreover, it is also required for subsequent transposition (7). IS608 transposition is strand specific. It occurs by precise excision of the "top" transposon strand to generate a circular intermediate with abutted copies of RE and LE (the transposon joint or RE–LE junction; Fig. 2c3) and resealing of the flanking DNA, which preserves the target TTAC (7). TnpA behaves as a dimer in solution and a crystal structure indicated that the molecule forms an elongated and flat dimer (8). The crystal structure of the complex formed by TnpA and a 22 nt long, single-stranded oligonucleotide that represents the RE palindrome showed a DNA hairpin (an imperfect palindromic dimer) bound to each of the two recognition sites in the TnpA dimer (8).

TnpA binds single strand (ss) DNA that carries either "top strand" LE or RE (see Fig. 2c2) much more strongly than double strand (ds) DNA ends. It did not bind the ss "bottom strand." TnpA catalyzes efficient strand-specific cleavage of a single "top" strand oligonucleotides, which includes LE or RE. IS608 transposition necessitates formation of an enzyme-substrate intermediate in which TnpA is attached covariantly at a DNA end via a 5' phosphotyrosine bond. Because of the conserved polarity of cleavages required at the ends, TnpA is joined to the 5' end of the transposon at LE but to the 5' end of the flanking donor DNA at RE (Fig. 2c2) (8). Nucleophilic attack of the LE phosphotyrosine bond by the free RE 3'OH results in resealing of the ss transposon to form a circle (Fig. 2c4), whereas attack of the RE 3' OH releases the donor backbone (Fig. 2c6). The transposon circle that carries an RE–LE junction can undergo insertion into a suitable TTAC target. The resulting donor molecule intermediate (Fig. 2c4) could be resolved by replication to generate a copy of the original donor plasmid molecule (Fig. 2c5) and a copy from the deleted transposon (Fig. 2c6).

Conclusions

Transposition is a general term that covers a variety of different TEs and includes several diverse chemistries. It should be underlined that although several partial structures of DDE enzymes have been determined, the structure of only a single complete DDE transposase has been obtained complexed with appropriate ends. For other types of transposase, two structures of Y1 transposases are available (8, 36), one of which includes its DNA substrate (25). A detailed structural information will be critical to understand how these fascinating enzymes function. The information presented above is derived largely from in vitro experiments, although a body of in vivo information also exists. One major challenge in the field of transposition at present is to determine how these elements interact with and are regulated by their respective hosts.

Group II Intron: Structure, Function, and Catalysis

Michael Roitzsch, Howard Hughes Medical Institute, Yale University, New Haven, Connecticut
doi: 10.1002/9780470048672.wecb679

The self-splicing group II introns are among the largest naturally occurring ribozymes and have been found primarily in organellar genomes of plants, fungi, bacteria, proteobacteria, and blue algae. More recently, a group II intron was found in a primitive metazoan. More than 200 different group II introns have been identified to date. All group II introns have a conserved secondary structure composed of six stem-loop structures termed domains D1–D6, which are arranged around a central wheel and provide distinct contributions to intron function. Group II introns catalyze their own excision from pre-RNA by two consecutive transesterifications and concomitant splicing of the flanking exons. The reaction requires Mg2+ ions, which are directly involved in catalysis and are also needed for proper folding of the intron. Intriguingly, group II introns share several mechanistic and structural features with the eukaryotic spliceosome, which suggests an evolutionary relationship. In vivo, group II intron splicing is generally assisted by proteins. With the help of proteins, some group II introns can also reverse the splicing reaction and integrate themselves into target genomes; this process resembles transposition of non-LTR retrotransposons and can be exploited for biotechnological applications.

It was long believed that protein enzymes were the only cellular machines that could conduct biological catalysis. In 1982, however, Thomas R. Cech described the self splicing group I intron from the ciliated protozoan *Tetrahymena thermophila*, which can excise itself from pre-rRNA and join the flanking exons in vitro (1). Cech coined the term "ribozyme" for this new class of biocatalysts. At the same time, Sidney Altman reported that the RNA components of RNase P from *Escherichia coli* and *Bacillus subtilis* could cleave tRNA precursor molecules in the absence of protein cofactors (2). Over time, it has become obvious that ribozymes are widespread in nature. Ribozymes that catalyze a broad range of reactions have been detected in numerous different organisms, which include plants, lower eukaryotes, bacteria, and viruses (3). More recently, a ribozyme was even found in the human genome (4).

Background

Group II introns are a distinct subgroup within the naturally occurring ribozymes

With exception of the ribosome that catalyzes peptidyl transfer reactions, all naturally occurring ribozymes catalyze phosphoryl transesterifications on their parent RNA (in cis) or other RNAs (in trans) and can be roughly divided into three categories based on their catalytic properties.

1. Nucleolytic ribozymes. Many smaller (40–150 nucleotides) ribozymes catalyze site-specific cleavage in cis. Mechanistically, they activate a 2'-OH group to allow nucleophilic attack of the adjacent 3'-phosphate, which results in formation of a cyclic 2',3'-phosphodiester and release of the downstream RNA strand (Fig. 1a). The reaction resembles non-specific base-catalyzed RNA cleavage. Members of this category are the hammerhead ribozyme, the hepatitis delta virus ribozyme, the structurally related mammalian CPEB3 ribozyme, the hairpin ribozyme, the varkud satellite ribozyme, and the glmS riboswitch. Their function is to process replication intermediates or, in the case of the glmS riboswitch, the metabolite-dependent control of gene expression.

2. RNase P. RNase P is a trans-acting ribozyme (150–500 nucleotides) that processes pre-RNAs by endonucleolytically cleaving off leader sequences from the 5'-end. RNase P positions and activates a water molecule to attack the scissile phosphate,
Figure 1 Schematic of phosphodiester bond-cleavage strategies used by different natural ribozymes. (a) In self-cleaving ribozymes, the 3′-OH group of the 3′-terminal nucleotide attacks the scissile phosphate, which results in a cyclic 2′,3′-phosphodiester. (b) RNase P activates a water molecule to allow a nucleophilic attack on the scissile phosphate, which forms a free 3′-OH group and a 5′-monophosphate at the resulting fragments. (c) In the first step of splicing of group I introns, the attacking nucleophile is provided by the 3′-OH group of a guanosine moiety. As a result, excised group I introns have an additional G at the 5′-terminus. (d) The attacking nucleophile in the first step of splicing of group II introns (branching pathway) is the 2′-OH group of a dedicated adenosine moiety (Abp) located close to the intron 3′-end in domain D6. This reaction results in a lariat form of the excised intron.

which results in a free terminal 3′-OH group

Figure 1b Although they are usually associated with proteins, RNase P ribozymes have been shown to catalyze strand cleavage in the absence of their protein cofactors.

3. Self-splicing ribozymes. These ribozymes are non-coding intervening sequences (introns) that can catalyze their own excision from the parent pre-RNA. Two groups of self-splicing ribozymes exist: the group I and group II introns. They can be very large with sizes of 200–1500 nucleotides (group I introns) and 400–2500 nucleotides (group II introns). Ribozyme-catalyzed self-splicing is a two-step reaction.

In group I introns, the attacking nucleophile in the first step is the 3′-OH group of an external guanosine (Fig. 1c). In the second step of splicing, the 5′-exon terminus attacks the 3′-scissile phosphate, which results in spliced exons and a linear intron with a 5′-terminal guanosine.

In group II introns, the attacking nucleophile in the first step is either the 2′-OH group of an adenosine located close to the intron terminus (Fig. 1d) or a water molecule (analogous to Fig. 1b). The second step is similar to that of group I introns and involves attack of the 5′-exon terminus on the 3′-splice site and ligation of the two exons.

Similarities to the eukaryotic spliceosome

In higher organisms, splicing is catalyzed by a ribonucleoprotein complex termed spliceosome. Several mechanistic and structural similarities suggest that the spliceosome may have derived from ancestral group II introns. Both group II introns and the spliceosome catalyze splicing in a two-step reaction that results in formation of excised lariat introns, and they share the same stereospecific preferences at the splice sites (vide infra). In both systems, the two splicing steps proceed through inversion at the scissile phosphates, which is consistent with an SN2 reaction mechanism (5). More strikingly, the highly conserved group II intron domain D5 has metal ion-binding properties and structural features similar to the stem loop of the spliceosomal small nuclear RNA U6. These similarities are so substantial that an isolated domain (D5) from a group II intron can functionally replace a subsection (U6) of the spliceosomal RNA in an in vivo assay (6). Group II introns are therefore considered a valuable model for studying functions related to the more complex spliceosome.

Protein assisted splicing

Group II introns are essentially unreactive under physiological salt conditions (vide infra). Therefore, splicing in vivo requires protein cofactors (7). Various proteins have been associated with splicing. These proteins can be roughly divided into three groups.
1. Intron encoded maturases. These proteins, which are normally encoded by an open reading frame (ORF) within the intron, bind specifically their own RNA and promote formation of critical tertiary contacts. In addition, most of these proteins have endonuclease and reverse-transcriptase domains, which allow intron mobility (i.e., retrotransposition and retrohomolog) by a mechanism termed targeted primed reverse transcription (TPRT) (vide infra).

2. Proteins recruited from the host. Many proteins have to the intron terminus. This reaction leads to a covalently linked branch point adenosine and formation of a new covalent link-age. To join the 5′-end of the 5′-oned 5′-exon (attacks in the first splicing step. In the branching pathway are two different pathways, which differ in the nucleophile that catalyzes self-splicing can proceed through

Reactions catalyzed by group II introns

Group II intron-catalyzed self-splicing can proceed through two different pathways, which differ in the nucleophile that attacks in the first splicing step. In the branching pathway (Fig. 2a), this nucleophile is the 2′-OH group of the branch point adenine, which is a bulged nucleotide located close to the intron terminus. This reaction leads to a covalently linked 2′,5′-branched intron structure with a lariat form. The second reaction step involves attack of the 3′-terminal OH-group of the cleaved 5′-exon on the 3′-splice site. The reaction products are the excised lariat intron and the ligated exons.

The alternative splicing mode is the hydrolytic pathway (Fig. 2b). As the name indicates, a water molecule is the nucleophile that attacks the 5′-splice site in this reaction mode, which generates a linear intron. The second splicing step is identical to that of the branching pathway.

It is remarkable that group II introns can also bind the spliced exons and use them as substrate for different reactions. The simplest of these reactions is the spliced exon reopening, which is an irreversible hydrolytic cleavage of the exons at the original splice site (Fig. 2c). A more interesting reaction is the complete reversal of both steps of splicing, which allow group II introns to reinvert themselves into the spliced exons (8). Reversal of the second step of splicing is an energetically neutral transesterification, which can be performed by linear and lariat introns. The situation is different for reversal of the first step of splicing, which has only been observed for the lariat intron. The lariat intron can reverse the first step of splicing by a second transesterification, which includes breaking of the 2′,5′-phosphodiester at the branch point adenosine and formation of a new covalent linkage with the 5′-exon. The linear intron cannot perform a second transesterification because it lacks the 2′,5′-phosphodiester linker.

Structure, Function, and Catalysis

1. Domain 1 (D1)

D1 is absolutely essential for catalytic activity. It provides a scaffold that helps the intron fold into the native tertiary structure. Several long-range interactions within D1, like the 3′-ε–1′-κ and the 3′-ω–ε–κ interactions, are part of a larger, functional substructure that also involves the II1 loop in the stem of D1. This substructure was named "3′-anchor" and is important for intron function because it positions the 5′-splice site near the bulge of D5. In all group II introns, D1 contains the exon-binding site EBS1; this site is a short sequence that base pairs with a complementary sequence termed intron binding site (IBS) located at the 3′-end of the 5′-exon. Group IIA and IIB introns have an additional second stretch of nucleotides (EB52) that interact with the 5′-exon. In addition, D1 contains a site termed EBS3 in group IIB and IIC and h in group IIA introns, which binds to the first nucleotide of the 3′-exon. The EBS1-IBS and, in group IIA introns, the h-ε–κ interactions are of fundamental importance for the introns as they allow recognition and binding of the exons and determination of the splice site.
Group II Introns: Structure, Function, and Catalysis

Figure 2  (a) In the branching pathway the phosphate at the 5′-splice is attacked by the 2′-OH group of the branch point adenosine. In the second step of splicing, the 3′-terminal OH-group of the 5′-exon attacks the phosphate at the intron 3′-exon junction, which results in spliced exons and excised lariat intron. (b) In the hydrolytic pathway, the first step nucleophile is a water molecule that cleaves the 5′-intron, which forms a linear intron. The second step of splicing is essentially the same as in the branching pathway. (c) Spliced exon reopening requires binding of the substrate. The substrate is then irreversibly cleaved by activation of a water molecule.

Domain 2 (D2)
In contrast to D1, D2 is not necessarily required for splicing, and most of this domain can be removed without severe effects on the catalytic activity. However, it stabilizes the tertiary structure by forming long-range interactions to D1 (θ–θ′) and D6 (η–η′).

Domain 3 (D3)
D3 functions as a catalytic effector that strongly enhances the chemical rate of catalysis. To date, the μ–μ′ interaction is the only identified tertiary interaction between D3 and D5.

Figure 3  All group II introns share a common secondary structure with six domains that radiate from a central wheel. Based on differences in some features, group II introns can be divided into subgroups IA, IB, and IC. Long-range tertiary interactions are indicated by greek letters. The folding control element is indicated. The catalytic triad in domain D5 is marked by a rectangle. The branch point adenosine in domain D6 is shown as a bold “A.” Exons are depicted as gray boxes and intron binding sites are indicated (adapted from Reference 20).
Domain 4 (D4)

D4 is not needed for splicing. In some introns, it contains an ORF encoding a maturase protein.

Domain 5 (D5)

D5 is a short stem-loop structure typically composed of 34 (group IIA and IIB) or 32 (group IIC) nucleotides with a conserved two-nucleotide bulge. It is the most conserved intronic domain and absolutely necessary for catalysis. It forms several contacts (i-ι', κ-κ', γ-γ') to D1 as well as a contact to D3 (ι-ι'). A very important feature of D5 is a highly conserved stretch of three consecutive nucleotides named the catalytic triad, which is located at the 5'-end of D5 and is absolutely required for catalysis. The sequence of the catalytic triad is AGC in group IIA and group IIB introns and CGC in group IIC introns. The catalytic triad and the nucleotides at the bulge form several direct contacts to divalent metal ions, which help to position them into the catalytic core.

Domain 6 (D6)

D6 is a hairpin structure that harbors the branch point adenosine, whose 2'-OH group acts as the nucleophile for the first step of splicing in the branching pathway. In addition, D6 contains an contact that forms the η-η' contact with D2. This element is a GWRA tetraloop-receptor interaction that is believed to mediate a conformational switch between the two steps of splicing.

J2/3 linker

Besides the six domains, the region joining domains D2 and D3 (J2/3) is particularly conserved and catalytically important. It forms the γ-γ' interaction, which joins J2/3 with the intron terminus and contains two consecutive nucleotides, GA, in group IIA and IIB introns and GC in group IIC introns, which are critical for intron function. Photocrosslinking studies have shown that J2/3 is located in the proximity of the catalytic triad in D5. A recent crystal structure confirms these findings and shows that J2/3 forms base triplets with the catalytic triad and the bulge of D5, which helps to bring together catalytically important residues of the intron (12).

Trans splicing constructs and kinetic investigations

In vitro kinetic assays are an important tool to study the catalytic mechanisms of ribozymes. Intron mutant and deletion constructs have been used in kinetic assays to study the role of particular nucleotides and to distinguish whether a mutation causes a defect in chemistry or binding of exonic substrate or intronic components.

A very interesting feature of group II introns is their modularity; the intronic domains can be provided separately to form a functional ribozyme (13). For example, the exD123 construct consists of a 5'-exon and D1, D2, and D3. This construct alone is inactive, but addition of the catalytically essential domain D5 in trans generates an active two-piece ribozyme that cleaves off the 5'-exon; it is therefore a mimic for the hydrolytic pathway of the first step of splicing. Similarly, an intron construct that consists of D5 and D6 (D56) can be combined with the exD123 construct to obtain a branching pathway mimic for the first step of splicing. To date, numerous other multipiece constructs have been successfully studied and some examples of naturally split group II introns have even been found plants (9). An important feature of trans splicing constructs in kinetic assays is that the individual constructs can be folded separately under appropriate conditions without reacting, and hence they allow the separation of folding from catalysis.

Group II introns are metal-dependent enzymes

Group II introns are metal-dependent enzymes that require Mg\(^{2+}\) for both folding and catalysis (14). Most group II introns are essentially unreactive at physiological salt concentrations. Hence, for in vitro experiments, nonphysiologically high salt concentrations, typically 500 mM of a monovalent and 100 mM Mg\(^{2+}\) are required to obtain optimal splicing conditions. In vivo, these high metal requirements are believed to be relieved by intron-encoded maturases and other cofactor proteins recruited from the host organism.

Metal ions have been localized by independent methods, which include phosphorothioate substitution (13), Tb\(^{3+}\) cleavage (14), X-ray crystallography (12), and NMR (15). Metal ion-induced metal contacts are provided by the phosphate backbone. Although the bridging phosphates are not chiral by chemical definition, the two nonbridging oxygen atoms are distinct in the tertiary structure. The nomenclature used to define these atoms is derived from phosphorothioate substitution experiments. Substitution of a single oxygen atom with sulfur at a bridging phosphate generates a chiral phosphorothioate diastereomer named as the Rp- and Sp-isomers according to the Cahn-Ingold-Prelog system. The nonbridging oxygens of a bridging phosphate can be identified accordingly as pro-S or pro-R oxygens.

Metal ions are required for folding

Studies with the group IIB intron ai5 from the mitochondrial genome of S. cerevisiae have suggested that group II introns fold slowly into the native state via an on-pathway intermediate (16). In contrast, most other ribozymes proceed along a "rugged" folding pathway with stable misfolded intermediates ("kinetic traps"). From the unfolded state, group II introns first fold slowly into a compact intermediate state and then, in a fast step, into the native state. At low Mg\(^{2+}\) concentrations, the introns can only reach the compact state, which was exploited to study this state in more detail. Using nucleotide analog interference mapping with compaction as the selection criterion, a small substructure in the heart of D1 was identified as a folding control element (Fig 2). This element must adopt the correct conformation before other tertiary contacts of D1 can be established, leading to a highly compact tertiary structure of D1. Once the D1 scaffold is formed, high Mg\(^{2+}\) concentrations or a cofactor can facilitate rapid docking of the other domains into their designated binding sites thus forming the native (i.e., catalytically active) ribozyme.
Figure 4 Chemical mechanism of group II intron splicing (branching pathway). The sequences and numbering are according to the ady intron from S. cerevisiae. The solid arrows between the panels mark the forward splicing direction, the dotted arrows the reverse splicing direction. (a) The first step is initiated by attack of the 2′-OH group of the branch point adenosine (A880) at the scissile phosphate as indicated by the arrow. The dotted lines indicate coordinative bonds to metal ions. Metal ion coordinations from the catalytic triad (A816-C818) and the bulge in DS (C837-C839) are indicated in this panel but omitted in the following panels for clarity. (b) In the transition state of the first step of splicing, the scissile phosphate is expected to have a trigonal bipyramidal arrangement. (c) In the splicing intermediate, the metal coordinated oxygen of the 5′-scissile phosphate has formally changed from pro-RP to pro-SP. The second step of splicing is initiated by attack of the 3′-terminal oxygen of the 5′-exon at the 3′-scissile phosphate as indicated by the solid arrow. The dotted arrow indicates the reverse splicing reaction. (d) The transition state of the second step of splicing is expected to have a trigonal bipyramidal arrangement at the scissile phosphate similar to the transition state of the first step of splicing. (e) Schematic of the products immediately after the second chemical step. This arrangement is also the initial configuration expected for the first step of reverse splicing as indicated by the dotted arrow.
Metal ions in the catalytic core

Many ribozymes and proteins that catalyze phosphoryl-transfer reactions use a mechanism employing two metal ions, and early on group II introns were hypothesized to use a similar mechanism (17). However, evidence for the existence of two metal ions in the catalytic core was only found very recently (12, 13, 18). A direct Mg$^{2+}$ coordination of the pro-S$_5$ oxygen of the first nucleotide of the catalytic triad is evident based on phosphorothioate substitution experiments (18). Recently, an intact group II was successfully crystallized for the first time (12). This structure confirms the metal contact from the first nucleotide of the catalytic triad and shows additional contacts to this metal ion from the second nucleotide of the catalytic triad and from the first nucleotide upstream of the bulge (Fig. 4a). This nucleotide is additionally coordinated to the second Mg$^{2+}$ ion in the core. The distance between the two Mg$^{2+}$ ions in the crystal structure is 3.9 Å, which is in agreement with the proposed two-metal-ion mechanism (17).

Because the data from phosphorothioate substitution experiments, which provide information about the metal binding situation before splicing, match the crystal structure that captures the situation after splicing, it may be concluded that the two metal ions are tightly bound in the catalytic center in an arrangement that remains essentially unchanged through both steps of splicing.

During splicing, the two metal ions form additional contacts to the substrate. Evidence from phosphorothioate substitution experiments are coordinative bonds to the pro-R$_5$ oxygens of the scissile phosphates at both splice sites and to the 3′-oxygen of the leaving groups in both steps of splicing (Fig. 4).

The chemical mechanism of group II intron splicing

The following paragraph will discuss the detailed chemical mechanisms of both steps of splicing by the branching pathway. Before the first chemical step of splicing takes place, the substrate is properly arranged in the catalytic core, which is mainly facilitated by the EBS-DSS and S-S interactions, and the metal ions are positioned as described above (Fig. 4a).

The first step of splicing

In the first step of splicing, the 2′-OH group of the branch point adenosine attacks the scissile phosphate at the designated 5′-splice site. It is not established how the nucleophile is activated; however, it is likely that the 2′-OH is coordinated to a metal ion in the core that could facilitate deprotonation (17).

Both steps of splicing are known to proceed with inversion at the scissile phosphates, which is consistent with an Sn2 substitution (5). In the transition state, the scissile phosphate is therefore expected to adopt a trigonal bipyramidal arrangement (Fig. 4b). Metal ion coordination to a nonbridging oxygen of this phosphate might help to compensate the emerging negative charge in the transition state. The leaving group (i.e., the 3′-oxygen of the 5′-exon) is likewise stabilized by metal ion coordination. In the resulting intermediate, the metal-ion coordinated oxygen atom of the 5′-splice site phosphate has formally changed from pro-R$_5$ to pro-S$_5$ because of the inversion (Fig. 4c).

The second step of splicing

The leaving group of the first step of splicing, which is the 3′-terminal OH group of the 5′-exon, becomes the attacking nucleophile in the second step of splicing. Metal coordination properties of the participating reaction centers are comparable to the first step. The pro-R$_5$ oxygen of the scissile phosphate, the 3′-oxygen of the 3′-terminal intron nucleotide (the leaving group) and the 3′-terminal nucleotide of the 5′-exon (the attacking nucleophile) are coordinated to divalent metal ions (Fig. 4c).

The transition state of the second step of splicing resembles that of the first step. The scissile phosphate adopts a trigonal bipyramidal arrangement and is stabilized by metal coordination to a non-bridging oxygen atom (Fig. 4d). The leaving group, i.e., the 3′-oxygen of the terminal intron nucleotide, is likewise stabilized by metal coordination. The resulting products are the lariat intron and the spliced exons (Fig. 4e). This arrangement is also the starting conformation for the reverse splicing reaction, which is indicated by dotted arrows in Fig. 4.

Future Research Topics

The story of group II introns is not at the end. The recent crystal structure of an intact group II intron will presumably lead to several follow-up studies. For example, it would be interesting to crystallize and compare group II introns from different subgroups or to capture different reaction states of the intron.

Group II introns naturally catalyze a broad range of reactions. The catalytic repertoire of other ribozymes was previously extended by in vitro evolution. It could be very exciting to apply this method to the versatile group II introns.

The ability to invade duplex DNA has led to useful technological applications. By manipulating the exon-binding sites in domain D1 of the intron, which recognize potential target sites, group II introns can be reprogrammed to attack a given sequence selectively. This method was used to develop group II introns into gene-targeting vectors ("targetrons") (19). Targetrons may have a great potential for medical applications. They could be used to knock out or to repair a malfunctioning gene of choice. A nother idea is to engineer the intron ORF in D4 to contain additional coding sequences; group II introns could then be used to introduce new genes into an organism.

Noncoding RNAs
Allison A. Henry and Jörg Vogel, Max Planck Institute for Infection Biology, Berlin, Germany
doi: 10.1002/9780470048672.wecb522

After decades of being either underestimated as a simple messenger in the expression of proteins from deoxyribonucleic acid (DNA), or revered as the molecule from which all life potentially originated, ribonucleic acid (RNA) is at last enjoying a well-deserved golden age as modern techniques allow researchers to uncover the myriad of subtle roles that this molecule plays in the cells of today. Noncoding RNAs, by definition, do not become translated into protein. This broad category includes cellular RNAs that range in size from 20 to 20,000 nucleotides, can contain chemical modifications, adopt a wide variety of secondary and tertiary structures, associate with proteins and other RNA molecules, and have physiological roles, in all organisms, that run the gamut from catalysis to regulating gene expression. As this article is intended to complement the other RNA-related sections of this volume, a brief introduction to all types of noncoding RNA will be followed by a comprehensive discussion of three important categories: riboswitches, small RNAs in bacteria, and large RNAs in mammals. Riboswitches are cis-acting RNA elements that modulate gene expression in a highly specialized manner by means of an aptamer domain, an RNA sequence that tightly and selectively binds a given metabolite. Small RNAs are 70–200 nucleotide molecules in bacteria that regulate gene expression, primarily at a posttranscriptional level. In mammalian cells, large RNAs of up to 19,000 nucleotides are essential to X-chromosome inactivation and genomic imprinting.

To a chemist, who is accustomed to thinking about the enormous diversity of structures and functions to be found in small molecules, ribonucleic acid (RNA) may seem humdrum. It is, after all, a polymer composed of only four subunits, which comprise a ribose ring and a purine or pyrimidine, that are linked together by phosphodiester bonds. From a simple-minded perspective, RNA has fivefold fewer types of functionality than proteins, which are made up of 20 different residues; in fact, RNA is similar in composition to deoxyribonucleic acid (DNA), the preferred molecule of genetic information storage that does not have a reputation for carrying out interesting chemistry inside the cell. Such an observer would likely be content with the notion that the roles of RNA are limited to coding for proteins and serving as viral genomes, in accordance with the biological dogma that existed until about three decades ago. Since then, new technologies have enabled significant progress in our understanding of the diversity of structures and functions of RNA molecules that exist in the cells of all organisms. Concomitant with our discovery and characterization of new RNA molecules, the nomenclature in the field has expanded, and for the sake of clarity, we risk stating the obvious: RNA that codes for protein is referred to as messenger RNA (mRNA) and all others are noncoding RNAs, by definition. Three categories of noncoding RNA, riboswitches, regulatory small RNAs in bacteria (sRNAs), and large noncoding RNAs in mammals, will be discussed in some detail in this article, but first a summary of the features and functional repertoire of noncoding RNAs in general is presented.

Sizing Up Cellular Noncoding RNAs
Noncoding RNAs populate virtually all polymer lengths between 20 and 20,000 nucleotides and are found in viruses, prokaryotic cells, and eukaryotic cells (Table 1). After they become transcribed, these molecules can be cleaved and chemically modified. As many as 100 potentially functionally meaningful nucleotide modifications have been reported, including nucleobase and sugar methylations, the substitution of sulfur for oxygen, C-glycosidic linkages like the one in pseudouridine, and even condensation products of amino acids and nucleobase exocyclic amino groups (1–3). However, most types of RNA

2RNA component of ribonucleoprotein complex; in order of appearance in the text.
3Approximate.
4Specifically, in the organelles of eukaryotic cells.
5Although biologists are used to thinking about tRNA, rRNA, and noncoding RNA as altogether different classes of RNA, for historical reasons, tRNA and rRNA are named here as types of noncoding RNA because they do not contain open reading frames that encode proteins.
6Isolated example of cis-acting elements in eukaryotic mRNAs have been reported, but this type of regulatory mechanism appears to be broadly used only by bacteria.
7Excluding internal open reading frames.
Noncoding RNAs

with the notable exception of transfer RNA (tRNA), are not heavily modified. In keeping with such complexity in primary structure, RNA is known to adopt an impressive array of secondary and tertiary structures, and many of these have been elucidated by molecular modeling, biochemical structure determination, and spectroscopic and crystallographic techniques. Two common RNA secondary structure motifs are the helix, defined as two or more consecutive GC, AU, or GU (canonical) pairs, and the loop, defined as a region in which the nucleotides do not form canonical pairs. Loop structures are further categorized as hairpin, bulge,内部branch, or pseudoknot (4). Beyond Watson–Crick base pairing, ribonucleotides also interact with one another by means of their Hoogsteen and sugar-edge surfaces, and combinations of such pairs as these define specific RNA motifs (5). RNA motifs mediate not only tertiary RNA–RNA contacts, but also quaternary RNA–protein interactions. It should be noted here that, without exception, RNAs within the cell are associated with proteins; however, in the interest of brevity, the discussion below will be limited primarily to the RNA component of each ribonucleoprotein.

Maintenance of Telomeric DNA

Telomerase is a ribonucleoprotein complex that exists in eukaryotic cells for the apparently sole purpose of synthesizing telomeric DNA, which consists of tandemly repeated sequences that contain clusters of G-residues and forms the ends of chromosomes. Telomerase comprises two essential core components, a protein subunit that has reverse transcriptase (RT) activity and an RNA sequence (hTR) that contains clusters of G-residues and serves as the template substrate for the RT (6). The template RNA and its G-rich RNA annex to form a partial duplex with DNA as the primer. RT-mediated polymerization of dGTP and other complementary triphosphate substrates produces a DNA terminus that has been extended by around six nucleotides. The new end can become a substrate for either another round of telomerase-mediated elongation or primase/polymerase-mediated ligation-synthetic synthesis.

Processing of RNA

RNA molecules that catalyze RNA strand scission and RNA ligation form one class of ribozymes, or RNA-based enzymes. Well-characterized examples of naturally occurring ribozymes include the RNA moiety of ribonuclease P (M1 in bacteria, H1 in mammals) (7), group I introns (8), group II introns (9, 10), and the hepatitis delta virus (11), hairpin (12), and hammerhead ribozymes (13). Other classes of noncoding RNA that either guide or participate directly in the cleavage, ligation, or chemical modification of various RNA molecules have emerged more recently. Small nuclear RNA (snRNA) is known for its nucleus of eukaryotic cells, and as a component of the spliceosome, which, in conjunction with 5m proteins, processes pre-mRNA and prepares it for export to the cytoplasm (14). Small nuclear RNA (snRNA), comprising many distinct individuals, and small Cajal body-specific RNA (scRNA) are also responsible for processing RNA in eukaryotic cells. snRNAs reside in the nucleolus and guide the cleavage and chemical modification, including sugar methylation and pseudouridylation, reactions that are necessary for large and small ribosomal RNA subunit assembly and export to the cytoplasm (15). Certain snRNAs are similarly acted upon by snoRNAs (16). snoRNAs are localized to foci in the nucleoplasm, known as Cajal bodies, and are involved in the chemical modification of most snRNAs that are transcribed by RNA polymerase II (17). Finally, the guide RNAs (gRNAs) that are found in bysynosome protists direct the site-specific insertion and deletion of uridines in mRNA sequences, a phenomenon referred to as editing (18).

Synthesis and Trafficking of Protein

Ribosomal RNA (rRNA) was long thought to play a passive, structural role in protein synthesis, but it is now known to also be a ribozyme that catalyzes peptide bond formation (19). The newest form of noncoding RNA that participates directly in protein synthesis is rRNA, the so-called adapter molecule found in all organisms that contains both the anticodon RNA sequence and its cognate amino acid residue as a chemically activated aminoacyl–methyl (20). Two housekeeping RNAs, tmRNA (21) and 4.5 S RNA (22), a component of the signal recognition particle, function to maintain the competence of the ribosome and to ensure the secretion of certain proteins, respectively.

RNA Interference

RNA interference, a mechanism of gene silencing in eukaryotic cells that relies on very short sequences of single-stranded RNA, is arguably the one area of recent noncoding RNA research that has come most to fruition. Small interfering RNAs (siRNAs), microRNAs (miRNAs), repeat-associated small interfering RNAs (rasiRNAs), and tiny-noncoding RNAs (tnRNAs) are short RNA molecules, approximately 22 nucleotides, that have been best characterized in the nematode, C. elegans (23, 24), but also studied in mammals, fish, insects, and plants. The genes that encode siRNAs and miRNAs are transcribed into double-stranded (dsRNA) or short hairpin primary (pri-mRNA) RNAs, respectively. Whereas dsRNA is exported directly to the cytoplasm, pri-mRNA is initially processed to pre-miRNA at rRNAase III-like endonuclease, Drosha, in the nucleus. In the cytoplasm, dsRNA and pre-miRNA are acted upon by the RNase III-like endonuclease, Dicer, to yield short dsRNA molecules with 2-nucleotide 3′ overhangs and 5′ phosphates that are known as siRNAs. In both cases, one strand of siRNA goes on to form a complex with a member of the Argonaute family of proteins, where it acts as a guide in binding to the miRNA target. This ribonucleoprotein complex is referred to as RISC in the siRNA pathway and miRNP in the miRNA pathway. The single-stranded siRNA then binds to its miRNA target by means of perfect (siRNA) or partial (miRNA) complementarity, and it brings about translational repression that may or may not be accompanied by protein-mediated endonucleolytic cleavage of the miRNA target. The newest class of these small mammalian RNAs, Piwi-interacting RNAs (piRNAs), was named for the interaction of its members with Piwi proteins, a subgroup of the Argonaute family (25, 26). Piwi proteins play a role in cell differentiation, and preliminary evidence suggests that piRNAs act as antagonists of their functions.
Riboswitches

RNA sequences that tightly and selectively bind to a molecule of choice, small or large, can be engineered with relative ease; they are referred to as aptamers. For example, in vitro selections have enabled the isolation of RNA sequences that bind to biologically interesting molecules like nucleotides (27), coenzymes (28), amino acids (29), sugars (30), and many others (31). In light of this observation, it is perhaps not surprising that this intrinsic property of RNA is also exploited by nature for the purpose of regulating gene expression with the utmost economy. Riboswitches are cis-acting regulatory RNAs that are found in the 5' untranslated region (5' UTR) of some mRNA molecules and are able to modulate gene expression in response to small molecule metabolites by means of their aptamer and expression platform domains (32). The structures of the domains are coupled in such a way that binding of the ligand directly changes the efficiency of transcription or translation of the mRNA, allowing the cell to circumvent the need for a protein-based metabolite sensor (33). Metabolite-responsive riboswitches represent one type of cis-acting regulatory RNA. Other types respond to temperature, protein ligands, and RNA ligands. Although these types will not be further discussed, recent reports regarding their structure and function are recommended to the reader (34–38).

The nature of the expression platform domain of the riboswitch, and the way in which its structure is coupled to the aptamer domain, in the presence and absence of ligand, dictates whether the riboswitch will affect the extent of transcription or the extent of translation of the mRNA of which it is part (39). Illustrative examples are given below for both transcription-based and translation-based mechanisms. Other less general riboswitch strategies have been reported, including RNA splicing (40, 41), self-cleavage (30), antisense (42), a potential role for RNase P (43), and ribosome-mediated attenuation (44), but these strategies will not be discussed further.

Transcription Effects

Genes are encoded by DNA and become transcribed into RNA through the work of RNA polymerases. This process has three distinct phases: initiation, elongation, and termination (45). On average, elongation in bacteria is highly processive, with about 50 nucleotides per second being incorporated over the length of the transcription unit; however, there do exist natural pauses 50 nucleotides per second being incorporated over the length average, elongation in bacteria is highly processive, with about distinct phases: initiation, elongation, and termination (45). On through the work of RNA polymerases. This process has three genes are encoded by DNA and become transcribed into RNA secondary structure formation occurs when the RNA segment favors a conformation in which an antiterminator (AT), rather than a terminator (T), is present and polymerase-mediated transcription proceeds. In the case of negative regulation, which is not depicted, the presence of ligand (L) causes the RNA segment to favor a conformation in which a terminator (T), rather than an antiterminator (AT), is present, halting polymerase-mediated transcription. The filled bars serve only as orientation guides and do not imply a certain extent of complementarity or stability within the hairpins.

Figure 1 Representation of transcriptional regulation by the binding of a ligand to a cis-regulatory element of nascent mRNA. Depicted is positive regulation: In the presence of ligand (L), the RNA segment favors a conformation in which an antiterminator (AT), rather than a terminator (T), is present and polymerase-mediated transcription proceeds. In the case of negative regulation, which is not depicted, the presence of ligand (L) causes the RNA segment to favor a conformation in which a terminator (T), rather than an antiterminator (AT), is present, halting polymerase-mediated transcription. The filled bars serve only as orientation guides and do not imply a certain extent of complementarity or stability within the hairpins.
in a fully bound state and, importantly, glycine binding is cooperative: the binding affinity of the second glycine is 100- to 1000-fold greater than that of the first glycine. This cooperativity of ligand binding, common in protein molecules, has the effect of increasing the sensitivity of the guanine riboswitch, allowing dramatic changes in transcription to take place in response to small changes in the concentration of guanine. It was suggested that this mechanism, found in the same study to also exist in the putative sodium and alanine sminporter encoded by the V. cholerae, evolved to ensure that excess glycine is efficiently used as an energy source.

Riboswitches negatively regulate gene expression if binding of the metabolite to the aptamer domain results in the formation of a terminator in the expression platform. Examples of riboswitches that conform to this mechanism are more numerous, as are associated structural studies. High resolution crystal structures exist for the liganded forms of both the 68 nucleotide aptamer domain of the guanine-sensing pur riboswitch of B. subtilis and the 5′-adenosylmethionine (SAM)-sensing riboswitch from T. tengcongensis (48, 49). In the G-riboswitch structure, the ligand is stacked within a five-tiered arrangement of base triples, and it participates in eight direct H-bonding interactions with four aptamer nucleotides; three H-bonds represent a canonical Watson-Crick base pair between guanine and a C nucleotide, determining specificity of the riboswitch; three H-bonds are formed between the minor groove heterocatoms of guanine and the Watson-Crick base edge of a U nucleotide; the two remaining H-bonds involve the minor groove oxygen and 2′ OH of two independent U nucleotides. In the SAM-riboswitch structure, the ligand adopts a compact conformation that enables both the formation of a cation-pi interaction between its main chain amino group and adenine moiety, and the possibility of participating in two distinct sets of aptamer interactions: the side of the ligand that presents the Watson-Crick face of adenine and the main chain atoms of methionine is engaged in H-bonding and stacking interactions with one helix while the ribose ring and side chain of SAM have favorable van der Waals interactions with a different helix. Despite their differences in ligand binding, the two riboswitches share a remarkably similar overall structure in which a key helix, the P1 helix, is formed as part of either a three-helix-turning-fork-type structure (G-riboswitch) or a four-way junction structure (SAM-riboswitch). In the presence of the cognate metabolite, each structure stabilizes an adjacent terminator helix and prevents transcription of the downstream genes. In the absence of the cognate metabolite, the P1 helix and the terminator dissociate, allowing the nucleotides that otherwise form the 3′ side of the P1 helix to form an anti- terminator helix with the nucleotides that otherwise form the 5′ side of the terminator. This mechanism is thought to be shared by other riboswitches that operate at the level of transcription, such as the FMN-responsive riboswitch that negatively regulates expression of the ribDEAHt operon in B. subtilis (50) and the divergent magnesium-sensing riboswitch that negatively regulates mpt expression in S. typhimurium (51).

**Translation Effects**

Protein biosynthesis in prokaryotes also proceeds through distinct phases known as initiation, elongation, and termination, which are not to be confused with the phases of transcription (see above). Initiation is characterized by the assembly of the small subunit (30S, comprising 21 proteins and the 1500 nucleotide 16 S rRNA) and the large subunit (50S, composed of 34 proteins, the 120 nucleotide 5S rRNA, and the 2900 nucleotide 23S rRNA) of the ribosome, together with the initiator tRNA that is charged with N-formylmethionine, on the 30 nucleotide ribosome-binding site (RBS) of a given mRNA (52). The RBS, located within the 5′ UTR of the transcript, has several important features that are common among most mRNAs. From 5′ to 3′, there is a pyrimidine-rich region that interacts with ribosomal protein S1; the Shine-Dalgarno (SD) sequence, typically GGAGG, forms base pairs with the 16 S rRNA; the initiation codon is AUG in the majority of cases, and UUG or UUA in a few cases; finally, there is a downstream box (DB) that also forms base pairs with the 16 S rRNA. Therefore, the precise sequence and structure of the mRNA are of paramount importance to the efficiency with which it becomes translated into protein. Many riboswitches regulate gene expression at the stage of translation initiation. Their mechanisms are analogous to riboswitch regulation at the transcriptional level, described above, except that ligand binding results in the formation of a structure that either sequesters or liberates the RBS.

A tautomeric structure of the liganded forms of both the 71 nucleotide adenine-sensing aptamer domain of the add riboswitch in V. vulnificus, an example of positive translational regulation, were recently solved. The structure of the A-riboswitch is very similar to that of the G-riboswitch, described above, except that the specificity-determining pyrimidine is a U rather than a C, and that the tuning fork structure containing the P1 helix coexists with a single-stranded downstream region in which the RBS is available to bind the 30S subunit of the ribosome (48). In this case, the expression of adenine deaminase is increased in the presence of adenine. In contrast, translation of this mRNA is reduced in the presence of TPP, and this negative regulatory mechanism is also made clear by inspection of the X-ray crystal structure (53). In the complex, TPP adopts an extended conformation in which it acts as a bridge between two parallel helical domains that are connected to the P1 helix by means of a three-way junction. The 4-amino-5-hydroxymethyl-2-methylpyrimidine moiety of the ligand engages in interaction with the P1 helix and base stacking, and base triple formation with one helical domain while the pyrophosphate group is bound to the other helical domain by H-bonding and electrostatic interactions that are mediated by two hexacoordinated divalent magnesium ions. The P1 helix stabilizes a downstream hairpin in which the SD sequence and start codon of thiM are sequestered, precluding translation initiation. It is likely that similar structures play a role in the negative translational regulation of yjaa in B. subtilis by a flavin mononucleotide (FMN)-responsive riboswitch (50), and that of bsbA in E. coli by a coenzyme B12-responsive riboswitch (54).
Chromosomally Encoded Regulatory sRNAs in Bacteria

sRNAs that regulate gene expression in bacteria are a newly identified class of noncoding RNAs. These molecules are commonly 70-200 nucleotides in length and are found encoded within the chromosome in either a cis (antisense) or trans location relative to their target protein-coding genes. Although sRNAs can influence gene expression by interacting with protein targets, most of the individuals that have been characterized thus far act by means of either extensive or limited base pairing with mRNA targets. This class of regulators was discovered long ago in the plasmids harbored by enterobacteria, in bacteriophage, and in transposons; all of these are cis-encoded antisense RNAs that exploit their perfect complementarity to bind to the cognate transcript, which encodes a replication factor, toxin, or transposase, to name a few, and bring about transcription attenuation, mRNA degradation, or inhibition of translation (55). Within the past 5 years, much more extensive work has been done to identify and characterize sRNAs that are encoded within the genomes of bacteria. The history of our knowledge of such sRNAs has been described as a chronology with two distinct periods: the classic and the modern (56). In the classic age, about 12 novel RNA molecules were discovered, either intentionally by means of metabolic labeling or serendipitously. In the modern age, which began in 2001, the existence of new information, generated by new technology, prompted eight research groups to carry out comprehensive, systematic searches for more sRNAs (57-64). Both computational methods and direct experimental detection were used, and these contributions increased the number of confirmed chromosomally encoded sRNAs in E. coli to about 70 (65). Although characterization of the physiological roles and mechanisms of action of these sRNAs in E. coli has not been fully reported (65-64), the following summary of the work done so far illustrates that their expression patterns and functions are too diverse to be generalized.

Regulation of sRNAs

It is known that the steady-state level of many sRNAs depends on the phase of growth or environmental conditions of the cell, and obviously the concentration of the sRNA at any given time represents a sum of its expression, processing, and degradation. With respect to expression, some regulatory mechanisms have been solved. RpoS sRNA is positively regulated by the CpxR-CpxB phosphorelay system (66). OxyS sRNA is induced in the presence of hydrogen peroxide by the transcriptional regulator, OxyR (67). isiR-2 sRNA is encoded adjacent to a LexA site, and its expression is induced by treating cells with the DNA-damaging agent, mitomycin C (68). RhlB sRNA is encoded adjacent to a Fur protein-binding site, and its expression is induced in response to iron depletion (69). OmrA (RygA), OmrB (RygB), and MicF sRNAs are regulated in part by the EnvZ-OmpR two-component system, which responds to changes in osmolarity (70). Apparently, many sRNAs are present in the cell in more than one length; for example, GadY was shown to exist simultaneously as 105, 90, and 59 nucleotide-RNA molecules (71). However, the details of sRNA biogenesis regarding active and inactive forms and the existence or extent of chemical modification are not well understood. Finally, the half-lives of sRNAs differ significantly from one to the next (61). As the protein factors that are known to play a role in the degradation of some sRNAs tend to be the same as those that are involved in the sRNA-mediated regulation of gene expression, they are described in the following section.

Regulation by sRNAs: RNA–RNA Interaction

Posttranscriptional regulation of gene expression can be achieved by base pairing interactions between sRNAs and their target mRNAs. It is important to note that the two sequences need not be perfectly complementary over a long patch; in fact, relatively short regions of complementarity interrupted by mismatches, small loops, or longer intervening sequences are the norm. The sRNA–mRNA binding event has been shown to result in a variety of outcomes, including mRNA accumulation, activation of translation, repression of translation, and mRNA degradation. Thus far, the involvement in these processes of three main proteins has been demonstrated, although the extent and nature of their roles cannot be generalized. First, the Sm-like host factor for Qp (Hfq) is an RNA-binding protein. It has been shown to have a high binding affinity for more than one third of the 70 known sRNAs, and to increase the half-lives and steady-state levels of certain sRNAs (72). Moreover, multiple studies have shown that it enhances interaction between sRNAs and their target mRNAs (73-75). Structural studies of Hfq have contributed to the development of a model in which the protein binds to relatively structureless A/U-rich segments of an RNA molecule that are in the vicinity of highly structured regions, and that the binding event has long-range effects on these secondary structures that allow intermolecular RNA–RNA interactions to take place (73, 76). Second, Rnase E is a hydrolytic endonuclease that cleaves single-stranded RNA (77). It has been shown to catalyze the degradation of certain sRNAs and their target mRNAs, some examples of which are given below. Whereas its N-terminal catalytic domain acts to cleave RNA, the well-conserved across species, the C-terminal domain of Rnase E is neither generally structured nor conserved, consisting rather of 15-40 amino acid stretches, referred to as microdomains, that bind to known protein partners like RhlB, enolase, and PNPase, components of the degradosome, but may also interact with other protein and RNA factors or enable self-assembly (78). For example, Hfq itself has been shown to interact with the C-terminal exonuclease (79). Third, Rnase III is a hydrolytic endonuclease that cleaves double-stranded RNA (80). It has also been shown to catalyze the degradation of certain sRNAs and their target mRNAs, some examples of which are given below. An sRNA can increase expression of its target gene, an outcome that appears to be relatively rare, by increasing the amount of target mRNA, increasing the efficiency with which it becomes translated into protein, or doing both. The cis-encoded antisense sRNA, GadY, was recently shown to increase the level of gadX mRNA in E. coli by means of perfectly complementary base pairing interactions involving the 3′ UTRs of both RNAs (71). The increase in gadX mRNA, which encodes a transcriptional
regulator of acid resistance genes, eventually results in an increase in the levels of two glutamate dehydrogenases, GadA and GadB. Examples of sRNAs that make use of a translational activation mechanism are also few; however, DsrA (85 nucleotides) and RpaA (105 nucleotides) are two sRNAs that act to positively and nonredundantly regulate the translation of rpsO mRNA into its product, the stationary phase sigma transcription factor, in E. coli (66, 83). In the absence of DsrA and RpaA, the intramolecular hairpin structure adopted by the unusually long (567 nucleotides) 5’ UTR of rpsO mRNA sequences its RBS, precluding translation initiation. When present, DsrA and RpaA form base pairs with the upstream region of the 5’ UTR of rpsO mRNA, competing with interactions it otherwise engages in with the downstream region of the 5’ UTR and liberating the RBS. Both DsrA-mediated and RpaA-mediated translational regulation of rpsO mRNA are Hfq-dependent (82).

In most cases described to date, base pairing of an sRNA to its target mRNA results in a negative effect on gene expression. By analogy to positive sRNA-mediated gene regulation, the RNA regulator can achieve its negative effect by decreasing the amount of target mRNA or, decreasing the efficiency with which it becomes translated into protein, or doing both. The strategy in which an sRNA represses translation by directly binding to the RBS of its target mRNA, in an Hfq-dependent manner, is highly represented in the regulation of expression of outer membrane proteins (Omp) in E. coli. ompC, ompF, andompA are selectively regulated in this way by MicC, MicF, and MicA sRNAs, respectively (83-86). Other sRNAs have been shown to bring about target mRNA cleavage by means of Hfq and RNase E. For example, RyhB sRNA leads to the degradation of sodB (encodes iron-containing superoxide dismutase) and sdiA (encodes iron-containing succinate dehydrogenase) mRNAs under iron-depleted conditions, and Sgrs sRNA leads to the degradation of ptsG mRNA, which encodes a major glucose transporter, under sugar phosphate stress (69, 87, 88). Two important aspects of this mechanism have recently come to light. First, the C-terminal domain of Rnase E interacts with Hfq, and a ribonucleoprotein complex composed of these two proteins and an sRNA is sufficient to bring about specific mRNA degradation (79). Second, although target cleavage often accompanies sRNA-mediated translational repression, making the effect irreversible, it may not be necessary to achieve the desired regulatory effect (89). In some cases, degradation of target mRNA in the presence of an sRNA has been shown to depend on Rnase III rather than Rnase E. For example, IsrR-1 sRNA and tisAB mRNA, which encodes a toxic peptide that is in-encoded with respect to its target, isrA, in the cyanobacterium, Synechocystis sp. PCC 6803 (90). The common feature shared by the IsrR-1/tisAB and IsrR/risA regulatory systems is a high degree of complementarity between the sRNA and its target mRNA, which likely enables the formation of a double-stranded RNA structure that is recognized as a substrate by RNase III.

### Regulation by sRNAs: RNA-Protein Interaction

Although the majority of chromosomally encoded regulatory sRNAs in bacteria, whose functions have been described, work by base pairing directly to an RNA target, there are also cases in which sRNAs have been shown to bind to a protein target to change the expression of genes at either the transcriptional or the posttranscriptional level. For example, 6S sRNA is known to impact global partitioning of transcription by directly interacting with a transcription factor. After becoming transcribed, together with an open reading frame as a dicistronic unit, and processed, to a 184 nucleotide sRNA, 6S goes on to tightly and specifically bind RpsD protein (91). RpsD, also known as σ70, is the vegetative transcription factor that directs RNA polymerase to transcribe the subset of genes that ought to be expressed under normal conditions. By folding into a long hairpin with a central internal loop that very much resembles an open promoter of DNA, 6S RNA is thought to compete with actual promoter DNA for the nucleic acid-binding site of RpsD, which in turn allows other regulators that use alternative sigma factors to become more expressed. A further testament to the versatility of sRNAs in bacteria is the paradigmatic CsrA protein/CsrB RNA system of posttranscriptional regulation. CsrA is a posttranscriptional regulator that binds to mRNAs, which code for a diverse set of proteins but share a conserved core sequence that the protein recognizes. By changing the stability or efficiency of translation of its targets, CsrA can have either positive or negative effects on their expression (92). CsrB and CsrC are sRNAs, 360 and 245 nucleotides in length, respectively, that bind CsrA by means of repeated hairpins that terminate in loops composed of the same conserved core sequence found in the mRNA targets of CsrA (93, 94). Whereas CsrB and CsrC comprise 18 and 9 such loops, respectively, the mRNA targets of CsrA have only one to three per molecule. In binding CsrA, CsrB and CsrC antagonize the numerous and diverse effects that this protein otherwise has as a posttranscriptional regulator.

### Large Noncoding RNAs and Mammalian X-Chromosome Inactivation

X-chromosome inactivation (XCI) is the process by which female mammalian cells, early in development, silence nearly all of the genes on all but one X-chromosome to achieve dosage parity between the sexes (95). Four distinct processes are associated with XCI: X-chromosome counting, chromosome choice, initiation and propagation of silencing, and maintenance of heterochromatin. All of these events are regulated by an 80-450-kb X-linked locus called the X-inactivation center (Xic). Interestingly, this locus can be described as having a death
The first large noncoding RNA gene of the Xic to be identified was Xist (98). In mice, it encodes a 17.4-kb untranslated RNA that is essential for XCI. Xist is expressed from the inactive X-chromosome and interacts physically with it, cis, via chromatin and the nuclear matrix, "coating" the chromosome. According to the current model, two conserved sequences in Xist, Repeat A and Repeat C, affect transcription from both the Xist promoter and promoters subject to XCI and recruit specific silencing proteins to the Xic, respectively. Likely protein partners in this process are enzymes that methylate or ubiquitylate chromatin. As Xist is transcribed, a process that could last up to 30 minutes, it spreads along the silenced chromosome and is thought to propagate these transcriptional and protein-recruiting effects as it goes. Xist is repressed by the antisense large noncoding RNA, Tsix (98). Before silencing, Tsix and Xist are both expressed, with Tsix being present in excess, from both the X chromosome to remain active and the X chromosome to be silenced. Once chromosomal choice has occurred, Xist is only expressed on the active X-chromosome until the process of XCI has ended. Tsix is encoded antisense to Xist, its transcription start site is downstream of Xist, and its function requires that it be transcribed to at least within the Xist gene. The persistence of Tsix is aided by another large noncoding RNA, Xite (X-inactivation intergenic transcription elements), which has multiple start sites clustered in two regions upstream of Tsix (98).

Although it is not yet known exactly how these and other large noncoding RNAs help to regulate XCI, and the related process of genomic imprinting, their mechanisms are likely to be complex. It is interesting to speculate that this particular physiological role is ideally suited to RNAs rather than proteins. That is, because protein-coding RNAs are transported to the cytoplasm for translation, their protein products are not usually traceable to the chromosome of origin of their corresponding transcript. Differently, noncoding RNAs remain in the nucleus to achieve the ends for which they evolved.

mRNA Untranslated Regions (UTRs)
Molecules composed of RNA perform many roles that are vital for the life and reproduction of all cellular organisms and viruses, one of which is the role of messengers that carry from genes the information required for the production of protein. A typical feature of messenger RNA (mRNA) is its relative instability, which ensures that the production of any particular protein soon comes to an end when it is no longer required and synthesis of the message is downregulated. Moreover, while a transcript is being produced, its rate of decay is as important as its rate of synthesis in determining its cellular concentration and thus, to a large extent, its level of function. The turnover of mRNA, and indeed all other types of RNA, is mediated by multiple ribonucleases. The activity of these enzymes in cells can be inhibited rapidly by chemical treatments; thus, for many experimental systems their presence does not pose a significant barrier to the study of gene regulation at the RNA level. However, the development of RNA-based therapeutics such as small interfering RNAs and aptamers has required the introduction of modifications to prevent their degradation by ribonucleases within the cells and body fluids of humans. This article describes the properties of RNA that make it susceptible to ribonucleases and the techniques used to determine the stability of RNA molecules. It also provides examples of how RNA stability in living cells is being modulated for biotechnology and clinical applications, and it reviews the strategies that are being adopted to increase the in vivo stability of RNAs with therapeutic potential.

The information encoded in the genomes of all forms of life is transmitted via mRNAs (L. 2) to the ribosomes, which are the macromolecular machines that produce proteins through a process called translation (see the WECB review on translation: topics in chemical biology). The mRNAs in effect are copies of the genes, the units of heredity within the genetic blueprint, hence the initial description of these intermediates as DNA-like RNA (3). The process of copying the information from a gene into an RNA is called transcription; (4–6) (see also the WECB reviews on the RNA polymerase, chemistry of and the Transcription, Initiation of.). In general, genes are transcribed only when their products are required (see also the WECB reviews on transcription factors and transcription, activators and repressors of). Moreover, most mRNAs are turned over at a high rate relative to the time required to generate new cells. This instability ensures that protein production comes to an end soon after the transcription of the corresponding gene ceases. Moreover, while a transcript is being produced, its cellular concentration, which in large measure can determine its level of function (e.g., the amount of protein produced by the translation of mRNA), is critically dependent on its rate of decay as well as its rate of synthesis. Thus, the instability of RNA is central to the control of gene expression (Fig. 1). The turnover of mRNA, and indeed all other types of RNA, is mediated by exoribonucleases (7–9), which seem to function in close concert with endoribonucleases in all eubacteria studied to date (10–12) as well as chloroplasts (13).
RNA Stability, Chemistry, Measurement and Modulation of

The details of the nucleases and mechanisms that facilitate the decay and processing of intracellular RNA in bacteria (10-12, 14), organelles (13, 15), plants (16), as well as yeast and animals (17-20) are not covered here because excellent, up-to-date reviews are available (see also the WECB review on the mRNA localization and mRNA levels, control of).

Molecules composed of RNA are integral components also of the ribosome, whereas others are involved in the transfer of amino acids to growing polypeptide chains through a process that is mediated by the base pairing of the transfer RNAs (tRNAs) with codons in the mRNA. The ribosomal RNAs are bound by numerous proteins, whereas the transfer RNAs fold into compact tertiary structures (21, 22). Consequently, these RNAs in their mature form are less accessible than most mRNAs to nucleases and have longer half-lives (23, 24). The latter makes biological sense because it would be wasteful to turnover rapidly RNA components of an apparatus that is essential for growth no matter the physiology of the organism.

Determining the Rates of RNA Turnover

The value that is used universally to record and compare the rate of decay of cellular RNA species is the “half-life,” the time required for the initial recorded level of an RNA to be reduced by half. The typical half-lives of mRNA in the bacterium Escherichia coli tend to be on the order of a few minutes (25, 26), whereas in the yeast Saccharomyces cerevisiae it is not uncommon for half-lives to be measured in hours (27). In plants and mammalian cells, the values of half-life range from less than 1 hour to days, with the average being several hours (28-30).

Inhibiting transcription

In the study of eubacterial RNAs, half-life values are obtained most commonly by measuring RNA levels after blocking transcription via the addition of rifampicin, a semisynthetic antibiotic that binds and inhibits the endogenous RNA polymerase 

After blocking transcription, RNA samples are collected at different time points and immediately frozen in liquid nitrogen (39) or mixed with an agent that rapidly permeates cells and inactivates enzymes, thereby stopping RNA turnover. Traditionally, phenol has been used as a chemical-halting agent, but now available is a proprietary agent called RNA later (Ambion, Inc., Austin, TX), which is aqueous and nontoxic and stabilizes RNA in a range of bacterial species as well as eukaryotic cells and tissues (40). Cells then are disrupted by mechanical, chemical, or enzymatic means, and the RNA is isolated; the precise procedures depend on the source of the biological material (41, 42).

Determining the relative levels of transcripts at different time points

The abundance of particular RNAs in samples taken at different time points can be determined by using relatively straightforward techniques, such as Northern blotting, nuclease protection, and primer extension assays (Fig. 2). A laboratory manual that describes these techniques in detail is available (43); thus, only a brief overview is provided here. Northern blotting (Fig. 2A) involves separating RNA molecules on the basis of their size by using denaturing gel electrophoresis, blotting the RNA to a membrane support, and probing for a specific transcript using a complementary nucleic acid that is labeled. In nuclease protection assays (Fig. 2B), a labeled, single-stranded nucleic acid that is complementary to a specific transcript is mixed with a sample of RNA and the two are allowed time to hybridize before the excess (unprotected) probe is removed by incubating it with a nuclease such as S1 that can cut single-stranded, but not double-stranded, nucleic acid. The amount of RNA in the sample then can be inferred from the amount of labeled probe that remains. Primer extension assays (Fig. 2C) involve incubating an RNA sample with a labeled oligonucleotide that is complementary to a particular transcript. When annealed to its target, the oligonucleotide serves as a primer that can be extended by an RNA-dependent DNA polymerase called reverse transcriptase to produce complementary DNA (cDNA). The amount of extended cDNA product that is synthesized is proportional to the amount of transcript in the original sample. In addition, with the recent development of polymerase chain reaction (PCR) machines that incorporate fluorescence detection, it is possible to determine quantitatively the levels of transcripts in different samples by using reverse-transcription PCR (44). As described for primer extension analysis, the first step in this approach is the synthesis of cDNA. This product is amplified then by PCR in the presence of a gene-specific fluorescent probe or a dye, such as SYBR Green I (an asymmetrical cyanine derivative), that fluoresces strongly when it binds to double-stranded DNA (45). By measuring the level of fluorescence at the end of each
RNA Stability, Chemistry, Measurement and Modulation of

Figure 1 The cycle of gene expression. Nucleotides are joined to form mRNA by a polymerase that uses a protein-coding gene as the template. This process is called transcription. The RNA polymerases initiate transcription at sites in genomes called promoters. In eubacteria, the primary product of transcription of most genes can be used as a message by ribosomes to synthesize polypeptides from amino acids (in the form of charged transfer RNAs). This process is called translation. However, in eukaryotes, modification of the primary transcript is required. Modifications include capping the 5′ end with 7-methyl guanosine via a 5′-to-5′ link, polyadenylating the 3′ end, and splicing out segments (introns) that separated protein-coding regions (exons). This step is called RNA processing. The mRNA has a relatively short lifetime and is converted to nucleotides by the combined actions of multiple ribonucleases. This process is called RNA degradation or decay.

cycle (i.e., in “real-time”), the kinetics of amplification can be determined, from which the amount of transcript in a sample can be determined (see also the WECB review on XXXX) (44).

Transcriptional pulse–chase experiments

The individual steps in the decay of a particular transcript can be followed by engineering the corresponding gene to place it under the control of an externally regulatable promoter that can be used to switch on and off transcription within minutes (46). Some of the most commonly used regulatable systems are based on elements derived from the tetracycline-resistance (tet) operon of Escherichia coli. Systems have been engineered so that transcription can be switched on or off rapidly in a reversible manner by adding tetacycline or a derivative, such as doxycycline. These systems are being used widely to study both eubacteria and eukaryotes (47). The creation of a pulse of transcription means that the bulk of the population of a particular transcript enters the decay pathway within a narrow time window. This approach can synchronize the process sufficiently for the order of steps in the pathway to be determined (46). To date, transcriptional pulse–chase experiments have been used mainly to study mRNA decay in S. cerevisiae and mammalian cells in culture. However, in principle they could be used to study the decay of RNA in any system, provided a transcriptional pulse can be created that is short relative to the lifetime of the RNA being studied. Externally regulatable promoters have been used also to switch off transcription of a specific gene so that the half-life of its mRNA can be determined (34). A n advantage of this technique is that should the decay require a factor(s) (RNA or protein) that is relatively short-lived, the continuing transcription of all other genes in the background will ensure that the abundance of any such factor does not diminish and become rate limiting. It is also possible to estimate the rate of decay of a particular transcript in a background of continuous transcription within organisms for which an easily regulatable promoter system is not yet available. This estimation can be achieved by measuring the “approach to steady-state labeling,” which involves monitoring the incorporation of 32P-labeled phosphate into specific transcripts (34). Although this method is rather cumbersome, the values obtained are comparable with those derived by other approaches (33).

The stability of transcripts on a genome-wide scale

More recently, with the advent of gene arrays, it has been possible to measure the rates of RNA decay on a genome-wide scale. This technology involves labeling an RNA population and then hybridizing it against a library of thousands of immobilized spots of DNA, each of which serves as a specific probe for a particular transcript (48–50). The amount of label that associates
with each spot is proportional to the amount of the corresponding transcript in the original RNA sample (see also the WECB reviews on Transcript Profiling, Tools for and Array-Based Tools for Nucleic Acids). Interestingly, this approach is starting to reveal new relationships between the functions encoded by mRNAs and their stability. For example, it seems that the shortest-lived mRNAs in E. coli tend to correspond to genes that as of yet have not been characterized (25, 26). Interestingly, genes with some of the shortest-lived mRNAs in eukaryotes have known functions. These genes include the c-myc and c-fos transcription factor genes in mammalian cells (51), several that are inducible by auxin in plants (52, 53), and many that are associated with the mating switch in yeast (54). Therefore, by analogy with eukaryotic systems, many uncharacterized E. coli genes with unstable mRNAs may be regulators. As E. coli has been characterized extensively in the laboratory, it is likely that the processes controlled by genes with unstable mRNAs are required only under some particular environmental condition (26). The decay rates of eukaryotic mRNAs also are being analyzed on a genome-wide scale. For example, this approach has revealed that similar to auxin-inducible genes (52, 53), genes responsive to mechanical stimulation and the circadian clock are rapidly degraded (37). The study of S. cerevisiae has revealed that, similar to what has been found for E. coli, genes involved in central metabolism tend to have longer half-lives (27).

Modulating mRNA Turnover

The measurement of the half-lives of individual transcripts has revealed that for all organisms studied, the values for different transcripts can vary over an order of magnitude. This finding has led to many investigations of the cis-acting elements within RNA and trans-acting factors that determine the rate of RNA decay (10–13, 15–20) (see also the WECB review on the mRNA localization and mRNA levels, control of). Moreover, the knowledge gained is being used to modulate gene expression. Extensive coverage of this area is beyond the scope of this article; however, the potential to manipulate gene expression at the level of RNA stability is illustrated below by using two different examples.

Enhanced protein production in bacteria

E. coli has long served as a host for the production of proteins (see the WECB review on protein expression, systems for ). Recently, it has been manipulated genetically to stabilized transcripts that are synthesized as part of the commonly used pET expression system. In this system, cloned genes are transcribed from a promoter that is recognized by the RNA polymerase of bacteriophage T7 (55). However, although the cloned gene is transcribed efficiently, the transcripts that are produced by T7 RNA polymerase can be highly unstable. This instability occurs because the bacteriophage enzyme transcripts genes more rapidly than the endogenous RNA polymerase of E. coli. As a
consequence, ribosomes cannot keep pace (in eubacteria, transcription and translation are coupled) and endoribonucleases gain access to "naked" stretches of RNA (56, 57). To counter this effect, strains of E. coli that host the pET system now are offered with a mutation that reduces the rate at which transcripts are cleaved by RNase E (58), an endoribonuclease that initiates much of the mRNA decay in E. coli (59). It also has been shown that mRNA produced using a T7 promoter can be stabilized by using a mutant polymerase that transcribes DNA at a slower rate (60).

The modulation of mRNA decay by a small molecule

A substantial proportion of the genetic and acquired diseases of humans stems from nonsense mutations, which create codons that signal the premature termination of translation. Normally the mRNA of genes that contain such codons is degraded rapidly by a "quality control" mechanism, the details of which are covered in several excellent reviews (17, 61-63). Recently, a small, orally available molecule (called PTC124) has been identified that reduces the fidelity of the ribosome such that it inserts an amino acid when it encounters a premature termination codon (PTC), but not a bona fide translational stop codon (64). This action suppresses rapid mRNA decay, which thereby permits the production of full-length polypeptides. Moreover, at least some molecules so produced have activity as PTC124 has been shown through two Phase 2 clinical trials to have efficacy in the treatment of patients with forms of Cystic Fibrosis (CF) or Duchenne Muscular Dystrophy (DMD) caused by nonsense mutations (65). However, further research is required to study the long-term effects of suppressing nonsense-mediated mRNA decay (NMD). In this context, it is perhaps worth noting that very recent studies indicate that NMD has a role in controlling the expression of a subset of normal (i.e., unmutated) genes (66, 67). Thus, although suppressors of NMD will likely have side effects, it is hoped that these side effects will be outweighed by alleviating the effects of severe disease in those individuals where the root cause is a nonsense mutation. For details of other strategies for the treatment of PTC diseases, readers are referred to a comprehensive review of this topic (68).

Small, Untranslated RNAs and RNA-Based Therapeutics

Nonsense-mediated decay is just one of many examples of gene regulation that occurs at a step after the initiation of transcription. In bacteria and eukaryotes, classes of small, untranslated RNAs (sRNAs) have been identified that regulate the translation of their targets through a physical interaction that involves intermolecular base pairing (see also the WECB review on RNA, noncoding). In such cases, the sRNA is described as being antisense (i.e., its sequence is the reverse complement of its target).

Antisense RNA and interference

In eubacteria, antisense RNAs originate from genetic loci that either overlap or are distant from the genes of their targets (14, 69, 70). The former, cis-encoded antisense RNAs are found associated with ancillary mobile genetic elements, such as viruses, and are synthesized always from a segment of the DNA strand opposite that used for synthesis of the mRNA target. In contrast, the trans-encoded antisense RNAs display only partial complementarity to their targets, can affect multiple targets, and seem to regulate core cellular functions in response to suboptimal or stressful growth conditions (14, 69, 70). Antisense RNAs that target mRNA targets have been shown to affect translation, which in turn can influence the rate of mRNA turnover (71). It is known that reducing ribosome coverage can provide ribonucleases with increased access to susceptible sites (56, 72). Plants, fungi, and animals have a class of sRNAs called micro RNAs (miRNAs) that are analogous to bacterial antisense RNAs insofar as intermolecular base pairing alters the translation, decay, or both of mRNA targets (73-75) [see also the WECB review on the MicroRNA (miRNA)]. However, unlike bacterial antisense RNAs, the actual RNA that targets the mRNA, the "guide" RNA, is generated via a double-stranded (ds) intermediate of 20-25 bp. Importantly, it has been found that short, chemically synthesized ds RNA, when introduced to plants and animals, can mimic effectively the short double-stranded intermediates of miRNAs and consequently interfere dramatically and selectively with the expression of genes that have a complementary sequence (76, 77). These short, interfering RNAs (siRNA), which can be synthesized readily by using phosphoramidite chemistry (78, 79) (see the WEBC review on the solid-phase synthesis of biomolecules), have revolutionized the study of eukaryotic gene function both in cell culture and in living organisms (80-82) and, as described below, have potential as therapeutic agents for the treatment of human disease (83-87) [see also the three WECB reviews on RNA Interference to Treat Human Diseases, Applications of; gene silencing techniques and the small interfering RNA (siRNA); chemistry of]. The machinery that mediates RNA interference in eukaryotes does not exist in bacteria, and the introduction of RNAi to prokaryotes exogenously does not provide a routine means of altering the expression of a targeted gene; however, it should be noted that the production of antisense RNA intracellularly has been shown to induce gene silencing in many bacteria and that libraries of constructs that produce such RNAi have been used (although not extensively) to study gene function on a genome-wide scale (88, 89).

Additional classes of sRNA

Antisense RNAs are not the only class of sRNAs that have key cellular and regulatory functions. In eubacteria, for example, an RNA called 6S RNA binds directly to the form of RNA polymerase that transcribes the general housekeeping genes; this interaction causes a reduction in the expression of these genes as part of a wider scheme that redirects the activity of the transcriptional machinery during periods of nutrient starvation (90, 91). Non-antisense sRNAs also target steps in gene expression other than transcription (92). When the progress of
a ribosome is arrested on a bacterial mRNA because of truncation of the coding region, an sRNA can enter the ribosome in a manner analogous to a normal tRNA, stimulate the release of the ribosome, and complete the cycle of translation by serving as a template that encodes a short peptide. The peptide added by the “trans-translation” of the aptly named transfer-messenger RNA (tmRNA) marks the improperly terminated protein as substrates for rapid proteolytic decay (92). Within the natural world, the functions of RNA extend to catalysis, for example, peptide bond formation in the ribosome (93). (see also the WE CB review on ribosome, chemistry of), the ribonuclease activity of RNase P, and splicing reactions (i.e., the cutting and ligation of RNA) are catalyzed by RNAs (94, 95) (see also the WE CB reviews on the Locked Nucleic Acids and Pre-mRNA splicing (96)).

The ability of RNA to bind other types of molecules with high affinity and specificity and to catalyze reactions is rooted in the complex 3-D structures it can form (96, 97). Although all RNAs are synthesized as a single-stranded transcript, stretches of complementary bases can pair to form a series of short, double-stranded helices that can generate several secondary structures. Examples include stem-loops, which are formed by transcripts looping back on themselves to form double helices (stems) at the base of the loops, and pseudoknots, where molecules loop back on themselves, but the looped segments are sufficiently long to contain secondary structures of their own. Such secondary structures are packed together with the assistance of metal ions to form higher-order, functional structures (98-100) (see also the WE CB reviews on crystallographic techniques: nucleic acids and NMR Tools for Nucleic Acids). Moreover, the strength of the interactions that form the secondary structure seems central to the thermostability of functional RNAs; strong correlations exist between both the GC-content and the predicted melting temperatures of RNA secondary structures and the optimal growth temperatures of the organisms in which they are found (101–103). In thermophiles, the functional conformation of RNAs may be stabilized also by nucleotide modifications, stronger tertiary interaction, macro-molecular crowding, and association with proteins.

Aptamers

The presentation of the four nucleotides of RNA within the context of a complex 3-D landscape permits RNA molecules to bind with specificity and high affinity to targets that range from small molecules to cells. This remarkable ability has been and continues to be demonstrated through an in vitro selection approach called the “systematic evolution of ligands by exponential enrichment” (SELEX) (104, 105). The details of the SELEX procedure are described in accompanying reviews (see WE CB reviews on the In Vitro Selection and Application of Nucleic Acid Enzymes (Ribozymes and Deoxyribozymes) and aptamer-based therapeutics), so only a brief overview is provided here. The process begins with the synthesis of a DNA template that can be transcribed by T7 polymerase to produce single-stranded RNA. The template contains a central region typically of 20-40bp that is randomized at each position. Therefore, when the template is transcribed, it produces a population of RNA molecules each with a different sequence and thus a different structure at its core about 1015 different sequences can be produced from about 2 nmoles of template, the amount used in a typical transcription reaction. RNA molecules that bind a target are selected, a complementary DNA (cDNA) strand is produced by reverse transcription, and then large amounts of the template are regenerated by using the polymerase chain reaction (see WE CB review on the Polymerase Chain Reaction (PCR) in Chemical Biology). The process then is repeated until RNA molecules with the desired affinity and specificity are obtained. Finally, after using cloning techniques to isolate individual templates from the successful pool, the RNAs can be sequenced, characterized, and synthesized chemically using phosphoramidite chemistry. The products of selections are called “aptamers” (Latin aptus means “fitted”) and have found a wide variety of uses as biosensors (106, 107), probes for drug target validation (108), diagnostic indicators, and therapeutics (109-114) (see also the two WE CB reviews on the In Vitro Selection and Application of Nucleic Acid Enzymes (Ribozymes and Deoxyribozymes) and on Combinatorial Libraries: Overview of Applications in Chemical Biology). Recently, Macugen (also called Pegaptanib), the first aptamer-based therapeutic agent, has entered clinical use for the treatment of age-related macular degeneration (AMD), which in the developed world is the leading cause of blindness in individuals over 50 years in age (115). Other aptamer-based agents are entering clinical trials (109-113) (see also the WE CB review on aptamer-based therapeutics).

Stabilizing RNA-Based Therapeutics

The body fluids of humans contain an array of ribonucleases (116-118); however, RNA molecules can be modified to greatly increase their stability in vivo. Modified RNAs differ from modified DNA in that body fluids of humans and other mammals are members of a large family of RNase A, a relatively small protein that was one of the earliest models for studying protein structure and function (119-121).

RNA Modifications

RNase A and its relatives cleave RNA molecules via a hydrolysis reaction that requires a hydroxyl at the 2’ position on the ribose of the nucleotide immediately on the 5’ side of a phosphodiester bond (Fig. 3). The 2’ OH is necessary for the transfer of an electron between two catalytic histidines (Fig. 3A) in order to form the transition state (122). Thus, protection can be provided by replacing the OH group at the 2’ position with a H, O-methyl, O-methoxymethyl, NH2 (aminoo), or F (fluoro) group, all of which cannot participate in the electron transfer (Fig. 3B). Protection also can be provided by ribose moieties that have an extra covalent “bridge” between the 2’ and 4’ positions (122). Not only does this bridge prevent electron transfer between the catalytic histidines, but also it “locks” the sugar in a conformation (C3’-endo pucker) that increases the affinity of the interaction between the modified RNA and its complementary target (123). Complementary base pairing is promoted similarly by 2 F substitutions. Replacement of oxygen with sulfur at
the 4’ position of the ribose and borophosphonate backbone (P = B) modifications also have been reported to confer increased resistance to nucleases (124). All modifications described above (Fig. 3B) can be introduced into phosphorodiester nucleosides, the building blocks for the solid-phase synthesis of nucleic acids (78, 79); indeed, most, if not all, are available currently from several commercial sources (e.g., Glen Research, Sterling, VA) (see also the WECB review on the solid-phase synthesis of biomolecules). The 2’ modifications also protect the 3’-5’ phosphodiester bonds of RNA against nonenzymatic alkaline hydrolysis, which requires a hydroxyl group at the 2’ position (125). This reaction is enhanced by magnesium, which stabilizes a cyclic 2’-3’ phosphate intermediate. Thus, unmodified RNAs should be stored at low temperatures under slightly alkaline conditions in the presence of a divalent-cation chelator, such as ethylenediaminetetraacetic acid (EDTA) or sodium citrate. The absence of 2’ OH groups in RNA explains the chemical stability of this macromolecule relative to RNA.

Assessing nuclease resistance

Usually the nuclease resistance of RNA is assessed first by using it as a source of nucleases body fluids such as urine (126), blood serum (127), or plasma (128); however, it is not uncommon for the source to be an extract of a tissue, such as pancreas (129), or purified nucleases (130). The range of methods that can be used to detect the continuing presence of synthetic RNAs is dependent on their length and mode of synthesis (see also the WECB review on labeling techniques: nucleic acids). Short oligonucleotides can be labeled readily during their solid-phase synthesis via a phosphoramidite that incorporates a fluorophore (131) (see also the WECB review on fluorescence spectroscopy: overview of applications in chemical biology) or post synthesis by adding the radioactive 32P to the 5’ end by using the enzyme polynucletidyl kinase (43). The latter also can be used to label RNA synthesized from a DNA template by using an RNA polymerase, provided the triphosphate group at the 5’ end of the synthesized RNA is removed first using a phosphatase (43).

Enzymatically synthesized RNA also can be labeled internally via the incorporation of fluorocarbon labeled nucleotides (131). Following incubation with a source of nucleases, the integrity of labeled RNAs then can be assessed by electrophoresing samples in a gel, most commonly for this purpose made of acrylamide, in a gel, most commonly for this purpose made of acrylamide, and visualizing the labeled species using the corresponding labeled RNAs then can be assessed by electrophoresing samples in a gel, most commonly for this purpose made of acrylamide, and visualizing the labeled species using the corresponding fluorophore. Specificity is achieved by careful calibration of the HPLC systems to determine the elution point of the RNA-based therapeutic. The stability of longer RNAs (L > 100 nt), which tend to be synthesized enzymatically, can be determined without labeling by using reverse transcription PCR (44). An amplicon will be produced no longer from an RNA once cleavage has occurred between or within either of the two segments recognized by the primers. This method is preferable to Northern blotting, which is less sensitive and more cumbersome to perform. The half-life of RNA in the body fluids of living animals can be determined by assaying samples taken at different time points after administration; however, the values obtained reflect not only degradation but also the rates of renal clearance and uptake into cells and tissue. In the development of M acugen, an HPLC-based assay was used to determine the plasma half-lives of aptamers in animal models (133).

Compatibility of stabilizing modifications with RNA interference

In the context of developing siRNAs for therapeutic applications, the RNA must resist intracellular nucleases as well as interact with cellular machinery to produce a complex that can silence (or at least dampen) the expression of the target gene(s). Fortunately, the effects of RNA-stabilizing modifications on silencing can be assessed relatively easily by targeting in cultured cells the mRNA of genes that encode readily assayable products; for example, the green fluorescent protein (129, 134). Through this type of study, it has been demonstrated that the resistance of siRNA to nucleases can be increased significantly without compromising silencing efficiency, at least ex vivo. Resistance has been achieved, for example, by modifying the RNA such that multiple nucleotides at positions in both strands have a 2’ fluoro group (130), particular positions have a 2’-O-methyl group (135), or nucleotides on both strands alternate between having a 2’ fluor and a 2’-O-methyl group (136, 137), or nucleotides of the sense strand have 2’-O-methoxyethyl (137) or 4’-thio modifications (138). It is likely that this list is far from exhaustive, given the number of potential modifications (e.g., the effect of the 2’-amino modification has yet to be studied within the context of an siRNA) and the multiplicity of positions within siRNAs that can be modified (79, 124, 139, 140). Recently, it has been found that the extent to which modified RNAs can bind the RNA-induced silencing complex (RISC) is a predictor of their potency in vivo (141). Whether this biochemical assay will be sufficient to replace cell-based assays remains to be determined at this time.

The final choice of stabilizing modifications is likely to be influenced by additional studies that will determine the influence of RNA modifications on renal clearance and cellular uptake and whether issues relating to cytotoxicity exist (124, 140). With regard to the latter, at least one study has indicated that siRNAs with phosphorothioate backbone modifications can have cytotoxic properties (142). That living organisms cannot metabolize all unnatural molecules without consequence on growth should not be surprising. Small interfering RNAs should not need modification to provide resistance to intracellular nucleases because the RNAs they mimic function effectively within cells.

The production of nuclease-resistant aptamers

In considering the therapeutic application of aptamers produced using SELEX, the contribution of the 2’ OH group to the 3-D structure of RNA needs to be taken into account. This group contributes to the physico-chemical properties of RNA, which in
RNA Stability, Chemistry, Measurement and Modulation of

Figure 3 Hydrolysis of RNA by members of the RNase A family. The mechanism is shown in Panel A. Modifications that stabilize RNA are shown in Panel B.

Turn influences the thermal stability of secondary structures, and contributes to bonding that can determine the arrangement of secondary structures in 3-D space (99). Thus, the introduction of modifications into an aptamer post selection can alter its interaction with the target. As such, aptamers that have increased resistance to nucleases usually are produced using “front-loaded” SELEX, in which the libraries are synthesized using nucleotides with modifications, such as 2′fluoro, O-methyl, or amino groups (111, 113). Indeed, Macugen was developed from a library made from pyrimidines with 2′fluoro modifications. Interestingly, the aptamers selected from this pool bound their target, which is an isoform of vascular endothelial growth factor (VEGF), with higher affinity than those derived from a library of equal complexity synthesized by using pyrimidines with 2′amino modifications (143). This occurrence may have been because a higher proportion of the 2′fluoro-modified aptamer population was in a conformation(s) that can interact with the target because of double-stranded segment(s) having greater thermal stability. Although front-loaded SELEX is used routinely as part of strategies to develop nuclease-resistant aptamers, once the minimal sequence required for binding to the target is defined, the RNA can be synthesized using solid-phase chemistry and additional modifications can be introduced. The introduction of 2′O-methyl substituted purines into aptamers raised against VEGF from the library made using pyrimidines with 2′F modifications increased the half-life by around eightfold (143). This result is not particularly surprising; although cleavage by many ribonucleases found in body fluids require a pyrimidine with a 2′OH immediately on the 5′side of a susceptible bond, some can cleave bonds that have an unmodified purine on the 5′side (116–118). 2′amino-modified or 2′fluoro-modified pyrimidines can be incorporated into RNAs using wild-type T7 RNA polymerase; however, the incorporation of 2′0-methyl pyrimidines required modification of the enzyme using directed evolution.
described recently for the chemical synthesis of 4-thio-modified nucleotides; moreover, these schemes are incorporated into RNA by wild-type T7 polymerase with an acceptable efficiency (145). From the above, it is clear that as described for the synthesis of siRNAs, several modifications can be introduced into aptamers to decrease their susceptibility to degradation by nucleases. RNA-stabilizing modifications can be introduced also into ribozymes and RNA-based antisense oligonucleotides (ASOs) that inhibit or alter gene expression independently of the RNA interference pathway (146-149) (see the WECB review on the oligonucleotide-directed inhibition of gene expression).

Stability also can be achieved by using aptamers that have nucleotides based on L- instead of D-ribose (150-152). Such aptamers are generated by a process that first selects aptamers composed of the naturally occurring sugar against an epitope (i.e., a complete mirror image of the intended target). Once an aptamer(s) with the required function is obtained, its L-ribose-based epitope, which is also called a Spiegelmer (from the German word Spiegel meaning “mirror”), is synthesized chemically. The RNA-Spiegelmer will be completely resistant to nucleases and will bind the intended target with the same characteristics that its D-ribose-based progenitor bound the epitope in the initial selection. The only limitation to this approach will be the ingenuity of chemists to synthesize the enantiomers of targets of interest. Schemes have been described already for the chemical synthesis of peptides composed of D-rather than L-amino acids (see WECB review on the Natural and Unnatural Amino Acids, Synthesis of).

Future Perspectives

In all likelihood molecules based on RNA will be used increasingly as diagnostic tools and therapeutic agents. As this article illustrates, the inherent instability of RNA can be overcome effectively via the introduction of an increasing number of modifications. Concomitantly, renal clearance has been reduced sufficiently to increase bioavailability via the encapsulation of RNA within lipoproteins or by attachment to the 5′ or 3′ end of bulky groups such as polyethylene glycol, cholesterol, or biotin–streptavidin (111, 113, 114, 124). Moreover, promising developments exist in the area of delivery to specific cell-surface receptors can be isolated, the approach of using a chimera was processed effectively by the silencing machinery. Binding to the receptor induced internalization, whereupon the siRNA as a chimera with an aptamer that binds the receptor.

A particular receptor. This delivery was achieved by producing the siRNA-resistant to nucleases and will bind the intended target with the same characteristics that its D-ribose-based progenitor bound the epitope in the initial selection. The only limitation to this approach will be the ingenuity of chemists to synthesize the enantiomers of targets of interest. Schemes have been described already for the chemical synthesis of peptides composed of D-rather than L-amino acids (see WECB review on the Natural and Unnatural Amino Acids, Synthesis of).

doi: 10.1002/9780470048672.wecb452

The unique Watson–Crick arrangement of hydrogen-bonded bases in DNA accommodates two different, complementary purine–pyrimidine pairs, \( A \cdot T = T \cdot A \) and \( G \cdot C = C \cdot G \), in a common spatial setting. Nature takes advantage of these isomorphous structures, which store genetic information in terms of the proton donor and acceptor atoms that hold the bases in place. As outlined here, the Watson–Crick base pairs carry other chemical signals that are used to recognize and to process specific sequences of bases. The relative stabilities of \( G \cdot C \) versus \( A \cdot T \) pairs reflect their different electronic structures. The distributions of electronic charge on the exposed major-groove and minor-groove edges of the base pairs present unique motifs for direct sequence recognition, and the deformations of the paired bases from ideal, planar configurations provide subtle, indirect recognition elements. The biologic significance of the latter signals is not fully understood but is becoming clearer as more and more high-resolution structures of DNA and RNA are determined.

The simple, yet elegant structure of double-helical DNA—two sugar-phosphate strands wrapped along antiparallel right-handed pathways around a central core of stacked and hydrogen-bonded base pairs—provides the molecular basis to interpret the storage, duplication, and rearrangement of genetic information. The same type of base pairing persists in double-stranded RNA, DNA–RNA hybrid duplexes, and synthetic multi-stranded polymers, such as PNA (1), which allow the chemical message to be duplicated, transcribed, blocked, and so on. The information reported below draws on the three-dimensional spatial arrangements of Watson–Crick base pairs and bound ligands in the many DNA and RNA structures now stored in the Nucleic Acid Database (NDB) (2).

Complementarity

Classic Watson–Crick base pairs are formed by unique hydrogen-bonding interactions between the nitrogenous bases of DNA and RNA. The purine adenine associates specifically with the pyrimidine thymine in DNA (or the related unmethylated analog, uracil, in RNA), and the purine guanine interacts with the pyrimidine cytosine. These complementarity rules, \( A \cdot T \) or \( A \cdot U \) and \( G \cdot C \) pairs, make it possible to build regular double-stranded structures of arbitrary base sequence and to provide a mechanism to copy the genetic code. That is, if the sequence of one strand of DNA is known, the sequence of the other strand is determined automatically. Therefore, if the strands are separated and new DNA is synthesized, two double-stranded DNA molecules are obtained, each an exact copy of the original.

These complementarity rules owe their discovery to the chemical analysis of DNA by Chargaff and associates (3). The DNA from many different organisms shows the same patterns of base composition, namely A and T are always present in equal quantities, as are G and C. The immediate corollary of this observation, that a purine base (R) exists for every pyrimidine base (Y) and vice versa, led Watson and Crick to propose that two helical strands in DNA are held together by specific, intermolecular purine–pyrimidine (R·Y) interactions (4). In turn, this unique chemical complementarity of the double-helical structure, proved to be a major breakthrough to understand the self-recognition and self-reproduction of DNA and forms the cornerstone of structural biology as we know it today, more than half a century later.
By contrast, the proportion of G–C versus A–T base pairs is highly variable in the DNA from different organisms, with over-representation and under-representation of residues found at dimeric, i.e., adjacent base-pair step, and higher levels (5). Factors, which may underlie the observed compositional patterns, are not yet understood.

Isomorphous Base Pairs

The Watson–Crick postulate places complementary bases in similar spatial configurations so that the two-stranded molecule can adopt a regular structure. The bases of each purine-pyrimidine pair lie in a common plane, with the distance, between C1′ sugar atoms approximately constant (~3.05 Å) and the C1′···C1′ vector forming roughly equivalent (~55°) angles with the (purine C1···N9 and pyrimidine C1···N1) glycosidic bonds that join the bases to the sugar-phosphate backbone (Fig. 1). A pseudo-twofold symmetry axis, also referred to as the dyad axis, passes through the center of each base pair, which permits the exchange of complementary bases without change in the relative positions of either the attached sugar residues or the selected base-recognition elements (see below). In particular, an A·T base pair is converted into a T·U pair; and a G·C base pair is converted into a C·G pair by a 180° rotation about this axis. As a result of this isomorphous geometry, any base-pair combinations can be fitted into the same regular structural framework. As a first approximation, the “ideal” double-helical structure of Watson and Crick is sequence-independent. As noted below, this regularity breaks down in high-resolution crystal structures of DNA and is impossible without the R·Y base-pairing interactions.

Hydrogen-bond Recognition and Stability

In turn, the isomorphous structures of the Watson–Crick base pairs dictate specific hydrogen-bonding recognition patterns. The A·T pairs associate via two hydrogen bonds that involve N1(A)····H···N4(T), and N6(A)····H···O4(T), and the G·C base pairs are held in place by three such interactions: N1(G)····H···N3(C), N2(G)····H···O2(C), and O6(G)····H···N4(C) (Fig. 2). The extra hydrogen bond of the G·C pair apparently gives rise to the higher melting temperature of G·C versus AT-rich DNA (8). Direct in vacuo measurements of the binding energies support this idea. Isolated G·C base pairs are more stable than free A·T pairs (~21 vs. ~13 kcal mol⁻¹) (7,8). Furthermore, G·C pairs are typically less deformed from ideal planar geometry than A·T pairs (see Table 2 and discussion below).

Base pairing is substantially weaker in solution. For example, the G·C hydrogen-bonding energy drops to ~5.8 kcal mol⁻¹ in chloroform (9). The hydrogen-bonding energies in water, however, are uncertain because isolated planar bases prefer to associate in parallel stacked arrays rather than to pair with complementary bases (10). According to direct experimental solution measurements of the melting properties of oligonucleotides (which contain both base side groups and the sugar-phosphate backbone), hydrogen bonding adds 0.5–1.8 kcal mol⁻¹ stabilization per base pair depending on DNA sequence (11). Thus, base-pair formation in aqueous solution is governed by base-base hydrogen bonds only slightly more favorable than base-water hydrogen bonds.

The electrostatic character of hydrogen bonding brings the protons of one base and the (N and O) acceptors of the complementary base closer together (1.9–2.0 Å) than their characteristic (2.7–2.8 Å) van der Waals’s separation distance. Accordingly, the base-pairing interaction is stronger and more specific than ordinary van der Waals’s interactions. The hydrogens, which are “shared” in the hydrogen-bonding interactions, have partial positive charges because of their attachment to nitrogen donor atoms, whereas the (carbonyl) oxygen C=O or imidazole nitrogen N) acceptors on the complementary bases bear partial negative charges. To maximize the electrostatic attraction, the hydrogen usually approaches the donor atom along the direction of and in a plane with the lone-pair orbitals of O or N. The partial charges of the donor, hydrogen, and acceptor atoms of the common bases (Fig. 2) determine the overall character of the electrostatic potentials that guide the mutual recognition of base pairs and their interactions with other molecules (see below).

Interestingly, the pairing of guanine and cytosine depicted initially by Watson and Crick (12) entailed only the two hydrogen bonds, O6(G)····H···N4(C) and N1(G)····H···N3(C), congruent with the N6(A)····H···O4(T) and N1(A)····H···N3(T) hydrogen bonds holding adenine and thymine in place. Later, Pauling and Corey (13) showed that guanine and cytosine were joined by a third N2(G)····H···O2(C) hydrogen bond in the minor groove, and Crick (14) used the three G·C hydrogen bonds to account for the higher stability of the Watson–Crick pair compared with a “wobble” G·U pair. Subsequent crystallographic investigations have revealed the existence of “weak” C·H···O hydrogen bonds between nitrogenous bases, also somewhat shorter than the sum of the van der Waals’s distances (15), see Table 2. The geometry of the Watson–Crick A·T base pair naturally forces a third such C2(A)····H···O2(T) hydrogen bond (16), which emphasizes its similarity to the G·C base pair (Fig. 1). Alternatively, the direct contact between adenine and thymine in the minor groove can be interpreted as an electrostatic attraction (17). In any case, this additional interaction in the A·T pair is advantageous for selective recognition during replication and transcription.
Hybridization

In principle, the hydrogen atoms of the purine and pyrimidine bases can rearrange in different tautomeric or hybridized forms. The exocyclic nitrogen atoms attached to the adenine and cytosine rings usually are in the amino (NH₂) form rather than the imino (NH) configuration. Likewise, the exocyclic oxygen atoms attached to the carbons of guanine and thymine rings normally adopt the keto (C=O) form rather than the enol (C–OH) configuration. Watson and Crick suggested that keto to enol or amino to imino base tautomerism could be the origin of the point mutations that underlie evolution (12). Such rearrangements would allow adenine to associate with cytosine or guanine to bind to thymine in geometries close to those of the canonical base pairs. For example, the normal d:d:a pattern of hydrogen-bond donors (d) and acceptors (a) in guanine is converted by keto-enol tautomerism to the d:a:d motif, which complements the preferred a:d:a motif of thymine (Fig. 1). Errors like these destroy the perfect complementarity between opposing chains that gives DNA its capacity for self-replication.

In this regard, significant chemical modification is required to effect either keto-enol or amino-imino tautomerism of the nitrogenous bases, with the consequent formation of A·C and G·T mispairs that fit into the canonical double-helical structure. Notably, the N6-methoxy A*·C mispairs and the O6-methylated G*·T mispairs, which are observed in crystalline duplex structures, are isomorphous with standard A·T and G·C base pairs (Tables 1 and 2; NDB entries: bd0009, bd0126, and bd05819-21).

Fortunately, the imino forms of A and C and the enol forms of G and T occur rarely. Most A·C and G·T mispairs observed to date in high-resolution crystal structures (e.g., References 22 and 23) associate through a “wobble” configuration (14), with the bases “sheared” past one another relative to the Watson-Crick configuration (Tables 1 and 3). These structural perturbations alter the patterns of atomic charges and accessibility that are presumably required for protein recognition and enzymatic action (see discussion below).
Figure 2  Color-coded electrostatic surface of A · T (left) and G · C (right) base pairs produced with the GRASP software package (25, 26) from ideal planar atomic coordinates (27) and partial atomic charges of the CHARMM27 nucleic acid force field (28): (top) the major-groove edges showing the unique donor-acceptor patterns of the base pairs; (middle) the upper faces (24) of purines and the under sides of pyrimidines (see also Fig. 1); (bottom) minor-groove edges showing the common Watson–Crick donor atom “signature.” Conventional hydrogen-bond donor and acceptor atoms on base-pair edges are designated respectively by – and + symbols. The CH and CH₃ groups in the major and minor grooves are noted by (⊥) to emphasize their moderate positive charges and their tendency to be in close contact with O and N acceptor atoms (17, 29). Isopotential contours, in units of kT (numerical scale at top of figure), reveal the approximate electrostatic equivalence of the minor-groove edges of the base pairs. Molecular surfaces generated using a spherical probe with 1.4 Å radius. Bases “neutralized” by adjustment of the partial charges on C1′ atoms. Electrostatic potential omits counterions and incorporates the difference in dielectric between water and bases, i.e., 80 vs. 2. Essentially, the same results are found with other well-known sets of partial atomic charges (30, 31), including those determined with state-of-the-art quantum mechanical methods (32).

Antiparallel Strand Alignment

Because of the lack of symmetry in their chemical structures, individual nucleic acid bases have unique faces (24), which specify the directions of the DNA strands in the Watson–Crick model. The upper faces (tops) of complementary bases point in opposite directions, with the two attached sugar-phosphate backbones aligned in an antiparallel sense. The top of a base corresponds with the configuration that orients the C1′ → N glycosidic bond vector in a “northeast” heading with respect to its “north–south” Watson–Crick base-pairing edge (found between the associated bases in Figs. 1 and 2). If the base and sugar are attached by the normally preferred anti glycosidic linkage (with the six-membered purine ring or the pyrimidine O2 directed away from the sugar ring), the DNA backbone roughly runs perpendicular to the plane of the base, with the 3′-oxygen displaced above the top side and the 5′-oxygen below the bottom side of each base. The vector that connects the tops of consecutive bases coincides with the 5′ → 3′ direction of the sugar-phosphate chain (Fig. 3).

Duplex Grooves and Recognition

The attachment of the sugars to the same side of each Watson–Crick base pair introduces an asymmetry in base-pair accessibility inside the grooves formed by the DNA backbone. The edge of the Watson–Crick base pair that contains the pyrimidine O2 and the purine N3 atoms is called the minor groove, and the longer edge on the opposite side of the glycosidic bonds is termed the major groove (Fig. 1). The hydrogen-bond donors and acceptors that line each groove (Figs. 1, 2) serve as recognition motifs for interactions of DNA with proteins, drugs, and solvent molecules. The pseudo-symmetric positioning of the N3 acceptor atoms of A and G and the O2 acceptor atoms of T and C provides a common minor-groove recognition element for all four Watson–Crick base pairs (33) (shown by the pattern of red and blue atoms in Fig. 2).

The positioning of the N3/O2 acceptor atoms provides a simple and reliable mechanism to distinguish the Watson–Crick pairs from the “wobble” pair and other mismatches. As suggested initially by Brudov and Poltev (34), the fidelity of
nucleic-acid biosynthesis would be increased substantially if the recognition elements of a polymerase had NH or OH groups that interacted with the invariant N3/O2 atoms in the minor groove. The orientation of the amino proton attached to the N2 donor on G differentiates the G-C and C-G base pairs from each other as well as from the A-T and T-A pairs. The latter base pairs can be discriminated by small synthetic molecules that take advantage of both the asymmetric steric structure of the adenine C2-H and the capability of the thymine O2 (with two sets of lone pair electrons) to form an additional hydrogen bond not possible with the pseudo-symmetrically related adenine N3 (37, 38). It is not yet clear whether naturally occurring, DNA-binding proteins use similar principles to distinguish between A-T and T-A base pairs in the minor groove.

By contrast, all four bases present unique protein recognition patterns in the major groove (Figs. 1 and 2). The N7 acceptor atoms of A and G set the purines apart from the pyrimidines, whereas the pseudo-symmetrically placed N6 donor and O6 acceptor, respectively, separate A from G. The corresponding isomorphic interchange of the O4 acceptor and N4 donor on T and C discriminates the two pyrimidines. On the other hand, the latter motifs provide a common identification mechanism for C or A and G or T.

In addition to the classic donor-acceptor recognition mechanism described above, hydrophobic and electrostatic interactions facilitate the discrimination of the base pairs one from another. As shown in Figs. 1 and 2, the pyrimidines are hydrophobic in the vicinity of C5 and either have a positive charge (cytosine) or are of the opposite sign. The positioning of Watson–Crick pairs along the global axis of the double-stranded B-DNA structure enhances the accessibility of major-groove versus minor-groove atoms, thereby favoring the binding of proteins that recognize specific sequences. The narrow B-DNA minor groove is less receptive to proteins but easily accommodates long, crescent-shaped drugs (e.g., Ref. 37 and 38). The binding of proteins in the minor groove often necessitates a partial and sometimes a complete B → A conformational change in DNA, which displaces the base pairs

$\lambda^Y = \angle C1'(Y)–N1(Y)\cdot C1'(R)$ and $\lambda^R = \angle C1'(R)–N9(R)\cdot C1'(Y)$ describe the pivoting of complementary bases in the base pair plane (Fig. 3).
pairs designate the origins of the base-pair frames. The gray arrows designate the positive signs of rotations for created with 3DNA (18) illustrate positive values of the designated right-handed B-DNA structure by enhancing stacking overlaps positive propeller is illustrated). This deformation stabilizes the negative propeller (see parameter definitions in Fig. 3 where positive propeller is illustrated). This deformation stabilizes the right-handed B-DNA structure by enhancing stacking overlaps with bases in adjacent residues (46). The degree of propeller twisting depends on both base-pair and conformational context. The A-T pairs in B-DNA are more distorted on average than the G-C pairs (–13° vs. –10°), and almost no propeller twisting of base pairs exists in the left-handed Z-DNA conformation, e.g., –3° in the d(CGCCCGG); duplex structures (NDB entry: zdf001) (47). Buckle, although fixed on average near zero, shows more pronounced variability than propeller and, for G-C base pairs, exhibits a notable dependence on helical conformation. The G-C base pairs tend to buckle in a positive sense in B-DNA duplexes (as shown in Fig. 3) and in a negative direction in A-DNA structures. The constraints of hydrogen-bond stretching and bending (Table 2) presumably lead to the more limited variations in opening and stretch (Table 3) compared with the other complementary base-pair angles and distances. On average, the A-T pairs are characterized by relatively small magnitudes of buckle, especially in the B form (Table 1), but they normally show a larger variability in propeller twisting compared with the G-C pairs. This observation is consistent with the different hydrogen bonding of A-T versus G-C. Both the buckle and the propeller angles enhance base stacking in B DNA. In G-C pairs, stabilized by three strong hydrogen bonds, excessive propeller twisting is expected to be unfavorable, as this would distort two NH-O bonds in the minor and major grooves (Fig. 3). Thus, propeller twist is expected to be less pronounced in G-C than in A-T pairs. To improve base stacking, apparently the G-C pairs “take advantage” of the other angular, degree of freedom, buckle, which is less prohibitive for the hydrogen bonds. In A-T pairs with only two strong hydrogen bonds (Fig. 3), a large propeller of 15–20° is acceptable. A s a result, there is no need for a large buckle, which remains –1° on average (Table 1, B-DNA).

### Nonplanar Geometry

The Watson-Crick double-stranded model of DNA has been confirmed abundantly and refined with fiber and single-crystal X-ray diffraction studies. The high resolution crystal structures accumulated to date, starting with the 0.84-Å resolution structure of the d(CCGGCGG)2 uridine miniduplex (43) and now including structures of oligonucleotide duplexes of comparable resolution (44, 45), show that complementary Watson-Crick base pairs are not perfectly coplanar. The bases in most solved structures are twisted with respect to each other like the blades of a propeller, with the C1'-atom on the sequence strand typically shifted below and that on the complementary strand displaced above the mean base-pair plane, i.e., negative propeller (see parameter definitions in Fig. 3 where positive propeller is illustrated). This deformation stabilizes the right-handed B-DNA structure by enhancing stacking overlaps away from the global axis and concomitantly exposes unpaired atoms on the minor-groove edges (40). On the other hand, small molecules bind specifically to the narrow major groove of double-stranded RNA (44), which adopts only A-type geometry.

### Protein-induced Base-pair Deformations

The associations of DNA with proteins and drugs introduce additional deformations of Watson-Crick geometry. Several examples, which are illustrated in Fig. 4, demonstrate the functional importance of the base-pair deformations discussed above.

#### Buckle

The partial intercalation of aromatic side groups of the yeast TATA-box binding protein between DNA base pairs (48) is accompanied by a pronounced (32°) buckling in one of the two adjacent A-T pairs, which apparently facilitates “penetration” of the phenylalanine rings into the minor groove (NDB entry: pdb012; Fig. 4a). A second example involves the integration host factor-DNA complex (49) (NDB entry: pdb040; Fig. 4b), where the partial minor-groove insertion of arginine 63 and close association of arginine 60 result in marked buckling in the opposite direction of the surrounding T-A-T and G-C-C base pairs (with respective buckle angles of –47° and –35°).
Watson–Crick Base Pairs: Character and Recognition of…

Figure 4  Protein-induced distortions of complementary base-pair parameters in representative crystal structures: (a) view from the major groove of the large buckling of the (upper) A₈T₂₂ base pair in the DNA complexed with the yeast TATA-box binding protein (48) brought about by the partial minor-groove visitation at the A₈₉₂₂ (major) step of phenylalanine 99 (wire-frame ring connected to the magenta (glutamic acid 93 and isoleucine 103) polypeptide ribbon; NDB entry: pdt022); (b) major-groove view of negatively buckled (upper) T₃₇A₃₇ and (lower) G₃₆C₃₆ base pairs, the hydrogen-bonded (arginine 60 (lower right) and arginine 63 (upper left) side groups, and a fragment (glutamine 59 and lysine 66) of the minor-groove-bound, extended β-sheet recognition element of integration host factor (49) (NDB entry: pdt040); (c) view of the upper face of the opened A₁₃T₁₉ base pair and the minor-groove contacting (serine 183 and asparagine 190) C-terminal ribbons of the Hin recombinase (50) (NDB entry: pde009); (d) major-groove view of the extreme opening and base-pair displacement of the chemically modified 4′-thio-2′-deoxycytidine in the C₅Me₄₀₇G₄₀₈C₄₀₉·G₄₂₈C₄₂₇G₄₂₆ trimer step (C₅Me₄₀₇·G₄₂₈ at top, C₄₀₉·G₄₂₆ at bottom) and closely associated amino acids (glycine 78 and lysine 91) in the complex of DNA with HhaI methyltransferase (51) (NDB entry: pde141); (e) minor-groove view of the staggered (lower) T₄₉₉A₅₄₁ base pair, the H6(G₁₄₁)···O6(C₁₄₄) inter-strand hydrogen bond (dashed line), and the major-groove recognition helix (serine 1151 and lysine 1165) of RXR-a in the complex with its idealized direct repeat DNA target (52) (NDB entry: pd0071). Images created with 3DNA (18) and Raster3D (53). Planes of bases colored as follows: A—red; T—blue; G—green; C—yellow.

Opening and stretching

A subtle (24°) base-pair opening of A₁₃T₁₉ is induced by contacts of Hin recombinase (50) with the minor-groove edge of T₁₉ (NDB entry: pde009; Fig. 4d). By contrast, the major-groove capture of cytosine by HhaI DNA cytosine-5-methyltransferase (51) introduces nearly maximal opening (178°) and extreme lateral base-pair displacement, i.e., stretch (8.5 Å), of the broken base pair (NDB entry: pde141; Fig. 4c).

Stagger

The close fit of the recognition helix of the 9-cis retinoic acid receptor, RXR, against the DNA major groove is responsible for the noticeable stagger (1.2 Å) of the T₁₄₉₉A₅₄₁ base pair.
the accompanying inter-strand N6(A1541)···O6(G1498) hydrogen bonding (52) (NDDB entry: pd0071; Fig. 4e).

Summary

The Watson–Crick base-pairing scheme is characterized by several unique structural properties, including the complementarity and perfect isomorphism that are used in replication and in transcription of the genetic code. These general features underlie the ability of DNA to incorporate any arbitrary sequence in a nearly regular duplex. On the other hand, the subtle, sequence-dependent variability of A·T versus G·C base-pairing geometry is used by the DNA-binding proteins involved in regulation. The ingenious base-pairing principle postulated more than half a century ago and subsequently confirmed in high-resolution crystal structures of DNA and RNA continues to surprise us by its beauty, simplicity, and complexity.

Approaches to Enzyme Inhibition

Richard B. Silverman, Northwestern University, Evanston, Illinois
doi: 10.1002/9780470048672.wecb157

This article describes various approaches to inhibition of enzyme catalysis. Reversible inhibition includes competitive, uncompetitive, mixed inhibition, noncompetitive inhibition, transition state, and slow tight-binding inhibition. Irreversible inhibition approaches include affinity labeling and mechanism-based enzyme inhibition. The kinetics of the various inhibition approaches are summarized, and examples of each type of inhibition are presented.

Enzyme inhibitors are compounds that interact with an enzyme and slow down or prevent catalysis from occurring. Natural enzyme inhibitors are often present to control metabolism; synthetic inhibitors generally are used for the purpose of blocking enzyme-catalyzed reactions in the treatment of human and lower animal disease and in agriculture. Many biological systems are controlled with two molecules that have opposite activities, such as excitatory and inhibitory neurotransmitters or hypertensive and hypotensive peptide hormones. Specific enzymes are responsible for the biosynthesis of these molecules can be selectively inhibited. Diseases often develop from an excess or deficiency of a particular metabolite, from infestation of a foreign organism, or from aberrant cell growth. All of these disease etiologies, at least when related to an enzyme activity, can be addressed by specific enzyme inhibition. For example, if an excess of a particular metabolite exists, then inhibition of the enzyme that produces that metabolite would decrease its concentration; inhibition of an enzyme that degrades a particular metabolite would lead to an increase in that compound, thereby reversing a deficiency of that molecule. Inhibition of an essential enzyme for a foreign organism, particularly if humans do not have that enzyme, would be an ideal method for selective toxicity of the foreign organism. A similar approach can be taken to destroy insects, fungi, or weeds for agricultural purposes, namely by inhibiting an essential enzyme for those pests. Inhibition can occur either reversibly or irreversibly. In this article, the various common approaches of reversible and irreversible inhibition are summarized with relevant examples provided for each. The reversible inhibition methods include competitive, uncompetitive, mixed, noncompetitive, transition state analog, multisubstrate analog, slow-binding, and slow tight-binding inhibition. Irreversible inhibition includes affinity labeling and mechanism-based inhibition. Derivations of the kinetic equations are given in the books in the Further Reading section at the end of this review.

Reversible Enzyme Inhibition

The most common type of inhibition is reversible inhibition. As the name implies, a reversible inhibitor functions by binding reversibly (generally noncovalently) to the target enzyme. An inhibitor forms a complex with the enzyme (an E·I complex); the dissociation of that complex is measured by the Ki (the ratio of the rate of dissociation of the inhibitor to association of the inhibitor, koff/kon; the concentration of inhibitor that gives half the maximal inhibition). As it is a dissociation constant, the smaller the Ki value for an inhibitor, the tighter the binding, and the more potent is the inhibitor. How these dissociation constants for the various types of inhibition are determined experimentally is described in the respective sections below.

Reversible inhibition that produces complete loss of catalytic activity is referred to as linear inhibition because the plots of K_m/V or 1/V versus [I] are straight lines. When some catalytic activity remains, even at saturating amounts of inhibitor, it is referred to as hyperbolic inhibition because these plots are nonlinear (this case will not be considered here). Both of these types of reversible inhibition are further classified according to the various apparent Michaelis-Menten parameters that are affected by the inhibitor. The two limiting cases are competitive inhibition and uncompetitive inhibition; a third type is mixed inhibition, which includes as a special case noncompetitive inhibition.

The simplest method to determine whether an inhibitor is reversible after enzyme inhibition with excess inhibitor is to remove the inhibitor by dialysis or gel filtration. If full enzyme activity returns, then inhibition is reversible. However, it
Approaches to Enzyme Inhibition

Scheme 1

Competitive inhibition. does not answer the question of whether the compound is non-covalently bound or covalently bound with a weak, reversible covalent interaction.

Competitive Reversible Enzyme Inhibition

The most common type of reversible inhibition is when the inhibitor binds to the free enzyme in the substrate binding site (called the active site), which is known as competitive reversible inhibition. Competitive inhibition prevents the substrate from binding because of a competition between the substrate and inhibitor for binding to the active site (Scheme 1). Particularly in medicinal chemistry, another common expression of inhibition, in addition to the other approaches (i.e., non-competitive inhibition), is the IC$_{50}$ value, the concentration of an inhibitor that results in 50% inhibition of the enzyme in the presence of a specific concentration of substrate. The IC$_{50}$ and $K_i$ values for a competitive reversible inhibitor are roughly interconverted by the following expression (Eq. 1) (1–3)

$$IC_{50} = \frac{(1 + [S]/K_m)}{K_i}$$

Kinetics of Simple Competitive Inhibition

The rate of the reaction, which depends on [I], $K_i$, [S], and the $K_m$, is depicted in Equation 2.

$$v = \frac{V_{max}[S]}{[K_m(1 + [I]/K_i)] + [S]}$$

The reciprocal of this equation, known as the Lineweaver-Burk equation (4), is shown in Equation 3.

$$\frac{1}{v} = \frac{K_m}{V_{max}}\frac{1}{[S]}\frac{1}{[I] + [I]/K_i} + \frac{1}{V_{max}}$$

The Lineweaver-Burk expression is depicted graphically in Fig. 1. This graph correlates the rate as a function of [S], first in the absence of inhibitor (line a), then with added inhibitor concentrations (lines b–e). Note that as more inhibitor is added, the slope of the line increases, but the $V_{max}$ does not vary. As 1/[S] approaches zero (infinite [S]), the lines converge on the data in the absence of inhibitor (all of the inhibitor is displaced by substrate), namely, 1/$V_{max}$. At low [I], inhibitor competes effectively with substrate for the enzyme. When a competitive inhibitor binds to the free enzyme, there are fewer enzyme molecules for the substrate to bind to, so the rate decreases. According to Equations 2 and 3, the reciprocal of the rate is proportional to $K_m/V_{max}$, so the slopes of the lines vary with [I] (in the presence of inhibitor, it requires more substrate to attain the same $V_{max}$ as in the absence of inhibitor). Therefore, the $K_m$ appears to be larger in the presence of inhibitor (a larger $K_m/V_{max}$ means a larger slope). The apparent $K_m$ ($K_{m,app}$) at each [I] can be calculated from each negative x-axis intercept using Equation 4.

$$-\frac{1}{K_{m,app}} = -\frac{1}{K_m(1 + [I]/K_i)}$$

Other ways of displaying kinetic data are with the use of Dixon (5) and Cornish-Bowden (6) plots.

Example of Simple Competitive Inhibition

As the most common type of inhibition, myriad examples of competitive reversible inhibition exist in the literature. The following is a selection from Thomas Poulos and my laboratories related to the selective inhibition of the neuronal isozyme of

![Graphical depiction of Lineweaver–Burk expression for determination of competitive inhibitor kinetic constants.](image-url)
Approaches to Enzyme Inhibition

nitric oxide synthase (NOS) (7). Nitric oxide (NO) is a ubiquitous biological messenger involved in a variety of physiological processes that acts as a signal transducer but also exerts a variety of regulatory and cytostatic functions (8). It is produced by the enzyme NOS, which catalyzes the oxidation of L-arginine to L-citrulline and NO in a NADPH- and O2-dependent process (9, 10). There are at least three distinct isoforms of NOS. The constitutive endothelial isoform (eNOS) is involved in the regulation of smooth muscle relaxation and blood pressure and in the inhibition of platelet aggregation (11). A second constitutive isoform is neuronal NOS (nNOS), which is important for neurotransmission (12). A third isozyme is inducible NOS (iNOS), which is located in activated macrophage cells and acts as a cytotoxic agent in normal immune responses (13). All of the isoforms use NADPH, FAD, FMN, tetrahydrobiopterin, and heme as cofactors. The constitutive isoforms also require Ca2+ and calmodulin for activity, whereas the inducible isoform has tightly bound Ca2+ and calmodulin. They share only approximately 50% of primary sequence homology, suggesting that they may differ from each other in regulatory aspects. The use of NOS inhibitors in pathologically elevated synthesis of NO has great therapeutic potential (14, 15). NO overproduction by nNOS has been associated with neurodegeneration during stroke, spinal transmission of pain, migraine headaches, Parkinson’s disease, and Alzheimer’s disease. Thus nNOS represents an important therapeutic target for nNOS-selective inhibitors (16). Enhanced formation of NO after the induction of iNOS appears to be important in the tolerance to and dependence on morphine, development of colitis, cancer, and tissue damage and inflammation (17, 18). Selective inhibition of one isozyme over the others is essential because the three isoforms of NOS have unique roles in separate tissues (19).

Figure 2  (a) Replot of data from Lineweaver–Burk plots (Fig. 1) for determination of $K_i$ values for competitive inhibitors. (b) Alternative replot of data from Lineweaver–Burk plots (Fig. 1) for determination of $K_i$ values for competitive inhibitors.

Figure 3  (a) Compound 1 bound to active site of nNOS. (b) Compound 1 bound to active site of eNOS.
An analog of (L)-nitroarginine, L-nitroargininyl-L-2,4-diaminobutyramide (1), was shown to be a potent $K_i$, 130 nM and highly selective inhibitor of nNOS (1538-fold more potent than with eNOS and 192-fold more potent than with iNOS) (20). In addition to a kinetic analysis that demonstrated competitive inhibition, dialysis of the inhibited enzyme led to the return of enzyme activity, indicating that 1 is a reversible inhibitor. The competitive nature of the inhibition was firmly established by X-ray crystallography, showing 1 in the active site (7) of both nNOS (Fig. 3a) and eNOS (Fig. 3b). The nitroargininyl moiety binds at the guanidino binding site for L-arginine. However, in nNOS 1 adopts a somewhat curled conformation, whereas in eNOS it has an extended conformation. It is thought that this binding difference develops from two sources: a 1 amino acid difference in the active site, namely, Asp597 in nNOS is Asn368 in eNOS, which is responsible for an important electrostatic interaction in nNOS that is missing in eNOS, and the smaller Val106 side chain in eNOS near the active site entry, which allows inhibitors to adopt an extended conformation while the larger Met336 in nNOS encourages a curled conformation. If Asp597 in nNOS is mutated to Asn, then 1 adopts an extended conformation in D597 N nNOS as if it was binding to eNOS. Furthermore, the $K_i$ value for 1 with the D597 N mutant is 223 times larger (weaker binding) than wild-type nNOS, again simulating binding interactions like those with eNOS (21). Conversely, if Asn368 in eNOS is mutated to Asp, then 1 adopts a curled conformation in N368D eNOS, as if it was nNOS, and the $K_i$ value for 1 bound to N368D eNOS is 10 times lower (more potent) than in wild-type eNOS, again simulating binding to nNOS rather than to eNOS. A double mutant of eNOS, N368D/V106 M eNOS, was prepared to make the active site of eNOS appear even more nNOS-like, and the $K_i$ value for 1 was an additional fivefold lower than the single mutant; the crystal structure showed that 1 was still in the curled conformation, as in the case with wild-type nNOS. Likewise, 1 bound to the D597N/M336V double mutant of nNOS was in the extended conformation (Fig. 4) as if it was bound to eNOS, although there was little change in the $K_i$ value relative to that of the single mutant.

Uncompetitive Enzyme Inhibition

The other extreme is when a compound binds only to the $E\cdot S$ complex but not to the free enzyme, in which case uncompetitive inhibition occurs (Scheme 2). Although it is rare in single substrate reactions, it is common in multiple substrate systems. An inhibitor of a two-substrate enzyme that is competitive against one of the substrates often is found to give uncompetitive inhibition when the other substrate is varied. The inhibitor binds at the active site but only prevents the binding of one of the substrates.

Kinetics Of Uncompetitive Inhibition

The rate of this type of inhibition is described by Equation 5; the Lineweaver–Burk transformation of this rate equation is given
Approaches to Enzyme Inhibition

Figure 5 Lineweaver–Burk plots for determination of uncompetitive inhibitor kinetic constants.

\[ v = \left( \frac{V_{\text{max}}[S]}{1 + [I]/K_i} \right) / \left( \frac{K_m}{1 + [I]/K_i} + [S] \right) \]

(5)

\[ \frac{1}{v} = \left( \frac{K_m}{V_{\text{max}}} \right) \left( \frac{1}{[S]} \right) + \left( \frac{1}{V_{\text{max}}} \left( \frac{1}{1 + [I]/K_i} \right) \right) \]

(6)

As uncompetitive inhibitors do not bind to free enzyme, the inhibitor has no effect on the \( V_{\text{max}}/K_m \), and the slopes are independent of inhibitor concentration (Fig. 5). The \( K_i \) values can be obtained from replots of either \( 1/V_{\text{max,app}} \) (the y-axis intercepts) versus [I] (Fig. 6a) or \( 1/K_{m,app} \) (the x-axis intercepts) versus [I] (Fig. 6b).

The \( IC_{50} \) value for an uncompetitive inhibitor is related to the \( K_i \) by Equation 7 (22). When \([S] \gg K_m\), which is often the case, the \( IC_{50} = K_i \).

\[ IC_{50} = K_i (1 + K_m/[S]) \] (7)

Example of Uncompetitive Inhibition

Tuberculosis is responsible for 2,000,000 deaths worldwide annually (23). It is one of the leading opportunistic infections in AIDS patients (24) and is spreading because of multidrug-resistant strains of the organism that causes tuberculosis, namely Mycobacterium tuberculosis (25). The principal drug used for tuberculosis is isoniazid (\( 2, Scheme 3 \)), which inhibits the biosynthesis of mycolic acids, thereby disrupting the mycobacterium’s cell wall (26). The target for isoniazid is the enoyl reductase (known as InhA) in the type II fatty acid biosynthesis pathway (27). InhA is inhibited by the product of the mycobacterial catalase-peroxidase (KatG) (28) reaction of isoniazid and NADH (\( 3, Scheme 3 \)) (29–31). Resistance to isoniazid principally develops from mutations in KatG, which blocks the activation of isoniazid (32). Compounds that directly inhibit the ultimate target, InhA, without requirement of activation by KatG should be more promising drugs for resistant Mycobacterium tuberculosis.

![Figure 5](image-url)
A series of uncompetitive inhibitors of InhA were developed using structure-based design from the crystal structure of triclosan (4) bound to both E. coli enoyl reductase (called ecFabI) (33) and to InhA (Fig. 7) (34). Triclosan was shown by kinetic analysis to be an uncompetitive inhibitor of InhA (35). The structure of triclosan bound to InhA confirmed its uncompetitive inhibition properties; triclosan binds to InhA only in the presence of NAD\textsuperscript{+}. The phenol ring of triclosan π-stacks with the nicotinamide ring of NAD\textsuperscript{+} as well as forming a hydrogen bond to Tyr158 and the 2′-hydroxyl group of NAD\textsuperscript{+}. Based on this structure, a series of alkyl diphenyl ethers, which are uncompetitive inhibitors of InhA and do not require activation by KatG, was designed. The most potent analog (5) has a \(K_i\) value of 1 nM for InhA and MIC\textsubscript{99} (minimum inhibitory concentration to destroy 99% of the organisms) values of 2–3 \(\mu\)g/mL (6–10 \(\mu\)m) for drug-sensitive and drug-resistant strains of Mycobacterium tuberculosis.

**Mixed Enzyme Inhibition**

Sometimes an inhibitor can bind to both the free enzyme (E) and to the enzyme-substrate (E·S) complex, resulting in mixed inhibition (Scheme 4). This type of inhibition involves binding of the inhibitor to a site other than at the active site for binding to the E·S complex to occur. A special case of mixed inhibition when \(K_m\) and \(K_m'\) are equal is called noncompetitive inhibition.

**Kinetics of Mixed Inhibition**

If dissociation of the substrate from the E·S complex is the same as that from the E·S·I complex (i.e., \(K_m = K_m'\)), then pure noncompetitive inhibition occurs, and the rate is given as Equation 8. The Lineweaver-Burk equation from this is shown in Equation 9, which is depicted graphically in Fig. 8. Unlike competitive inhibitors, noncompetitive inhibitors affect \(V_{max}\) (interception on the y-axis) is different at different inhibitor concentrations but not \(K_m\) (all concentrations of inhibitor give lines with the same interception on the x-axis). A replot of these data either as the slope versus \(I\) (Fig. 9a) or \(1/V_{max}\) versus \(I\) (Fig. 9b) provides the \(K_i\) value, Dixon (5) and Cornish-Bowden (6) plots also can be constructed.

The situation above, where \(K_m = K_m'\), for dissociation of the substrate from both the E·S and the E·S·I complexes, is actually relatively rare compared with the case of different dissociation constants. If the E·I complex has a lower affinity for
Appropes to Enzyme Inhibition

Figure 8  Graphical depiction of Lineweaver–Burk expression for determination of pure noncompetitive inhibitor kinetic constants.

Figure 9  (a) Replot of data from Lineweaver–Burk plots (Fig. 8) for determination of $K_i$ values for pure noncompetitive inhibitors. (b) Alternative replot of data from Lineweaver–Burk plots (Fig. 8) for determination of $K_i$ values for pure noncompetitive inhibitors.

the substrate than free enzyme, then inhibition is a mixture of competitive and uncompetitive inhibition, referred to as mixed inhibition. In the presence of inhibitor, there will always be some ESI complex, which lowers the free enzyme concentration, and $V_{max}$ will be less than with just free enzyme (the ESI complex is nonproductive). As the EI complex has a lower affinity for substrate than free enzyme, the $K_m$ will be greater (lower affinity) for the EI complex than that with free enzyme. The Lineweaver–Burk equation for this case is shown in Equation 10.

$$\frac{1}{V} = \frac{\frac{K_m}{V_{max}}}{(1/S)(1 + [(I)/K_i])}$$

$$+ \frac{1}{V_{max}}(1 + [(I)/K_i]) \quad (10)$$

In this case, the interception of lines as a function of inhibitor concentration can occur either above the x-axis (Fig. 10a) or below the x-axis (Fig. 10b). $K_i$ values for mixed inhibition are obtained by replotting the data from the Lineweaver–Burk plot as the slope ($\frac{V_{max}}{V_{max}}[1 + [(I)/K_i]]$) versus $[I]$ (Fig. 11a) or as the y-axis intercept ($\frac{1}{V_{max}}$) versus $[I]$ (Fig. 11b). With Fig. 11a, the x-axis intercept is $-K_i$; with Fig. 11b, the x-axis intercept is $-K_i'$. The $IC_{50}$ value for a mixed inhibitor can be related to the $K_i$ by Equation 11 (36). For a noncompetitive inhibitor, in which $K_i = K_i'$, or when the $[S] \gg K_m$, $IC_{50} = K_i$.

$$IC_{50} = \frac{(K_m + [S])/(K_m/K_i) + ([S]/K_i')]}{(1 + [(I)/K_i'])} \quad (11)$$

Example of Mixed Inhibition

The mitogen-activated protein kinase (MAPK) signaling pathway is responsible for the regulation of cell growth and differentiation consisting of a MAPK (such as ERK1 and ERK2), a MAPK kinase (such as MEK1 and MEK2), and a MAPKK kinase (such as M KK1 and M KK2). The MAPK signaling pathways are important for the formation, progression, and survival of tumors (40) as well
as being intracellular mediators in many inflammatory processes (41). MEK1 and MEK2 phosphorylate ERK at specific tyrosine and threonine residues, which is a prerequisite for cell proliferation. MEK1 and MEK2 are equally competent to phosphorylate ERK (42), so both are targets for the design of antitumor agents. Compound 6 has been found to be a potent and highly selective inhibitor of MEK1 and MEK2; it was shown kinetically to be a mixed inhibitor with both Mg·ATP and MAPK and went into clinical trials for the treatment of colon cancer (43). Further evidence for the mixed inhibition properties of 6 was provided by crystal structures of an analog of 6 (compound 7) bound to an N-terminally truncated form of human MEK1 containing Mg·ATP (to 2.4 Å resolution) and compound 8 bound to an N-terminally truncated form of human MEK2 containing Mg·ATP (to 3.2 Å resolution) (44). Therefore, the inhibitors bind to the E-S complex. The Mg·ATP in MEK1 binds in a location similar to that in other protein kinases; 6, however, binds in a separate binding site adjacent to Mg·ATP (Fig. 12). The side chains of Lys97 and Met143 separate these two binding pockets. When Mg·ATP and 6 are bound to unphosphorylated MEK1, the two lobes adopt a closed conformation, causing conformational changes in the activation loop and helix C, which interferes with an important electrostatic interaction between a conserved glutamate residue (Glu114) and a conserved lysine residue (Lys97) in the ATP binding site, resulting in stabilization of an inactive conformation of the enzyme. A similar structure was obtained for 8 bound to MEK2 containing Mg·ATP. It is believed that the specificity of these mixed inhibitors derives from their binding in a region where sequence homology to
Approaches to Enzyme Inhibition

other protein kinases is very low and distinct from the highly homologous ATP binding site.

Transition State Analog Inhibition and Slow Tight-Binding Inhibition

A special type of reversible inhibition in which the inhibitor resembles the transition state structure of the enzyme-catalyzed reaction is known as transition state analog inhibition. It has long been believed that an enzyme catalyzes its reaction by an initial interaction of the substrate with the active site of the enzyme, triggering a conformational change in the enzyme, which induces the chemistry of the reaction (45, 46). As the reaction approaches the transition state, the binding interactions with the substrate increase until, at the transition state, maximal binding interactions result. These interactions produce transition state stabilization, which is responsible for lowering the activation energy and accelerating the rate of the reaction.

This process suggests that enhanced binding by an inhibitor to an enzyme would occur if the inhibitor structure resembled that of the transition state of the reaction rather than the ground state (i.e., the substrate structure) (47-50), which has been shown to be the case in many examples (51). Typically the kinetics of inhibition of transition state analog inhibitors are different from that of other types of reversible inhibitors, which exhibit instantaneous inhibition (millisecond time scale); transition state analog inhibitors generally produce time-dependent inhibition (t1/2 of seconds or even hours) as a result of a conformational change that is induced when these inhibitors bind to the enzyme, leading to a slow isomerization of the initial E·I complex to another complex (E·I*) in which the inhibitor is bound more tightly to the enzyme than in the E·I complex (Scheme 5). This process is known as slow-binding inhibition.

Kinetics of Slow-Binding Inhibition and Slow Tight-Binding Inhibition

Reversible inhibitors that attain equilibrium between enzyme, inhibitor, and the E·I complex slowly, as compared with the enzyme-catalyzed substrate reaction, are called slow-binding inhibitors (52). In some cases, the ratio of total inhibitor to total enzyme must be high, as in the case of the classic competitive inhibitors; but in other cases, the attainment of the equilibrium of E, I, and the E·I complex occurs when the inhibitor concentration is approximately the same as the enzyme concentration, in which case the inhibitors are called slow tight-binding inhibitors (53, 54). Slow-binding and slow tight-binding inhibition generally occur in competition with the substrate, but also can be a mixed type inhibition. The lifetimes of enzyme complexes with slow-binding inhibitors
Approaches to Enzyme Inhibition

or slow tight-binding inhibitors are relatively long and exhibit slow off rates \(k_{-2}\); the on rates \(k_{2}\) may be fast or slow. As the rate of release of the inhibitor from the E·I complex becomes exceedingly slow, inhibition approaches irreversible. The overall dissociation constant for the E·I* complex \(K_i^*\) is defined by Equation 12.

\[
K_i^* = \frac{[E][I]}{[E·I] + [E·I^*]} = \frac{k_{-2}}{k_{2} + k_{-2}}
\]

Equation 12

Progress curves for a slow-binding or slow tight-binding inhibitor are described by general Equation 13, where \(v_o\), \(v_s\), and \(k\) represent, respectively, the initial rate, the final steady-state rate, and the apparent first-order rate constant for establishment of the equilibrium between E and E·I*. The following equations are valid only under specific simplifying conditions (52). Equilibria to the formation of the E·S (from E + S) and E·I (from E + I) complexes must be attained rapidly. In addition to a slow establishment of equilibrium between E·I and E·I*, the reverse rate \(k_{-2}\) of this equilibrium must be much less than the forward rate \(k_{2}\). The initial rate is obtained from Equation 14, where \(V_{\text{max}}\) is the maximum rate, \([S]\) is the concentration of the substrate for which I is an inhibitory analog.

\[
v_o = \frac{V_{\text{max}}[S]}{K_m}\frac{1}{1 + [I]/K_i} + [S]
\]

Equation 14

The final steady-state rate is obtained from Equation 15, where \(K_i^*\) is the overall inhibition constant as defined in Equation 12. The apparent first-order rate constant \(k\) for the interconversion of E·I and E·I* in the presence of substrate S is expressed in Equation 16. Figure 13 gives an example of a progress curve for a slow-binding inhibitor. For each curve with inhibitor present, there is an initial burst followed by a slower steady-state rate.

\[
k = k_{-2} + k_{2}\left(\frac{[I]}{K_i} + \frac{[S]}{K_m}\right)
\]

Equation 16

Example of a Transition State Analog Inhibitor that Exhibits Slow Tight-Binding Inhibition

5′-Methylthioadenosine/S-adenosylhomocysteine nucleosidase (MTAN) catalyzes the hydrolysis of 5′-methylthioadenosine (MTA), a byproduct of polyamine synthesis, to adenine and 5-methylthio-D-ribose (MTR) (Scheme 6). MTA is a feedback inhibitor of polyamine synthesis, so inhibition of MTAN would inhibit polyamine synthesis and the salvage pathways for adenine and methionine, which would result in antibacterial (55) or antitumor activity (56). Kinetic isotope effects on this reaction were measured to determine the transition state structure (57). A large 1′-3H and small 1′-14C isotope effect suggest that the MTAN-catalyzed reaction proceeds by a dissociative (S_{+1}) mechanism with little involvement of the leaving group or attacking nucleophile at the transition state, which indicates that the transition state has significant ribooxacarbenium ion character. Based on this hypothetical transition state structure, two series of transition state analog inhibitors were designed (9 and 10) to mimic the transition state structure. The protonated
Approaches to Enzyme Inhibition

Scheme 6

\[ \text{5'-Methylthioadenosine/S-adenosylhomocysteine nucleosidase (MTAN)-catalyzed hydrolysis of 5'-methylthioadenosine (MTA) to adenine and 5-methylthio-D-ribose (MTR).} \]

1. Nitrogens in each series mimic the ribooxacarbenium ion intermediate (related to the transition state) and a methylene bridge was added between the ribooxacarbenium ion mimic and the 9-deazaadenine base to emulate the N-ribosidic bond distance of a fully dissociated transition state. A kinetic analysis shows that 9 and 10 are competitive inhibitors; progression curves demonstrated the time dependence of the inhibition. Application of Equations 14–16 to the 9 series resulted in dissociation constants in the picomolar range and for the 10 series in the femtomolar range. Compound 11 has a \( K_i = 2.6 \mu M \) and a \( K^* = 47 \mu M \) with a \( K_m/K_i^* \) value of 9.1 million and 91 million (11 binds this amount greater) relative to the substrates MTA and S-adenosylhomocysteine, respectively! These are some of the most potent noncovalent competitive enzyme inhibitors known. Furthermore, there is no MTAN in humans; 5'-methylthioadenosine phosphorylase (MTAP) is the only enzyme in humans capable of metabolizing MTA, and MTAN has a larger 5'-alkylthio binding site. Specificity factors in the thousands between inhibition of MTAN in bacteria over MTAP in humans were achieved, which allows for selective toxicity against microorganisms.

The crystal structures of 9 (\( R = CH_3 \)) and 10 (\( R = CH_3 \)) bound to MTAN at 2.2 Å resolution revealed a new ion pair between the positive charge on the ring and the nucleophilic water (hydroxide ion) (58). Based on the distances of these interacting atoms, 9 (\( R = CH_3 \)) appears to be a mimic of an early transition state, and 10 (\( R = CH_3 \)) mimics a highly dissociated transition state, for the MTAN-catalyzed reaction.

Example of a Multisubstrate Analog Inhibitor

Purine nucleoside phosphorylase (PNP), which catalyzes the reversible phosphorolysis of ribonucleosides to ribose 1-phosphate and the free base (Scheme 7), plays an important role in purine nucleoside metabolism and in T-cell development (59, 60). PNP inhibitors have therapeutic utility for selective destruction of T cells in T-cell leukemias and T-cell lymphomas as well as in the treatment of T-cell-mediated autoimmune diseases and for the suppression of the post-organ transplant T-cell response (61).

To mimic the long bond length in the transition state, compound 12 was synthesized as a multisubstrate inhibitor (62). This compound mimics both substrates of PNP, the purine nucleoside, and phosphate. The two-carbon bridge between the ribose ring and the phosphate group was incorporated to place the phosphonate moiety into the phosphate-binding site. A crystal structure of 12 bound in PNP at 1.7 Å resolution (Fig. 14) resembles that of a previously determined structure of bovine
Scheme 7  Purine nucleoside phosphorylase (PNP)-catalyzed phosphorolysis of ribonucleosides to ribose 1-phosphate and the free base.

Figure 14  Stereographic projection of 12 bound to active site of PNP at 1.7 Å resolution.

PNP with substrate analogs (inosine and sulfate) bound (63). The nucleoside part of 12 binds in the purine nucleoside binding pocket, and the phosphate binds in the phosphate binding pocket. The IC_{50} for 12 is 30 nM, one of the most potent PNP inhibitors reported.

Substrate and Product Inhibition

Michaelis-Menten kinetics predict that as the concentration of the substrate increases, the rate increases hyperbolically. However, some enzymes exist in which a maximum velocity is obtained at low substrate concentration, but further increases in the substrate concentration lead to a decrease in velocity. This effect is known as substrate inhibition and can eventually lead to complete enzyme inhibition or partial enzyme inhibition. It is thought that substrate inhibition occurs if two substrate molecules bind to the enzyme simultaneously in an incorrect orientation and produce an inactive E·S·S complex, analogous to that discussed for uncompetitive inhibition. The rate of the enzyme reaction that undergoes substrate inhibition is given by Equation 17, where $K_i$ represents the equilibrium constant for formation of the E·S·S complex from E·S and S and $K_{m}^{'}$ is a modified Michaelis constant. The reciprocal of Equation 17 is described by Equation 18, which is analogous to the Lineweaver-Burk equation and is depicted graphically in Fig. 15.

$$
\frac{1}{v} = \frac{1}{V_{max}[S]} + \frac{1}{V_{max} + (K_{m}^{'}[S]/V_{max})} 
$$  (18)

Another type of inhibition results from the product formed in an enzyme-catalyzed reaction (64). The rate of substrate turnover in the presence of preexisting product is less than the initial rate at the same substrate concentration in the absence of product. This process occurs for two reasons: Some of the enzyme is in an E·P complex so there is less enzyme available to which the substrate can bind, which increases the apparent $K_m$ for the substrate; some of the product is being converted back to substrate, which makes it appear as if less substrate is available.

Irreversible Enzyme Inhibition

Irreversible enzyme inhibition, also called enzyme inactivation (or active-site directed irreversible inhibition, because it is generally competitive with substrate), occurs when a compound blocks the enzyme activity for an extended period of time, generally via covalent bond formation. Therefore, even though some slow tight-binding inhibitors functionally block the enzyme activity irreversibly, they are still considered reversible.
inhibitors because they can dissociate from the enzyme, albeit very slowly. The most effective inactivators are ones whose structures are similar to those of the substrates or products of the target enzyme, but this is not essential when studying an isolated enzyme. Once the reaction has occurred, it is no longer necessary to sustain a concentration of the inactivator to retain the E-I complex because of the covalent nature of the bond formed. In some cases only a stoichiometric amount of inactivator is needed to produce complete irreversible inhibition. Irreversible inhibition is generally determined by dialysis or gel filtration of the inactivated enzyme; no enzyme recovery is expected. Two general types of irreversible enzyme inhibitors exist, affinity labeling agents and mechanism-based inactivators.

Affinity Labeling Agents

Affinity labeling agents are intrinsically reactive compounds that initially bind reversibly to the active site of the enzyme then undergo chemical reaction (generally an acylation or alkylation reaction) with a nucleophile on the enzyme (Scheme 8). To differentiate a reversible inhibitor from an irreversible one, often the dissociation constant is written with a capital I, K_I (65), instead of a small i, K_i, which is used for reversible inhibitors. The K_I denotes the concentration of an inactivator that produces half-maximal inactivation. Note that this kinetic Scheme is similar to that for substrate turnover except instead of the catalytic rate constant, k_cat, for product formation, k_inact is used to denote the maximal rate constant for inactivation.

Kinetics of Affinity Labeling Inactivation

When the equilibrium for reversible E-I complex formation (K_I) is fast relative to k_inact (the most common situation), then k_inact is the rate-determining step, and time-dependent loss of enzyme activity occurs. Under these conditions, when [I] >> [E], then Kitz and Wilson (65) described k_app by Equation 19. Two limiting situations can be considered. For [I] >> K_I, k_app = k_inact, and pseudo first-order kinetics are observed, as shown in Fig. 16a. For [I] < K_I, then k_app = k_inact/K_I, which gives simple bimolecular kinetics, in which case the straight line in Fig. 16b would pass through the origin rather than the +y-axis. To determine the K_I and k_inact values, first a plot of the log of the enzyme activity versus time is constructed (Fig. 16a). The rate of inactivation is proportional to low concentrations of the inactivator, but becomes independent at high concentrations. In these cases, the inactivator reaches enzyme saturation (just as substrate saturation occurs during catalytic turnover). Once all of the enzyme molecules are in the E-I complex, the addition of more inactivator does not affect the rate of the inactivation reaction. The half-lives for inactivation (t_{1/2}) at each inactivator concentration (lines a-e in Fig. 16a) are determined. The t_{1/2} at any inactivator concentration equals log 2/k_inact, in the limiting case of infinite inactivator concentration, t_{1/2} = 0.693/k_inact (log 2 = 0.693). A replot of these half-lives versus the inverse of the inactivator concentration, referred to as a K-I and Wilson replot, is constructed to obtain the K_I and k_inact values (Fig. 16b).

Example of an Affinity Labeling Agent

7-Aminocephalosporanic acid (15, Scheme 9) is an important intermediate in the production of many semisynthetic cephalosporin antibiotics (66, 67). However, direct deacylation of cephalosporin C (13) to 15 by cephalosporin C acylase is unfavorable, so an enzymatic process is used involving D-amino acid oxidase (DAAO) oxidation of 13 to D-glutaryl-7-aminocephalosporanic acid (14, GL-7-ACA) followed by deacylation to 15 and glutaric acid, catalyzed by GL-7-ACA acylase from Pseudomonas sp. 130 (Scheme 9) (68, 69). GL-7-ACA acylase underwent pseudo first-order time-dependent inactivation by 7-bromoacetyl aminocephalosporanic acid (16) (70). Dialysis did not regenerate enzyme activity, indicating irreversible inhibition. The rate of inactivation was lowered by the presence of either glutaric acid or 15.
Figure 16  (a) A plot showing time-dependent inactivation by affinity labeling agents and mechanism-based inactivators used for determination of kinetic constants. (b) Replot of the half-lives of inactivation from Fig. 16a versus the inverse of the inactivator concentration to determine the $K_I$ and $k_{inact}$ values for affinity labeling agents and mechanism-based inactivation.

Scheme 9  D-Amino acid oxidase (DAAO) oxidation of 13 to N-glutaryl-7-aminocephalosporanic acid (14, GL-7-ACA) followed by deacylation to 15 and glutaric acid catalyzed by GL-7-ACA acylase from Pseudomonas sp. 130. indicating that inactivation is active-site directed (competitive inhibition). The site of covalent attachment was identified as the indole ring of Trp-B4 by LC-MS peptide mapping, tandem MS analysis, and NMR spectroscopy. MALDI-TOF spectrometric analysis showed that the fourth tryptophan residue in the $\beta$-subunit (Trp-B4) was alkylated. $^{1}H-^{13}C$ HSQC NMR spectrometry of the acylase inactivated by [2-13C]-16 demonstrated that a C-C bond was formed, and it was the tryptophan residue that was alkylated. Based on other inactivations, it is reasonable that attachment is at C-2 of the indole ring of the tryptophan after rearrangement from the C-3 alkylation product (71) (17). As Trp-B4 is in the middle of an $\alpha\beta\beta\alpha$ sandwich structure, which does not have sufficient space for the inactivator to fit, it is believed that a conformational change has to occur to allow alkylation. Mutations at Trp-B4, except WB4Y, prevented covalent modification of the enzyme.
Mechanism-Based Enzyme Inactivators

Mechanism-based inactivators are unreactive compounds that bear a structural similarity to the substrate or product of a specific enzyme and are converted by the normal catalytic mechanism of that enzyme into a product that, before its release, inactivates the enzyme. These inactivators, when active, act initially as substrates for the target enzyme. Generally, the product undergoes a covalent bond reaction with the target enzyme, but it may just form a tight-binding complex that is functionally irreversible. The key features are an unreactive compound that is enzymatically converted to the actual inactivating species, which binds to the same enzyme before the inactivator’s release. Inactivation by these compounds requires knowledge of the mechanism of the enzyme. Alternatively, because these compounds act as substrates, they can be designed to test a hypothetical catalytic mechanism for an enzyme and determine if a particular type of intermediate is reasonable.

Kinetics of Mechanism-Based Inactivation

As activation of a mechanism-based inactivator requires a catalytic step, an additional intermediate (E-I) is required relative to affinity labeling agents (Scheme 10). If $k_4$ is a fast step and the equilibrium $k_{eq}$ is established rapidly, then $k_2$ is the inactivation rate constant ($k_{inact}$), which determines the maximal rate for the inactivation process leading to E-I'. As both affinity labeling agents and mechanism-based inactivators initially form reversible E-I complexes, which then lead to inactivation of the enzyme (affinity labeling agents by direct covalent reaction and mechanism-based inactivators by initial [generally] rate-determining modification to the activated species followed by rapid reaction), the kinetic constants ($K_i$ and $k_{inact}$) for both types of inactivators are determined in the same way (see Figs. 16a and 16b). The key features of mechanism-based inactivators that differentiate them from affinity labeling agents are their unreactivity and the requirement for an enzyme-catalyzed conversion to the activated species before inactivation. Often this activated species is quite reactive, so it acts as an affinity labeling agent already at the active site. However, inactivation ($k_2$ in Scheme 10) does not occur every time the inactivator is activated because the enzyme will attempt to eject it from the active site as a product ($k_3$ in Scheme 10). It would not be a favorable process if the activated species is highly reactive because it could attach to other parts of the enzyme or, if more than one enzyme was present, could attach to another enzyme. The ratio of the number of turnovers that leads to product release per inactivation event ($k_3/k_2$) is known as the partition ratio.

Example of a Mechanism-Based Inactivator

There are many examples of mechanism-based inactivators from which to choose, but I have selected an example from mine and Tilman Schirmer’s laboratories that relates to the inactivation of γ-aminobutyric acid aminotransferase (GABA-AT). This enzyme is a pyridoxal 5'-phosphate (PLP) dependent enzyme that catalyzes the conversion of the inhibitory neurotransmitter GABA to succinic semialdehyde with concomitant conversion of L-ketoglutarate to the excitatory neurotransmitter L-glutamate (Scheme 11). When the concentration of GABA in the brain diminishes, convulsions can occur. Inhibition of GABA-AT prevents the degradation of GABA, resulting in an increase in the brain GABA concentrations, which is one approach for the treatment of epilepsy. Based on the structure of 4-amino-5-fluoropentanoic acid (18), which was shown to be a very efficient mechanism-based inactivator of GABA-AT (72), (19, 35, 45)-3-amino-4-fluorocyclopentane-1-carboxylic acid (19) was designed as a potentially more lipophilic analog (73). Two inactivation mechanisms were envisioned for 19, one leading to 23 (pathway a) and one leading to 24 (pathway b) (Scheme 12). A crystal structure refined to 1.9 Å resolution of the enzyme inactivated by 19 (Fig. 17) showed explicitly that the more reasonable mechanism is that shown in pathway a to give 23 (74). Inactivator 19 is a classic example of a mechanism-based inactivator; it is an unreactive molecule that is converted by the normal catalytic mechanism of GABA-AT.

Scheme 10  Mechanism-based enzyme inactivation.
Approaches to Enzyme Inhibition

Scheme 11  Mechanism for GABA-AT.

to 20. Deprotonation leads to elimination of fluoride ion (probably via an E1cB mechanism into the PLP) to give a product (22), which after reaction with the active site lysine produces 23. Before its release from the active site, 22 undergoes an enamine reaction with Lys-bound PLP to give covalent adduct 23, the structure identified in the crystal structure. The partition ratio for this inactivator was measured by determination of the number of fluoride ions released per inactivation event to be 147; 148 molecules are turned over, one of which leads to inactivation. Therefore, the crystal structure was able to differentiate these two mechanistic possibilities. The use of crystallography to resolve mechanistic alternatives has been referred to as mechanistic crystallography.

The vitamin B₁₂ cofactor called coenzyme B₁₂ (adenosylcobalamin) assists enzymes called mutases and eliminases in the catalysis of molecular rearrangements. The mutases comprise reactions in which a substrate equilibrates with a product by migration of an amino group (as with β-lysine 5,6-aminomutase) or a carbon-based group (e.g., COSCoA in methylmalonyl-CoA mutase, which interconverts methylmalonyl-CoA with succinyl-CoA). The eliminases (e.g., propane-1,2-diol dehydratase) have either hydroxyl or amino as the migrating group, but they differ from the mutases by affording an intermediate that eliminates water or ammonia to give the observed product (e.g., propanal from propane-1,2-diol via propane-1,1-diol). Methylcobalamin is essentially an intermediary for synthetic reactions catalyzed by methyltransferases. These reactions depend on the “supernucleophility” of reduced vitamin B₁₂ (cob(II)alamin) and in humans provide for the synthesis of the amino acid methionine.

The pursuit of the “antipernicious anemia factor” seemingly ended with the publication in Science in 1948 by Karl Folkers (1906–1997) of a paper entitled “Crystalline vitamin B₁₂.” Just a few weeks later, Lester Smith (1904–1992), who had been guided by testing column fractions on pernicious anemia patients, independently obtained crystals of the vitamin [for a review of the early history of B₁₂ isolation and characterization, and references to the work described in this section see Lester Smith's monograph (1)]. He identified cobalt in B₁₂ and gave the crystals to Dorothy Hodgkin (1910–1994) that led to the structure of the isolated vitamin as cyanocobalamin (CN-Cbl: see Fig. 1 for cobalamin structures and other aspects of nomenclature of so-called corrinoids). In 1958, Horace A. (bet Barker (1907-2000) discovered coenzyme B₁₂ (adenosylcobalamin, AdoCbl); the structure determination of which, again by Dorothy Hodgkin, revealed the presence of a Co-C σ-bond. Finally, methylcobalamin (MeCbl) was recognized as another member of this very exclusive club of natural organometallic compounds. In this article, we review the fundamental chemistry of the B₁₂ cofactors in selected enzymatic reactions for which they are obligatory participants.

**Biological Context**

**Human cobalamins and dietary requirements**

Quantitative assays have shown that the plasma of nonsmoking, healthy adults contains MeCbl (250 pg cm⁻³), AdoCbl, and hydroxocobalamin (OH-Cbl) [AdoCbl + OH-Cbl (125 pg cm⁻³ with AdoCbl] of total cobalamin), which is derived from hydrogen cyanide in tobacco smoke. CN-Cbl can also develop from the consumption of foods (e.g., cassava) that release cyanide ions. In erythrocytes, the chief cobalamin is AdoCbl (>50% of total cobalamin) followed by OH-Cbl. The blood of smokers contains CN-Cbl (~2% of total cobalamin), whereas CN-Cbl has no established role in humans. The total human body store of the corrinoids described is ~5 mg, and the recommended daily requirement of corrinoids is ~2 µg; this nutrient is provided by a typical “Western” diet but may not be included in a vegan diet. Whether 2 µg per day is sufficient to maintain health and protect against disease, especially of a degenerative kind, is a subject of current debate in which some believe it wise to consume larger amounts of
ery?” We know that coenzyme B12 assists a group of enzymes whose mechanisms of action could begin to be understood; today one may (Eq. 1, 2). Corrinoids are sequestered from food sources by a glycoprotein of mass ∼45 kDa called “intrinsic factor,” which is secreted in the stomach and binds B12 derivatives very tightly to form a 1:1 complex (for CN-Cbl, K = 1.5 × 10^10 mol⁻¹ dm³). Several other proteins bind and transport B12 into cells (3). The disease pernicious anemia has been recognized since the early nineteenth century and linked to a deficiency of what William Castle called “extrinsic factor” (i.e., vitamin B12) in 1928 (1). This disease develops because of the failure of the patient to secrete sufficient intrinsic factor (i.e., hydroxocobalamin (OH-Cbl); R = CN denotes cyanocobalamin (CN-Cbl), whilst R = Me a methylcobalamin (MeCbl). By definition all cobalamins contain 5,6-dimethylbenzimidazole, which is the so-called 6th ligand to cobalt in an evolutionary origin, whereas the eliminases evolved separately. Possibly the mutases and methyltransferases have a common origin, whereas the eliminases evolved separately. N-methylcobalamin is completely different from adenosylcobalamin because it is essentially a conduit for synthetic reactions catalyzed by methyltransferases, illustrated in Scheme 2 for the case of methionine. These reactions depend on the “supernucleophilicity” of cob(I)alamin. In one case, this species removes a methyl group from N⁵-methyltetrahydrofolate with the formation of methylcobalamin, and then transfers this group to the acceptor homocysteine, which results in the synthesis of methionine (see Scheme 2). Examples of mutases, eliminases, and methyltransferases are discussed in detail below.

**Coenzyme B12: Nature’s Most Complex Cofactor**

Coenzyme B12 (adenosylcobalamin, Fig. 1) has the most complex structure of all of the cofactors used by nature to aid enzymatic catalysis. Although many unusual features are observed in the structure, it is the cobalt–carbon sigma (σ) bond that is vital, above all, for the mode of action of the coenzyme. The bond dissociation energy (BDE) of ∼130 kJ mol⁻¹ (6) is typical for a metal–carbon bond, although this value is much lower than for σ-bonds from carbon to hydrogen, nitrogen or oxygen, or another carbon (BDE ∼ 350 kJ mol⁻¹), the coenzyme is rather stable in water provided light is excluded. The

---

**Figure 1** In the above structure, R = CN denotes cyanocobalamin (CN-Cbl), whilst R = OH is hydroxocobalamin (OH-Cbl). R = Me denotes methylcobalamin (MeCbl). By definition all cobalamins contain 5,6-dimethylbenzimidazole, which is the so-called 6th ligand to cobalt in the above structure. Substances containing the corrin ligand, i.e. the planar 14 electron p-system embracing cobalt in the above structure, are also called corrinoids.

**Overview of cobalamin-dependent reactions**

With the identification of vitamin B12’s cofactors, their mechanisms of action could begin to be understood; today one may ask, “What do we know some 50 years after their discovery?” We know that coenzyme B12 assists a group of enzymes (Table 1, entries 1–9) in the catalysis of molecular rearrangements, which can all be described by Scheme 1. In Table 1, these enzymes are subdivided into mutases and eliminases. The mutases catalyze equilibrations and comprise reactions in which a carbon skeleton rearranges (entries 1–4, sometimes called Class I reactions; substituted carbon atom as migrating group) as well as the amino mutases (entries 5 and 6, Class II reactions; amino as migrating group) (4). The eliminases (entries 7–9, Class II reactions (4)) have either hydroxyl or amino as the migrating group, but they differ from the mutases in that the rearrangement affords an intermediate that eliminates water or ammonia to give the observed product. Coenzyme B12-dependent ribonucleotide reductase (entry 10) is included in Table 1 because its catalytic reaction exhibits some features of the diol and glycerol dehydratase reactions (i.e., elimination of OH from a 1,2-diol moiety), although the overall reaction is a redox process and not a rearrangement. How the reactions of Table 1 occur remains in part a puzzle, but this review intends to enlighten the reader. The coenzyme B12-dependent mutases and eliminases are a distinctive class of so-called “radical enzymes” (Fig. 2) (5), which are unique among enzymes because their catalytic pathways function via species with an unpaired electron (i.e., radicals). These species are normally highly reactive, but containment within a protein “stranglehold” enables their reactivity to be tamed and harnessed without destructive side reactions. The term “negative catalysis” was coined by János Rétyi in 1990 to describe this phenomenon.

An important structural difference between eliminases and mutases concerns the axial base coordinated to the cobalt, perpendicular to the plane of the corrin ring. Whereas in all the eliminases, the axial base is the dimethylbenzimidazole of the coenzyme itself (Fig. 1), the mutases use a conserved histidine residue of the enzyme for this purpose. On binding of the coenzyme to the apo-enzyme, the axial base is replaced by the histidine and moves into a distinct pocket of the protein. Possibly the mutases and methyltransferases have a common origin, whereas the eliminases evolved separately.

Methyltransferases (see below) also use a protein histidine as axial base, whose reactivity is fine tuned by protonation.

rate constant for decomposition of coenzyme B12 at 30°C in water was determined to be $1.16 \times 10^{-8} \text{ s}^{-1}$, which corresponds to a half-life of 1.9 years (4). The power of the primary organic radical $5'$-deoxyadenosyl that develops from homolysis of the coenzyme's Co-C bond is only unleashed when the coenzyme is bound to a partner enzyme in the presence of a substrate molecule. The $5'$-deoxyadenosyl radical initiates the group of reactions summarized by Scheme 1 (4). In these reactions, a protein-bound radical is initially formed from a substrate molecule. The basic pathway requires at least two participating radicals, with one of these ($S^\bullet$) being structurally related to the substrate (SH) and the other ($P^\bullet$) structurally related to the product (PH). In addition, there may be an intermediate radical ($I^\bullet$) in some, if not all, cases. Homolysis of coenzyme B12 also releases cob(II)alamin, a paramagnetic ($d^7$) species, which is easily detected by electron spin resonance (EPR) spectroscopy of reaction mixtures created by incubating enzyme, coenzyme, and substrate molecules for a few seconds and then freezing in liquid nitrogen.

Coenzyme B12-Dependent Mutases

A common feature of the six known mutases is that a hydrogen atom has to be reversibly abstracted by the $5'$-deoxyadenosyl radical from a nonactivated methyl group to yield a methylene radical, which is $S^\bullet$ or $P^\bullet$ depending on the identity of the substrate and product and is not stabilized by any adjacent group. However, the partner radical is always stabilized by a neighboring group, which is a carboxylate or CoA-ester for entries 1-5 and methyl for entry 6.

Glutamate mutase: the first coenzyme B12-dependent mutase

Glutamate mutase was discovered by Barker, who showed that the enzyme catalyzes the equilibration of (S)-glutamate with (2S,3S)-3-methylaspartate (Entry 1, Table 1; $\Delta G^{\circ} = +6.3$ kJ mol$^{-1}$; $K = 0.095$) (for a review of glutamate mutase see Reference 7). This reaction is one of three distinct methods that nature uses to ferment glutamate to butyrate (5). Surprisingly, they all proceed through intermediate radicals. The coenzyme B12-dependent fermentation is the only one of the three that

\[ \text{Coenzyme B12-dependent enzyme-catalyzed rearrangements (for examples of a, b, X, and Y see Table 1).} \]
The reason is because the C-3 protons of glutamate have an hydrogen atom of glutamate to give 5′-deoxyadenosine to afford 3-methylaspartate (cf. pathways for 2-methyleneglutarate mutase, Scheme 5). The most convincing experimental evidence for this “fragmentation-recombination” mechanism was the isolation of similar amounts of acrylate and glycine (−0.06 mol of each per mol of enzyme) when the working enzyme was interrupted by addition of trifluoroacetic acid (9).

To achieve its catalytic reaction, glutamate mutase faces the problem of how to surmount the two relatively high transition-state energy barriers that lead from the 4-glutamyl radical to acrylate and the glycyl radical and then the recombination of these radicals to the 3-methyl-aspartate radical (Scheme 4). These barriers were computed as ∆H°+ = +59.9 and +66.5 kJ mol−1 (10), respectively, and the 3-methylene-aspartate radical was found to be significantly less stable than the resonance-stabilized 4-glutamyl radical (∆H°+ = +20.3 kJ mol−1). Likewise, with methylmalonyl-CoA mutase and 2-methyleneglutarate mutase the substrate and product radicals are interconnected via transition states of relatively high energy. In each case, the intermediate methylene radical (P• for glutamate and 2-methyleneglutarate mutase, S• for methylmalonyl-CoA mutase) is much less stable than the partner methine radical, which is stabilized by a carboxylate or CoA-ester group. It was recently suggested that stabilization of the methylene radicals by cob(II)alamin in the role of “conductor” might be required to lower the activation energy for the process of radical exchange (11). However, this proposal lacks experimental support.

2-Methyleneglutarate mutase: glutamate mutase in disguise?

The equilibration catalyzed by 2-methyleneglutarate mutase is similar to the glutamate mutase reaction but with a methylene group (−CH2) in 2-methyleneglutarate/3-methylitaconate in place of the amino center of glutamate/3-methylaspartate. However, this feature enables a different mechanism (addition-elimination, Scheme 5, path a) to be followed, although an analogous mechanism (fragmentation-recombination, Scheme 5, path b) to that of glutamate mutase is also possible in principle.
In all known mutases, but not in the

The mechanism of path a and possibly that of path b are consis-
tent with the results of a study in which 2-methylene glutarate
was shown to catalyze the equilibration of (Z)-3-methyl(1Z,2H1)
itaconate with an equal quantity of its (E)-isomer, as well as with
2.1 mixture of (E) and (Z) 2-methylene 2- H1 glutarate (12). Newcomb and Miranda (13) performed model studies in
which radicals that correspond to S•, P•, and I• (Scheme 5)
were generated, and their rates of interconversion were mea-
sured. It was concluded that these rates were too slow by a factor
of ∼ 103 relative to the known enzymatic kcat (30 s−1) for
either of the mechanisms of Scheme 5 to be kinetically plausi-
bile. To explain this discrepancy, there could be a role for cob(II)
alamin in the rearrangement as mentioned above and discussed
below.

Methylmalonyl-CoA mutase
This enzyme’s role in humans is to assist the detoxification
of propionate derived from the degradation of the amino acids
methionine, threonine, valine, and isoleucine. Propionyl-CoA is
carboxylated to (S)-methylmalonyl-CoA, which is epimerized to
the (R)-isomer. Coenzyme B12-dependent methylmalonyl-
CoA mutase isomerizes the latter to succinyl-CoA (Fig. 2),
which enters the Krebs cycle. Methylmalonyl-CoA mutase was
the first coenzyme B12-dependent enzyme to be characterized
crystallographically (by Philip Evans and Peter Leddlay). A
mechanism for the catalytic reaction based on ab initio molec-
ular orbital calculations invoked a “partial protonation” of the
oxygen atom of the substrate thioester carbonyl group that fa-
cilitated formation of an oxycyclopropyl intermediate, which
connects the substrate-derived and product-related radicals (14).
The partial protonation was supposed to be provided by the hy-
drogen bonding of this carbonyl to His 244, which was inferred
from the crystal structure of the protein. The ability of the sub-
strate and product radicals to interconvert even in the absence
of the enzyme was demonstrated by model studies (15).
The role of Cob(II)alamin in mutases
In mutases, the separation between cob(II)alamin and the in-
termediate radicals is ∼ 6 Å (cf. ∼ 11 Å in eliminases—see
below), which was taken to suggest the participation of cob(II)
alamin during turnover. In all known mutases, but not in the
Unusually high isotope effects have been observed for several
coaenzyme B12-dependent reactions. For methylmalonyl-CoA
mutase acting on (CD3)methylmalonyl-CoA, a primary deu-
terium isotope effect of 35.6 at 20 °C was recorded (16).
This effect was ascribed to quantum tunneling in the transi-
tion state for hydrogen (or deuterium) atom abstraction by the
5-deoxyadenosyl radical. To probe the nature of the hydro-
gen abstraction steps with glutamate, mutase experiments were
performed using labeled coenzyme, substrate, or product (17).
The results were interpreted as providing evidence for hydrogen
tunneling and a coupled motion of the hydrogen atoms at the
adenosyl C-5’ with the hydrogen atom being transferred from
substrate to product.

Coenzyme B12-Dependent Eliminases
Diol and glycerol dehydratase
Soon after the discovery of glutamate mutase, Robert Abeles
(1926-2000) recognized that the apparently simple conver-
sion of glycerol to 3-hydroxypropionaldehyde catalyzed by
diol dehydratase, was a coenzyme B12-dependent process (18).
It had been long been known that acrolein could develop
from the fermentation of glycerol. During the production of
whiskey, infection of the broth may lead to the production of
3-hydroxypropionaldehyde and hence to acrolein on distillation.
Isotopic labeling studies with glycerol dehydratase showed a re-
markable control of the movement of the oxygen atoms in the
rearrangement of 1,2-ethanediol to acetaldehyde and glycerol
of cob(II)alamin during turnover. In all known mutases, but not in the
below), which was taken to suggest the participation of cob(II)
alamin in the rearrangement as mentioned above and discussed
below. To explain this discrepancy, there could be a role for cob(II)
alamin in the rearrangement as mentioned above and discussed

Methionine synthase

The crucial steps in the pathway catalyzed by human cytosolic enzyme methionine synthase (MetH) are the transfer of a methyl group, first from N1-methyltetrahydrofolate to the cobalt of cob(I)alamin to give methylcobalamin (MeCbl), and then from cobalt to the sulfur of homocysteine to give methionine (Scheme 2). Our knowledge of MetH is largely from the incisive experiments of Liptak et al. (23), with crystallographic characterization of the enzyme by Martha Ludwig and Catherine Drennan underpinning all else. One large polypeptide (1227 amino acids, 136 kDa) comprises all functions of MetH, which has four modules. The substrates N5-methyltetrahydrofolate and homocysteine bind to a module each. The cobalamin cofactor binds to a third module with its dimethylbenzimidazole replaced by His759. The function of the fourth module is to reactivate the oxidized cobalamin to MeCbl using SAM as source of the methyl group and flavodoxin as reductant (see below). Profound conformational changes bring the reacting components together in turn.

The key intermediate in the catalytic pathway is the “supernucleophile” cob(I)alamin, which attacks N5-methylthetrahydrofolate, generating tetrahydrofolate and MeCbl. Then homocysteine (probably as its thiolate) attacks MeCbl to regenerate cob(I)alamin and methylcobalamin (Scheme 2). The demethylation of N5-methyltetrahydrofolate is not trivial, even for the “supernucleophilic” cob(I)alamin, and considerable efforts have been invested into understanding this reaction, dubbed “improbable” by Duilio A. Togni. The obvious mode of activation is by proton transfer to N5 of N5-methyltetrahydrofolate, but as this is weakly basic (pKa 5.1) the nature of the proton source and mode of transfer has been difficult to pin down. Recent research from the Matthews group has shown that the reactivities of cob(I)alamin and methylcobalamin are modulated by the ligand trans to the lone pair of cob(I)alamin and methyl group of methylcobalamin (21).

It is interesting that E. coli contains two genes that code for methionine synthase: metH for the cobalamin-dependent enzyme and metE for a cobalamin-independent enzyme that depends on an active site Zn2+ to stabilize deprotonated homocysteine (24). This thiolate species demethylates N5-methyltetrahydrofolate, which is activated by proton transfer to N5 of N5-methyltetrahydrofolate, and so in the absence of E. coli it produces much more MetE to compensate for the lack of MetH.

Cobalamin-dependent methionine synthase contains a built-in repair mechanism. If accidental oxidation of cob(I)alamin leads to inactive cob(I)alamin, then the enzyme employs SAM and reduced flavodoxin to regenerate cob(I)alamin. Although the redox equilibrium below lies mainly on the left side, any cob(I)alamin formed is trapped by SAM-dependent methylation to yield methylcobalamin.

\[
\text{Cob(I)alamin} + \text{flavodoxin semiquinone} \rightarrow \text{Cob(I)alamin} + \text{flavodoxin hydroquinone} + \text{methylcobalamin}
\]

The anodic nitrous oxide (N2O) oxidizes E. coli by reacting with cob(I)alamin, which probably yields reactive hydroxyl radicals that damage the MetH protein (25). Model studies have shown that N2O reacts with cob(I)alamin, but not cob(II)alamin or cob(III)alamin complexes, which affords dinitrogen (N2) and hydroxocobalamin. Repeated anesthesia with N2O over a few days can be life threatening because the production of methionine is suppressed, and more seriously, turnover of folate cofactors stops because folates are trapped as N5-methyltetrahydrofolate (“methyl trap hypothesis”). This mechanism leads to inhibition of DNA and protein synthesis, and hence cell death.

Other methyltransferases

Coralidoxanthins participate in the global C1 carbon cycle through the synthesis of methane and acetyl-CoA. Methane formation by methanogenic archaea exhibits a cobalamin-dependent step in which an overall methyl transfer occurs from N5-methyltetrahydrodromethanopterin to coenzyme M (26). This methionine synthase-like process is exergonic (\(\Delta G° = -30 \text{ kJ mol}^{-1}\)) and is catalyzed by a multienzyme complex that comprises eight different subunits. The subunit MtrA binds a cob(II)amide cofactor, which reacts with N5-methyltetrahydrodromethanopterin during the catalytic cycle to give a methylcobamide. This reaction undergoes an Na+-dependent demethylation by coenzyme M. The methylcobamide has a formal Cob(III) center with the cobinamide in a base-off/His-on state, whereas the cob(I)amide is in the four-coordinate His-off state. The conformational change between these two states may drive the Na+-pump of a Na+-translocating, membrane-associated process.

The synthesis of acetyl-CoA by the Jorgensen-Wood path- way of autotrophic carbon fixation in diverse bacteria and archaea is catalyzed by a Co- and Fe-containing corrinoid iron-sulfur protein (CofFeSP). This protein participates in the transfer of a methyl group from N5-methyltetrahydrofolate to the cob(II)amide of CofFeSP to give a methylcob(III)amide, of which an overall methyl transfer occurs from CofFeSP to coenzyme M (27).

The astonishing reactivity of cob(I)alamin is exploited in several other demethylation reactions, for example, the transfer of the methyl group of methanol to 2-mercaptoethanesulfonic acid (coenzyme M) catalyzed by methanol-2-mercaptoethanesulfonic acid methyltransferase. In this case, protein crystallography has shown that the methanol molecule is activated for nucleophilic attack by cob(I)alamin by coordination of its hydroxy group to a Zn2+ (28). Even more remarkable is the ability of cob(I)alamin to affect the dechlorination of vinyl halides, for example, tetrachloroethene to tetrahydrofuran, generating tetrahydrofuran and MeCbl. Then yields methionine and regenerates cob(I)alamin (29).

Biosynthesis of Nonribosomal Peptides

Georg Schoenafinger, Philipps-University of Marburg, FB Chemie/Biochemie, Marburg, Germany

Mohamed A Marahiel, Philipps-University of Marburg, FB Chemie/Biochemie, Marburg, Germany
doi: 10.1002/9780470048672.wecb398

Many microorganisms have evolved an unusual way of producing secondary peptide metabolites. Large multidomain enzymatic machineries, the so-called nonribosomal peptide synthetases (NRPSs), are responsible for the production of this structurally diverse class of peptides with various functions, such as cytostatic, immunosuppressive, antibacterial, or antitumor properties. These secondary metabolites differ from peptides of ribosomal origin in several ways. Their length is limited to a mere 20 building blocks, roughly, and mostly a circular or branched cyclic connectivity is found. Furthermore, aside from the proteinogenic amino acids, a larger variety of chemical groups is found in these bioactive compounds: D-configured amino acids, fatty acids, methylated, oxidized, halogenated, and glycosylated building blocks. These functional and structural features are known to be important for bioactivity, and often natural defense mechanisms are thus evaded. In this article, we describe the enzymatic machineries of NRPSs, the chemical reactions catalyzed by their subunits, and the potential of redesigning or using these machineries to give rise to new nonribosomal peptide antibiotics.
Biologic Background

Nonribosomal peptides are produced by a large number of bacteria, fungi, and lower eucaryotes. For most of these compounds, their biologic role is unknown. One might suspect that these secreted molecules are used for unknown forms of communication or simply to critically increase the chance of survival for the producing cell in its habitat, because the metabolic cost of their production is enormous. However, the function of some nonribosomal compounds has been identified: The well-studied penicillin produced by Penicillium notatum, for instance, is a weapon against nutrient competitors, and the siderophore bacillibactin helps its producer, Bacillus subtilis, acquire iron and thereby prevent iron starvation. For us, natural products produced by microorganisms attract considerable attention because they observed bioactivities range from antibiotic to immunosuppressive and from cytotoxic to antitumor. Not only have these secondary metabolites been optimized for their dedicated function over millions of years of evolution, but they also represent promising scaffolds for the development of novel drugs with improved or altered activities.

Catalytic Domains of Nonribosomal Peptide Synthetases

The catalytically active entities that NRPSs are composed of can be classified as being essential to all NRPSs or being responsible for special modifications. Only when a set of domains correctly acts in appropriate order, the designated product can be synthesized (3) (Fig. 3). The function, chemistry, and interactions of these domains are discussed in the following section (Fig. 4).

Essential domains of NRPSs

Before any peptide formation can occur, the amino acids or, generally speaking, the building blocks to be condensed need to be recognized and activated (12). The adenylation (A) domains are responsible for special modifications. Only when a set of domains correctly acts in appropriate order, the designated product can be synthesized (3) (Fig. 3). The function, chemistry, and interactions of these domains are discussed in the following section (Fig. 4).

(a) Gene → mRNA: Codons → Ribosomal Protein → Nonribosomal Peptide
(b) Gene → NRPS: Modules → Enzymatic Machinery → Peptide

Figure 1 Comparison of ribosomal and nonribosomal peptide synthesis. (a) In the ribosomal information pathway, the sequence of codons in the mRNA determines the sequence of amino acids in the protein, whereas (b) the sequence of modules in the nonribosomal peptide synthetase intrinsically determines the primary sequence of the peptide product.
Figure 2. A selection of nonribosomal peptides. Chemical and structural features that contribute to the vast diversity of this class of metabolites are highlighted: Heterocycle (bacitracin), lactone (surfactin, daptomycin), ornithine and lactam (Tyrocidine), sugar, chlorinated aromatics, C–C crosslink (Vancomycin), N-formyl groups (Coelichelin and linear gramicidin), fatty acid (daptomycin), dihydroxybenzoate and trimeric organization (bacillibactin), dimeric organization (gramicidin S), and ethanolamine (linear gramicidin).
translocation model implies that the biosynthesis is linear—altogether dependent on delicate, situationally changing affinities that guarantee correct timing for each reaction and that prevents side reactions (Fig. 4). Even though this model successfully puts the biosynthetic enzymes in relation with their products for most known NRPS systems, some exceptions are known: The structures of syringomycin (16) or coelichelin (17) cannot be sufficiently explained by merely deciphering the build-up of their NRPSs when using this model. Obviously, other regulatory mechanisms and forms of inter-domain communication are not yet fully understood.

When the last condensation reaction has occurred, the linear precursor needs to be released from the enzyme. For this important last step, several mechanisms are known: Simple hydrolysis of the thioester (bacitracin, vancomycin), intramolecular cyclization leading to a lactam (tyrocidine, bacitracin) or a lactone (surfactin), or even reductive thioester cleavage (linear gramicidin). In some cases, the linear precursor is dimerized (gramicidin S) or even trimerized (bacillibactin, enterobactin) before cyclization (Fig. 2). Even though these reactions are critical for the compound’s bioactivity, the catalytic domains responsible for the release are not found in all NRPS systems and will therefore be called “modifying” domains.

Modifying domains of NRPSs

Apart from the essential domains in NRPSs, several so-called modifying domains are not found in every NRPS system. Nevertheless, they are required for proper processing of their designated substrate within their synthetase. Deletion or inactivation of these modifying domains usually results in the production of compounds with bioactivities severely reduced or altogether abolished.

Most nonribosomal peptides have a cyclic connectivity. In these cases, a C-terminal so-called thioesterase (TE) domain, is often found in the synthetase. These TE domains all share an invariant serine residue belonging to a catalytic triad (Asp-His-Ser), which is known to be acylated with the linear peptide before cyclization (18). Once the substrate is translocated from the PCP domain onto the TE domain, the regiospecific and stereospecific intramolecular attack of a nucleophile onto the C-terminal carbonyl group of the substrate is directed by the enzyme. This nucleophile can be the N-terminal α-amino group of the linear peptide (tyrocidine, gramicidin S), a side-chain amino (bacitracin) or hydroxyl group (surfactin). Since the ester bond between the substrate and the TE domain is cleaved by these cyclization reactions, the resulting lactams or lactones are released from the synthetic machinery by this step. In a few cases, the modular arrangement of NRPSs suggests that only one half (gramicidin S) or one third (bacillibactin, enterobactin) of the extracted peptide product can be produced by one assembly line-like synthesis (Fig. 2). These synthetases are considered iterative (19) because they have to complete more than one linear peptide synthesis before one molecule of the secondary metabolite can be released. According to a proposed model, the first precursor is translocated onto the TE domain, the second monomer is then produced and transferred to the TE domain-bound first monomer leading to a dimer. An analogous trimerization occurs—if applicable—and finally the product is released by cyclization.

Another modifying reaction that is commonly found in NRPSs is the epimerization (E) of an amino acid (5). E domains that are always situated directly downstream of a PCP domain catalyse these reactions. The most C-terminal amino acid of the reaction intermediate is racemized by an E domain, no matter whether the substrate is an aminoacyl group alone or a peptidyl group. The mechanism of these E domains is so far unclear, even though a catalysis that involves one or more catalytic bases to deprotonate the α-carbon atom as a first step seems likely. The resulting planar double-bond species then needs to be reprototated from the other side to invert the absolute configuration of the building block. This result can be accomplished by a nearby protonated catalytic base in the enzyme or water, which is positioned opposite of the first catalytic base. Nevertheless, a mixture of both stereoisomers always can be detected when the substrate bound to the enzyme is analyzed, which is indicative for either a non stereospecific or a reversible reaction. Once the epimerized substrate undergoes the subsequent condensation reaction, only the species with an inverted stereocenter is found.
Biosynthesis of Nonribosomal Peptides

Figure 4 Single reactions in NRPSs and their timing. (a) After ribosomal synthesis of the apo-enzymes, the PCP domains are postsynthetically modified with 4′-Phosphopantetheine cofactors by a 4′Ppan transferase, e.g., Sfp. (b) In a second step, the A domains bind their cognate substrates as well as ATP and form the corresponding acyl-adenylate intermediates. These are transferred onto the cofactor of the neighboring PCP domains. (c) The C domains catalyse the condensation of two building blocks. The specificities of C domains and the affinities of aminoacyl-/peptidyl-PCP domains ensure that no internal start reactions occur. (d) Only after the first condensation domain has acted does the second C domain seem to process the intermediate. During synthesis, the growing product chain is continuously translocated toward the C-terminal end of the enzyme.

Techniques for the Production of Novel Nonribosomal Peptides

With a constantly growing number of pathogenic bacterial strains resistant to the known antibiotics, the demand for novel antibiotics or, more generally speaking, therapeutic agents is evident. Because many NRPS products already have such activities and their chemical and structural diversity is so huge, efforts have been made to use NRPSs to broaden the known spectrum of therapeutics. In this section, the possibilities of using NRPS machineries or parts of them to produce new bioactive compounds are addressed.
Module or domain exchange

When considering the modular buildup of NRPSs, the possibility of altering the peptide product by insertion, deletion, or exchange of modules seems to be an obvious approach for the production of new compounds. Because the A domains determine the specificity of each module, even an exchange of fractions smaller than whole modules in a synthetase could lead to an altered product. In the past, various attempts have succeeded using these strategies (24, 25). For instance, the exchange of an A domain in the surfactin NRPS with other A domains of both bacterial and fungal origin lead to the formation of the expected variants of surfactin (26). However, in all of these early studies, the apparent turnover rates were significantly lower than in the wild-type systems. Accordingly, two explanations for the drastically slowed down synthetic process can be given. First, the borders chosen to dissect and to fuse the catalytic domains might have been unsuitable. Even though the reoccurring, highly variable so-called linker regions between each pair of catalytic domains seem not to exhibit secondary structures, their sequence and length might be critical for proper inter-domain communication. So far, no structure of any enzyme consisting of two or more NRPS domains has been published, which makes it difficult to define the right domain border when preparing a cloning strategy for fusion or for dissection. Second, the specificity of the C domains might result in a reduced product turnover. Even though a relaxed specificity for the donor substrate has been reported, the acceptor site seems to be highly specific, which discriminates against artificial substrates (27). Both the mode of catalytic action and the molecular and structural basis for the selectivity are not fully understood for C domains so that a straightforward and approach for overcoming these low turnover rates currently cannot be given.

Changing the specificity code for A domains

Sequence alignments of A domains have revealed that domains activating the same type of building block share a set of conserved residues in the primary protein sequence (13). With the A domain’s crystal structure, one can find that these residues form the substrate binding pocket (28). These residues are therefore referred to as the “selectivity-conferring code” of NRPS (13). One can now rationally exchange these sets of residues and can obtain fully functional A domains with altered substrate recognition. For example, this process has been done for the first module of the surfactin synthetase srfA (31). A major advantage of using these strategies is their regiospecificity, stereospecificity, and chemoselectivity (29). Thus, no protective groups are needed during these reactions is their regiospecificity, stereospecificity, and chemo- selectivity. In many different cases, the peptide product is produced very quickly. The reason why one can use such peptides as substrates lies in the relaxed substrate specificity of many TE domains. The TE domain of the Tyrocidine synthetase, which carries out a head-to-tail cyclization of the decapeptide DPhe-Pro-Phe-DPhe-Asn-Gln-Tyr-Val-Orn-Leu, for instance, only recognizes the two N-terminal and C-terminal amino acids of the natural substrate. The side chains of the amino acids at other positions are not recognized by the enzyme, and experiments with substrates that carry substitutions to alarinate these positions still lead to analogous cyclodecamers (31). The major advantage of using TE domains for cyclization reactions is the regiospecificity, stereospecificity, and chemoselectivity. Thus, no protective groups are needed during these enzymatic cyclization reactions, and undesired side product formation is minimized. Additionally, these reactions are carried out under mild aqueous conditions, usually pH 7-8.

To follow this chemoenzymatic approach, the synthetic substrates must be transferred onto the catalytically active serine residue of the TE domain. This transfer can either be done directly or with the help of a PCP domain. In the natural system, translocation is realized by the interaction between the PCP and the TE domain. The substrate, which is bound to the 4Ppan cofactor of the PCP domain as a thioester, acylates the hydroxy group of the serine. Chemically speaking, the acylation of the TE is a result of a trans-esterification. When using TE domains, the substrate provided in trans must also have an appropriate acylation potential. Several key techniques have been developed to covalently attach synthetic substrates to PCP and TE domains. In the first method, the relaxed substrate specificity of the 4Ppan transferase Sfp is used to load aryl moieties are predicted to be very low. As discussed, the C domains that have to process the artificial substrates are predicted to discriminate against non-natural substrates, which kinetically impede product formation drastically. On the other hand, this method is limited to the building blocks that other known A domains activate. Yet, the vast diversity and bioactivity of nonribosomal peptides mainly arises from their unusual connectivities and a large number of post-synthetic modifications, which one cannot address when merely changing the A domains’ specificities.

Chemoenzymatic approaches

A very powerful method for producing novel antibiotics is the chemoenzymatic approach (30). The idea behind this strategy is to leave out the enzymatic buildup of the linear peptide scaffolds and replace it by solid-phase peptide synthesis (SPPS) (Fig. 5). Once the desired peptide is produced, its C terminus needs to be synthetically activated (usually as a thioester) before the substrate can be subjected to enzymatic cyclization using a TE domain. The advantages of solid-phase synthesis (SPPS) are obvious. Virtually any oligo-peptide can be made in a short time and in large quantities. Even though this is true for most oligo-peptides, some amino acid sequences seem very difficult to synthesize, and the popular Fmoc protective group strategy always imposes the risk of racemization. Many different building blocks (already modified with protective groups necessary for SPPS) can be purchased, and by automated parallel peptide synthesis whole libraries can be produced very quickly. The reason why one can use such peptides as substrates lies in the relaxed substrate specificity of many TE domains. The TE domain of the Tyrocidine synthetase, which carries out a head-to-tail cyclization of the decapeptide DPhe-Pro-Phe-DPhe-Asn-Gln-Tyr-Val-Orn-Leu, for instance, only recognizes the two N-terminal and C-terminal amino acids of the natural substrate. The side chains of the amino acids at other positions are not recognized by the enzyme, and experiments with substrates that carry substitutions to alarinate these positions still lead to analogous cyclodecamers (31). The major advantage of using TE domains for cyclization reactions is their regiospecificity, stereospecificity, and chemo-selectivity. Thus, no protective groups are needed during these enzymatic cyclization reactions, and undesired side product formation is minimized. Additionally, these reactions are carried out under mild aqueous conditions, usually pH 7-8.

To follow this chemoenzymatic approach, the synthetic substrates must be transferred onto the catalytically active serine residue of the TE domain. This transfer can either be done directly or with the help of a PCP domain. In the natural system, translocation is realized by the interaction between the PCP and the TE domain. The substrate, which is bound to the 4Ppan cofactor of the PCP domain as a thioester, acylates the hydroxy group of the serine. Chemically speaking, the acylation of the TE is a result of a trans-esterification. When using TE domains, the substrate provided in trans must also have an appropriate acylation potential. Several key techniques have been developed to covalently attach synthetic substrates to PCP and TE domains. In the first method, the relaxed substrate specificity of the 4Ppan transferase Sfp is used to load aryl moieties...
onto PCP domains enzymatically. Just like in the natural priming reaction in which the 4Ppn part of CoA is transferred onto the conserved serine residue of the apo-PCP domain, Sfp does analogously attach S-acylated 4Ppns, which originates from 5-acylated CoA substrates (32). These CoA substrates can readily be obtained by a coupling reaction directly after solid phase synthesis. With this technique, virtually any substrate can be brought to a desired position in recombinant NRPS enzymes containing an apo-PCP domain. This result is of great value when elucidating the catalytic properties and substrate specificities of other domains. When investigating TE domains, for example, the corresponding apo-PCP-TE would be the starting point for screening the cyclization abilities of the TE domain with a synthetic substrate library. However, the major disadvantage of this method becomes evident when looking closely at the enzyme after the release of the product. The PCP domain is now in its holo-state, and therefore, subsequent enzymatic loading of substrates with Sfp is impossible. Because product formation is limited to a single turnover, other methods have been developed to allow for multiple turnover.

For multiple turnover reactions, the TE domains must be supplied with substrates in trans; yet the acylation potential must be sufficient and the compound must be recognized by the enzyme. The first approach made was inspired by the natural system where the substrate is activated as a thioester bound to the Ppan cofactor. The idea was to minimize the 4Ppn moiety by replacing it with N-acetyl-cysteamine (SNAc) (33). This method works fairly well; however, it seems in later studies that the acylation potential is of greater importance than the similarity to the natural situation and a variety of peptidyl-thioesters with better leaving groups than SNAc was tested. The fastest turnover rates were found when thiophenol-esters were used (30, 34). Thiophenol has several advantages: it does not have any functional groups other than the thiol group; it is inexpensive, and it can easily be separated from the product. This method has been successfully used to shed light on the promiscuity of the TE domain of the daptomycin NRPS (35).

Even though these techniques allow for the production of new potentially bioactive compounds, they are usually closely related to known substances, which basically implies an analogous mode of action, and the deviations normally alter quantitative...
parameters such as solubility and affinity. Nevertheless, hundreds of nonribosomal systems still need to be explored, and the discoveries of new ones are frequently reported. The basic understanding of the catalytic functions of nonribosomal domains and modules that we have today is a good starting point for additional exploration and use of systems that are not yet understood fully.

doi: 10.1002/9780470048672.wecb007

A complete understanding of protein folding, protein recognition, enzyme catalysis, and allosteric regulation will require intimate knowledge about the fundamental physico-chemical properties of amino acids. This article will summarize the chemistry of the 20 naturally occurring amino acids with special emphasis on the relationship to protein folding and biologic activity. The major features of the amino acids are classified into three categories, which are as follows: 1) physico-chemical properties, 2) biologic properties, and 3) electronic properties. Cross-correlations among more than 34 different parameters revealed that these measures segregate into four main properties that are largely independent, as follows: 1) steric effects (polarizability), 2) hydrophilicity (Hp index), 3) inductive effects, and 4) field effects. Advances in quantum chemistry, nuclear magnetic resonance (NMR) analysis, and theoretic physics encourage efforts to derive all-electronic expressions for the fundamental properties of amino acids that will provide mechanistic insights into protein structure and function.

Proteins are complex polymers composed mainly of the 20 naturally occurring amino acids arranged in a series of peptide linkages. The precise sequence of amino acids determines the folding of a polypeptide chain and its ultimate 3-dimensional (3-D) structure. In addition, the amino acid sequence and the geometry of amino acid side chains specify protein binding sites and functional activities. Based on a comparison of heavy atoms, the 20 amino acids are on average greater than 50% identical in terms of their composition. Yet, it is the differences (sometimes very subtle) among individual amino acids that cause the variety of proteins in nature: from heat-stable DNA polymerases of thermal vent bacteria to antifreeze proteins of arctic fish, and from highly conserved structural proteins of microtubules to highly diverse signaling molecules of the G-protein-coupled receptor family. These differences are the focus of this review. The article is divided into three main sections that highlight the overall biologic relevance, the specific chemical properties of amino acid side chains, and methods for additional characterization of these properties.

Biologic Background

What is the biologic significance of diversity in amino acid side chains? The amino acid sequence is the blueprint for protein structure. Consequently, the complexity of protein structures is a function of the variety and the length of the sequences of polypeptide chains. In fact, multiple amino acid sequence alignments have improved the accuracy of secondary structure prediction and homology modeling greatly. Nevertheless, it is not known exactly how the properties of a single amino acid or a short stretch of amino acids determine the probability of that residue or sequence assuming a particular secondary structure. This issue is complicated additionally by the fact that identical sequences of five or more amino acids assume different secondary structures in proteins depending on the context (1, 2). A deeper appreciation of the chemical properties of amino acid side chains may improve modeling efforts and the prediction of secondary structure.

Whereas the 3-D structure of a protein is specified by its amino acid sequence, the active sites of receptors and enzymes are determined largely by the topological arrangement of non-contiguous amino acid side chains. Typically, ligand binding and enzyme catalysis require a precise geometry of functional groups of side chains to achieve specificity and catalytic activity. Moreover, amino acid side chains with distinct chemical properties are well suited for specialized tasks. For example, the presence of a cysteine residue in the active site defines a family of proteases (the caspases) that cleave at aspartic acid motifs in substrate proteins involved in apoptosis.
Chemical Properties of Amino Acids

Chemistry

Before discussing the chemistry of amino acid side chains, it is worthwhile to consider briefly the unique structure of amino acids and the functional implications. During evolution, amino acids likely were among the first chemical compounds to emerge on primitive earth (6, 7). Early experiments on the origins of life sought to recreate primordial atmospheric conditions with hydrogen, methane, ammonia, and water, and then to introduce a source of energy (e.g., electric discharges to mimic lightning strikes) or ultraviolet light to catalyze chemical reactions. Over time, these reactions yielded amino acids and other simple organic molecules that served as building blocks for the eventual synthesis of proteins, polynucleotides, and complex carbohydrates (6). Amino acids seem to have been formed from an initial reaction between aldehyde and ammonia and from additional convention in the Strecker synthesis (7). From a chemical standpoint, it is interesting that the first two building blocks of amino acids have opposite properties with respect to electron affinity. The amide group of ammonia releases electrons, whereas the aldehyde group tends to withdraw electrons when acting as a substituent group. This point is important because the bipolar construction of amino acids confers two of their most significant features. First, amino acids in aqueous solutions at physiologic pH are zwitterions (i.e., they carry a positive charge at the amino group and a negative charge at the carboxyl group). A single C₂ carbon separates these two oppositely charged species. Second, amino acids combine readily in condensation reactions to form polymers. This feature enabled the modular assembly of proteins from a diverse collection of interchangeable units that differ only in the side chain attached to the C₆ atom.

Electron delocalization in peptides

The bipolar nature of amino acids has additional ramifications. Amino acids are about 1000 times stronger than comparable aliphatic carboxylic acids because of electron withdrawal by the charged amino group. Thus, significant electronic effects (inductive and field effects) exist among the main chain atoms of an amino acid. Several findings support the existence of electron delocalization along the main chain of proteins. The peptide bond in proteins is planar with the partial double-bond character that reflects short-range electron delocalization clearly. Measurement of the pKₐ of dipeptides, tripeptides, and tetrapeptides (8) and nuclear magnetic resonance (NMR) studies of inductive effects (9) demonstrate that the delocalization is not restricted to the peptide bond, but it extends over a span of 3–4 residues. In addition, electron tunneling in proteins enables charge migration over very long distances and proceeds more efficiently through bonds than through space (10). Charges can migrate across the peptide bond (11), and, in fact, proteins behave as semiconductors under appropriate conditions (12). Finally, the bipolar nature of amino acids generates a distinct dipole in α-helical segments of proteins that is powerful enough to stabilize the binding of cofactors and ligands of opposite charge (13).

The C₆ atom is located in a unique position along the main chain because of electron delocalization between the amino and carboxyl groups. As discussed elsewhere, amino acid side chains can be considered as substituents along the peptide backbone that affect resonance and electron density at main chain atoms (14, 15). In turn, this reaction will affect bond lengths and rotational flexibility—the ultimate determinants of secondary structure. The chemical features of the side chains modulate the properties of localized segments of a protein in the same way that different substituent groups affect the reactivity and orientation of reactions that involve substituted molecules in classic chemistry. The idea that amino acid side chains affect the electron density along a polymer composed of repetitive units is consistent with observations of the effects of side chain composition on the conduction of semiconducting materials (16). We will return to this important notion of side chains as substituent groups along the peptide backbone during discussion of the electronic properties of amino acids. The next three sections will summarize the physico-chemical, biologic, and electronic properties of amino acid side chains.

Physico-chemical properties

For the purpose of this article, the various properties of amino acid side chains have been classified into three separate categories. The physico-chemical properties are represented by...
values that can be measured directly for each amino acid or that can be calculated directly from the behavior of component atoms or chemical groups. The biologic properties reflect indirect measures or context-dependent behavior of the amino acids (e.g., their preference for coil or helical conformations in proteins, and their partitioning into different solvents (hydrophobicity scales)). Finally, the electronic properties refer to a mixture of measured and calculated parameters that attempt to describe fundamental electronic effects of amino acid side chains. The electronic properties of an amino acid determine ultimately its physico-chemical properties; however, these two categories are discussed separately here to highlight the need for better characterization of these electronic effects. Summaries of these various properties are presented in Tables 1–3.

The physico-chemical properties of amino acids are summarized in Table 1. This includes a wide array of measures, from refractivity and melting point to the pKa at the amino group. Some of the parameters span a narrow range of values (e.g., the molecular weights and melting points). Other parameters differ by a factor of 100-fold or more, which include the pKas at the amino group and solubility. The AAindex database compiled by Kawashima et al. (21) is an excellent source of additional information that concerns the physico-chemical properties of amino acids.

<sup>1</sup>The preferences for α-helix, β-strands, and coil structures, P<sub>α</sub>, P<sub>β</sub>, and P<sub>coil</sub>, respectively, were taken from Dwyer (14).

<sup>2</sup>Secondary structural preference data were obtained from Chou and Fasman (C-F) (26).

<sup>3</sup>The bulk measure was derived by Kidera et al. (22).

<sup>4</sup>Levitt (23) calculated the gyration index.

<sup>5</sup>Polarizability and hydrophilicity (Hp) measures were derived from QM calculations by Dwyer (15, 32). Polarizability refers to the α-component calculated with the PM3 QM method.

<sup>6</sup>The hydropathy scores from Kyte and Doolittle (K-D index) (30) are presented.

<sup>7</sup>The RF data were obtained from Zimmerman et al. (31). These values were based on the average mobility of the amino acids in a series of solvents determined by paper chromatography.

<sup>8</sup>The hydrophobicity index of Manavalan and Ponnuswamy (M-P) (33) was calculated from the average surrounding hydrophobicity based on 3-D structures of proteins.

<sup>9</sup>The hydrophobicity index of Palliari and Parry (P-P) calculated a hydrophobicity index based on the average normalized values of 127 scales (35).

<sup>10</sup>Gromiha and Selveraj (34) determined the average number of medium and long range inter-residue interactions (IIMED and IILONG, respectively) for each of the 20 amino acids based on crystallographic data.
Other significant correlations were observed among the following: 1) melting point and dipole moment, average hydrophobicity (P-P), and long-range inter-residue interactions (IILONG), 2) solubility and pKa, and 3) pKa at the amino group and the z2 score of Hellberg et al. (25). The last relationship likely reflects the fact that pKa was one of the multiple components used to derive the z2-score, which is a composite of different electronic effects. An inverse relationship exists between free energy of solution and field effects (Table 4). This relationship may result from the polarity of the amino acid side chains.

**Biologic properties**

The three major groupings in the biologic properties correspond to preference for secondary structure (P-P, P-H, and P_a), steric or bulk effects (bulk, gyration, and polarizability), and hydrophobicity (K-D, R_H, H_p, M-P, P-P, and IILONG) (see Table 3).

Preferences for secondary structure (P-P) were derived by Dwyer (14) and Chou and Fasman (26) from statistical analysis of large databases of nonredundant protein structures. These data are in close agreement with similar statistical analyses of structural propensities of amino acids, for example that of Williams et al. (27). A second method to evaluate the preference of amino acids for secondary structure is host-guest analysis of short synthetic peptides (13). In these studies, amino acids are substituted into peptides that assume α-helical or β-strand structures and the effects of the substitution on structural stability are assessed. Several limitations to this approach exist; for instance, an overemphasis on preference at central positions within a segment leads to underestimates of the structural propensity of amino acids that are found commonly at the ends of secondary structures (e.g., asparagine and aspartic acid), which are excellent N-cap residues in α-helices (28). Nevertheless, the α-helix preferences summarized in Table 3 show significant correlation (r = 0.7) with indices derived from host-guest analysis, such as that of O’Neil and DeGrado (29). Finally, secondary structural preferences show significant correlations with electronic properties, including dipole, 〈focal charge〉, and NMR shift (Table 4).

Some amino acids show a clear preference for a particular secondary structure. For example, glutamic acid and alanine show a very high propensity for α-helices and are found at much lower frequencies in other structures. Similarly, valine, phenylalanine, cysteine, and threonine mainly prefer β-strands, whereas glycine, proline, and serine favor coil or turn conformations strongly. Other amino acids such as arginine, glutamine, and lysine, do not show an overwhelming preference to which a residue is buried in the native protein (related to hydrophobicity) and the number of inter-residue interactions it forms (32). The fact that amino acids prefer certain secondary structures seems to be valid and reflect fundamental properties of the side chain.

The fact that amino acids prefer certain secondary structures does not address the question of why these structural preferences are observed. This issue will be discussed in greater detail in a later section. Here, the role of steric effects and hydrophobicity will be considered. The composite bulk scale of Kidera et al. (22) and the gyration scale of Levitt (23) represent faithfully the bulk or the steric effects of amino acids. Therefore, it was interesting to observe such a striking correlation between these scales and polarizability, which is based on the calculation of a single, defined electronic feature of a molecule. Data in Table 4 suggest that the scales for steric effects are reasonably pure, and show no correlation with secondary structure. That is not to say that steric effects are unimportant in protein folding. Rather, it seems safe to conclude that they are not a primary driving force for the formation of secondary structure.

Two of the hydrophilicity scales in Table 2 were derived from experimental measures of the behavior of amino acids in various solvents, namely partitioning coefficients (K-D index of Kyte and Doolittle (30) or mobility in paper chromatography (R_f index of Zimmerman et al. (31))). By contrast, the H_p index was obtained from quantum mechanics (QM) calculations of electron densities of side chain atoms in comparison with water (32). The H_p index is correlated highly with these two established hydrophobicity scales (Table 4). Therefore, like the polarizability index, it is possible to represent fundamental chemical properties of amino acids (hydrophobicity, H_p) with parameters derived from ab initio calculations of electronic properties. However, in contrast to polarizability (steric effects), hydrophilicity shows significant correlation with preference for secondary structure. Thus, hydrophobic amino acids prefer β-strands (and β-sheet conformations) and typically are buried in protein structures, whereas hydrophilic residues are found commonly in turns (coil structure) at the protein surface.

Several scales have been derived to quantify the degree to which a side chain is exposed to the solvent (34). The z3-score, which is a composite of different physical and chemical properties, including dipole, 〈focal charge〉, local and non-local, and NMR shift, shows significant correlation (r = 0.70–0.89) with hydrophilicity scales and with strand versus coil conformations (Table 4). NMR studies reveal that the amide proton is shielded to a greater extent in coil conformations as compared with extended (g) structures (37); increased electron density exists at this atom in the coil conformation. Taken together, the data suggest strong interactions between hydrophilicity and electronic parameters in folding and provide support for additional refinement of the H_p index.
shift data for the amide proton, the $\gamma$ electronic effects. An empirical data set (40), and they represent a composite of coefficients, and to some degree the dipole index are related to some degree the dipole index are related to some degree.

Additional analysis of these electronic parameters reveals that they fall into two major categories. The NMR chemical shift data for the amide proton, the $\delta_{\text{LOCAL}}$ and $\delta_{\text{NON-LOCAL}}$ coefficients, and to some degree the dipole index are related closely to the hydrophilicity of the amino acid side chains. These findings are shown in Table 4, and they include significant correlations with K-D, H-P, M-P, and P-P indices. Given the extent of cross-correlation, it is probably best to consider the first three electronic scales in particular as surrogate indicators of hydrophilicity. The parameters that remain in Table 4 bear some relationship to each other and are considered, for the purpose of this article, to represent conventional electronic effects of amino acid side chains. This includes $\delta_{\text{LOCAL}}$, inductive and field effects, $z_3$, and VHSE5 parameters. The correlation between VHSE5 and inductive field and resonance effects is remarkable. Whereas VHSE5 is a composite from principal components analysis, the inductive and resonance effects are derived directly from simple QM calculations (15). Thus, the cross-correlations between empirically derived electronic parameters (VHSE5) and QM-derived calculations suggest that the QM measures are valid expressions of the electronic properties of amino acids.

Closer examination of the electronic properties of individual amino acids reveals good agreement with expectations. Thus, arginine and lysine with positively charged ammonium groups are the strongest electron withdrawing side chains (inductive effects), whereas the side chains of aspartic acid and glutamic acid are the strongest electron donors. Conversely, field effects (with respect to the amide proton) are opposite in direction for the

Electronic properties

The electronic properties of amino acid side chains are summarized in Table 3, and they represent a wide spectrum of measures. The NMR data are derived experimentally (37). The dipole (38), $\delta_{\text{LOCAL}}$, inductive, field, and resonance effects were derived from QM calculations (15). The VHSE5 (39) and z3 (25) scales were developed for use in quantitative structure-activity relationship analysis of the biologic activity of natural and synthetic peptides. Both were derived from principal components analysis of assorted physico-chemical properties, which included NMR chemical shift data, electron-ion interaction potentials, charges, and isoelectric points. Therefore, these scales are composites rather than primary measures of electronic effects. The validity of these measures is indicated by their lack of overlap with hydrophobicity and steric parameters and by their ability to predict biologic activity of synthetic peptide analogs (25, 39). Finally, coefficients of electrostatic screening by amino acid side chains ($\delta_{\text{LOCAL}}$ and $\delta_{\text{NON-LOCAL}}$) were derived from an empirical data set (40), and they represent a composite of electronic effects.

Additional analysis of these electronic parameters reveals that they fall into two major categories. The NMR chemical shift data for the amide proton, the $\delta_{\text{LOCAL}}$ and $\delta_{\text{NON-LOCAL}}$ coefficients, and to some degree the dipole index are related closely to the hydrophilicity of the amino acid side chains. These findings are shown in Table 4, and they include significant correlations with K-D, H-P, M-P, and P-P indices. Given the extent of cross-correlation, it is probably best to consider the first three electronic scales in particular as surrogate indicators of hydrophilicity. The parameters that remain in Table 4 bear some relationship to each other and are considered, for the purpose of this article, to represent conventional electronic effects of amino acid side chains. This includes $\delta_{\text{LOCAL}}$, inductive and field effects, $z_3$, and VHSE5 parameters. The correlation between VHSE5 and inductive field and resonance effects is remarkable. Whereas VHSE5 is a composite from principal components analysis, the inductive and resonance effects are derived directly from simple QM calculations (15). Thus, the cross-correlations between empirically derived electronic parameters (VHSE5) and QM-derived calculations suggest that the QM measures are valid expressions of the electronic properties of amino acids.

Closer examination of the electronic properties of individual amino acids reveals good agreement with expectations. Thus, arginine and lysine with positively charged ammonium groups are the strongest electron withdrawing side chains (inductive effects), whereas the side chains of aspartic acid and glutamic acid are the strongest electron donors. Conversely, field effects (with respect to the amide proton) are opposite in direction for the...

*Linear regression analysis was performed to compare the various scales listed in Tables 1–3. The r values shown here are only for the significant correlations where p < 0.01 or p < 0.05 as noted by an asterisk. The (–) signs indicate the slope of the regression line.
Substituent effects of amino acid side chains

The concept of amino acid side chains as substituent groups along the peptide backbone has been developed previously (14, 15, 32). A corollary to this idea, the amino acids side chains affect the electron density at main chain atoms as a function of their physico-chemical properties (e.g., the degree to which they donate or withdraw electrons from the peptide backbone). The side chains modulate local electron density, and thus the bond lengths and rotation along the main chain (15, 32). Summed together, the various electronic effects (e.g., inductive effects and \( H_{\beta} \)) determine the preference of a protein segment for a particular secondary structure. Of course, this preference is modified by solvent effects, electrostatic screening, and ultimately by interactions between residues that are only brought into contact through the folding process. These long-range interactions determine both the folding rate and the stability of the folded protein (33, 34, 41).

Theoretic and experimental studies of charge migration in proteins support the notion of gating effects of amino acid side chains (8–12). Thus, movement of charge between adjacent residues through the peptide bond depends on the molecular motion and orientation of the side chains (11). Moreover, ab initio analysis of the electronic features of amino acids reveals that electronic effects are conformation sensitive (42). Therefore, different side chain rotamers will produce distinct electronic effects at the main chain, although the rotational preference of a side chain is also a function of its fundamental physico-chemical (electronic) properties. Quantum effects in molecular electronic devices reveal that side chain groups affect electron density and current flow through main chain (nonpeptide) atoms such that current transmission is blocked at eigenvalues of the side chains (16). The effects of various side chains are additive in this system. Therefore, main chain structure and rotational flexibility (i.e., folding) is linked inextricably to the electronic properties of amino acid side chains and to the propagation of electronic effects along the peptide backbone.

Nearest-neighbor effects

Nearest-neighbor effects refer to the reciprocal influence of adjacent amino acids on protein folding. In some cases, this term also refers to amino acids that are close in the 3-D structure of the protein (\( \sim 10 \) Å away), but distant in the sequence. Early studies found a nonrandom assorting of amino acids in secondary structures by pair-wise analysis of protein sequences (43). More recently, it was reported that the preference of pairs of amino acids for secondary structure was determined, in part, by the electronic properties of the neighboring residues (14, 32). Thus, adjacent pairs of amino acids that act as strong electron donors preferred \( \alpha \)-helical conformations, whereas adjacent residues with ambivalent electron affinity preferred strongly coil conformations. The existence of nearest-neighbor electronic effects in proteins is confirmed by NMR studies (9, 37), \( \varepsilon\alpha \) measurements (8), and QM analysis of electron densities in dipeptides (32). Finally, nearest-neighbor interactions in the final folded state contribute to the stability of a protein (44).

The electronic properties of neighboring amino acids can affect protein folding in complex ways. Theoretically, the electronic effects of adjacent residues may be additive, opposing, or neutral. Some effects extend over 3-4 residues in a peptide or protein (8, 9), which corresponds roughly to a loop, short \( \beta \)-strand, or the first turn of an \( \alpha \)-helix. The summation of these various nearest-neighbor effects will then determine the electron density along the peptide backbone, bond lengths, and rotational flexibility. Consequently, segments of a protein where strong electronic effects are exerted on the main chain atoms will tend to form different secondary structures than segments where the electronic effects are weak.

Chemical Tools and Refinements

A compelling case can be made for replacing empirically-derived scales of amino acid properties with parameters either measured directly (e.g., chemical shift data or infrared spectra) or calculated from basic principles. The goal would be to develop all-electronic expressions for the physico-chemical properties of amino acids based on computational methods that include QM calculations. A start in this direction was provided by the successful description of steric effects in terms of polarizability and hydrophilicity as a function of electron density (32). Application of more sophisticated computational approaches will speed progress toward this objective.

As discussed here and elsewhere, NMR chemical shift data reveal details about the secondary structure environment of amino acids in proteins and thus are measures of protein folding. The pioneering work of Oldfield and colleagues (45) and other groups demonstrated that QM calculations on model peptides estimated NMR chemical shifts accurately. Furthermore, chemical shifts at the amide proton are excellent indicators of \( \beta \)-strand and coil conformation (Table 4). Therefore, the fact that QM calculations can be used to derive chemical shifts in peptides suggests that these calculations also provide insight into protein folding. For some of the QM analysis of amino acids, older semiempirical methods have been used (15). These methods are sufficiently accurate for the relative assessment of electronic properties (i.e., for comparisons between amino acids). However, higher-level approaches will be needed to obtain more precise quantitative values for various electronic parameters, for example, through the application of density functional theory with correction for electron correlation effects (46). Alternatively, perturbation methods such as Miller-Plesset have also proven useful to derive the electronic properties of amino acids (46).
Several scales presented in Table 3 show promise as measures of fundamental electronic properties of amino acids as does the $H_p$ index of hydrophilicity. Nevertheless, additional improvements are desirable. The polarizability index of electronic derivatives for the component atoms of amino acid side chains. A more integrative approach with higher-order theory is likely to refine this measurement additionally.

Of the other electronic parameters described here, inductive effects and field effects seem to represent distinct properties as calculated from QM analysis and equations of localized substituent effects. However, inductive and resonance effects need to be better isolated from each other. QM calculation of these effects in a series of different host molecules may improve discrimination between these two parameters. Finally, it will be important to characterize the electronic properties of amino acid side chains in short dipeptides and tripeptides, which will lead to a better understanding of nearest-neighbor and context effects in proteins.

Conclusions

A better understanding of the chemical biology of amino acids is key to clarifying issues related to protein structure and function. Interactions that involve amino acid side chains contribute to the rate of protein folding, the stability of the protein fold, molecular recognition (e.g., ligand binding), and catalysis. Participation of amino acids in these processes is a function of the properties of the side chain groups. For example, the hydrophilicity of a side chain determines largely whether it is found at the protein surface or buried in the interior. Similarly, the propensity of an amino acid for medium to long-range inter-residue interactions is related to preference for secondary structure. Electronic properties of side chain groups contribute to folding preferences and create electric fields involved in recognition and catalysis. Many empirical measures of the properties of amino acids are now available. An important goal for the future will be to replace these empirical measures with fundamental parameters derived from QM calculations. Finally, the conceptualization of amino acid side chains as substituent groups that affect electron density along the main chain through gating effects may provide insight into how the amino acid sequence specifies the 3-D structure of a protein.

This article will describe the different chemical strategies used by enzymes to achieve rate acceleration in the reactions that they catalyze. The concept of transition state stabilization applies to all types of catalysts. Because enzyme-catalyzed reactions are contained within an active site of a protein, proximity effects caused by the high effective concentrations of reactive groups are important for enzyme-catalyzed reactions, and, depending on how solvent-exposed the active site is, substrate desolvation may be important also. Examples of acid–base catalysis and covalent (nucleophilic) catalysis will be illustrated as well as examples of “strain” or substrate destabilization, which is a type of catalysis observed rarely in chemical catalysis. Some more advanced topics then will be mentioned briefly: the stabilization of reactive intermediates in enzyme active sites and the possible involvement of protein dynamics and hydrogen tunneling in enzyme catalysis.

Introduction

Enzymes are biologic catalysts that speed up chemical and biochemical reactions. Three particular characteristics of enzyme catalysis that distinguish enzymes from most man-made catalysts are speed, selectivity, and specificity. Enzymes are capable of rate accelerations of $10^7$–$10^{17}$ compared with the uncatalyzed reaction. Enzymes are highly selective catalysts; they can recognize and bind a single enantiomer of racemic mixture because the active site of the enzyme is chiral. The specificity of enzyme-catalyzed reactions is very high also; in reactions that generate a new chiral center (e.g., reduction of a ketone to an alcohol), only one enantiomer of the product is obtained. Again, this result is because of the chirality of the enzyme active site and the selective binding of the substrate by the enzyme.

This article will describe the different chemical strategies used by enzymes to achieve rate acceleration in the reactions that they catalyze. The concept of transition state stabilization applies to all types of catalysts. Because enzyme-catalyzed reactions are contained within an active site of a protein, proximity effects caused by the high effective concentrations of reactive groups are important for enzyme-catalyzed reactions, and, depending on how solvent-exposed the active site is, substrate desolvation may be important also. Examples of acid–base catalysis and covalent (nucleophilic) catalysis will be illustrated as well as examples of “strain” or substrate destabilization, which is a type of catalysis observed rarely in chemical catalysis. Some more advanced topics then will be mentioned briefly: the stabilization of reactive intermediates in enzyme active sites and the possible involvement of protein dynamics and hydrogen tunneling in enzyme catalysis.

Transition State Theory for Enzyme Catalysis

The rate of a chemical reaction of substrate S to product P is governed by the activation energy ($E_{act}$), which is the difference in free energy between the reactant(s) and the transition state for the reaction. The relationship between rate and $E_{act}$ is described by the Arrhenius equation:

$$k = A \cdot e^{-E_{act}/RT}$$

The transition state theory for enzyme catalysis predicts that catalysis is achieved by reducing the activation energy for the catalyzed reaction. This reduction in activation energy can be achieved either by stabilization (and hence reduction in free energy) of the transition state by the catalyst or by the catalyst finding some other lower energy pathway for the reaction. To illustrate the above equation, if a catalyst can provide 10kJ mol$^{-1}$ of transition stabilization energy for a reaction at 25°C, then a 55-fold rate acceleration will result, whereas a 20kJ mol$^{-1}$ stabilization will give a 3000-fold acceleration and a 40kJ mol$^{-1}$ stabilization a 10$^7$-fold acceleration.
Chemical Strategies for Enzyme Catalysis

Figure 1 illustrates the free energy profile of a typical acid-catalyzed chemical reaction that converts a substrate $S$ to a product $P$. In this case, an intermediate chemical species $SH^+$ is formed upon protonation of $S$. If the activation energy for conversion of $SH^+$ to $PH^+$ is lower than for the conversion of $S$ to $P$, then the reaction will go faster. It is important at this point to define the difference between an intermediate and a transition state: An intermediate is a stable (or semistable) chemical species formed during the reaction and therefore is a local energy minimum, whereas a transition state, by definition, is a local energy maximum.

An enzyme-catalyzed reaction can be analyzed thermodynamically in the same way as the acid-catalyzed example, except that enzyme-catalyzed reactions are multistep sequences that involve several intermediates. An enzyme-substrate intermediate $ES$ is formed during binding of the substrate, which then is converted to the enzyme-product complex $EP$ either directly or via one or more additional intermediates.

Under saturating substrate concentrations, the rate of the enzyme-catalyzed reaction will be governed by the activation energy for the conversion of the $ES$ complex to the $EP$ complex.

Exactly how do enzymes achieve transition state stabilization? I will illustrate three examples: the first two involve hydrogen-bonding interactions, and the third involves electrostatic interactions. The first example is the well-studied serine protease enzyme, $\alpha$-chymotrypsin, which cleaves polypeptide substrates via hydrolysis of the peptide bond adjacent to phenylalanine or tyrosine residues. The active site of $\alpha$-chymotrypsin contains a catalytic triad comprising Ser-195, His-57, and Asp-102. Active site base His-57 deprotonates the hydroxyl side chain of Ser-195, which attacks the amide carbonyl of the substrate, as shown in Fig. 2a [1]. The oxyanion intermediate that is generated is stabilized via hydrogen bonding to two backbone amide N–H groups, those of Ser-195 and Gly-193, in the "oxyanion hole," which is illustrated in Fig. 2b. These hydrogen bonds are formed only with the oxyanion, not with the bound substrate, and hence provide transition state stabilization.

The second example is a sialyltransferase enzyme from Campylobacter jejuni, which catalyzes the transfer of a 9-carbon sialic acid sugar from CMP–Neu5Ac to an acceptor substrate [2]. Analysis of the crystal structure of this enzyme revealed that the phosphate-leaving group of CMP interacted with two active site tyrosine residues, Tyr-156 and Tyr-162. Replacement of each tyrosine residue by phenylalanine gave 100-fold and 300-fold reduction in $k_{cat}$, respectively, which indicates that these residues are important in catalysis. As C–O cleavage takes place, the lengthening of the C–O bond and the additional negative charge on the phosphate group lead to much stronger hydrogen bonds with Tyr-156 and Tyr-162 in the transition state, as shown in Fig. 3 and hence transition state stabilization.

The third example is a phosphoryl transfer enzyme, alkaline phosphatase. The active site of alkaline phosphatase contains two Zn$^{2+}$ ions, with a separation of 3.9 Å. One zinc center is used to bind the phosphate monoester substrate, the other to activate Ser-102 for nucleophilic attack on the phosphate group of the substrate via an associative mechanism, as shown

in Fig 4(3). Situated between the Zn$$^{2+}$$ ions is the guanidinium side chain of Arg-166, which provides electrostatic stabilization for the additional negative charge in the transition state of this phospho-transfer reaction.

Proximity Effects

Intramolecular reactions in organic chemistry generally proceed much more rapidly and under much milder reaction conditions than intermolecular reactions because the two reactive groups are “in close proximity” to one another. This effect also operates in enzyme-catalyzed reactions because of the binding of substrate(s) close to the catalytic groups at the enzyme active site.

One example is illustrated in Fig 5. Acid-catalyzed hydrolysis of sugar glycosides occurs via initial protonation of the departing hydroxyl group. An intramolecular example of glycoside hydrolysis is shown, in which a carboxylic acid group is positioned close to the departing hydroxyl group. The close proximity of the carboxylic group increases the local concentration of H$$^+$$, which increases the probability of the desired reaction.
Chemical Strategies for Enzyme Catalysis

![Figure 4](image_url) Alkaline phosphatase.

![Figure 5](image_url) Rate accelerations in glycoside hydrolysis.

A reaction and leads to a 10^4-fold increase in rate of glycoside hydrolysis. In the enzyme β-galactosidase, the substrate is bound in close proximity to a catalytic glutamic acid residue, which protonates the leaving group. The turnover number (k_cat) of the enzyme-catalyzed reaction is 10^3-fold higher than the intramolecular reaction, which indicates that the enzyme can employ additional strategies to achieve rate acceleration.

Another way of bringing reactants into close proximity, which is encountered commonly in transition metal chemistry, is through metal ion complexation. The coordination of a reactant to a metal ion complex often activates its reactivity and can bring the reactants into close proximity with a second reactant or with a catalytic group. One example, shown in Fig. 6, is a zinc (II) complex of 1,5,9-triazacyclononane, as a model for the enzyme carbonic anhydrase, which contains a zinc (II) cofactor in its active site (4). In the aqua complex, the bound water molecule has a dramatically reduced pK_a value of 7.3, which is similar to the pK_a of the active site nucleophilic water. The corresponding cobalt (III) complex catalyzed ester hydrolysis at twice the rate because Co(III) can coordinate both the hydroxide nucleophile and the ester carbonyl via a 5-coordinate intermediate, which is shown in Fig. 6. Many enzymes use metal ion cofactors, which can bind cosubstrates at a metal ion center, close to active site catalytic residues.

**Acid/Base Catalysis In Enzymatic Reactions**

All enzyme-catalyzed reactions that involve proton transfer use acid or base catalysis, so most enzyme active sites contain acidic or basic amino acid side chains that participate in catalysis. Because enzyme-catalyzed reactions take place close to pH 7, only fairly weak acids and bases are available, as shown in Fig. 7. Amino acid side chains with pK_a values below 7, such as aspartic acid or glutamic acid, will be deprotonated at pH 7 and, therefore, will be used normally in general base catalysis. Amino acid side chains with pK_a values above 7, such as lysine or tyrosine, will be protonated at pH 7 and, therefore, will be used normally in general acid catalysis. The imidazole side chain of histidine has a pK_a value of 6–8 and, therefore, might
Chemical Strategies for Enzyme Catalysis

Figure 6. Zinc (II) and cobalt (III) complexes of 1,5,9-triazacyclododecane as mimics of carbonic anhydrase.

Figure 7. Amino acid side chains involved in acid/base chemistry.

be either protonated or deprotonated (or a proportion of each) at pH 7; thus, histidine can be employed as either acid or base in enzyme catalysis and is found widely as an acid/base group in enzymes.

The actual pK_a value of an active site catalytic group will be influenced by the particular microenvironment of the active site, which could raise or lower the pK_a. For example, the enzyme acetoacetate decarboxylase contains an active site lysine residue that forms an imine link with its substrate; its pK_a value was found to be 5.9, which is much less than the expected value of 9. Adjacent to this residue in the active site is a second lysine residue, which in protonated form destabilizes the protonated amine and, therefore, reduces the pK_a. Conversely, aspartic acid or glutamic acid residues that are positioned in hydrophobic active sites can have increased pK_a values near 7 because the anionic form of the side chain is destabilized.

Enzyme active sites frequently have a pair of acid/base groups, one of which deprotonates one part of the substrate while the other protonates another part of the molecule; this dual action is known as bifunctional catalysis. One example is the enzyme ketosteroid isomerase, whose active site contains two catalytic residues; aspartate-38 acts as a catalytic base, and tyrosine-14 acts as an acidic group (5). The mechanism involves the formation of a dienol intermediate via a concerted step that involves simultaneous deprotonation of the substrate by Asp-14 and protonation of the substrate carbonyl by Tyr-14, as shown in Fig. 8.

Finally, enzymes that bind metal cofactors such as Zn^{2+} and Mg^{2+} can use their properties as Lewis acids, for example, electron pair acceptors. An example is the enzyme thermolysin, whose mechanism is illustrated in Fig. 9. In this enzyme, glutamate-143 acts as an active site base to deprotonate water for attack on the amide carbonyl, which is at the same time polarized by coordination by an active site Zn^{2+} ion (6). The protonated glutamic acid then probably acts as an acidic group for the protonation of the departing amine.
Nucleophilic Catalysis in Enzymatic Reactions

Several enzyme-catalyzed reactions involve the nucleophilic attack of an active site amino acid side chain on the substrate, which results in an immediate reaction that is attached covalently to the enzyme. This type of catalysis is known as nucleophilic (or covalent) catalysis.

Several different amino acid side chains can act as nucleophiles in enzyme catalysis. The most powerful nucleophile is the thiol side chain of cysteine, which can be deprotonated to form the even more nucleophilic thiolate anion. One example in which cysteine is used as a nucleophile is the enzyme glyceraldehyde 3-phosphate dehydrogenase, which uses the redox coenzyme NAD$^+$. As shown in Fig. 10, the aldehyde substrate is attacked by an active site cysteine, Cys-149, to form a hemi-thioketal intermediate, which transfers hydride to NAD$^+$ to form an oxidized thioester intermediate (7). Attack of phosphate anion generates an energy-rich intermediate 3-phosphoglycerate.

The ε-amino group of lysine is used in several enzymes to form imine links with ketone groups; for example, it is used in acetoacetate decarboxylase, shown in Fig. 11. Treatment of this enzyme with substrate and sodium borohydride leads to irreversible enzyme inactivation via in situ reduction of the enzyme-bound imine intermediate by borohydride, which indicates that a covalent link is formed. As mentioned, the $pK_a$ of this lysine group is abnormally low at 5.9, which is sufficiently low for it to act as a nucleophile at pH 7 (8).

The other nitrogen nucleophile available to enzymes is the versatile imidazole ring of histidine. This group is used more often for acid/base chemistry, but it is used occasionally as a nucleophile, for example, phosphotransfer reactions. The serine proteases, such as α-chymotrypsin, which is illustrated in Figs. 2a and 2b, are classic examples of the participation of serine as a nucleophile. Additional examples exist of nucleophilic mechanisms that employ the hydroxyl groups of threonine and tyrosine and the carboxylate groups of aspartate and glutamate.
Substrate Desolvation

Enzyme active sites sometimes are hydrophobic, buried sites that are excluded largely from water molecules. In these cases, the substrate(s) and enzyme catalytic groups are likely to be “desolvated.” In aqueous solution, a charged nucleophile is surrounded by several layers of water molecules, which greatly reduces its polarity and reactivity. However, a desolvated nucleophile at a water-excluded active site will be a much more potent nucleophile than its counterpart in solution. This effect particularly benefits nucleophilic substitution reactions, found in nucleophilic catalysis.

One recently discovered example is a “fluorinase” enzyme that is involved in the biosynthesis of fluoroacetic acid in Streptomyces cattleya. This enzyme catalyzes the nucleophilic...
the reaction will be accelerated (bound conformation and the transition state will be reduced and formation. In these cases, the difference in energy between the reactions, the enzyme binds the substrate in a strained conformation, which is closer to the transition state than the ground state conformation. In these cases, the difference in energy between the bound conformation and the transition state will be reduced and the reaction will be accelerated (Fig. 13).

One example of this is the enzyme lysozyme, which catalyzes the hydrolysis of the polysaccharide chain of the peptidoglycan layer of bacterial cell walls and, therefore, protects organs such as the human eye from bacterial infection. When the X-ray crystal structure of this enzyme was solved, attempts to model the substrate into the active site were possible only if a “kink” in the substrate was made at the point at which hydrolysis took place (10). The consequence of this kink was a flattening of the sugar ring that was cleaved; this flattened conformation is closer in structure to the oxonium ion formed during C-O bond cleavage, as shown in Fig. 14. Energetically, the enzyme compensated for the local flattening of this ring by more favorable binding interactions elsewhere in the substrate so that substrate binding still was a favorable process, but the activation energy for the bound substrate was reduced by this effect.

The Use of Strain Energy in Enzyme Catalysis

It is thought that in a small number of enzyme-catalyzed reactions, the enzyme binds the substrate in a strained conformation, which is closer to the transition state than the ground state conformation. In these cases, the difference in energy between the bound conformation and the transition state will be reduced and the reaction will be accelerated (Fig. 13).

One example of this is the enzyme lysozyme, which catalyzes the hydrolysis of the polysaccharide chain of the peptidoglycan layer of bacterial cell walls and, therefore, protects organs such as the human eye from bacterial infection. When the X-ray crystal structure of this enzyme was solved, attempts to model the substrate into the active site were possible only if a “kink” in the substrate was made at the point at which hydrolysis took place (10). The consequence of this kink was a flattening of the sugar ring that was cleaved; this flattened conformation is closer in structure to the oxonium ion formed during C-O bond cleavage, as shown in Fig. 14. Energetically, the enzyme compensated for the local flattening of this ring by more favorable binding interactions elsewhere in the substrate so that substrate binding still was a favorable process, but the activation energy for the bound substrate was reduced by this effect.

Stabilization of Reactive Intermediates

One remarkable feature of enzyme-catalyzed reactions is the ability to generate at enzyme sites reactive intermediates, such as carbanions, carbocations, and radicals, that normally would require strong reaction conditions to generate in chemical reactions and would be very unstable in aqueous solution.

Terpene cyclase enzymes catalyze the cyclization of allylic pyrophosphate substrates to form carbocyclic products via carbocation reaction intermediates. One well-studied example is pentalenene synthase (11,12), which catalyzes the cyclization of farnesyl pyrophosphate to give pentalenene, whose reaction mechanism is shown in Fig. 15. Cyclization of farnesyl pyrophosphate is proposed to form an 11-membered intermediate, humulene, which is followed by a five-membered ring closure to form a bicyclic tertiary carbocation. 1,2-Hydride migration followed by an additional five-membered ring closure gives a tricyclic carbocation, which gives pentalenene, at elimination.

How do these cyclase enzymes control the precise regiochemistry and stereochemistry of these multistep cyclizations? The active site of pentalenene synthase consists of a hydrophobic cleft, which is lined with aromatic and nonpolar residues. It is thought that the carbocation intermediates might be stabilized by the formation of π-cation interactions, with aromatic residues such as phenylalanine, tyrosine, and tryptophan. In pentalenene synthase, replacement of Phe-76 or Phe-77 by Ala gave >10-fold reduction in activity, which suggests that they may stabilize carbocationic intermediates through π-cation interactions.

One example of an enzyme-catalyzed reaction involving a radical intermediate is the enzyme ribonucleotide reductase, which catalyzes the conversion of ribonucleotides (used for RNA biosynthesis) to 2'-deoxyribonucleotides (used for DNA biosynthesis), as illustrated in Fig. 16. Spectroscopic studies of the R2 subunit of Escherichia coli ribonucleotide reductase have shown that it can form a stable, long-lived, tyrosyl radical species—the first protein radical to be discovered (13).

Single electron transfers within the protein lead to the formation of a cysteine radical on Cys-439 in the enzyme active site, which abstracts, then, the C-3 hydrogen to initiate a radical mechanism, as shown in Fig. 17. Protonation of the C-2-
Figure 14  Lysozyme mechanism.

The Involvement of Protein Dynamics in Enzyme Catalysis

Examination of protein structure in solution by nuclear magnetic resonance spectroscopy has revealed that a significant amount of internal motion exists in a protein on a timescale of 1 to 10 ns. Such internal motion could transmit kinetic energy from a distant part of the protein to the active site to assist in catalysis. It has been proposed that dynamic fluctuations in the protein structure are used by enzymes to organize the enzyme-substrate complex into a reactive conformation.

One example is in the enzyme dihydrofolate reductase, where replacement of Gly-120 to valine disrupts the internal motion of a protein loop, as illustrated in Fig. 18, which leads to a 500-fold reduction in rate; this reduction in rate implies that internal motion is involved in catalysis (14).

In conclusion, enzymes use a variety of strategies to achieve high rates of catalysis. Transition state stabilization seems to be the dominant factor in catalysis, but in some enzymes, the more sophisticated strategies such as substrate destabilization and protein dynamics seem to play an important role.

Chemistry of CoA-Dependent Enzymes

Dale G. Drueckhammer, Department of Chemistry, State University of New York at Stony Brook
doi: 10.1002/9780470048672.wecb093

Coenzyme A (CoA) and its thioesters play a diverse array of roles in biologic systems. The enzymes that catalyze reactions of CoA are of interest for a variety of reasons, including, but not limited to, their potential as drug targets. The enzymology of CoA biosynthesis is now well understood, and the genes for all of the enzymes involved have been identified. Thioesters are inherently reactive toward acyl transfer reactions and toward reactions involving deprotonation of the α-carbon, and these are the primary reactivity patterns in enzyme-catalyzed reactions of CoA thioesters. CoA utilizing enzymes have been widely studied mechanistically and structurally. Analogs of the natural CoA thioester substrates have been widely used in these studies, including thioesters of unnatural or uncommon acyl groups as well as a large number of analogs in which the thioester is replaced with alternative functionality. Recent technical applications of CoA have included the tagging of carrier protein domains and carrier protein fusions with tagged phosphopantetheine derivatives transferred enzymatically from the corresponding tagged CoA derivatives using promiscuous phosphopantetheinyl transferases.

Coenzyme A (CoA) is a cofactor that has been estimated to be used by about 4% of all enzymes, although more recent analysis of the BRENDA database (http://www.brenda.uni-koeln.de/) suggests the number may be closer to 9% (1). The biochemical pathways and processes involving CoA thioesters are diverse and widespread, whereas the kinds of reactions involved primarily follow the inherent reactivity of the thioester functionality. This article provides a brief overview of CoA biosynthesis and a summary of the common types of reactions of CoA thioesters. Also presented is a brief introduction to structural studies and a more extensive description of some types of analogs of natural CoA thioesters that have been employed as mechanistic probes for CoA using enzymes. The application of CoA derivatives and CoA biosynthetic enzymes for the tagging of carrier proteins and carrier protein fusions is also described.

Biologic Background

Coenzyme A (abbreviated CoA or CoASH, \( \text{G} \)) was discovered by Lipmann in the 1940s, and its structure was first reported in 1953 (2, 3). The structure of CoA consists of 3′-phosphoadenosine and pantetheine, linked by a phospho-phosphate group (Fig 1). The pantetheine moiety is derived from pantetheine 5′-diphosphate (4), also known as vitamin B5, CoA, and its thioester derivatives are involved in a wide range of biologic processes, including the TCA or Krebs cycle, fatty acid biosynthesis and degradation, antibiotic resistance mechanisms, gene expression, hormone biosynthesis and regulation, and nerve impulse conductance. Numerous CoA utilizing enzymes are either established or potential drug targets. The enzymes HMG-CoA reductase and acyl-CoA cholesterol acyltransferase (ACAT), which are involved in cholesterol biosynthesis and metabolism, are targets of drugs for cholesterol management. Inhibitors of malonyl-CoA decarboxylase may act as cardioprotective agents (4), whereas fatty acid synthase inhibitors have been explored as antimicrobial agents (5). CoA thioesters may also be involved in fatty acid-induced insulin resistance (6). Acetyl-CoA carboxylase and other acyl-CoA carboxylases are potential targets for anticaner and antiobesity agents as well as are herbicidal targets (7). Thioesters of CoA serve as the building blocks for the polyketide synthases that make a wide variety of natural bioactive compounds and are also involved as building blocks and intermediates in the biosynthesis of natural bacterial polyesters (8, 9). The interesting organometallic mechanism of the nickel-containing enzyme carbon monoxide dehydrogenase, which forms acetyl-CoA from carbon monoxide, CoA, and a methyl group donor, has been the target of extensive fundamental mechanistic studies (10). CoA thioesters have also been studied in ribozyme-catalyzed reactions (11). Thus, the roles...
Chemistry of CoA-Dependent Enzymes

of CoA utilizing enzymes in biology and the reasons for their interest are widespread and diverse.

Chemistry and Reactivity of CoA

CoA is involved in the activation and transfer of acyl groups in a wide variety of enzymatic reactions. Whereas many coenzymes function as co-catalysts that remain bound to a single enzyme molecule, CoA acts as a diffusible carrier of acyl groups between different enzymes.

CoA biosynthesis

The biosynthesis of CoA from pantothenic acid is shown in Fig. 1. Extensive coverage of this topic and references to the original literature can be found in recent reviews (1, 12). Pantothenic acid 1 is phosphorylated by pantothenate kinase to form 2. At least three distinct types of pantothenate kinases from different organisms have been observed (1). The cysteamine moiety is introduced by initially coupling with L-cysteine catalyzed by the phosphopantothenylcysteine synthetase activity to form 3 followed by a decarboxylation reaction to form phosphopantetheine 4. These two steps are catalyzed by a single bifunctional enzyme in most prokaryotes but by distinct enzymes in higher organisms. The bacterial phosphopantothenylcysteine synthetase is CTP-dependent, whereas the plant and mammalian enzymes prefer ATP. 3 is not inherently prone to decarboxylation, but this reaction has recently been shown to occur by temporary oxidation of the thiol to the thioaldehyde, which readily undergoes decarboxylation to an enethiolate intermediate (13). Phosphopantetheine is coupled with ATP to form dephospho-coenzyme A 5 followed by phosphorylation of the 3′hydroxyl group to form CoA. The final two steps are catalyzed by a single bifunctional enzyme in mammals, although they are catalyzed by separate enzymes in bacteria (1). The genes coding for all of the enzymes of this pathway (coaA-E) have now been identified, as have the genes for the four enzymes of pantothenic acid biosynthesis in bacteria (1, 12, 14). Pantothenic acid biosynthesis has also been studied in plants (15). Pantetheine kinase is a key regulatory point in CoA biosynthesis and is subject to feedback inhibition by CoA in most species (1). Pantetheine kinase can also catalyze the phosphorylation of pantetheine and pantetheine analogs (16, 17), although phosphorylation occurs before coupling with L-cysteine in the biosynthetic pathway.

Reactions and processes involving CoA

The reactions of CoA involve only the thiol group and the acyl moieties attached to the thiol group as thioesters, with the remainder of the structure serving as a recognition element that facilitates binding to the appropriate enzymes. The notable exception is the phosphopantetheinytransferases that catalyze transfer of the phosphopantetheine moiety of CoA to a serine...
Inherent reactivity of thiols and thioesters

Thiols are structurally similar to alcohols and can generally undergo the same kinds of reactions. However, a typical thiol group (pk of 9-10) is substantially more acidic than the corresponding hydroxyl group (pk ca 16). The thiolate ion is also much more nucleophilic than the corresponding alkoxide. This combination of acidity to form the thiolate and nucleophilicity of the thiolate facilitates both alkylation and acylation reactions of thiols, with acylation being the primarily relevant reaction of CoA. A thioester has two inherent modes of reactivity that are both observed in enzyme-catalyzed reactions of CoA thioesters. One common type of reaction is initiated by reaction of a basic group to remove a proton from the carbon alpha to the carbonyl to form an enolate nucleophile, which then reacts with an electrophilic substrate. The other common type of enzymatic reaction of CoA thioesters involves acyl transfer by attack of an acyl acceptor nucleophile at the thioester carbonyl carbon. The inherent characteristics of the thioester make it more reactive than esters or amides in both of these types of reactions. The α-protons of a typical thioester (pk ca 23) are about 104-fold more acidic than those of an ester (pk ca 25), whereas the α-protons of an amide are even less acidic than those of an ester (19). The free energy of hydrolysis of a thioester is about 2 kcal/mol greater than that of an ester and, again, the difference relative to an amide is even greater (20), which provides a thermodynamic driving force in acyl transfer from CoA to an alcohol or amine nucleophile, whereas acyl transfer reactions to carbanion nucleophiles are also common. Thioesters are also kinetically much more reactive than esters toward most nucleophiles including thiols, amines, and carbamions, with amides being much less reactive even than esters (21, 22). However, the rates of reaction of esters and thiesters toward hydrolysis by aqueous base are essentially identical, with thiesters even appearing to be slightly less reactive than oxesters in some examples (21). This unique reactivity of thiocarboxylates provides for their reasonable stability in aqueous solution despite their substantial thermodynamic reactivity and inherently high kinetic reactivity toward most nucleophiles.

Acyl-CoA synthetases and related enzymes

Acetyl-CoA is formed from CoA and acetate by the enzyme acetyl-CoA synthetase, an ADP-forming ligase. Phosphotrans-acylase forms acetyl-CoA from CoA and acetyl-phosphate, which in turn is formed from acetate and ATP catalyzed by acetate kinase. Other enzymes that can form acetyl-CoA from CoA and other acetyl group donors include ATP citrate lyase and thiolase. Longer chain acyl-CoA thioesters are typically formed from CoA and a fatty acid catalyzed by ligases generally known as acyl-CoA synthetases.

Acyltransferases

Most acyltransferases catalyze acyl transfer to a hydroxyl or amine group of the acceptor substrate, whereas CoA ester hydrolysis by thioestersases is in effect acyl transfer to water. Choline acetyltransferase catalyzes transfer of the acetyl group from acetyl-CoA to the hydroxyl group of choline. The product acetylcholine is a major neurotransmitter (23). Serotonin acetyltransferase controls the sleep cycle by catalyzing acetyl transfer to the primary amine group of serotonin, which is the rate-limiting step in metabolism biosynthesis (24). Chloramphenicol acetyltransferase catalyzes acetyl transfer to a primary hydroxyl group, which destroys the antibiotic activity of chloramphenicol thereby conferring antibiotic resistance, whereas the antibiotics gentamicin and kanamycin are similarly inactivated by acetyltransferases (25). Other extensively studied acetyltransferases include the histone acetyltransferases (HATs), which mediate a major control element in gene expression (26). A cytochrome P450 also catalyzes acyl transfer from longer chain acyl-CoA. The highly studied protein N-myristoyltransferase catalyzes transfer of the myristoyl group to the amine group of N-terminal glycine of a protein substrate (27). The palmitoyltransferases catalyze transfer of palmitic acid to a cysteine thiol group of certain proteins (28). These post-translational acyltransfer reactions are important in membrane anchoring of proteins and may play a role in signaling events (29). Carnitine palmitoyltransferase catalyzes acyl transfer to the hydroxyl group of carnitine (30). The two general mechanisms for acyltransferases are a direct transfer to the nucleophilic acceptor or a two-step process involving initial acyl transfer to a nucleophilic group (usually a cysteine thiol) of the enzyme to form an acyl enzyme intermediate. Examples of both types of mechanisms are well documented, although the direct transfer mechanism appears to be more common.

Claisen enzymes

The enzymes that form a nucleophilic enolate intermediate by deprotonation of the methyl group of acetyl-CoA, which then reacts with a second electrophilic substrate, are generally referred to as Claisen enzymes in the literature, although not all catalyze true Claisen condensation reactions. Some common examples of Claisen enzymes and their electrophilic substrates are shown in Fig. 2. Thiocarbamylates a true Claisen condensation reaction in which the electrophilic substrate is a second equivalent of acetyl-CoA, whereas in enzymes recognizing longer chain substrates, the electrophilic substrate can be a medium or long chain acyl-CoA (31). From the perspective of the electrophilic substrate, thiolase is also an acyltransferase in which the acyl group is transferred to a nucleophilic carbon. Acetyl-CoA carboxylase catalyzes transfer of the carboxylate group from carboxybiotin to the enolate (32). Both citrate synthase and HM-CoA synthase catalyze reactions of the enolate with an electrophilic carbonyl group of a ketone substrate in what is formally an aldol reaction (33). In both of these examples, the enzyme also catalyzes a subsequent thioester hydrolysis reaction to release free CoA. Malate synthase catalyzes a very similar reaction (34). Although an enol intermediate for the Claisen enzymes and other mechanistically related enzymes has gained some consideration, an enolate intermediate stabilized by hydrogen bonding or in some cases possibly metal ion coordination to the carbonyl oxygen seems generally preferred (35). The low barrier or short-strong hydrogen bond proposal would favor the
proton of the hydrogen bond being equally shared between the substrate oxygen and the hydrogen bond donor group (36).

Enzymes catalyzing reactions of the acyl moiety
Certain CoA thioester using enzymes catalyze reactions at the $\beta$-carbon or other carbons of the acyl group more distant from the thioester functionality. The fatty acid $\beta$-oxidation cycle provides some examples (Fig. 3). Fatty acids enter the cycle by initial conversion to the CoA ester which is then oxidized to the $\alpha,\beta$-unsaturated thioester catalyzed by the enzyme crotonase, which is the centerpiece of the crotonase superfamily of enzymes that catalyze related reactions (37), which is followed by oxidation of the alcohol to form the $\beta$-keto thioester. Addition of water to the double bond to form the $\beta$-hydroxy thioester is catalyzed by the enzyme crotonase, which is the centerpiece of the crotonase superfamily of enzymes that catalyze related reactions (37), which is followed by oxidation of the alcohol to form the $\beta$-keto thioester. A retro-Claisen reaction catalyzed by thiolase forms acetyl-CoA along with a new acyl-CoA having a carbon chain two carbons shorter than in the initial or previous cycle.

Chemical Tools and Techniques

Structural studies of CoA utilizing enzymes
There is no single sequence motif common to all CoA utilizing enzymes, although homology has been observed across some fairly broad subsets. X-ray crystallography has been a powerful tool in the structural elucidation of CoA utilizing enzymes, and some structural studies have also been performed using NMR. Crystal structures for several of the enzymes of CoA biosynthesis have been solved while the solved structures of different CoA and CoA ester utilizing enzymes in the protein data bank numbers near 100, not including multiple structures of different complexes of the same protein and of the same protein from multiple sources. The conformation of CoA thioesters in solution has also been studied by NMR and comparisons made to the enzyme-bound conformation (38).

Applications of analogs of natural CoA thioesters
Synthetic analogs of natural CoA ester substrates have been widely used as mechanistic probes in studies of CoA ester utilizing enzymes (39). The most readily available are CoA thioesters of unnatural or uncommon acyl groups prepared by simple acylation of CoA. A number of haloacyl-CoA derivatives have been prepared, including fluoroacyl-CoA (40). Fluoroacyl-CoA is accepted as a substrate by citrate synthase to form fluorocitrate, which is an inhibitor of aconitase. This enzymatic processing to fluorocitrate and resulting inhibition of aconitase is responsible for the high toxicity of fluorocitrate. Bromoacyl-CoA was shown to inhibit carnitine acetyltransferase in the presence of carnitine as shown in Fig. 4. Enzyme-catalyzed transfer of the bromoacyl group to carnitine to form bromoacyl carnitine is followed by bromide displacement by the nucleophilic thiol group of CoA to form the bisubstrate adduct, which is the actual inhibitory species that binds tightly to the enzyme (41). Similar bisubstrate adducts have been employed as inhibitors of serotonin acetyltransferase (24). Other halo-acyl CoA thioesters as well as CoA thioesters having an epoxide in the acyl moiety have been employed as reactive electrophiles to trap nucleophilic residues in the active site of their target enzymes.

CoA thioesters of unsaturated acids have also been widely used. Hexadienoyl-CoA, cinnamoyl-CoA, and other $\alpha,\beta$-unsaturated acyl-CoAs having extended conjugation or having a heteroatom in place of the $\gamma$-carbon have been employed as spectroscopic probes of their enzyme complexes. The additional unsaturation or the heteroatom substituent serve to shift the UV absorbance to longer wavelength and, in some cases, also shifts the equilibrium of a reversible enzyme-catalyzed reaction toward the $\alpha,\beta$-unsaturated substrate (42, 43). 3-Alkynoyl-CoA were used as mechanism-based inhibitors of thiolase, with enzyme-catalyzed isomerization to the allenoyl-CoA being followed by conjugate addition of an active site nucleophile to form the inactive enzyme adduct (44).
Chemistry of CoA-Dependent Enzymes

Figure 4  Some unnatural CoA thioesters and related analogs. E1: carnitine acetyltransferase; E2: thiolase.

... was preceded by studies of inactivation of the dehydratase component of fatty acid synthase by 3-alkynoyl thioesters (45). In later work, simplified 3-alkynoyl pantetheine thioesters were employed similarly to identify the active site base in thiolase (46). Similar compounds have also been used to inactivate acyl-CoA dehydrogenases and enoyl reductase (47, 48). Several CoA thioesters of acids bearing cyclopropyl groups have been studied with special interest in those that undergo cyclopropyl ring opening of radical intermediates (49-51). Various other CoA thioesters bearing functionality, including photoaffinity labels (52, 53) and nitroxide spin labels (54) in the acyl moiety, have been prepared and employed as mechanistic tools. The dihydroxy analogs of acetyl-CoA and of fluoroacetyl-CoA and octanoyl-CoA were prepared and shown to have interesting spectral properties, with a λ max of 306 nm and enhanced acidity of the α-protons (pKa = 12.5) (55). CoA dithioesters have also been employed in studies of thiolase, HMG-CoA lyase and HMG-CoA reductase. Structure 22 is illustrative of a number of keto thioether analogs in which a methylene group is inserted between the sulfur and carbonyl carbon of the thioester. Such analogs are prepared by alkylation of CoA with a halomethyl ketone. These analogs do not have a cleavable bond between the CoA and acyl moiety and are often good inhibitors of acyltransferase enzymes (56). CoA has also been derivatized in the adenine base for attachment to a solid support for use in affinity chromatography (57, 58).

CoA thioester analogs have also been prepared that cannot be made by derivatization of natural CoA. Some early examples were made by nonenzymatic synthesis (59) generally following the original synthesis of CoA developed by Moffatt and Khorana (60). More recently analogs have been made enzymatically using the enzymes of CoA biosynthesis. One approach uses pantetheine kinase, phosphopantetheine adenylyltransferase, and dephospho-CoA kinase to convert synthetic pantetheine analogs (e.g., 23 to the corresponding CoA analogs, with phosphoenolpyruvate and pyruvate kinase included to regenerate the ATP consumed in the kinase steps as shown in Fig. 5 for the synthesis of an oxoester analog 26 of crotonyl-CoA (16). The three biosynthetic enzymes have been shown to accept substrate analogs having significant modification relative to the natural
substrates, including analogs having long chain acyl groups. This synthetic method takes advantage of the ability of pantetheine kinase to phosphorylate pantetheine and its analogs and derivatives in addition to the natural substrate pantothenic acid. The other primary synthetic approach has used the final enzymes of CoA biosynthesis to make a CoA analog in which the outermost amide bond is replaced with a thioester group (61). This analog serves as a general synthon for other CoA analogs by reaction with a primary amine bearing the functionality of interest in place of the thiol group of CoA (Fig. 6).

The oxoester analog of crotonyl-CoA shown in Fig. 5 was used as an alternative substrate for crotonase and exhibited about 300-fold decreased activity relative to the natural thioester (16). Some other representative analogs are shown in Fig. 6. Several dethia analogs in which the thioester sulfur atom is replaced with a methylene group have been prepared, as represented by the acetyl-CoA analog (59, 61). These analogs are generally inhibitors of enzymes that catalyze reactions involving cleavage of the thioester such as acyltransferases, while serving as substrates for enzymes catalyzing reactions that do not involve cleavage of the thioester such as some of the Claisen enzymes. The carboxylate analog is representative of compounds prepared as stable mimics of the enolate (or enol) intermediate of the Claisen enzymes (61, 62). It was shown to be a potent inhibitor of citrate synthase, binding about 1000-fold more strongly than acetyl-CoA, and the structure of the enzyme-inhibitor complex was solved (33). The analog 31...
having the orientation of the thioester reversed was shown to be an inhibitor of thiolase, apparently forming an acyl-enzyme with the CoA moiety in a step mimicking the formation of the acetyl-enzyme intermediate from acetyl-CoA (63).

**Other Technical Applications of CoA**

A recent interesting application of CoA and CoA analogs has been in protein labeling. Initially, a CoA molecule derivatized on the thiol group with a maleimide-linked reporter group was employed as a substrate for a phosphopantetheinyl transferase. The reporter-modified phosphopantetheine moiety was thereby enzymatically transferred from the CoA derivative 35 to the apo-form of the carrier protein of polyketide synthases and nonribosomal peptide synthetases to form the labeled holo-carrier protein analog 36 (Fig. 7) (64). The reporter group was either a fluorophore, for fluorescent visualization of the reporter-modified protein or biotin or other affinity tag to facilitate isolation of the labeled protein. In subsequent developments of this technology, it has been applied to the labeling of fusion proteins between the relatively small carrier protein and another protein, the fused carrier protein domain thereby directing labeling to the protein of interest (65). This methodology has also been applied to the labeling of fusion proteins on cell surfaces (66). More recently, it has been demonstrated that the CoA-reporter derivatives 35 can be prepared from synthetic pantetheine-reporter conjugates 32 using the pantothenate kinase, phosphopantetheine adenyltransferase, and dephospho-CoA kinase enzymes of CoA biosynthesis (67). The enzymes are quite promiscuous in converting analogs containing only the pantolic amide moiety of the natural pantetheine or pantetheine substrate, generally with a flexible tether between the amide and the labeling group of interest. Pantolic amide analogs containing reactive acide, alkyne, and ketone functionality as well as biotin and fluorescent labels have been employed to incorporate the functionality into the protein substrate of the phosphopantetheinyl transferase. The significance of the enzymatic generation of the CoA analog substrates for the phosphopantetheinyl transferase is that simple cell-permeable pantolic amide analogs can be processed all the way to the labeled carrier protein or fusion protein thereof in vivo. A set of bioorthogonal pantolic amide analogs have been developed for use in this in vivo protein tagging method (17). Other recent work has demonstrated that a simple 11-residue peptide incorporated into the targeted protein can be recognized by the phosphopantothenyl transferase Sfp from Bacillus subtilis (68), which promises to be a very general and versatile method for in vivo protein tagging and labeling.

Collagen Triple Helix,
Stability of

Hans Peter Bächinger and Kazunori Mizuno, Shriners Hospital for Children, Portland, Oregon
doi: 10.1002/9780470048672.wecb096

Collagens are the most abundant extracellular matrix proteins in multicellular animals. They all contain a name-giving collagen triple helix, which connects their three chains and varying amounts of other noncollagenous protein domains. To form the triple helix a repeated sequence of -Gly-Xaa-Yaa- is required, where Xaa and Yaa can be any residue. Each chain forms a polyproline-II like left-handed helix. The three chains are staggered by one residue from each other, and form a right-handed helix. Twenty eight types of collagen molecules have been identified in mammals. The stability of the collagen triple helix is based on the length and the amino acid sequence of each polypeptide chain, and also by the presence of interchain cross-links and/or trimerization domains. The 4(R)-hydroxylation of proline residues in the Yaa position significantly increases the stability of the collagen triple helix.

Collagens are proteins that have a typical triple helical higher order structure, and the triple helix is a protein motif that can be found in other proteins. The chemistry of collagen covers more than seven orders of magnitude from subnanometer scale to centimeter scale (from amino acids to a tendon) including a wide range of both noncovalent and covalent interactions. Collagen research covers a wide range of fields such as biochemistry, organic chemistry, and biophysical chemistry.

Biologic Background

Collagen is the major component of the extracellular matrix of multicellular animals. In humans, the collagen molecules are classified into 28 types (Table 1). In addition, other proteins contain collagen-like triple helical domains (Table 2). Most mammals have a similar set of these proteins. Collagens in vertebrates are numbered in the order of their discovery using Roman numerals as type I, type II, type III, and so on. In invertebrates, collagens vary from one species to another including differences in posttranslational modifications. The Caenorhabditis elegans genome has upward of 150 distinct collagen genes (1). If a collagen molecule of an invertebrate is highly homologous to a specific type of vertebrate collagen, then it is referred to the specific number type of the vertebrate collagen. For example, one of the basement membrane collagens, type IV collagen, is found in both vertebrates and also invertebrates such as Drosophila melanogaster and C. elegans as highly homologous primary structures. In that case, the molecule is called a type IV collagen. In general, the gene of collagen molecules of invertebrates are different from those of vertebrates. Most proteins with a collagen triple helix were found as a component of the extracellular matrix (ECM). However, some proteins contain a transmembrane domain, for example, type XVII collagen molecule is a type II transmembrane protein in hemidesmosomes. In addition, some triple helical proteins are found in the serum as soluble proteins such as collectins and complement C1q. Usually, they are related to natural innate immunity. The most abundant collagen protein in vertebrates is type I collagen. It is distributed ubiquitously in the vertebrate body and forms fibrils with a variety of diameter (25 nm–200 nm). Type I collagen molecules self assemble at physiologic temperature to fibrils in vitro. When type I collagen molecules are denatured into single polypeptides at higher temperatures, they form a gel at lower temperature (gelatin), which consists of partially refolded molecules. Type I collagen interacts with a wide range of other extracellular matrix molecules to form the specific tissue. The local concentration of the collagen molecules, pH, temperature, the direction of mechanical force, and the order of interactions with other molecules affect the supramolecular organization of the collagen fibrils and the entire ECM. Tendon, skin, and cornea are composed mainly of type I collagen, but their physical properties, such as the length and the diameter of collagen fibrils and the direction of collagen fibrils are different. Cells and ECM interact with each other. The homeostasis of cell-ECM interaction is essential for all biologic phenomena of multicellular animals.

Structure of the Collagen Triple Helix

The general sequence of the collagen triple helix requires a repeat of \(-\text{Gly-Xaa-Yaa}-\) where the Xaa and the Yaa residues can be any amino acid. Glycine in every third residue is required to form the triple helix. Figure 1 shows a model of the collagen triple helix. In the triple helix, all residues in the Xaa and the Yaa positions are exposed to the molecular surface. Each polypeptide forms a polyproline-II like left-handed helix. Three chains are staggered by one residue, and they form a right-handed superhelix (Fig. 1). The carboxyl group of the collagen helix is almost perpendicular to the molecular axis. This orientation is different from the alpha-helix, in which the carboxyl groups are almost parallel to the helical axis.

In the analysis of crystals of collagen model peptides, the carboxyl oxygen of the Yaa position residue has two hydrogen bonds with water molecules and that of Gly has one, because the other site for a hydrogen bond is hindered stericly by the neighboring peptide chain. In addition, the carboxyl oxygen in the Xaa position of Pro is directed to the center of the triple helix and participates in a direct hydrogen bond with the NH of Gly in the neighboring chain. This interchain Gly(NH\_\_O)Xaa hydrogen bond is almost perpendicular to the molecular axis. Based on the diffraction data of crystals, the left-handed 7/2-helical structure (Fig. 1) with a 20 Å axial repeat is obtained when both the Xaa and the Yaa positions are occupied by imino acids (2). Hence, left-handed 7/2-helical symmetry means the seven Gly-Xaa-Yaa tripeptide units from three chains make two left-handed turns in an axial repeat.

Each peptide strand forms a right-handed 7/1-helix in which seven tripeptide units and one helical unit turn in a 60 Å axial repeat. Therefore, the tripeptide unit twist and the tripeptide unit height of the strand are 51.4 (\(\approx 360/7\)) and 8.57 Å (\(\approx 60/7\)), respectively. The type I collagen molecule has a major triple helical domain with 1,014 amino acid residues of repeated \(-\text{Gly-Xaa-Yaa}-\) sequence. The pitch of each residue is 2.85 Å along the molecular axis. Therefore, the length of type I collagen molecule is about 300 nm. In collagen fibrils or the crystals of collagen model peptides, the distance between each triple helix is almost 1.5 nm.

The triple helical domain of collagen has a unique amino acid composition. Glycine accounts for one third of the total amino acid content. In homothermal animals, proline and 4(R)-hydroxyproline (Hyp) accounts for about 10% each. These three residues comprise more than half of the amino acids in collagen. Glycine and proline are usually regarded as two exceptional residues in proteins. Glycine is the only non-chiral amino acid, and it has only a hydrogen atom as side chain; usually, the composition is less than the other amino acid residues in globular proteins. Because of the smallest side chains, the dihedral angles of glycine are the most conformationally flexible among the 20 amino acids. In contrast, proline is the least conformationally flexible because of the five-membered pyrrolidine ring structure that restricts the phi angle. Proline is the only imino acid among the 20 coded amino acids. The high content of Gly and Pro (4(R)Hyp give the collagen triple helix unique properties not found in globular proteins. The content of hydrophobic residues in the triple helix is much lower than in globular proteins. In the collagen triple helix, more positively charged residues exist (Lys + Arg) than negatively charged residues (Glu + Asp). Because of the highly extended rod-like structure of the collagen triple helix, the accessible surface area per residue is much larger than that of globular proteins. All residues in the Xaa and the Yaa position are exposed to the molecular surface in a radial pattern.

Proline ring puckering

The pyrrolidine ring of (hydroxy)proline is not planar. The analyses of model collagen peptides at high resolution have revealed that there is distinct propensity of ring puckering in the Xaa and the Yaa position. In most cases, the imino acid residues in the Xaa position have the C\(_\text{y}-\text{endo}\) (down) puckering (Fig. 2). In contrast, most of imino acid residues in the Yaa position have the C\(_\text{y}-\text{exo}\) (up) puckering conformation.
Sometimes hydroxylysine is modified even more to O-β-Lys in the Yaa position is modified to 5-hydroxylysine. About a quarter of residues in the Yaa position; however, prolyl 3-hydroxylation avians, prolyl 4-hydroxylation occurs in almost all Pro 5-dioxygenases LH 1, 2a/2b & 3: EC 1.14.11.4) in some Gly-Pro-4Hyp-Gly- sequences, and 5-hydroxylation of lysine to 5-hydroxylysine (5-lysylhydroxylases, ly- syl hydroxylases (LHs), procollagen-lysine 2-oxoglutarate dioxygenases LH 1, 2a/2b & 3: EC 1.14.11.4) in some Gly-Xaa-Lys-Gly- sequences. In almost all mammals and avians, prolyl 4-hydroxylation occurs in almost all Pro residues in the Yaa position; however, prolyl 3-hydroxylation is much less frequent. Each type I collagen polypeptide chain has one 3-hydroxyproline. About a quarter of Lys in the Yaa position is modified to 5-hydroxylysine. Sometimes hydroxylysine is modified even more to O-β-galactosylhydroxylysine (enzyme: galactosyltransferase, EC 2.4.1.50) and 2-O-D-galactosyl-O-β-D-galactosylhydroxylysine (enzyme: galactosylhydroxylysyl glucosyltransferase, EC 2.4.1.66). This type of glycosylation has been found only in the collagen triple helical domain. LHS also possesses relatively low levels of collagen glucosyltransferase activity and very low levels of collagen galactosyltransferase activity in addition to the lysyl hydroxylase activity. The posttranslational modifications of invertebrate collagens are more complex than in vertebrates. The cuticle collagen of the sea hydrothermal tube worm contains glycosylated threo- proline and some other amino acid residues on the stability of the triple helix. Regarding the stabilizing effect of 4(R)-hydroxyproline on the triple helix, studies with model peptides showed that the or- der of the stability of the triple helix is -Gly-Pro-4(R)Flp- > -Gly-Pro-3(R)Hyp- > -Gly-Pro-4(R)Hyp-Gly-Pro-3(R)Hyp-Gly-Pro-NH2 and acetyl-(Gly-Pro-4(R)Hyp-Gly-Pro-3(R)Hyp-Gly-Pro-Yaa-(Gly-Pro-4(R)Hyp)3-Gly-Pro-4(R)Hyp-(Gly-Pro-4(R)Hyp)3-Gly-Pro-Yaa-(Gly-Pro-4(R)Hyp)3-(Gly-Pro-4(R)Hyp)3-Gly-Pro-NH2 (8).

Some residues, such as Gly and aromatic residues significantly destabilize the triple helix. Galactosylations of threonine (9) and that of the lysine (10) increases the stability of the triple helix. The thermal stability of collagen from different animal species is correlated with their highest environmental temperature. In general, the thermal stability of collagen is increased with the content of imino acid, proline, and 4(R)-hydroxyproline. Es- pecially, the contribution of 4(R)-hydroxyproline in the Yaa position is important. An additional stabilization of the collagen triple helix occurs on the formation of fibrils. The melting temperature of the collagen triple helix in fibrils is around 55°C. To clarify the mechanism of the stability of the triple helix, synthetic collagen model peptides have been used. The effect of 20 types of amino acid residues on the stability of the triple helix was analyzed in the context of host-guest system, that is, acetyl-(Gly-Pro-4(R)Hyp)3-Gly-Pro-4(R)Hyp-Gly-Pro-NH2 and acetyl-(Gly-Pro-4(R)Hyp)-Gly-Pro-Yaa-(Gly-Pro-4(R)Hyp)3-Gly-Pro-NH2 (8).

To determine the effect of 4(R)-hydroxyproline on the triple helix, studies with model peptides showed that the or- der of the stability of the triple helix is -Gly-Pro-4(R)Flp- > -Gly-Pro-4(R)Hyp-.

Stability of the Collagen Triple Helix

The temperature where one half of the polypeptide exists as a triple helix is termed the melting temperature (Tm), and is specific for different collagens from different species. The Tm of soluble collagen at neutral pH physiologic salt solution is around the body temperature of the organism from which it is isolated. The thermal unfolding of interstitial fibrillar collagens, type I, II, and III, occurs in a very narrow temperature interval of less than 3 degrees in passing from a 90% native to a 90% denatured conformation. Also, the guanidinium chloride induced transition of collagen is very sharp and occurs after increasing the concentration of the denaturant by only 0.2 M. The denaturation of these types of collagen is highly coopera- tive. The enthalpy change of the triple helix ↔ coil transition for type I collagen was determined to be ΔH = 15-18 kJ/mole triple peptide unit. The enthalpy change per residue of triple helix is significantly greater than that of globular proteins. The source of this greater enthalpy change is still controversial. Another unique thermodynamic property of collagen molecules is the absence of a change in heat capacity after the denaturation. The stability of the collagen triple helix depends on the se- quence and the length of the three polypeptide chains. The thermal stability of collagen from different animal species is correlated with their highest environmental temperature. In gen- eral, the thermal stability of collagen is increased with the content of imino acid, proline, and 4(R)-hydroxyproline. Es- pecially, the contribution of 4(R)-hydroxyproline in the Yaa position is important. A additional stabilization of the collagen triple helix occurs on the formation of fibrils. The melting temperature of the collagen triple helix in fibrils is around 55°C. To clarify the mechanism of the stability of the triple helix, synthetic collagen model peptides have been used. The effect of 20 types of amino acid residues on the stability of the triple helix was analyzed in the context of host-guest system, that is, acetyl-(Gly-Pro-4(R)Hyp)3-Gly-Pro-4(R)Hyp-Gly-Pro-NH2 and acetyl-(Gly-Pro-4(R)Hyp)-Gly-Pro-Yaa-(Gly-Pro-4(R)Hyp)3-Gly-Pro-NH2 (8).

Some residues, such as Gly and aromatic residues significantly destabilize the triple helix. Galactosylations of threonine (9) and that of the lysine (10) increases the stability of the triple helix. To determine the effect of 4(R)-hydroxyproline on the triple helix, studies with model peptides showed that the or- der of the stability of the triple helix is -Gly-Pro-4(R)Flp- > -Gly-Pro-4(R)Hyp-.
-Gly-Pro-4(R)Hyp- > Gly-Pro-Pro-, where Flp is fluoroproline. Fluorine is the most electronegative atom, and organic fluorine forms only weak hydrogen bonds. Neither -Gly-4(R)Hyp-Pro nor -Gly-Pro-4(S)Hyp- form a triple helix. These properties can be explained by a stereoelectronic effect of the 4-substitution (11). The inductive effect, the gauche effect of the pyrrolidine ring (4-substitution and the amide group), and an n → π* interaction. These effects adjust the optimum phi and psi angles of both the Xaa and the Yaa positions of collagen peptides and the puckering of the pyrrolidine ring.

Solvent affects the stability of collagen molecules and the triple helix of collagen model peptides. Polyols, such as glycerol, 1,2- and 1,3-propanediol, polyethylene glycol, sugars, and glycosaminoglycans increase the melting temperature of the triple helix. Trimethylamine N-oxide (TMAO) also stabilizes the triple helix of collagen model peptides. Urea and guanidinium hydrochloride decrease the Tm of collagen concentration linearly with increasing concentrations.

The stability of the triple helix is not affected as much by pH as globular proteins. There is a slight destabilization of the triple helix at acid pH. The effect of salt ions on the stability is similar to the Hofmeister series (12).

Chemical Tools and Techniques for Collagen Research

Collagen is one of the most popular proteins for biophysical and biochemical analysis because of its unique shape, ease of acquisition, and stability. The structure of the collagen triple helix seems more homogeneous and simpler than that of globular proteins. However, the difficulties of collagen preparations for biochemical and biophysical analysis are the heterogeneity of the sample by posttranslational modifications, intermolecular covalent cross-linking, the large molecular weight, the aggregation properties at physiologic temperatures, and the hysteresis of the folding-refolding reaction. Almost all biochemical and biophysical techniques have been applied to collagen such as circular dichroism (CD), analytical ultracentrifugation, differential scanning calorimetry (DSC), isothermal titration calorimetry, transmission electron microscopy, scanning electron microscopy, atomic force microscopy, scanning tunneling microscopy, second harmonic generation microscopy, laser scattering, electric birefringence, X-ray analysis, IR and NMR.

The collagen triple helix has a unique CD spectrum. The spectrum shows a positive peak at 220–225 nm, and a negative peak at 195–200 nm. In contrast, the polyproline II-like poly-4-hydroxyproline helix has a positive peak at 228 nm, and a negative peak at 206 nm. The polyproline II-like poly-4-hydroxyproline helix has a positive peak at 219 nm and a negative peak at 205 nm (13). The thermal stability of the triple helix can be monitored easily by the CD
The CD signal monitored as a function of temperature shows a sigmoidal denaturation curve. NMR is used for the characterization of the triple helical structure and also for the folding kinetics of the triple helix. NMR studies with synthetic model peptides of the triple helix are difficult because of overlapping resonances of the repeated sequence and by peak broadening from the shape. Isotopic labeling is used to observe specific residues using heteronuclear NMR techniques. Hydrogen exchange studies are used to show the Gly amide exchange. The exchange is faster in the imino acid-poor regions of a synthetic peptide compared with the Gly-Pro-4(R)Hyp region.

DSC was used to characterize the thermodynamic properties of the collagen triple helix to coil transition in individual molecules and in fibrils. Many microscopy techniques were used to visualize individual collagen molecules and their supramolecular assemblies.

Collagen model peptide synthesis

Because the natural collagen molecules are large, heterogeneous, and difficult to purify, collagen model peptides are used for many analyses. Recent developments in solid-phase peptide synthesis techniques have made the synthesis of longer peptides easier than before. The commercial availability of Fmoc-derivatives of 4(R)-hydroxyproline, 4(R)-fluoroproline and 3(S)-hydroxyproline, the synthesis of glycosylated-Fmoc-threonine and glycosylated-Fmoc-hydroxylysine, and other unusual amino acids have extended the range of collagen-like peptides that have been synthesized. Overlapping cysteine linked peptides of type III collagen have been made, which covers the whole triple helical region of type III collagen (1029 amino acids) (14). Several cross-links were introduced to stabilize the three chains of the triple helix (see below).
Collagen Triple Helix, Stability of

1. 2. 3-propane tricarboxylic acid (PTC)

Trimerized triple helical model design

In vivo, collagen molecules have domains that initiate trimerization of the synthesized alpha chains. Usually, globular domains at the carboxyl terminal end of the molecule have this role. Once this domain is removed, refolding of the three collagen polypeptides to the correctly staggered molecules is very difficult or impossible. The folding reaction from three polypeptides into a triple helix is affected by the concentration of the peptides. For the kinetic refolding analysis of triple helical model
peptides, several techniques have been developed to link the three polypeptides (Fig. 5). These are

Enzyme Kinetics

W. Wallace Cleland, University of Wisconsin, Madison, Wisconsin
doi: 10.1002/9780470048672.wecb159

Enzyme kinetics is an important tool for assaying enzyme activities and for determining enzyme mechanisms. Although other techniques can provide useful information on enzyme mechanisms, the kinetics has to be the ultimate arbitrer because it looks at the reaction while it is taking place. Initial velocity patterns, inhibition patterns, patterns of isotopic exchange, pH profiles, and isotope effects are all kinetic tools that allow one to determine kinetic mechanisms, chemical mechanisms, and transition state structures.

All chemical reactions in living cells are catalyzed by enzymes, because it is the only way to control reaction rates. Kinetics is one of the best ways to study enzyme-catalyzed reactions, because one follows the reaction while it takes place. Structural studies such as X-ray structures are extremely helpful in understanding enzymatic catalysis, but the kinetics must be the ultimate arbiter.

Reasons for Study of Enzyme Kinetics

One determines enzyme kinetics for several reasons. First, kinetic assays are needed to measure enzyme activity during purification and to establish that one has an active enzyme. Such assays also allow one to determine the effects of potential drugs as inhibitors. Second, kinetic studies are one of the best ways to determine the mechanism of the reaction, and we will focus in this article mainly on the use of kinetics for this purpose. For determination of mechanism we need:

1. The kinetic mechanism, which is the order of events during a catalytic cycle in terms of the order of substrates combining with and products dissociating from the enzyme. We need to know the complexes that form, how many sites exist, and their specificity for binding reactants. This information is qualitative.
2. The relative rates of steps in the mechanism, which is quantitative information on which steps are rate limiting at high or low concentrations of substrates. Are substrates sticky (that is, react once they combine faster than they dissociate)?
3. The chemical mechanism, which includes the nature of any intermediates and the identification of enzymatic groups involved in binding and catalysis.
4. Transition state structure. Isotope effects will often give a very clear picture of what the transition state looks like for an enzymatic reaction.

One Substrate Concentration Varied

An enzyme has a pocket or cleft in which substrates bind, and usually a flap exists that then closes around the substrates once they are bound. Thus, an enzyme has open and closed conformations, with reactants coming and going from the open form and catalysis taking place in the closed form. As the enzyme and substrate(s) form a complex, the basic rate equation when one substrate concentration is varied (any others being held constant) usually is:

\[ v = \frac{V A}{K + A} \]  

where \( v \) is velocity, \( V \) is the maximum velocity when the substrate concentration is saturating, \( K \) is the Michaelis constant, and \( A \) is the substrate concentration (bold type will indicate concentrations in this article). The Michaelis constant measures affinity in the steady state and is the level of substrate that gives half of \( V \). \( K \) can be greater than, smaller than, or the same as the dissociation constant of the substrate. We will assume that the enzyme is operating in the steady state, that is, that the substrate concentrations exceed the enzyme level by at least an order of magnitude, which is normally the situation in an enzyme assay, but for very slow mutants it may not be a valid assumption. Steady-state studies with enzyme levels equivalent to or exceeding substrate concentrations also require the use of more complicated rate equations.

The usual practice is to measure the initial velocity with which the reaction starts and to determine such initial velocities for separate reaction mixtures containing different levels of substrate. Although it is possible to integrate Equation 1 and determine residual substrate concentrations or product formation as the reaction proceeds, this procedure is subject to more uncertainties as the pH may change or the enzyme may die. The high correlation between the various data points also makes statistical analysis tricky. See References 1 and 2 for a discussion of this method and its problems.
In Equation 1, the rate when \( A \) is very high is \( V \), whereas at low \( A \), it is given by:

\[
v = \frac{V}{K}\frac{1}{A}
\]  

(2)

where \( V/K \) is an apparent first-order rate constant. \( V \) and \( V/K \) are the two kinetic constants that vary independently with the levels of other substrates, inhibitors and activators, \( pH \), ionic strength, and so forth. \( K \) is not an independent constant, but just the ratio of \( V \) and \( V/K \), it does indicate the likely concentration of the substrate \( A \) at which only in this concentration range does one get proportional control of the rate. At substrate levels well above \( K_a \), the rate does not vary with substrate concentration, whereas at low substrate concentrations, one is not using the potential activity of the enzyme.

As Equation 1 is not linear, but a rectangular hyperbola, it is usually inverted for graphing purposes to give a double reciprocal plot:

\[
\frac{1}{v} = \frac{1}{V} + \frac{1}{V/K}\frac{1}{A}
\]

(3)

Thus, \( 1/v \) plots linearly against \( 1/A \), with a slope of \( V/K \) and a vertical intercept of \( V \). Note that the slope and intercept are the reciprocals of the two fundamental kinetic constants, \( V/K \) and \( V \). In the discussion that follows, we will refer to slope and intercept effects, and one needs to keep in mind that these are effects on \( V/K \) and \( V \).

Although Equation 3 is the usual form used for graphing, one should not make unwarranted least squares fits of the experimental data to it. Such fits require \( v^0 \) weighting factors if errors in the velocities are thought to be roughly constant or \( v^2 \) weights if errors are proportional to velocities. The proper fits are made to Equation 1 directly by nonlinear least squares fitting (for constant errors), or to the equation with logarithms taken of \( v \) and \( v/K \) if errors are proportional to velocities, for graphing purposes, Equation 4 is inverted to give:

\[
\frac{1}{v} = \frac{1}{V}(1 + \frac{K_a}{V}) + \frac{1}{V/K}\frac{1}{A}
\]

(4)

Equation 6 describes an intersecting initial velocity pattern where \( 1/v \) is plotted versus \( 1/A \) at different values of \( B \), whereas Equation 6 describes the pattern where \( 1/v \) is plotted versus \( 1/B \) at different values of \( A \). Both the slopes and the intercepts of the reciprocal plots are functions of the other substrate concentration, and replots of slopes or intercepts versus the reciprocal of the other substrate concentration allow determination of all kinetic constants.

The reciprocal plots in these patterns cross to the left of the vertical axis at:

\[
\frac{1}{v_{cross}} = \frac{1}{V}(1 - \frac{K_a}{V})
\]

(7)

The crossover point is above the horizontal axis if \( K_a < K_{in} \) and below it if \( K_a > K_{in} \), and is the same regardless of which substrate concentration is varied.

Sequential mechanisms are typical of kinases and dehydrogenases. Some mechanisms are ordered and some are random, and one get proportional control of the rate. The approach outlined above is sufficient when there is only one substrate or in an assay where one varies only the concentration of one substrate. However, where two or more substrates exist, and one wants to know the order of their combination with the enzyme, one needs to determine an initial velocity pattern. One varies the concentrations of one substrate at several different levels of a second substrate and determines the initial velocities for the different reaction mixtures. It is, of course, necessary to have the same enzyme level in each reaction or correct the rates to constant enzyme concentration.

Three initial velocity patterns are commonly observed.

**Use of Kinetics for Study of Mechanism**

**Initial Velocity Studies**

The approach outlined above is sufficient when there is only one substrate or in an assay where one varies only the concentration of one substrate. However, where two or more substrates exist, and one wants to know the order of their combination with the enzyme, one needs to determine an initial velocity pattern. One varies the concentrations of one substrate at several different levels of a second substrate and determines the initial velocities for the different reaction mixtures. It is, of course, necessary to have the same enzyme level in each reaction or correct the rates to constant enzyme concentration.

Three initial velocity patterns are commonly observed. When both substrates have to add to the enzyme before any products are released, one has a sequential mechanism. The rate equation for most sequential mechanisms is:

\[
v = \frac{V}{V/K}(A + B - AB)
\]

(8)

where \( V \) is initial velocity; \( V \) is maximum velocity; \( A \) and \( B \) are substrate concentrations; \( K_a \) and \( K_b \) are Michaelis constants for \( A \) and \( B \), and are the levels that give half of \( V \) when the other substrate is saturating; and \( K_{in} \) is the dissociation constant of \( A \), the first substrate to add to the enzyme if the mechanism is ordered. If the mechanism is random, a dissociation constant for \( B \) of \( K_{ib} \) also exists, and \( K_aK_b = K_{ib}K_{in} \).

Although experimental data should be fitted directly to Equation 1, or to the log form of it if errors in velocities are proportional to velocities, for graphing purposes, Equation 4 is inverted to give:

\[
\frac{1}{v} = \frac{1}{V}(1 + \frac{K_a}{V}) + \frac{1}{V/K}\frac{1}{A}
\]

(9)

Equation 6 describes an intersecting initial velocity pattern where \( 1/v \) is plotted versus \( 1/A \) at different values of \( B \), whereas Equation 6 describes the pattern where \( 1/v \) is plotted versus \( 1/B \) at different values of \( A \). Both the slopes and the intercepts of the reciprocal plots are functions of the other substrate concentration, and replots of slopes or intercepts versus the reciprocal of the other substrate concentration allow determination of all kinetic constants.

The reciprocal plots in these patterns cross to the left of the vertical axis at:

\[
\frac{1}{v_{cross}} = \frac{1}{V}(1 - \frac{K_a}{V})
\]

(10)

The crossover point is above the horizontal axis if \( K_a < K_{in} \) and below it if \( K_a > K_{in} \), and is the same regardless of which substrate concentration is varied.

Sequential mechanisms are typical of kinases and dehydrogenases. Some mechanisms are ordered and some are random,
but the initial velocity pattern does not distinguish between them and inhibition studies are required (see below).

When one substrate adds to the enzyme and a product is released before the second substrate adds, one has a ping-pong mechanism, and the rate equation is

\[ v = V_{AB}/(K_{A}A + K_{B}B + AB) \]  

(8)

The constant term is missing, which leads to a parallel initial velocity pattern (Fig. 2) regardless of which substrate concentration is varied:

\[ 1/v = (K_{A}V)(1/A) + (1/V)(1 + K_{B}/B) \]  

(9)

\[ = (K_{A}V)(1/B) + (1/V)(1 + K_{A}/A) \]  

(10)

The slopes of the reciprocal plots do not vary with the level of the other substrate, but the intercepts do. Replots of intercepts, and comparison with slopes, allow determination of the kinetic constants.

Ping-pong mechanisms are shown by transaminases and nucleoside diphosphate kinase (4). One must be cautious about assuming that a parallel-looking initial velocity pattern represents a ping-pong mechanism, as some sequential mechanisms give patterns in which the crossover point is far down in the third quadrant and the pattern looks parallel. Isotopic exchange studies will distinguish the mechanisms (see below).

The third type of initial velocity pattern results from a mechanism in which 1) the substrates add in obligatory order and 2) the off-rate constant for the first substrate to bind exceeds the turnover number (V/Et or kcat) sufficiently that its binding is at equilibrium, which is called an equilibrium ordered initial velocity pattern (Fig. 3). The rate equation is

\[ v = V_{AB}/(K_{A}K_{B} + K_{A}A + AB) \]  

(11)

and in reciprocal form

\[ 1/v = (K_{A}K_{B}/V)(1/A) + (1/V)(1 + K_{B}/B) \]  

(12)

\[ = (K_{A}/V)(1 + K_{A}/A)(1/B) + (1/V) \]  

(13)

The patterns are not the same when plotted versus 1/A or 1/B. Equation 13 plots as a pattern intersecting to the left of the vertical axis at 1/V, with the slope at infinite B being zero. That is, a replot of slopes versus 1/B goes through the origin. Equation 13 plots as a pattern intersecting on the vertical axis at 1/V. Note that the differences in the patterns given by Equations 13 and 13 establish the order of combination of the two substrates as well as showing that they add in an obligatory order.

Equilibrium ordered mechanisms are rare, because in most ordered sequential mechanisms the off-rate constant of the first substrate to add is not much larger than the turnover number. Examples of equilibrium ordered mechanisms are creatine kinase at pH 7 or below (5), malic enzyme at pH 4 (6), phosphofructokinase with fructose-6-phosphate as an alternate substrate (7), and glycerokinase with amino analogs of glycerol as substrates (8). More common are cases in which reactant A is an activator that cannot dissociate once the substrate adds. In this case, the off-rate constant of the activator need not be large, as the activator is not used up during the reaction and its binding will come to equilibrium in the steady state. An example is the addition of Mn2+ followed by UDP-galactose to lactose synthetase (9).

When three substrates exist for an enzymatic reaction, the usual procedure is to vary the concentration of one of them at fixed levels of a second, with the concentration of the third held constant. This process gives three initial velocity patterns (A–B, A–C, and B–C). The pyruvate dehydrogenase complex shows three parallel patterns as the mechanism is a three-site ping-pong mechanism (10). A number of enzymes show intersecting patterns between two substrates and parallel patterns with either one of these and the third substrate. Examples are synthetases where MgATP and an acid combine to generate an acyl-adenylate intermediate with liberation of Mg-pyrophosphate. The intermediate then reacts with the third substrate to give the final product and A-MP. Biotin carboxylases show similar patterns with MgATP and bicarbonate generating carboxy-l-phosphate that carboxylates biotin with the release of Mg°D°P and phosphate. Carboxy-biotin then carboxylates the acceptor.
Sequential terreactant mechanisms can be ordered, random, or partly random. A fully random mechanism gives only intersecting patterns. An ordered mechanism gives a parallel pattern when the first and third substrate concentrations are varied and the level of the second one is saturating. An example is glutamate dehydrogenase, with NADPH, α-ketoglutarate, and ammonia adding in that order (11). The same pattern is seen if the first two substrates add in obligate order, but the third can add randomly. An example is β-hydroxy-β-methylglutaryl-CoA reductase (12). If one substrate must add first, but the other two can add randomly to the EA complex, the A–B pattern becomes parallel at infinite C and the A–C pattern becomes parallel at infinite B. For a detailed description of the kinetics of reactions with three substrates, see Reference 13.

Inhibition Studies

The determination of kinetic mechanisms requires more than just initial velocity patterns, and inhibition studies are usually required. Several types of inhibitors are useful. The products are substrates in the reverse reaction and thus have some affinity for the enzyme and will give inhibition unless their inhibition constants exceed their solubility. Dead-end inhibitors are molecules that play musical chairs with the substrates for open portions of the active site but do not react. Substrates may act as dead-end inhibitors by combining at points in the mechanism where they are not intended and thus cause substrate inhibition. The inhibition patterns caused by these inhibitors are useful in distinguishing between different kinetic mechanisms.

Three common types of inhibition exist. The first causes changes only in V, and inhibition studies are usually required. Several types of inhibitors are useful. For a detailed description of the kinetics of reactions with three substrates, see Reference 13.
In the reverse reaction, free ADP gives competitive substrate inhibition versus MgADP. MgATP and MgADP do not show substrate inhibition as they are too large to fit into the site for AMP or ADP.

Isotopic Exchange

Initial velocity and inhibition patterns involve following the chemical reaction catalyzed by an enzyme. In isotopic exchange studies, one follows the transfer of label between reactants at equilibrium, or from product back into substrate while the reaction is proceeding. In ping-pong mechanisms, exchange occurs without all reactants being present. Thus, one can observe an exchange between A and P in the absence of B and Q and vice versa. The reaction comes rapidly to equilibrium as indicated by E + A = F + P, where A and P are the reactants between which exchange takes place and E and F are the two stable enzyme forms. Observation of such exchanges establishes a ping-pong mechanism as long as Equation 21 holds.

\[ \frac{1}{V_{A+}} + \frac{1}{V_{B-}} = \frac{1}{V_{A}} + \frac{1}{V_{B}} \]  

(21)

\( V^{*}_{AP} \) and \( V^{*}_{BQ} \) are the maximum exchange rates given by Equations 24 and 24, whereas \( V_{1} \) and \( V_{2} \) are the maximum velocities of the chemical reaction in the two directions as given by equations such as Equation B.

\[ V_{1} = V_{B} + AP \left( K_{b}A + K_{b}P + AP \right) \]  

(22)

\[ V_{2} = V_{B} + BQ \left( K_{b}Q + K_{b}B + BQ \right) \]  

(23)

The forms of Equations 24 and 24 resemble that of Equation B, and reciprocal plots of exchange rate versus the level of one reactant at fixed levels of the other will give a parallel pattern. The kinetic constants determined are dissociation constants, rather than Michaelis constants, as the exchange takes place at equilibrium. One can vary the levels of reactants freely, because equilibrium is maintained by the ratio of E and F.

In more complicated ping-pong mechanisms where two substrates combine before release of one or two products, the exchange pattern between a substrate and product when A and B levels are varied will tell whether the addition of A and B is ordered or random. For example, with a synthetase where MgATP reacts with an acid to give Mg-pyrophosphate and an acyl-adenylate, one can observe exchange between pyrophosphate and ATP at different levels of MgATP and acid at a fixed level of Mg-pyrophosphate. If MgATP levels are varied at fixed levels of acid, one has three cases:

1. The mechanism is ordered with MgATP as A and the acid as B. One sees an intersecting pattern with competitive substrate inhibition by B.
2. The mechanism is ordered with the acid as A and MgATP as B. One sees an equilibrium ordered pattern (Eq. 13).
3. The mechanism is random. One sees an intersecting pattern with no substrate inhibition.

With sequential mechanisms, one can follow isotopic exchange at equilibrium only if one varies the levels of one substrate and one product at a constant ratio and has all reactants present. The usual protocol is to vary the concentrations of like reactants together at fixed levels of the others and determine exchange rates. For example, with an alcohol dehydrogenase, one varies the levels of NAD and NADH together and alcohol and aldehyde together. One determines exchange between NAD and NADH, and between alcohol and aldehyde. In an ordered mechanism, reciprocal plots of exchange rate versus reciprocal levels of reactants are linear when A and Q levels are varied together, and the plots for the A–Q and B–P exchanges have the same apparent dissociation constant (the plots cross on the horizontal axis). The B–P exchange is faster. When the levels of B and Q are varied together, the reciprocal plots for A–Q exchange and B–P exchange are parallel, but the A–Q exchange shows total substrate inhibition (Eq. 20), which is a very sensitive test for an ordered mechanism, as partly random ones will not show complete substrate inhibition, and the apparent dissociation constants when A and Q levels are varied together will not show the same dissociation constants for the two exchanges.

Random mechanisms will not show substrate inhibition of exchanges unless the levels of reactants that can form an abortive complex are varied together. The relative rates of the two exchanges will show whether catalysis is totally rate limiting (a rapid equilibrium random mechanism), or whether release of a reactant is slower. For kinases that phosphorylate sugars, the usual pattern is for sugar release to be partly rate limiting, but for nucleotides to dissociate rapidly (15, 16).

It is also possible in a sequential mechanism to follow the exchange of label from a product back into substrate while the reaction is occurring. Only the first product to be released will exchange back into substrate, which allows determination of the order of product release (17).

pH Studies

The pH variation of kinetic parameters allows one to identify enzyme groups required for binding or catalysis. The parameters...
that are plotted versus pH are log(V/K), log(V), and pK, [log (K/Ki)], where Ki is the dissociation constant of substrates, other than the last one to add to the enzyme, or of competitive inhibitors. Any pK values seen in a pK profile have their correct values for the enzyme form involved or the molecule that is binding, as K, is an equilibrium dissociation constant.

The log(V/K) profile shows the pKs of groups in substrate or enzyme required for binding, as well as ones involved in catalysis (Fig. 5). Thus, if a substrate binds only as a dianion, the V/K profile will decrease a factor of 10 per pH units below the pK of the substrate. If a group on the enzyme has a required protonation state for catalysis, this pK will also appear. The pK's seen in V/K profiles may not appear at their true values if the substrate is sticky (that is, reacts to give products as fast or faster than it dissociates). The pK will be displaced outward on the profile by log (1 - S), where S is the stickiness ratio (the ratio of the net rate constant to produce the first product and the off-rate constant for the substrate). Comparison of pKs in V/K and pK profiles allows one to determine stickiness of the substrate.

The log V profile shows only the pK's of groups responsible for the catalytic reaction after the substrate has bound and the pKs are typically displaced from values seen in free enzyme or substrate. The pKs of neutral acids (carboxyl, sulfhydryl, phosphate) are elevated by a pH unit or more by being removed from solvent. Specific hydrogen bonding interactions can displace a pK either upwards or downwards by 1-2 pH units. For fumarase, for example, the pK of the group probably a carboxyl) that removes the proton during reaction of malate is elevated by binding of either malate or fumarate, whereas the pK of the group that protonates the OH of malate to give water is elevated by 2 pH units by the binding of malate, and lowered by 2 units by the binding of fumarate (18).

Another reason for displaced pK values in log V profiles is the switch in rate-limiting steps. If the catalytic step that is pH-sensitive is 10-fold faster than pH-independent second product release at neutral pH, the pKs in the log V profile will be displaced outward by one pH unit, as catalysis has to be slowed by an order of magnitude before it becomes rate limiting.

pH profiles are log-log plots and consist of horizontal lines when all groups are properly protonated and lines with slopes of 1, 2, -1, -2, and so on. These segments are connected with a curved portion 2 pH units wide that is centered on the pK. If protonation causes loss of binding or catalysis, the profile decreases a factor of 10 per pH unit below the pK. If deprotonation does the same, the profile drops at high pH. When one group must be protonated and the other unprotonated, the profile will drop at both low and high pH. In this case, when the pKs are not far apart, one cannot tell from the pKs which group has to be protonated and which has to be unprotonated for activity. When the group with the lower pK has to be protonated and the one with the higher pK unprotonated, one has reverse protonation. The profile will have the same shape as if the other protonation states were required, but the amplitude will differ, which is evident in the V/K profiles for fumarase (18). As the equilibrium constant is pH-independent in the neutral pH range, the V/Kfumarate and V/Kmalate profiles are identical, with apparent pKs of 5.7 and 7.1. For reaction of maleate, the low pK group must be ionized and the other one protonated, whereas for reaction of fumarate, the states of protonation have to be reversed. This reversal is the typical situation when acid-base catalysis is involved in enzymatic reactions.

Isotope Effects

Isotope effects result from replacing the normal isotopes of hydrogen, carbon, nitrogen, or oxygen with deuterium or tritium, 13C, 14C, 15N, or 18O. The effects of such replacements are expressed as klight/kheavy for kinetic isotope effects, or Keq light/Keq heavy for equilibrium isotope effects. Equilibrium isotope effects compare the stiffness of bonding of the isotopic atom in product versus substrate, whereas kinetic ones compare the transition state to the substrate. The heavy isotope enriches in the more stiffly bonded position and the light isotope effect in the less stiffly bonded position.

Equilibrium isotope effects are normal (<1.0) if the substrate is more stiffly bonded and inverse (>1.0) if the product is more stiffly bonded. Primary kinetic isotope effects are almost always normal, as the atom being transferred is more weakly bonded in the transition state. Isotope effects in positions not subject to bond breaking or making are secondary and are good tools for determining transition state structure. They may be either normal or inverse.

Isotope effects on enzymatic mechanisms are determined for each V/K value and for V. A leading superscript indicates the nature of the isotope effect. Thus (V/K) is a deuterium isotope effect on V/K (the value for unlabeled substrate divided by that for deuterated substrate). The leading superscripts used by
Enzyme Kinetics

Isotope effects are useful in determining chemical mechanisms. In an oxidative decarboxylation where a hydride ion is removed from one carbon and CO₂ is lost from another, one can tell whether the reaction is concerted or stepwise by the effect of deuteration on the ¹³C isotope effect in the CO₂ (21). In a concerted mechanism, deuteration makes the chemical step more rate limiting and thus diminishes the same one if commitments were small to start with. In a stepwise mechanism, however, deuteration of the substrate makes the decarboxylation step less rate limiting and thus diminishes the size of the observed isotope effect.

If an appreciable equilibrium deuteron isotope effect exists on a stepwise mechanism (>1.1), one can tell which step comes first. In the direction where the deuteron-sensitive step comes first (21),

\[
\frac{1}{1.1}(V/K)_{D} - 1 = 0(V/K)/0K_{eq}
\]

and in the reverse direction with the ¹³C-sensitive step first,

\[
\frac{1}{1.1}(V/K)_{H} - 1 = 0V/K_{eq}(V/K)_{D} - 1.1K_{eq}
\]

These are really the same equation, but Equation 28 is expressed in terms of parameters of the forward reaction and Equation 29 in terms of ones for the reverse reaction.
The size of intrinsic isotope effects can be used to determine transition state structure. For example, in the concerted oxidative decarboxylation catalyzed by prephenate dehydrogenase, a large deuterium isotope effect (7.3) but a small 13C isotope one (1.5%) indicates an asynchronous transition state with considerable C-H bond cleavage, but only a small degree of C-C cleavage, as most decarboxylations show -- 5% 13C isotope effects (24). The shift in isotope effects as the redox potential of the nucleotide substrate was changed (thus changing $K_w$) for the formate dehydrogenase reaction showed that the transition state became earlier as $K_w$ increased (25). Similar results were seen with liver alcohol dehydrogenase (26).

Flavins react with oxygen and can form stable flavin peroxides in an aprotic solvent or buried in a protein. It is this hydroperoxide or peroxide that is the oxygenating agent in flavoproteins. This property is used in nature to carry out aromatic hydroxylations, halogenations, Baeyer-Villiger oxygenations, hydroxylation of xenobiotics and some metabolites, as well as light emission from luciferase. Several groups of enzymes seem to have evolved hydroxylating properties independently of each other. One group consists of the two-component flavin-dependent hydroxylases that use many of the same principles as the single component hydroxylases, although they also have some special requirements. After a brief introduction to the reactivity of flavins with oxygen, we examine \( \text{p}-\text{hydroxybenzoate} \) hydroxylase as the paradigm for the chemistry and protein functions exhibited by these enzymes. We then discuss unique features of each group of enzymes and the exciting prospects for future research.

In the context of this section, hydroxylation refers to enzymatic catalysis in which one atom of molecular oxygen is incorporated into the structure of a substrate, which causes its oxidation. A large variety of enzymes can carry out this type of reaction, and they are called oxygenases or hydroxylases. They have one common property: They use cofactors in catalysis that are reactive with molecular oxygen. Flavoprotein hydroxylases are a major subgroup of oxygenases, and they are found in all types of aerobic organisms, although particularly in bacteria and fungi. A more detailed overview of flavoprotein hydroxylases can be found in References 1 and 2. These enzymes oxygenate various aromatic compounds and ketones, electron-rich atoms in many compounds, and halogen ions that then halogenate aromatic compounds. However, the enzymes do not hydroxylate less reactive compounds, such as hydrocarbons. We have chosen to emphasize in this section the enzyme \( \text{p}-\text{hydroxybenzoate} \) hydroxylase, because it has been the outstanding model for the chemistry of these enzymes (3, 4) and has been studied extensively. Most other enzymes can be understood as variations on this model.

Reaction of Flavins with Oxygen

The chemistry and biological context of flavins are described in the article, “Chemistry of Flavoenzymes.” Reduced forms of flavins are usually very reactive with \( \text{O}_2 \), which is somewhat surprising because most organic compounds are not very reactive with \( \text{O}_2 \). Although reactions between dioxygen and most organic molecules are extremely favorable in thermodynamic terms (consider what happens in wild fires), the reactions are usually slow. Reactivity is lacking because organic compounds have singlet spin states, whereas \( \text{O}_2 \) has a triplet spin state. However, in the case of reduced flavins and some other molecules, this impediment can be overcome because one-electron reduced states of flavins are readily accessible, and reactions with \( \text{O}_2 \) to form radicals is spin allowed (5). The accidental formation of various reactive oxygen species by electron transfers from reduced flavins to oxygen in cells is generally avoided because free flavins are usually present in very low concentrations. Hydroxylation can only occur if the formation and reaction of reactive oxygen species are tightly controlled. This control comes from the specific environments of enzyme active sites. One control strategy is to prevent the formation of the reactive reduced cofactor until conditions are suitable for hydroxylation—many flavoproteins use this strategy. Hydroxylases bind to and interact with flavins to decrease the thermodynamic stability of the free-radical form relative to the oxidized and reduced forms. As a result, when the reduced flavin reacts with oxygen inside the protein environment, the first electron is transferred to form a flavin radical and a superoxide radical (\( \text{O}_2^- \)) pair. This pair...
Flavin-Mediated Hydroxylation Reactions

PHBH catalyzes the reaction shown in Fig. 1 with a high degree of specificity and a turnover rate of 50–60 s⁻¹ at standard conditions of optimum pH (7.5–8) and 25 °C. A characteristic feature of PHBH and similar enzymes is the formation of some hydrogen peroxide during catalysis when conditions are not ideal for the enzyme (see Fig. 1, k8). This property, which is called uncoupling, comes about when the unstable flavin hydroperoxide (E F1 HpOH−S in Fig. 1) that is essential to catalysis decomposes. All of these flavin-dependent oxygenases function to limit the amount of toxic hydrogen peroxide formed during catalysis.

Catalytic cycle

PHBH catalyzes the reaction shown in Fig. 1 with a high degree of specificity and a turnover rate of 50–60 s⁻¹ at standard conditions of optimum pH (7.5–8) and 25 °C. A characteristic feature of PHBH and similar enzymes is the formation of some hydrogen peroxide during catalysis when conditions are not ideal for the enzyme (see Fig. 1, k8). This property, which is called uncoupling, comes about when the unstable flavin hydroperoxide (E F1 HpOH−S in Fig. 1) that is essential to catalysis decomposes. All of these flavin-dependent oxygenases function to limit the amount of toxic hydrogen peroxide formed during catalysis.

Catalytic cycle

PHBH catalyzes the reaction shown in Fig. 1 with a high degree of specificity and a turnover rate of 50–60 s⁻¹ at standard conditions of optimum pH (7.5–8) and 25 °C. A characteristic feature of PHBH and similar enzymes is the formation of some hydrogen peroxide during catalysis when conditions are not ideal for the enzyme (see Fig. 1, k8). This property, which is called uncoupling, comes about when the unstable flavin hydroperoxide (E F1 HpOH−S in Fig. 1) that is essential to catalysis decomposes. All of these flavin-dependent oxygenases function to limit the amount of toxic hydrogen peroxide formed during catalysis.
Flavin-Mediated Hydroxylation Reactions

**Figure 1** Catalytic cycle of p-hydroxybenzoate hydroxylase. In the first step, pOHB and NADPH bind (k1) and the FAD becomes reduced (k2). NADP is released (k3) and O2 reacts (k4) to form the C4a-hydroperoxy-FAD (E FlHOOH-S) in complex with substrate. Hydroxylation occurs via k5 to yield the dienone form of product and the C4a-hydroxy-FAD (Int II). Tautomerization yields 3,4-dihydroxybenzoate in complex with the enzyme (E FlH OH-P). Dissociation of 3,4-DOHB and H2O via k7 leads to free enzyme (E Flox). Uncoupling occurs via the loss of H2O2 from the C4a-hydroperoxy flavin (k8).

is incorporated into pOHB, and the other is reduced to water. Depending on the conditions, the primary rate-determining step in catalysis is either the dissociation of NADP from the enzyme after reduction, or the dissociation of 3,4 DOHB after oxidation (or both). The transient chemical intermediates in this oxidative half reaction were initially discovered and studied in the early 1970s by using stopped-flow spectrophotometry and fluorimetry to track the changes in FAD (8). Reduced, oxidized, and C4a-substituted flavins have unique absorption spectra (Fig. 2), and sometimes have unique fluorescence characteristics. For example, the C4a-hydroperoxyflavin and C4a-hydroxyflavin species often have very similar UV-visible spectra. However, the hydroxyflavin is often very fluorescent whereas the hydroperoxyflavin is not. These properties, which make it possible to study the kinetics directly of the chemical changes in catalysis with considerable specificity and sensitivity, are an enormous help to mechanistic investigations of flavoproteins.

**Role of proton exchanges and electrostatics in catalysis**

As is the case with most enzymes, catalysis by PHBH is sensitive to pH because proton associations and dissociations are important to the overall process. The structure of PHBH shows that the isoalloxazine in the active site is in a positive electrostatic field (10, 11). When pOHB is bound in the active site, its 4-OH group is linked into a chain of hydrogen bonds to the surface of the protein (Fig 3 Reference 12). These structural features are highly conserved in PHBH. This enzyme was an excellent model to study the effects of proton exchanges because pH-dependent changes occur to the spectra of both FAD and pOHB in the protein, and it is feasible to make specific stable mutants that involve the hydrogen bond chain and other residues in the enzyme.

When pOHB binds to the oxidized enzyme at neutral pH in the positive electrostatic field of the active site, the phenolic
The role of protein dynamics in catalysis has to be inferred from several pieces of mostly indirect evidence, which includes important kinetic observations. For example, why does NADPH reduce FAD in the enzyme 105-fold faster with pOHB bound than without, when the thermodynamics are essentially the same for each reaction? Under specific conditions, the 3-D structure of the enzyme is significantly different (10, 17), and these different structures can be logically ascribed to catalysis. For example, individual mutant forms of PHBH stabilize the structure in one or another particular conformation with specific dramatic effects on catalysis. Recently, single molecule fluorescence studies of PHBH have been used to demonstrate a specific conformational change in PHBH and to suggest a possible role of the protein dimer in promoting binding of pOHB (18). The accumulated evidence has provided the following minimum picture of functional protein dynamics.

The enzyme forms at least three highly interactive conformations during catalysis—named the in, out, and open conformations. Without ligands bound, the enzyme is in rapid equilibrium between the in and open conformations (which were measured in single-molecule studies) (18). It has been suggested that because of this dynamic equilibrium, the native protein fails to form high-resolution crystals without substrates bound. The open conformation has a more open active site and permits solvent access. This conformation has been illustrated by the structure of the Arg220Gln variant of PHBH, which gives a high-resolution crystal structure without any substrate bound (17). To form the open conformation, the highly conserved peptide loop that includes a strained peptide bond between Arg44 and Ala45, and that covers the substrate aromatic ring toward electrophilic attack. This effect was demonstrated by the ~100-fold decrease in the rate of hydroxylation in the mutant, Tyr201Phe, which cannot release the 4-OH proton (15). The positive electrostatic field in the active site is also important to the catalysis of hydroxylation. It was shown that making the field more positive increases the rate of hydroxylation, and making the field more negative decreases the rate of hydroxylation (16). These observations are consistent with the fact that the flavin hydroperoxide has a limited ability to carry out electrophilic attacks. For example, PHBH fails to hydroxylate either the less reactive benzene or p-fluorobenzene substrate analogs, even though they bind appropriately in the active site. After formation of the 3,4 DOHB product in the active site, the hydrogen bond network can again promote dissociation of the proton from the 4-OH position of 3,4 DOHB as part of a controlled conformational change in the protein that results in release of the 3,4 DOHB product and loss of water from the flavin (see the next section).

Protein dynamics in catalysis

In the positive electrostatic field of the active site, reduced FAD, which is formed by hydride transfer from NADPH, exists primarily as its anion (Fig. 3), which is ideal for its reaction with oxygen. The reaction of O2 with the anionic reduced flavin results in a peroxide that must be protonated to form the hydroperoxide for the subsequent electrophilic attack on pOHB. This protonation is extremely fast and has only been detected at high pH with a mutant form of PHBH (14). It is not known what is the source of the proton, but it is likely to be delivered through a water channel on the re side of the isalloxazine ring. The hydrogen bond network also has an important function during the oxidative half-reaction. With the formation of the neutral flavin hydroperoxide, the 4-OH proton of pOHB can be removed and transferred to the hydrogen bond network; this transfer promotes electrophilic attack of the distal hydroxyl of the C4a-hydroperoxide on the 3-position of pOHB (14). Thus, the enzyme activates the substrate aromatic ring toward electrophilic attack. This effect was demonstrated by the ~100-fold decrease in the rate of hydroxylation in the mutant, Tyr201Phe, which cannot release the 4-OH proton (15). The positive electrostatic field in the active site is also important to the catalysis of hydroxylation. It was shown that making the field more positive increases the rate of hydroxylation, and making the field more negative decreases the rate of hydroxylation (16). These observations are consistent with the fact that the flavin hydroperoxide has a limited ability to carry out electrophilic attacks. For example, PHBH fails to hydroxylate either the less reactive benzene or p-fluorobenzene substrate analogs, even though they bind appropriately in the active site. After formation of the 3,4 DOHB product in the active site, the hydrogen bond network can again promote dissociation of the proton from the 4-OH position of 3,4 DOHB as part of a controlled conformational change in the protein that results in release of the 3,4 DOHB product and loss of water from the flavin (see the next section).
right orientation and distance from the C4 of the nicotinamide of the bound NADPH to foster rapid hydride transfer and reduction of the flavin. In PHBH, this chemically productive orientation is associated with the formation of a charge-transfer complex between flavin and NADPH that can be monitored spectrally at long wavelengths (20). Similar conformational control of reduction is probably common to many one-component hydroxylases. However, the mechanism for triggering the change is likely to be different with each enzyme.

A free FAD is reduced, the enzyme reverts to the in conformation, probably because of the electrostatic attraction between the newly formed reduced flavin anion and the positive electrostatic field of the active site after protonation of pOHB by the hydrogen bond network (14). The conformational change is somehow linked to the dissociation of NADP, which is the rate-determining step in catalysis under optimal conditions for catalysis. The reaction with oxygen and the subsequent hydroxylation occurs with the protein in the in conformation. As with all of these hydroxylases, the enzyme reacts rapidly with oxygen in the enclosed hydrophobic active site. For PHBH, a hydroxylation with average reactivity with oxygen, the rate constant is $2 \times 10^9 \text{M}^{-1} \text{s}^{-1}$ at 4 °C, which is at least 10-fold faster than the reaction of oxygen with free reduced flavin. A structural explanation probably existed for this reaction. PHBH has a hydrophobic pocket on the face of the flavin with just the right space for oxygen to contact the isoalloxazine ring for reaction. Because the redox potential for the first electron transfer to oxygen (forming $\text{O}_2^-$) is not favorable, the electron transfer occurs over a short distance to oxygen, which is in the pocket, thus, the $\text{O}_2^-$ that is initially formed as a capped pair with the flavin radical rapidly collapses to form the peroxide. This property of short-range electron transfer may help to avoid the formation of free superoxide that might otherwise escape to solution. In the conformation, the flavin hydroperoxide has sufficient stability to execute hydroxylation of pOHB with 100% efficiency under the right conditions ($pH$ between 6 and 7). The ring of the product, 3,4-DHOB, is rotated in the active site by comparison to pOHB, which helps trigger a conformational shift to the open form, permitting product dissociation and loss of water from the flavin to complete the catalytic cycle. PHBH, like most of these hydroxylases, is subject to substrate (pOHB) inhibition. Kinetic analysis has shown that mM concentrations of pOHB rapidly bind to PHBH after dissociation of the 3,4 DHOB product and thus stabilize in conformation with the flavin trapped as the flavin-C4a-hydroxide (Fig. 3). This dead-end complex inhibits catalysis.

For PHBH to function as an efficient catalyst, the series of four conformational changes in a catalytic cycle have to be fast and coordinated compared with the chemical reactions of catalysis. For example, the observation that the reduction of flavin under optimal conditions for catalysis exhibits a full primary deuterium isotope effect (13) implies that the rate of reduction of flavin is limited by hydride transfer and not by conformational rearrangements. However, when the enzyme is stabilized in the in conformation (as with the mutant form, A1a45G/I), then a large fraction of flavin reduction becomes much slower under the same conditions and shows only a small deuterium isotope effect (21).

Two-Component Flavin-Dependent Hydroxylases

The one-component hydroxylases like PHBH have been recognized since the process of biological oxidation was first demonstrated in the 1960s. Many similar enzymes have been discovered over the years. For example, although phenol hydroxylation from yeast has very little sequence similarity to PHBH, it has a 3-D structure with the same folding pattern as PHBH (22), and almost certainly undergoes similar protein dynamics in catalysis. In the 1990s, another completely different group of flavin-dependent hydroxylases was found in bacteria—the two-component enzymes. These two-component hydroxylases consist of one protein that catalyzes the reduction of flavin and an oxygenase that binds the reduced flavin product and carries out the hydroxylation step. These enzyme systems are often called two-component-flavin diffusible monooxygenases (TC-FDM). In this section, we examine briefly p-hydroxyphenylacetate hydroxylase as a model for a large subset of this group of enzymes that, like PHBH, hydroxylate aromatic compounds. Another group of two-component enzymes has evolved with a different function—to halogenate substrates. We use tryptophan halogenase as an example of this expanding group. Finally, we refer to bacterial luciferase. This unique enzyme was the first two-component flavin-dependent hydroxylase to be recognized about 40 years ago. In the past 15 years, hydroxylations that involve catalysis by two-component enzymes of a huge diversity of substrates have been found. A summary of these can be found in Reference 2. The special case of epoxidation reactions should be noted. The best example is styrene monooxygenase (23, 24). As a two-component enzyme, it is similar to other enzymes of this type and uses a C4a-hydroperoxyflavin as a hydroxylating intermediate (24). However, the oxygenase component has no sequence similarity to other equivalent oxygenase components (23). We look forward to detailed mechanistic studies on hydroxylation by this enzyme because it may provide new insights into the process of oxygen insertion into double bonds by flavinoids as well as aromatic hydroxylations.

Para-hydroxyphenylacetate hydroxylase (HPAH)

This enzyme system, which has been isolated from several different organisms, subdivides into two distinct groups. The enzyme system from Acinetobacter baumannii is a model for one group, and the enzyme system from Pseudomonas aeruginosa is a model for the other. The P. aeruginosa hydroxylase is very similar to HPAH from E. coli (25), but it is more amenable for mechanistic studies. HPAH from A. baumannii is isolated as a reductase that contains flavin mononucleotide (FMN) and an oxygenase without flavin. The reductase is a homodimer with monomer mass of 35,000, whereas the oxygenase is a homotetramer with monomer mass of 47,000 Da. The two proteins together carry out a catalytic reaction analogous to that of PHBH; curiously, no detectable complex formation exists between the...
reductase and oxygenase proteins (26). The reductase reaction is almost identical to the reductive half-reaction of PHBH. NADH reduces the bound FMN slowly unless p-hydroxyphenylacetate (HPA) is present. However, when HPA is bound, the reductase binds FMN tightly and rapid reduction of the FMN ensues (27). The reduced FMN (FMNH\(^\cdot\)) is bound much less tightly to the reductase than is the oxidized FMN. In contrast, the oxygenase binds FMN\(^\cdot\) tightly and then catalyzes a reaction similar to the oxidative half-reaction of PHBH. Nevertheless, notable differences from PHBH are observed. Without HPA, the oxygenase forms a stable flavin hydroperoxide, then binds HPA to form the product, 3,4-dihydroxyphenylacetate and releases it into solution (28). To complete catalysis, the separate proteins must coordinate their functions. It has been shown that when FMN is reduced by the reductase in the presence of HPA, FMNH\(^\cdot\) dissociates into solution with a rate constant of 80 s\(^{-1}\) at 4 °C (26). FMNH\(^\cdot\) binds FMN\(^\cdot\) very rapidly to the oxygenase and reacts with oxygen with a rate constant of 1.1 × 10^8 M\(^{-1}\) s\(^{-1}\) at 4°C. Because these events are so fast, the reaction of oxygen with free FMNH\(^\cdot\) in transit between the two proteins is negligible, providing that the oxygenase is in excess over the available FMN, which is generally the case (25).

This two-component system is most effective with no external flavin added and with a slight excess of oxygenase active sites over reductase sites. Under these conditions, coupling of reducing equivalents from NADH to hydroxylation is maximal. How does the performance of this system compare with PHBH? Under the same conditions, turnover of PHA is ∼2 s\(^{-1}\) compared with ∼50 s\(^{-1}\) for PHBH. Moreover, HPAH always generates a small amount of H\(_2\)O\(_2\), but PHBH generates almost none. The HPAH from P. aeruginosa consists of a reductase that is a flavin hydratase with monomer molecular weight of 13,000 and is isolated with only some protein that contains FAD. The oxygenase is isolated as a colorless homotramer with monomer mass of 46,000. In this system, in contrast to the A. baumannii HPAH, the reductase does not bind HPA, and it catalyzes reduction of FAD by NADH and release of FAD\(^\cdot\) into solution with no regulation of catalysis by HPA. Thus, for this HPAH to be effective, regulation of the reaction with oxygen must reside with the oxygenase. The reductase that is present reduces any free FAD for immediate uptake by the oxygenase, which, as established in E. coli (25), is present in cells at higher concentrations than the reductase. It has been found that the oxygenase forms a very stable C4a-hydroperoxyflavin, and this species is probably the predominant form of the enzyme in cells (25, 29). When the C4a-hydroperoxyflavin form of oxygenase binds HPA, it rapidly converts the HPA to product and releases it into solution. The release of FAD from the oxygenase follows and is the rate-determining step in catalysis (26). This HPAH has a turnover rate similar to the enzyme from A. baumannii. The structures of the oxygenases from the two types of HPAHs are different in detail (particularly the active sites) but have similar core scaffolds (30). A great deal of research must be performed to understand the unique dynamics of the P. aeruginosa-type oxygenase that probably do not occur in the A. baumannii-type oxygenase.

**Tryptophan-7-halogenase (TH)**

Many thousands of halogenated metabolites in nature become halogenated by reactions catalyzed by flavoproteins. To date, only a couple of enzymes have been studied in any detail. TH has now become the model for these enzymes. TH catalyzes the chlorination of the 7-position of tryptophan for the synthesis of pyrroloindin, which is an antifungal agent from P. fluorescens, and for the synthesis of rebeccamycin, which is an anticancer agent from Saccharopolyspora rebaudiana. TH consists of a flavin reductase and a halogenase. The halogenase is similar to the simple reductase of HPAH from P. aeruginosa, whereas the halogenase has structural similarity to PHBH (31). Thus, in general terms, TH is a two-component system with FAD that difuses between two proteins, but TH has evolutionary links to the one-component hydroxylases.

Recent transient-state kinetic analysis of the reaction of the halogenase component of TH has been very revealing (32). The halogenase binds FAD\(^\cdot\) and reacts with oxygen to form a stabilized C4a-hydroperoxyflavin. With Cl\(^{-}\) present, this intermediate converts to a fluorescent C4a-hydroxyflavin, which finally decomposes to FAD and water. Tryptophan has no influence on the kinetics of the flavin reactions. The implication of these observations is that Cl\(^{-}\) is hydroxylated by the hydroperoxide to form HOCl, which is subsequently used in the chlorination of tryptophan. The details of the regiospecific chlorination remain an outstanding question, although it is known from the crystal structures of TH from both P. fluorescens (PmA) and from S. aerocolonigenes (RebH) that tryptophan is separated from FAD by ∼10 Å, and they are connected by a channel in the active site. Chlorination is a slow reaction (first-order with a rate constant of 0.05 s\(^{-1}\) at 25°C) and inefficient—only ∼3% of starting reduced FAD equivalents result in chlorinated product (32). A static crystal structure is probably inadequate for a complete understanding of the details of the catalytic process. Unlike other hydroxylases, the halogenase undergoes some dynamic changes in the oxygen reactions that are not understood. For example, if the halogenase binds FAD\(^\cdot\), then the subsequent reaction with oxygen fails to form the flavin hydroperoxide, and only FAD and H\(_2\)O\(_2\) are produced. In contrast, if reduced flavin is added to RebH and O\(_2\) is present, this intermediate converts to a fluorescent C4a-hydroxyflavin, which is subsequently used in the chlorination of tryptophan. Recently, it was shown that when RebH, FADH\(^\cdot\), and O\(_2\) react in the absence of tryptophan, a long-lived intermediate (t\(_{1/2}\) = 63 h at 4°C) formed that could halogenate tryptophan (33). This result suggested that the initially formed HOCl reacted with a group on the enzyme to produce an intermediate, such as a chloramine, that was responsible for halogenating tryptophan. Lysine 97, which is required for catalysis, is a likely candidate, and it is in a position that could halogenate tryptophan in the 7-position.

**Bacterial luciferase**

A luciferase is an enzyme that catalyzes chemiluminescence. This property is widespread in marine environments (particularly deep-sea), in which many higher organisms cultivate specific bacteria for the production of light. All known bacterial luciferases are homologous. Although this enzyme has been
Flavin-Mediated Hydroxylation Reactions

studied for decades, its mechanism is still partly a mystery. Like the enzymes just discussed, luciferase is composed of a reductase and an oxygenase. These proteins are usually expressed from a single operon similar to other two-component enzymes (34). The reductase catalyzes an unregulated reduction of FMN by NADH (34). The oxygenase, which is usually referred to as luciferase, is structurally and functionally unique. It catalyzes the hydroxylation of a fatty aldehyde to form a fatty acid in a manner similar to the Bayer-Villiger enzymes discussed in the next section. However, mysteriously, the free energy liberated in the reaction is captured in an excited-state flavin. The usual intermediates in an oxygenase reaction are observed (35, 36)—formation of a flavin-C4a-peroxide, followed by a flavin hydroxide, return to oxidized flavin, and release of flavin from the enzyme. It is the excited-state C4a-hydroxyflavin that is the light emitter. Hypotheses put forward for the capture of an excited-state C4a-hydroxyflavin can be found in Reference 37. Currently, we do not even know how FMN is bound in luciferase. When we have a clear picture of the active site of this enzyme (showing the interactions between protein and FMN in different oxidation states) and the complex dynamics that seem to be part of the process, we may finally understand this chemistry.

Other One-Component Hydroxylases

Although the one-component aromatic hydroxylases (represented by PHBH above) are a major group of flavoproteins, they are not the only one-component flavin-dependent oxygenases. Many flavoproteins oxidize aliphatic compounds that are susceptible to nucleophilic attack by flavin peroxides. Oxygenation of aldehydes and ketones is a common reaction catalyzed. The mechanism is considered to involve a Bayer-Villiger rearrangement. We briefly examine the model enzyme cyclohexanone monooxygenase, which oxygenates the carbonyl of cyclohexanone and forms a lactone (cyclic ester) via a Bayer-Villiger rearrangement. A mother group of flavoproteins is important in the defensive armory of animals against electron-rich foreign compounds, and it is also involved in some metabolic pathways in animals and plants. An appropriate model for this group of enzymes is mammalian flavin monooxygenase. We finish with an example of a recently discovered enzyme BluB that although structurally unrelated to other flavoprotein hydroxylases, it catalyzes the oxygenation and conversion of FMN to dimethylbenzimidazole using flavin C4a-intermediates. Other novel flavoprotein hydroxylases/oxygenases are yet to be discovered.

Cyclohexanone monooxygenase (CHMO)

The CHMO that has been studied most extensively comes from a strain of Acinetobacter calcoaceticus. The monomeric form of the enzyme contains one FAD and has a molecular weight of 62,000. The structure of a homolog of this enzyme (phenylacetone monooxygenase) has been published (38). The structure and kinetic analysis of CHMO show that the overall catalytic cycle is similar to that of PHBH, although there are important differences (39). In contrast to PHBH, the reductive half-reaction is not regulated by substrate. Thus, the formation of cellular reactive oxygen species is prevented by a different mechanism.

After NADPH binds and reduces the FAD, independently of cyclohexanone, the NADP product remains bound to the enzyme, and the resultant reduced enzyme reacts rapidly (10^7 M^-1 s^-1) to form a stable NADP-flavin C4a-peroxide complex. In fact, it is this species that is the predominant form of the enzyme in the cell. The bound NADP has a critical role in stabilizing the flavin peroxide. When cyclohexanone binds to the enzyme, it is converted rapidly to the 7-membered ring, 1-caprolactone, with the ring-oxygen coming from the peroxide, which leaves the flavin in the form of a C4a-hydroxy-FAD. A faster it loses water to form oxidized FAD, the rate-determining step in catalysis is the dissociation of NADP. Kinetic and structural evidence suggests that the mechanism involves a nucleophilic attack of the flavin peroxide on the carbonyl carbon to form a Criegee intermediate that collapses to form product and flavin hydroxide (Fig. 4). These enzymes avoid producing reactive oxygen species because the C4a-peroxy-FAD is very stable until substrate binds and reacts rapidly with it. There is great potential for research into the relationship between the protein structure and function of these enzymes that use C4a-flavin peroxides.

Flavin monooxygenase (FMO)

The first known enzyme of this class was isolated from pig liver and was described as liver microsomal FAD-containing monooxygenase (40). It has several properties similar to CHMO, but it mainly oxidizes a wide range of heteroatom-containing soft nucleophiles, which are generally electron-rich compounds. Mammalian FMOs participate with cytochrome P450s in the oxygenation of hydrophobic xenobiotic compounds, which includes many drugs, making them more water soluble and ready for coupling with glutathione and other compounds so they can be excreted. Extensive rapid and steady-state kinetics studies have been carried out on pig liver FMO (40-42). FMO is first reduced by NADPH, and, like CHMO, the enzyme retains the NADP product. The reduced flavin reacts with O2 to form a stable NADP-C4a-hydroperoxyflavin. Its return to oxidized FAD with release of H2O2 occurs over a period of many minutes, which depends on the conditions. However, if a suitable heteroatom-containing substrate is present, FMO reacts quickly to oxygenate that substrate, which forms hydroxyl amines, sulfenic acids, and so on. The resulting C4a-hydroxyflavin releases water to reform the oxidized FAD in what is often the rate-determining step of catalysis. Therefore, the turnover numbers for most substrates are very similar. In the absence of NADP, the C4a-hydroperoxide is so unstable that it is almost undetectable. Five documented functional genes and some pseudogenes for FMO are observed in the human genome (43). FMOs also exist in plants (44) where they participate in numerous activities, which include the biosynthesis of the plant hormone, auxin.
BluB—A protein that converts FMN into dimethylbenzimidazole

The biosynthesis of vitamin B_{12} has intrigued some of the most famous chemists, and research on this topic has resulted in four Nobel prizes. Yet until recently, the synthesis of dimethylbenzimidazole (DMB), which is the alpha-axial ligand to B_{12}, has remained a mystery, except that it was known to derive from FMN. It has now been demonstrated that the BluB proteins from Sinorhizobium meliloti (45) and Rhodopseudomonas rubrum (46) catalyze the reaction of FMNH_{2} with O_{2} to form DMB and erythrose-4-phosphate. The C1′ from the ribityl moiety of FMN becomes the C2 of DMB, and the dimethyl-diamino benzene portion comes from the isoalloxazine ring of the flavin. This amazing reaction is unprecedented, and clearly, it must involve some unusual chemistry. Recent unpublished studies (D. Ballou and M. Taga) have shown that BluB binds FMNH, and this complex reacts with O_{2} with a rate constant $k_{1}$ of $10^6 M^{-1}s^{-1}$ at $4^\circ C$ to form a C4a-hydroperoxy-FMN. This species oxygenates itself and decays in several steps to form about 50% DMB with the remaining product being FMN. Thus, BluB is a special case of a flavin oxygenase. Future identification of intermediates along the pathway to DMB will surely provide some novel chemistry.

Flavoenzymes, Chemistry of
Flavoenzymes are omnipresent in nature and are involved in many cellular processes. Flavoenzymes typically contain the vitamin B2 derivatives FAD and FMN as a redox-active prosthetic group. By varying the protein environment around the isoalloxazine ring of the flavin, evolution has created a great diversity of flavoprotein active sites and catalytic machineries. Most flavoenzymes perform one- or two-electron redox reactions and belong to the following groups: Flavoprotein reductases primarily use NAD(P)H as electron donor and pass these electrons to a protein substrate or another electron acceptor. Flavoprotein dehydrogenases oxidize organic substrates and mainly use quinones and electron transfer proteins as electron acceptors. Flavoprotein disulfide oxidoreductases contain active-site thiols. They use a dithiol substrate and NAD\(^+\) to form a disulfide product and NADH or act in the other direction yielding NAD(P)\(^+\) and a reduced (dithiol) product. Some flavoprotein (d)thiol oxidoreductases stabilize a reactive and reversibly oxidized cysteine in their active site. Flavoprotein oxidases catalyze the conversion of a substrate single bond to a double bond. The reduced flavin generated during this reaction is reoxidized by molecular oxygen to form hydrogen peroxide. Flavoprotein monoxygenases mainly use NAD(P)H as an electron donor and insert one atom of molecular oxygen into their substrates. By doing so, they act in different biological processes, ranging from lignin degradation and detoxification to the biosynthesis of polyketides and plant hormones.

Flavoenzymes are widespread in nature and are involved in many different chemical reactions. Flavoenzymes contain a flavin mononucleotide (FMN) or more often a flavin adenine dinucleotide (FAD) as redox-active prosthetic group. Both cofactors are synthesized from riboflavin (vitamin B2) by microorganisms and plants. Most flavoenzymes bind the flavin cofactor in a noncovalent mode (1). In about 10% of all flavoenzymes, the isoalloxazine ring of the flavin is covalently linked to the polypeptide chain (2, 3). Covalent binding increases the redox potential of the flavin and its oxidation power, but it may also be beneficial for protein stability, especially in flavin-deficient environments.

Flavoenzymes constitute about 2% of all biological catalysts and are classified in several ways. One classification is based on EC number (enzyme nomenclature) and refers to the type of reaction catalyzed. More sophisticated classifications concern the inclusion of sequence, fold, and function. Historically, a distinction is made between “simple” and “complex” flavoenzymes (4). The latter proteins contain besides flavin other cofactors like heme, tetrahydrobiopterin, and metal ions.

The catalytic cycle of each flavoenzyme consists of two distinct processes, the acceptance of redox equivalents from a substrate and the transfer of these equivalents to an acceptor. Accordingly, the catalyzed reactions consist of two half-reactions: a reductive half-reaction in which the flavin is reduced and an oxidative half-reaction, in which the reduced flavin is reoxidized. This review summarizes the chemistry of “simple” flavoprotein reductases, dehydrogenases, (d)thiol oxidoreductases, oxidases, and monoxygenases (Table 1) (5–40). This grouping provides a good appreciation about what type of common mechanisms can be distinguished and what type of substrates can be converted. Information on the chemistry of “complex” flavoenzymes can be found in the Further Reading section.

Biological Background

The intrinsic chemical properties of the isoalloxazine nucleus, as modulated by the protein environment, are at the heart of the success of flavoenzymes in nature. The chemical versatility,

of the flavin cofactor is used in a wide variety of biological processes that range from energy production, light emission, protein folding, and neural development to detoxification, apoptosis, chromatin remodeling, and DNA repair (41). With the developments in molecular life sciences, it is expected that many more functions of flavoenzymes will develop. The biological background of certain flavoprotein reductases, dehydrogenases, (di)thiol oxidoreductases, oxidases, and monooxygenases is summarized below.

Reducases

Flavoprotein reductases have many important cellular functions. NADH-cytochrome b5 reductase (EC 1.6.2.2) is a crucial housekeeping enzyme that controls the level of iron in the blood. Mitochondrial NADPH-cytochrome P450 reductase (EC 1.6.2.4) is involved in hepatitis drug metabolism by transferring electrons to many cytochrome P450 isoenzymes. Cytosolic NAD(P)H quinone reductase (NQO1; EC 1.6.5.2) protects cells from oxidative stress by catalyzing the reduction of exogenous and endogenous quinones to the corresponding hydroquinones. Recent studies suggest that mammalian quinone reductases also control the lifespan of transcription factors, such as p53, and hence participate in the development of apoptosis and cell transformation (5). Flavin reductases (EC 1.5.1.30) are widespread in microorganisms and use riboflavin, FMN, or FAD as substrate (6). The reduced flavin product is used by other enzymes for various purposes like for instance the emission of light (7). Plant-type ferredoxin NADP⁺ reductase (FNR; EC 1.18.1.2) acts in the reverse sense. Being involved in carbon fixation this enzyme receives electrons one at a time from ferredoxin and then transfers them to a two-electron step to NADP⁺ (8).

Dehydrogenases

Flavoprotein dehydrogenases are also widespread. Many of them occur in mitochondria where they are involved in energy production and the biosynthesis of essential nutrients. Dysfunction of these enzymes may result in oxidative stress and neurobehavioral deficits. Acyl-CoA dehydrogenases (EC 1.3.3.9) play a crucial role in the mitochondrial β-oxidation of fatty acids (10). The reduced forms of these enzymes are reoxidized in two one-electron steps by ETF (electron transferring flavoprotein) (42). Medium-chain acyl-CoA dehydrogenase (MCAD) deficiency is a widely occurring inherited genetic disorder. During fasting or illness, it results in continued glucose consumption and strongly reduced ketone body production. L-galactono-1,4-lactone dehydrogenase (GALDH; EC 1.1.3.38) catalyzes the terminal step of vitamin C biosynthesis in plants (13). The mitochondrial enzyme uses cytochrome c as electron acceptor. GALDH homologues in animals (L-gulono-1,4-lactone...
oxidase), yeast (D-arabinono-1,4-lactone oxidase), and fungi (D-glucosonolactone oxidase) use molecular oxygen as electron acceptor and are involved in the synthesis of L-ascorbate or its analogs D-erythorbate and D-erythroascorbate (3).

Disulfide oxidoreductases
Flavoprotein disulfide oxidoreductases are crucial metabolic and detoxification enzymes. Dihydrolipamide dehydrogenase (EC 1.3.1.4) catalyzes the NAD^+ dependent oxidation of dihydrolipoyl groups, which are covalently attached to the lipoyl domain of the acyltransferase components of the mitochondrial a-ketooacid dehydrogenase and glycine decarboxylase multienzyme complexes. Mutations to this homodimeric flavoprotein cause the often-fatal human disease known as E3 deficiency (14). Glutathione reductase (EC 1.6.4.2) and thioredoxin reductase (TrxR; EC 1.6.4.5) supply cells with high levels of dithiols, which are essential in keeping other thiols reduced (15). In red blood cells, up to 10% of the glucose consumption may be used for the production of reduced glutathione. The TrxR/thioredoxin system is involved in important physiological functions, such as cell growth, inflammation reactions, and apoptosis and regulation.

NADH peroxidase (Npx; EC 1.11.1.7) and NADH oxidase (Nox; EC 1.6.99.x) are flavoprotein oxidoreductases-related enzymes that contain a single redox-active cysine (16). They supply strictly fermentative bacteria with NAD^+ for glycolysis and play an important role in redox signaling in response to oxidative and nitrosative stress (18).

Oxidases
Flavoprotein oxidases are ubiquitous enzymes involved in the biosynthesis and biodegradation of a huge variety of compounds. D-amino acid oxidase (DAAO; EC 1.4.3.3) is the prototype amino acid oxidase. This peroxisomal enzyme is spread from yeast to humans. Mammalian DAAO has been connected to the brain D-serine metabolism and to the regulation of glutamatergic neurotransmission (20). The outer mitochondrial membrane monooxygenase (MAD; EC 1.4.3.4) is perhaps the most well-known amine oxidase. In addition to the oxidation of neurotransmitters, such as dopamine and serotonin, this enzyme also oxidizes ingested amines such as phenethylamine and tyramine to prevent their functioning as false neurotransmitters. The human isoforms MAO-A and MAO-B are involved in many diseases and are important targets for antidepressant and neuroprotective drugs (22). Acyl-CoA oxidases (EC 1.3.3.6) are acyl-CoA dehydrogenase homologs involved in peroxisomal fatty acid breakdown in plants (30).

Monoxygenases
Flavoprotein monoxygenases are widely found in microorganisms and plants, and some are present in mammalian species (43). Aromatic hydroxylases like p-hydroxybenzoate 3-hydroxylation (PHBH; EC 1.14.13.2) are involved in lignin degradation. Bayer-Villiger monoxygenases like cyclohexanone monoxygenase (EC 1.14.13.22) participate in microbial catabolic pathways by converting ketones (or aldehydes) into esters or lactones (35). Flavin-containing monoxygenases (EC 1.14.13.8) oxidize nitrogen-containing compounds and primarily are found in mammals and plants. The mammalian isoforms assist in the detoxification of drugs and other xenobiotics, whereas the plant enzymes are involved in the biosynthesis of auxin, the metabolism of glucosinolates, and in pathogen defense (38). Flavoprotein halogenases play an important role in the biosynthetic pathways of antibiotics, antitumor agents, and other natural products (39).

Chemistry
The isoalloxazine moiety of the flavin cofactor forms the catalytic heart of a flavoenzyme. It can undergo one- and two-electron redox transitions and form covalent adducts with substrates and protein residues. The redox properties of the flavin cofactor are modulated by the protein environment. In free flavin, the one-electron reduced state is thermodynamically unstable. Flavoenzymes, however, can stabilize the neutral or anionic semiquinone state (see also Flavoprotein Protocols article). Oxidized (yellow) flavin has characteristic absorption maxima around 375 and 450 nm (Fig. 1b and 1c). The anionic (red) and neutral (blue) semiquinone show typical absorption maxima around 370 nm and 580 nm, respectively (Fig. 1b and 1c). During two-electron reduction to the (anionic) hydroquinone state, the flavin turns pale, and the absorption at 450 nm almost completely disappears (Fig. 1b and 1c). The optical properties of the flavin can be influenced through the binding of ligands (substrates, coenzymes, inhibitors) or the interaction with certain amino acid residues. In many cases, these interactions result in so-called charge-transfer complexes that give the protein a peculiar color.

The catalytic cycle of each flavoenzyme consists of a reduced half-reaction, in which the flavin is reduced, and an oxidative half-reaction, in which the reduced flavin is oxidized. The reduction and oxidation steps are in many cases irreversible, which enables the direct characterization of reaction intermediates (see “See Also” section and the Further Reading List).

Reductases
Flavoprotein reductases primarily use NAD(P)H (AH2) as electron donor:

\[
\text{EFAD} + \text{AH}_2 \rightarrow \text{EFADH}_2 + \text{A}
\]

and pass these electrons to a protein substrate or another electron acceptor (B) in two single-electron steps:

\[
\text{EFADH}_2 + \text{B} \rightarrow \text{EFADH}^* + \text{BH}^* \\
\text{EFADH}^* + \text{B} \rightarrow \text{EFAD} + \text{BH}^*
\]
Chemistry of Flavoenzymes

Figure 1  (a) Redox states of the flavin cofactor. Flavoenzymes generally stabilize the anionic hydroquinone state ($pK_a$ free reduced flavin = 6.7).
(b) Oxidized (---), anionic semiquinone (···), and hydroquinone (—) forms of the FAD cofactor of Arabidopsis thaliana GALDH (adapted from Reference 13).
(c) Oxidized (---), neutral semiquinone (···), and hydroquinone (—) forms of the FMN cofactor of Bacillus subtilis flavodoxin YkuP (adapted from Reference 44).

or, alternatively, in one two-electron step:

$$\text{EFADH}_2 + B \rightarrow \text{EFAD} + \text{BH}_2$$

Several of the reductases mentioned here belong to the same structural family (the FNR family), and they are mechanistically related to each other (9). A two-electron reduction of the flavin by NAD(P)H in these enzymes typically involves the transient formation of an oxidized flavin-reduced pyridine nucleotide charge-transfer complex, which is followed by hydride transfer. After reduction, the flavin can transfer its electrons to different redox partners. With NADH:cytochrome b5 reductase, this transfer occurs in separate single-electron transfer steps. With NADPH:cytochrome P450 reductase, an enzyme containing which a “complex” flavoenzyme that contains two flavins, one electron is first intramolecularly transferred from FAD to FMN, before the reaction with cytochrome P450 takes place. With FNR, NADP$^+$ first has to bind to the oxidized form, before the very fast one-electron transfer from the specifically interacting reduced ferredoxin (Fdred) occurs (8). Subsequent dissociation of the oxidized ferredoxin (Fdox) is rate-limiting in catalysis. The enzyme semiquinone-NADP$^+$ complex then reacts with another reduced ferredoxin molecule to yield the flavin hydroquinone state. In the final steps of the catalytic cycle, the NADP$^+$ is reduced and the NADPH dissociates.
Disulfide oxidoreductases contain active-site thiols. They use a diol or NAD+ to form a disulfide and NADH or act in the reverse direction yielding NAD(P)+ and a reduced (dihiol) product.

\[
\begin{align*}
\text{EFAD} + \text{NAD}^+ & \rightarrow \text{EFAD-NAD}^+ \\
\text{EFAD-NAD}^+ + \text{F}dred & \rightarrow \text{Fdox-} \text{EFAD}^+ \text{NAD}^+ \\
\text{Fdox-} \text{EFAD}^+ \text{NAD}^+ & \rightarrow \text{EFAD}^+ \text{NAD}^+ + \text{Fdred} \\
\text{EFAD}^+ \text{NAD}^+ + \text{Fdred} & \rightarrow \text{Fdox-} \text{EFAD}^+ \text{NAD}^+ \\
\text{Fdox-} \text{EFAD}^+ \text{NAD}^+ & \rightarrow \text{FDox-} \text{EFAD-NADPH} \\
\text{FDox-} \text{EFAD-NADPH} & \rightarrow \text{FDox} + \text{EFAD} + \text{NADPH}
\end{align*}
\]

Disulfide oxidoreductases are structurally related homodimers with residues from both subunits participating in the catalysis of the two active sites (see the Further Reading for more information). The reductive half-reaction of lipoamide dehydrogenase involves the reduction of the active-site disulfide by the dihydrolipoamide substrate. During this reaction, the enzyme turns red, and a typical absorbance develops around 530 nm because of the formation of a charge-transfer species between the oxidized flavin and the nearby thiolate. The intensity of the charge-transfer absorption band is strongly pH dependent as influenced by the pKₐ modulating properties of a C-terminal histidine, which acts as an acid-base catalyst. Binding of NAD+ then shifts the reducing equivalents from the disulfide to the flavin because of an increase of the redox potential of the FAD.

The catalytic cycle is terminated by flavin reoxidation and dissociation of NADH.

Thioredoxin reductase (TrxR) acts in the reverse direction and shows a somewhat different mechanism, which is dependent on the protein source. Prokaryotes, plants, and lower eukaryotes contain a 35-kDa TrxR with one redox-active disulfide. Higher eukaryotes produce a 55-kDa TrxR that has either an additional redox-active disulfide or a selenenylsulfide in the flexible C-terminal part of the neighboring subunit. In low Mr TrxR, a large conformational change is required to move reducing equivalents from the apolar flavin site to the surface of the protein where the thioredoxin redox partner binds. In high Mr TrxR, this transfer is mediated by the second disulfide or selenenylsulfide, and the conformational changes required are comparatively small (17).

\[
\begin{align*}
\text{EFAD(S-S)} & \rightarrow \text{NADH} + \text{H}^+ \rightarrow \text{EFAD(SH)} + \text{NAD}^+ + \text{H}_2\text{O} \\
\text{EFAD(SH)} + \text{NAD}^+ & \rightarrow \text{EFAD(SH)} + \text{NAD}^+ + \text{H}_2\text{O}
\end{align*}
\]

The thiolate is stabilized by a histidine, which facilitates the nucleophilic attack of the reduced enzyme-NADH complex by hydrogen peroxide:

\[
\begin{align*}
\text{EFAD(SH)} & \rightarrow \text{EFAD(SH)} + \text{NAD}^+ \\
\text{EFAD(SH)} + \text{NAD}^+ + \text{H}_2\text{O} & \rightarrow \text{EFAD(SH)} + \text{NAD}^+ + \text{H}_2\text{O}
\end{align*}
\]

Again, NADH reduces the sulfenate via the flavin, which prepares the enzyme for the next cycle:
Chemistry of Flavoenzymes

(a) Proposed hydride transfer mechanism for substrate oxidation in MCAD. (b) Proposed polar nucleophilic mechanism for the reductive half-reaction in MAO.

In Nox, NADH reduction of the thiolate form involves the stabilization of the four-electron reduced enzyme:

$$\text{EFAD(S}^-\text{)} + \text{NADH} + \text{H}^+ \rightarrow \text{EFADH}_2(\text{S}^-\text{)}-\text{NAD}^+$$

Subsequent reaction with molecular oxygen then yields the active-site sulfenate:

$$\text{EFADH}_2(\text{S}^-\text{)}-\text{NAD}^+ + \text{O}_2 \rightarrow \text{EFAD(SO}^-\text{)}^-\text{NADH} + \text{H}_2\text{O}$$

The Nox oxidizing substrate must be activated prior to its reaction with the active site thiolate. Kinetic studies with the Cys42Ser variant have indicated the formation of a flavin C4a-hydroperoxide as a primary oxygenated intermediate in reoxidation of the reduced enzyme-NAD$^+$ complex (16). In the Cys42Ser variant, hydrogen peroxide is eliminated directly to give the oxidized enzyme. In wild-type Nox, Cys42 is in a favorable position for nucleophilic attack on the distal peroxylflavin oxygen, which yields the sulfenate and the flavin C4a-hydroxide in a monooxygenase type of reaction (vide infra). The flavin C4a-hydroxide eliminates water directly to give the oxidized enzyme.

Oxidases

Flavoprotein oxidases catalyze the conversion of a substrate single bond to a double bond. They differ from flavoprotein dehydrogenases in that the reduced flavin is oxidized by molecular oxygen to form hydrogen peroxide.

$$\text{EFAD} + \text{AH}_2 \rightarrow \text{EFADH}^- + \text{A} + \text{H}^+$$

$$\text{EFADH}^- + \text{O}_2 + \text{H}^+ \rightarrow \text{EFAD} + \text{H}_2\text{O}_2$$

The reaction of singlet-reduced flavin with triplet oxygen is spin forbidden and therefore involves the initial formation of a flavin semiquinone-superoxide anion radical pair (11). This caged radical pair can dissociate into oxygen radicals, or it can undergo a second electron transfer that produces hydrogen peroxide and oxidized flavin. Or, it can collapse to form a flavin-C4a-(hydro)peroxide covalent adduct. This adduct is the essential oxygenation species in flavoprotein monooxygenases (vide infra) but has never been detected in flavoprotein oxidases. The oxygen reactivity of flavoprotein oxidases can vary dramatically, and it is not entirely clear what determines this reactivity (45).

Flavoprotein oxidases come in many flavors. They can have different folds and topologies (46) and are active with many different substrates, which include (amino) acids, mono- and polyamines, nitroalkanes, aliphatic and aromatic alcohols, monosaccharides and oligosaccharides, thios, thioesters, and so on. Flavoprotein oxidases obey either a ping-pong or ternary complex kinetic mechanism. In the latter case, the product (A) remains bound during the oxidative half-reaction. The rate-limiting step in catalytic turnover is often represented by the rate of flavin reduction or the rate of product release. The kinetic mechanism and also the rate-limiting step of catalysis may vary depending on the type of (model) substrate used.
DAAO is one of the most extensively studied flavoprotein oxidases. The homodimeric enzyme catalyzes the strictly stereospecific oxidative deamination of neutral and hydrophobic D-amino acids to give α-keto acids and ammonia (Fig. 3a). In the reductive half-reaction the D-amino acid substrate is converted to the imino acid product via hydride transfer (21). During the oxidative half-reaction, the imino acid is released and hydrolyzed. Mammalian and yeast DAAO share the same catalytic mechanism, but they differ in kinetic mechanism, catalytic efficiency, substrate specificity, and protein stability. The dimeric structures of the mammalian enzymes show a head-to-head mode of monomer–monomer interaction, which is different from the head-to-tail mode of dimerization observed in Rhodotorula gracilis DAAO (20). Benzamide is a potent competitive inhibitor of mammalian DAAO. Binding of this ligand strengthens the apoenzyme-flavin interaction and increases the conformational stability of the porcine enzyme.

MAO-A and MAO-B catalyze the oxidative deamination of aromatic amines to the corresponding aldehydes. Two active-site tyrosyl residues function in both isoforms as an “atomic cage” (23). The kinetic mechanism of MAO is similar to that of DAAO (Fig. 4). The active sites of either MAO-A or MAO-B do not contain basic residues that could possibly function as a proton acceptor in the reductive half-reaction. However, the bent conformation of the isoalloxazine ring of the flavin might provide a clue as to how proton abstraction might occur (23). The strained conformation of the isoalloxazine moiety results in a higher electron density at N5 and lowered electron density at the C4a position of the flavin ring. This conformation facilitates the nucleophilic attack of the basic substrate amine lone pair on the C4a position of the cofactor that results in a flavin-substrate adduct which would be isoelectronic with the reduced flavin ring (Fig. 2b). The N5 of the reduced flavin could constitute the strong base required to abstract the proton from the benzyl carbon of benzylamine substrates, and the “atomic cage” might polarize the amine moiety of the substrate to make it more nucleophilic in accord with the proposed mechanism (23).

Nitroalkane oxidase (NAO; EC 1.7.3.11) from Fusarium oxysporum catalyzes the oxidation of neutral nitroalkanes to the corresponding aldehydes or ketones with the production of nitrile and hydrogen peroxide (24). The enzyme is evolutionarily related to the acyl-CoA dehydrogenases and acyl-CoA oxidases, but it contains an asparagine (Asp402) instead of a glutamate as the catalytic base involved in water attack to the other site of the substrate-binding pocket (26).

Monooxygenases

Flavoprotein monooxygenases mainly use NADPH as electron donor and insert one atom of molecular oxygen into their substrates. Oxygen activation of flavoprotein monooxygenases involves the (transient) stabilization of a flavin C4a-(hydro)peroxide. This species performs either a nucleophilic or electrophilic attack on the substrate (Fig. 5). Oxygenation reactions catalyzed by flavoprotein monooxygenases include hydroxylation, epoxidations, Baeyer-Villiger oxidations, and sulfoxidations (43).

Porcine PHBH is the prototype of the flavoprotein aromatic hydroxylases. Each subunit of this dimeric enzyme contains two active sites which, during catalysis, are alternately visited by the isoalloxazine ring of the FAD cofactor (31). Catalysis is initiated by reduction of the flavin in the exterior active site. The reduced flavin then moves to the interior active site where the reactions with oxygen occur. A similar conformational flexibility of the FAD cofactor has been observed in the crystal structures of phenol hydroxylase (EC 1.14.13.7) and 3-hydroxybenzoate 4-hydroxylase (EC 1.14.13.23). PHBH obeys the following kinetic mechanism:

\[
\begin{align*}
\text{ESFAD} + S &\rightarrow \text{ESFAD}S \\
\text{ESFAD}S + \text{NADPH} &\rightarrow \text{ESFAD}SH + \text{NADP}^+ \\
\text{ESFAD}SH + \text{O}_2 + \text{H}^+ &\rightarrow \text{ESFADHOH} \\
\text{ESFADHOH} + \text{EPFAD} &\rightarrow \text{EPFADHOOH} \\
\text{EPFADHOOH} + \text{EFAD} &\rightarrow \text{EFAD} + \text{P} + \text{H}_2\text{O}
\end{align*}
\]

Binding of 4-hydroxybenzoate (S) in the phenolase form facilitates flavin reduction by NADPH. After NADP+ release, the flavin hydroquinone reacts with molecular oxygen to yield the flavin C4a-hydroperoxide oxygenation species. Protonation of the distal oxygen of the peroxiflavin facilitates the electrophilic attack on the nucleophilic carbon center of the substrate phenolate. After monooxygenase activity, the resulting hydroxyflavin is
decomposed, and the 3,4-dihydroxybenzoate product (P) is released (Fig. 6). Studies from site-directed mutants have provided many insights into the process of substrate hydroxylation (32). In general, flavoprotein aromatic hydroxylases display a narrow substrate specificity and are very regioselective.

Baeyer-Villiger monooxygenases are another class of flavoprotein monooxygenases. These enzymes typically depend on NADPH as an electron donor and catalyze a relatively broad range of asymmetric oxygenation reactions with high enantioslectivity or enantiotoposelectivity (35). The kinetic mechanism of Baeyer-Villiger monooxygenases differs from that of the aromatic hydroxylases:

Here, NADP+ stays bound throughout the entire reaction cycle. Furthermore, Baeyer-Villiger monooxygenases usually promote the deprotonation of the flavin C4a-peroxide (Fig. 6), which thereby facilitates nucleophilic substitution reactions.

**Chemical Tools and Techniques**

Understanding the action mechanism of flavoenzymes heavily relies on the combination of different chemical tools and techniques. First, it is of utmost importance to have a pure and stable (recombinant) protein. Size exclusion chromatography will provide information about the enzyme quaternary structure, and mass spectrometry can establish posttranslational modifications. For a detailed insight into the protein structure, well-diffacting crystals are needed to determine the X-ray structure. The properties of the flavin are exploited for flavoenzyme characterization. Absorbance spectroscopy (under anaerobic, as needed) can be used for binding studies, redox titrations, and rapid-reaction kinetics (Note the relevant articles in the “See Also” section). Other useful techniques include fluorescence spectroscopy (at equilibrium or time-resolved, although in most cases the flavin fluorescence is quenched in the holoenzyme), EPR, and NMR. Several of these techniques have been developed early on (also) thanks to research on flavoproteins. Preparation of the apoflavoprotein (1) and its reconstitution with 13C- and 15N-enriched flavins and subsequent NMR analysis yields information about the n-electron density of the atoms of the isoalloxazine ring in the different redox states (47). Reconstitution with chemically modified ("artificial") flavins can be of help in substrate structure-activity relationship studies (23) and provide information about the solvent accessibility of the active site (48).
Site-directed mutagenesis can be used to establish the function of individual amino acid residues. This method also allows to introduce chemical probes (e.g., fluorophores) that may give insight into the dynamic features and folding properties of a flavoenzyme and its interaction with other protein partners (33, 34). In this context, it is important to stress that catalytically relevant conformational changes of flavoenzymes have been demonstrated that actually exploit the flavin itself as an excellent intrinsic spectroscopic probe (18, 31).

Bioinformatic tools are of increasing importance for the characterization of flavoenzymes. This finding holds for protein sequence and protein structural analysis as well as for gaining insight into the reactivity of the flavin cofactor by combined quantum mechanical and molecular mechanical (QM/MM) simulations (13).

Practical Applications and Future Research Directions

The available knowledge about the structural and mechanistic properties of flavoenzymes is extremely valuable for the discovery and characterization of new flavoenzymes and for the development of practical applications. Several flavoenzyme-inspired applications already exist but many more can be foreseen. Glucose oxidase (EC 1.1.3.4) (27) and cholesterol oxidase (EC 1.1.3.6) (28) are widely applied in diagnostics. Many flavoprotein oxidases and monoxygenases serve as biocatalysts for the production of fine chemicals and pharmaceuticals (41). DAAO is used for the enzymatic synthesis of the cephalosporin precursor 7-aminocephalosporanic acid and in gene therapy for tumor treatment (20). Other flavoenzymes, like e.g., MAO (22) and TrxR (15) serve as drug targets.

Flavoenzymes may be ideal model systems for the development of new tools to be made available for the study of enzymes in general. One example may be the use of cholesterol oxidase for single molecule enzymology, which exploits the flavin fluorescence changes during the catalytic cycle (29). Sophisticated computational tools will facilitate the prediction of novel flavoenzyme functions from sequence, provide a better insight into enzyme and ligand dynamics, and improve methods for flavin-dependent biocatalyst design (41). Another challenge is to use the tools of chemical biology to study the functional properties of flavoenzymes in their natural environment, the living cell. In this article, only a selected group of "simple" flavoenzymes has been discussed. However, one should remember the "complex" flavoenzymes, and the flavin-dependent photoreceptors, and the emerging group of flavoenzymes that do not catalyze redox reactions (see Further Reading List).

Membrane proteins constitute a significant fraction of the proteins that are encoded in the typical genome, and they are critical to many cellular processes, which include transport, cell signaling, and energy transduction. This importance is underscored by the fact that membrane proteins represent the major class of protein targets for pharmaceuticals that are currently in use. However, despite their importance, there are relatively few high-resolution models for membrane proteins, and little is known about their molecular function. The lack of information on membrane proteins in part reflects the difficulties in efficient expression of this class of proteins and difficulties with structural approaches, such as high-resolution nuclear magnetic resonance (NMR), that are not well suited to membrane proteins.

In the field of structural biology, membrane proteins represent a significant challenge, and in recent years new structural and biochemical tools have been developed to characterize these systems. In this review, we discuss the functions and properties of membrane proteins, and we discuss the approaches and tools that yield new information on their structure and molecular function.

Membranes define the boundaries and compartments that make up the cellular matrix, and they are responsible for defining the chemical environment within the cell. Membranes also provide an interface that facilitates protein–protein interactions and other biochemical reactions necessary for cell signaling and trafficking. It is estimated that protein domains that reversibly associate with membrane interfaces represent the most abundant domains found in water-soluble proteins (1). Although the number of proteins that interact with or function at the membrane interface is large, this review will focus on membrane proteins that are sometimes termed integral membrane proteins. Integral membrane proteins are generally defined as proteins that cannot be isolated and purified without first dissolving the bilayer structure, typically with detergents. When compared with water-soluble proteins, membrane proteins have unique properties and present unique challenges in terms of their expression, isolation, and structural characterization. Inducing membrane protein expression in high yield can be more challenging than that of water-soluble proteins. Because the forces that dominate the fold of a membrane protein differ from those that stabilize water-soluble protein folds, purified membrane proteins must be studied in heterogeneous environments, such as membrane mimetic detergent micelles or reconstituted lipid bilayers. It is estimated that approximately 30% of the genome codes for membrane proteins (2), although the exact percentage is unknown. However, when compared with the total number of entries in the protein databank, membrane proteins represent less than 1% of the total number. Although X-ray crystallography remains the single most important method for generating structures of membrane proteins, several new spectroscopic methods are being employed to study membrane protein structure and dynamics.
Membrane Proteins, Properties of Biological Functions and Distribution of Membrane Proteins

Classification of membrane proteins: nomenclature and architecture

Membrane proteins carry out a wide range of critical functions in cells, and they include passive and active transporters, ion channels, many classes of receptors, cellular toxins, proteins involved in membrane trafficking, and the enzymes that facilitate electron transport and oxidative phosphorylation. For example, the voltage-gated ion channels that facilitate the passive diffusion of sodium and potassium across the axonal membrane are responsible for the formation of an action potential. Active transport proteins establish ion gradients and are necessary for the uptake of nutrients into cells. Soluble hormones bind to membrane receptors, which then regulate the internal biochemistry of the cell.

At the present time, representative structures exist for approximately 21 unique β-barrel membrane protein families and 35 polytopic α-helical protein families. This sample is a small fraction of the predicted 300–500 α-helical folds and 700–1700 families (3). Although the structural biology of membrane proteins is in its infancy, it is clear that membrane proteins display a rich variety of structures that vary greatly in size and topology (Fig. 1). Of the structures observed thus far, all are based on two fundamental architectures: the α-helical bundle (4) and the β-barrel (5, 6).

The membrane β-barrel fold is unique to the outer membrane of mitochondria, chloroplasts, and Gram-negative bacteria, and they are found to be composed of an even number of β-strands that vary in number between 8 and 22. The inter-strand hydrogen-bonding pattern within the barrel allows structures to form, which do not have unsatisfied hydrogen bonds within the membrane interior. Frequently, these strands are configured so that amino acid side chains with an aliphatic composition reside on the barrel exterior facing the membrane hydrocarbon, and as observed in membrane proteins based on helical bundles, β-barrel proteins display more aromatic side chains at regions near the membrane bilayer interface. Membrane proteins based on transmembrane α-helices (Fig. 1) are typically localized to the plasma membrane, organelle membranes, and inner membrane of mitochondria and bacteria. Thus, these proteins not only differ in secondary structure, but also they differ in localization. Helical membrane proteins can be formed from 1 to 19 transmembrane segments. When they possess a single transmembrane pass, they are sometimes referred to as either monotopic or bitopic. When these proteins have two or more transmembrane helices, they are referred to as polytopic. The transmembrane helices of a polytopic membrane protein associate into a bundle, and to maintain unsatisfied hydrogen bonds to a minimum, these helices are usually regular. Although helical membrane proteins may be quite flexible and dynamic, elements of helical structure within the bilayer are thought to be rigid.

Membrane protein folding and membrane insertion

Integral membrane proteins must be stable and function in a unique and highly anisotropic environment. The aqueous facing...
domains of a membrane protein experience a very different environment than do the membrane facing regions of the protein, which must be stable in a low-dielectric region devoid of water (7). Because of the absence of a bulk aqueous phase, significant numbers of unsatisfied hydrogen bonds are highly unfavorable, and the folds of β-barrel or helical membrane proteins, as indicated above, must always be arranged to satisfy backbone hydrogen bonding.

In water-soluble proteins, the hydrophobic effect is believed to be a major force that drives the folding of proteins, dominating over van der Waals forces (8, 9). However, in membrane proteins, the hydrophobic effect is relatively unimportant in comparison to side-chain hydrogen bonding and van der Waals forces. Van der Waals forces in a helical bundle would be maximized by complementarity of the interacting surfaces on transmembrane helices; as expected, sequence motifs, such as GxGxG, have been identified that maximize the packing of membrane helices (10–12). Interhelix hydrogen bonding is also important in driving the association of helices, and it may be an important determinant of helix association during membrane protein synthesis (13). Although both interactions play important roles, a mutational study on one helical bundle suggests that van der Waals forces make the largest contribution to the stability of the bundle (14).

The arrangement of the transmembrane segments of a membrane protein and the orientation of the protein C and N termini are determined by two main features of a membrane protein sequence: the stretch of hydrophobic residues that ultimately span the bilayer, and the position of positively charged segments (15, 16). The hydrophobic residues (Ala, Ile, Leu, Val) have the highest frequency in helical regions that lie in the center of the bilayer, whereas the two aromatic residues Tyr and Trp are most abundant near the bilayer interface (17). The balance of charge on either side of a transmembrane segment determines the orientation of the segment, so that the more positively charged portions of a membrane protein sequence are found on the cytoplasmic side of the bilayer. This structure is sometimes referred to as the “positive-inside rule” (18). By altering hydrophobicity and charge, differing topologies can be generated, and it is even possible to find homologous proteins that have naturally evolved different topologies by modifying these features (19). Biosynthetically, the insertion of the growing polypeptide chain into the bilayer is mediated by a translocon, which is a helical membrane protein that is believed to have a lateral gate that opens to the bilayer interior. In the rough endoplasmic reticulum, this protein is Sec61. It is generally thought that the growing polypeptide chain may sample the surrounding bilayer throughout this stage, so that a thermodynamic equilibrium is established with the surrounding lipid (16, 19).

The lipid bilayer is not passive in determining membrane protein activity and function, and an accumulating body of evidence indicates that there is a coupling of membrane proteins to lipid bilayer properties. These properties include the effect of bilayer curvature strain (20), the role of specific lipids such as phosphoinositides, (21) and the effect of thickness on membrane protein function (22). The lipid composition, as well as the bilayer properties that result from this composition, act as allosteric regulators of membrane protein function.

**Molecular function of membrane proteins**

Structural methods and other genetic and biochemical studies have provided clues to the molecular function of membrane proteins. For example, in the case of the bacterial K^+ channel KcsA, the protein is designed to lower the energy for a potassium ion as it passes through the center of the channel. This function is facilitated both by a central cavity that is hydrophobic and by a helix that is positioned toward the channel pore so that its negatively charged end points toward this cavity (23). In the case of visual rhodopsin, a salt bridge that exists between Lys296 and Glu133 functions to maintain the protein in an inactive state. Disruption of this ionic interaction is responsible for the movement of helix 6, which activates the G-protein transducin (24), and mutations that disrupt this ionic interaction are responsible for the retinal diseases retinitis pigmentosa and congenital night blindness (25). Among outer membrane bacterial transporters, TonB-dependent transporters function to move rare nutrients, such as iron chelates, into the cell. They contain a large N-terminal domain of approximately 150 residues that is sometimes referred to as a “hatch.” The available high-resolution structures suggest that substantial rearrangements or an unfolding of this hatch domain takes place to allow the passage of substrates (26).

**Expression, Isolation and Purification of Membrane Proteins**

Difficulties in obtaining protein samples

In general, membrane proteins present challenges at every step on the way to structural determination. The synthesis and processing of these proteins is complex and often involves specific folding factors or chaperones (see References 27 and 28 for reviews). Expression in bacteria is favored because of the low cost to grow large culture volumes by fermentation, the potential for high yields (up to 100 mg protein per liter of culture), the very fast growth rate, and the simplicity and flexibility of expression systems. However, intrinsic differences in how proteins are processed often prevent the expression of adequate amounts of protein with the proper fold, and it may not be possible to isolate and purify sufficient quantities of a membrane protein to a homogenous state. As a result, understanding the processing pathways for the specific protein of interest can be the important factor to achieve successful expression.

The biosynthetic membrane insertion of eukaryotic membrane proteins almost always takes place cotranslationally, whereas many prokaryotic proteins can be posttranslationally inserted, typically with the aid of chaperones. In eukaryotic cells, the proofreading mechanisms in the endoplasmic reticulum prevent misfolded proteins from leaving to the Golgi. Some of these mechanisms include glycosylation of the protein on
its luminal domain (29). In addition, other protective mechanisms such as the yeast unfolded protein response may lead to increased degradation rates of improperly folded proteins (30).

Some proteins require specific types of processing. For example, β-barrel proteins in the outer membrane of Gram-negative bacteria must pass through the cytoplasmic membrane in a linear fashion before being assembled in the outer membrane (for a review, see Reference 31). Processing of β-barrel proteins in the outer membranes of mitochondria and chloroplasts may also involve passage of the protein through the organelle’s outer membrane before insertion, but this process is not well understood (32). Several chaperones have been identified that help the assembly of mitochondrial and chloroplast membrane proteins. Some of these proteins are encoded in the nucleus and are imported to the proper compartment posttranslationally, whereas a few are encoded on the organelle’s own chromosome and processed from within. For these reasons, structural approaches for such proteins always rely on isolation from the native organelle.

Bacterial expression systems are often not an option for eukaryotic membrane proteins. Even if the protein is found embedded in the bacterial membrane, obtaining correctly folded protein is always a concern. Frequently, most or all expressed protein is found in an intracellular aggregate or inclusion body, and only a few examples have been refolded to their native state (33). In many cases, the apparent toxicity of the expressed membrane protein blocks expression as well as growth. Several reasons can explain protein toxicity (see Reference 34 for a review). For example, Miroux and Walker (35) suggest that the overproduction of a single mRNA in a typically used T7 polymerase-driven transcription system resulted in the uncoupling of transcription and translation. A strain, such as C43(DE3) (Lucigen, Middleton, WI) selected to avoid the effects of toxicity, demonstrated better yields of proteins despite a slower rate of synthesis. The requirement of a slower rate of synthesis suggests that cellular machinery, which is not overexpressed, may be required for proper folding. On the other hand, mixed results are observed in providing the cell with extra cytosolic proteins. Interestingly, one of the more productive strategies is to use seleno-methionine or selenium-free media instead of selenium-containing media. Although this scenario is more likely, it is certainly not true in all cases. As mentioned above, other factors may be necessary for proper folding. Furthermore, a protein that is part of a complex may not express in a stable or properly folded manner in the absence of its partners or assembly factors.

Although the optimization of growth conditions for eukaryotic cells is limited, the growth conditions for bacterial systems can be varied widely, and they have a large influence on the expression of the protein target. Many “tricks” investigators use are anecdotal and may be specific to their protein of interest. Several publications detail the approaches and often many different conditions must be tested (see References 33 and 38 for extensive reviews). We will not attempt a thorough listing of such methods, but a few are worth noting. First, medium strength promoters are used to slow down synthesis rate. As mentioned above, the cell may respond to an overwhelming synthesis of a specific protein by activating degradation systems. Second, a lower culture temperature is used, as low as 15 °C, with expression induced for many hours to days. Third, using a defined minimal medium may also result in accumulation of considerable amounts of protein, as the cells grow much more slowly. Development of expression protocols in defined medium is always advantageous for structural approaches because the investigator hopefully will need to generate selenium-methionine derivatives for NMR. We will not attempt a thorough listing of such methods, but a few are worth noting. First, medium strength promoters are used to slow down synthesis rate. Membrane Proteins, Properties of

Furthermore, the homogeneity of the protein can be evaluated by gel filtration. Light scattering, or sedimentation velocity (39–41). Figure 2

To characterize the protein preparation, the critical parameters are purity, which is estimated by SDS-PAGE, the fold and evaluated by secondary structure content via circular dichroism spectroscopy, as well as the oligomeric state determined by gel filtration, light scattering, or sedimentation velocity (39–41). Furthermore, the homogeneity of the protein can be evaluated by mass spectrometry. Detergents will normally interfere with mass spectrometry, but MALDI TOF approaches have been developed to avoid such problems (42). As discussed in the next section, a range of detergents must be explored for protein structural determination, and as a result, the characteristics of the protein in different detergents must be determined (see Fig. 2).

Structure Determination

Figure 2: A flow chart that outlines the general strategies in preparing membrane proteins for structural studies.

If possible, the function of the protein should be assessed. Unfortunately, detergent solubilization can often make it difficult to assay protein activity, as in the case of an ion channel; however, other parameters may be assessed in such instances. Ligand binding affinity, enzymatic activity, or association with another protein may provide a convincing assessment of protein function. Other biochemical techniques will also indicate folding and homogeneity, such as limited protease digestion, reactivity with reagents such as sulfhydryl reactive compounds, or chemical cross-linking patterns. Spectroscopic approaches have also been used. The dynamics of specific regions on the protein can be evaluated by nitroxide spin labeling and electron paramagnetic spectroscopy. If the protein can be metabolically labeled with 7H-15N, then a relatively quick heteronuclear single quantum coherence NMR experiment can provide critical information on the homogeneity and fold of the protein (39).

Structural Characterization of Membrane Proteins

X-ray crystallography

High-resolution membrane protein structures are determined predominantly using X-ray crystallography. Although notoriously difficult to crystallize, several methods have been applied successfully to crystallize membrane proteins either by manipulating the detergent/lipid components or by altering the protein component. Most membrane protein structures have been determined using detergent solubilized protein in which the entire protein detergent complex is crystallized. Often, the best-quality crystals of a membrane protein may be obtained only in one or a few detergents, and extensive screening based on detergent properties is required (42).

Thirty-three detergents have been used to crystallize membrane proteins, and three of those detergents have been used to determine three NMR structures (43). Some detergents are fold-specific. For example, C8E4 is predominantly used for β-barrel proteins; whereas DDM has been mostly successful for α-helical membrane proteins. The four detergents that have been used to crystallize most membrane proteins are octyl-glucoside, lauryl dimethyl amine oxide, C8E4, and dodecyl maltoside. These four detergents vary in aliphatic chain length and shape and size of the head group; however, they are all neutral. This commonality is very significant. For three-dimensional protein crystals to form, protein molecules need to contact each other to form crystal contacts that are essential to propagate the lattice. It is likely that charged or even zwitterionic repulsive forces would hinder the association of the protein detergent complexes, which is a process that must occur at early stages of crystal nucleation.

Membrane protein crystals have significantly more solvent (64%) content than soluble proteins [47% (44)] presumably because of the detergent in the crystal. The organization of the detergent in the membrane protein crystal has been investigated in a select few cases and is different in each case. In the LH2 crystal, the detergent forms a belt around the hydrophobic surface of the protein consistent with the dimension of the OG...
detergent molecule (45). Similar to LH2, the OG detergents form a belt around the hydrophobic surface of phospholipase A in the crystal; however, the belts fuse to form a continuous three-dimensional network throughout the crystal (46). The continuous density of detergent was also observed in crystals of porin and two photoreaction centers. Snijder et al. (44) suggest the possibility that organic amphiphile additives in the crystal screen could facilitate this fusion; however, no experimental data correlate the detergent structure observed in the crystal and the physical properties of the detergent/amphiphile mixed micelle. In addition to the detergent used for solubilizing the membrane protein, the native (or synthetic) lipid concentration may have profound effects on diffraction quality as in the micelle. In addition to the detergent used for solubilizing the channel KcsA (65). NMR structure determination of sequential chemical shift assignment achieved for two polytopic strides with the first step to NMR structure determination, the remains a challenge. Several research groups are making great advances, Oberai et al. (3) estimate that if no acceleration of membrane protein structure determination occurs, then it will take more than three decades to determine at least one structural representative of 90% of the α-helical membrane protein sequence families (3).

Solution nuclear magnetic resonance spectroscopy

Although solution NMR techniques do not require crystallization, a molecular weight limit does exist (32 kD is the largest to date (59)), and optimization of detergent conditions has proven to be difficult (60). Several NMR structures of β-barrel outer membrane proteins have been determined (59, 61–63); however, a solution structure of a polytopic α-helical membrane protein remains a challenge. Several research groups are making great strides with the first step to NMR structure determination, the sequential chemical shift assignment achieved for two polytopic membrane proteins (44) and the potassium channel KcsA (65). NMR structure determination of β-barrel proteins has been more successful than α-helical membrane proteins primarily because the nuclear Overhauser effects (NOEs) between amide protons are across strands (i.e., between secondary elements), rather than within the secondary element as in α-helices, which provides valuable structural constraints. The lack of NOE data is currently being overcome with measurements from paramagnetic relaxation (66) and residual dipolar coupling experiments (67).

In addition to the limited distance restraints, the preparation of membrane protein samples has proven to be a major challenge to high-resolution NMR. Similar to X-ray crystallography, the selection of detergent strongly influences the quality of NMR spectra. No single detergent is well suited for NMR studies of membrane proteins; solubility, dynamics, the hydrophilic surface area of the protein, and other physical properties differ for each protein detergent complex, and the proper combination still needs to be determined empirically through extensive screening (39, 68).

Beyond structure determination, solution NMR can be used to investigate backbone dynamics and protein–ligand interactions. Bax and colleagues (65, 69) have characterized backbone dynamics (69) and ion binding affinity of the tetrameric KcsA potassium channel (65). These studies added additional structural insights to the crystal structure. On the ps–ns time scale, the selectivity filter is not dynamic. In SDS micelles, the intra–cellular C-terminal α-helix is dynamic on the ns–ps timescale and does not associate into a tetrameric bundle. In addition to determining the PagP NMR solution structure (62), Hwang et al. (70) characterized a two state dynamic rearrangement in which the more flexible state facilitates the entry of the substrate into the central cavity of the β-barrel.

Site-directed spin labeling

Site-directed spin labeling (SDSL) is used to investigate membrane protein structure and dynamics in lipid bilayers as well as in detergents. In SDSL, a nitroxide probe is introduced to a unique site within a protein. In most cases, a cysteine residue is introduced and subsequently reacted with a sulfhydryl-reactive nitroxide reagent. The resulting nitroxide side chain is sensitive as in detergents. In SDSL, a nitroxide probe is introduced to a unique site within a protein. In most cases, a cysteine residue is introduced and subsequently reacted with a sulfhydryl-reactive nitroxide reagent. The resulting nitroxide side chain is sensitive to the molecular environment, which allows the determination of secondary and tertiary structure (71), conformational dynamics (72), and site-specific dynamics (73). Unlike solution NMR, the technique does not have a molecular weight limit, and membrane proteins can be investigated in detergent solutions or lipid bilayers.

From the electron paramagnetic resonance (EPR) spectrum of the nitroxide side chain, four primary parameters are obtained: 1) solvent accessibility, 2) mobility of the R1 side chain, 3) a polarity index for its immediate environment, and 4) the distance between R1 and another paramagnetic center in the protein. Solvent accessibility of the side chain is determined from the collision frequency of the nitroxide with paramagnetic reagents in solution. The mobility, polarity, and distances are deduced from the EPR spectral line shape. For regular secondary structures, accessibility, mobility, and polarity are periodic functions of sequence position. The period and phase of the function reveal the type of secondary structure and its orientation within the protein, respectively (71, 74). In the case of membrane proteins, the topography of the secondary structure with respect to the membrane surface can also be described (75, 76).

When a pair of spin labels is incorporated into a protein or a protein complex, the dipolar interactions between labels
Membrane Proteins, Properties of

can be used to measure the distance and distance distribution between labels (77). If the labels are separated by 7 to 20 Å, then the dipolar interactions are sufficiently strong that they can be observed and quantified by continuous wave (CW) EPR spectroscopy (78–81). If the labels are separated by a distance greater than 20 Å, then the resulting weak dipolar interactions can be measured with newer pulse methods such as double electron-electron resonance (DEER) or double quantum coherence (82–84). These methods have been used to measure internitroxide distances and distance distributions out to 60 Å or more. An advantage of the CW EPR measurements is that they can be performed at room temperature (78), whereas the pulse measurements, such as DEER, require that the samples be frozen, typically at liquid nitrogen temperatures or lower.

Changes in any of the SDSL parameters measured can be used to detect changes in protein conformations, and most importantly, the data can be interpreted in terms of helix rigid body motions, relative domain movement, and changes in secondary structure. Recently, SDSL distance measurements were used to map ligand-induced conformational changes in BtuB (85), LacY (86), and the NhaA antiporter (87). Figure 3 shows an example of the use of SDSL and DEER to determine structural changes that accompany ligand binding to the extracellular loops in the outer membrane transporter, BtuB (88).

Solid-state nuclear magnetic spectroscopy

Solid-state NMR also can be applied to membrane proteins in lipid bilayers, and recent advancements in magic angle spinning solid-state NMR show promise for structure determination. Although the structures of small crystalline proteins (89) and membrane bound peptides (90) have been determined, the structure of a polytopic membrane protein has yet to be reported. The major necessity that is required to push the technique forward is the de novo sequential chemical shift assignment of the amino acid residues, and in the last few years, several groups have reported successful strategies (91, 92). Beyond structure determination, solid-state NMR has been used to investigate the structures of membrane bound ligands. Several recent examples are a low-resolution structure of neuretinin bound to its G protein coupled receptor (93), scorpion toxin bound to a chimeric potassium channel (94), rhodopsin and the metarhodopsin II intermediate (95), and acetylcholine bound to its receptor (96). These studies have great potential for designing and optimizing drugs-targeting membrane proteins (97).

Concluding Remarks

Several biophysical tools can provide information on the structure, dynamics, and conformational changes of membrane proteins. Many of these methods are beyond the scope of this review and were not mentioned here. However, each of these approaches has strengths and weaknesses; to investigate membrane protein structure and functional dynamics fully, a multitude of techniques is required. Static high-resolution structures are highly informative and provide a good starting point to generate hypotheses; however, they do not provide a complete understanding of protein molecular function.

Membrane Proteins, Properties of Protein Targeting and Transport
NAD(P)-Dependent Dehydrogenases

Robert S. Phillips, University of Georgia, Athens, Georgia

doi: 10.1002/9780470048672.wecb363

NAD(P)H is the major carrier of reducing equivalents in cells. NAD(P)-dependent dehydrogenases and reductases catalyze the reversible transfer of hydrogen equivalents between substrates and NAD(P). These enzymes include alcohol dehydrogenases, 2-hydroxyacid dehydrogenases, aldehyde dehydrogenases, amino acid dehydrogenases, secondary amine dehydrogenases, disulfide oxidoreductases, transhydrogenases, azoreductases, sulfite and nitrite reductases, and phosphite dehydrogenase. NAD(P)-dependent dehydrogenases are structurally diverse, but many contain a Rossmann fold for NAD(P) binding. Usually, alcohol dehydrogenases contain an essential metal ion cofactor that serves as a Lewis acid for substrate activation. However, most dehydrogenases use general acid/base catalysis to activate substrates for reaction. NAD(P)-dependent dehydrogenases have been used in biocatalysis for stereoselective reductions of ketones and imines to give chiral alcohols and amines, respectively. Several important drug targets (e.g., dihydrofolate reductase) are NAD(P)-dependent dehydrogenases.

Properties of NAD(P)

Two different chemical forms of NAD(P) exist, NAD+ and NADP+ (Fig. 1), which differ by the presence of a phosphate ester at C-2' of the adenosine. NAD+ is the abbreviation for nicotinamide adenine dinucleotide, and NADP+ stands for nicotinamide adenine dinucleotide 2'-phosphate. The reduced forms of NAD+ and NADP+ are called NADH and NADPH, respectively (Fig. 1). In this review, NAD and NADP are used to designate either oxidized or reduced forms of the cofactor, whereas NAD+ and NADP+ are used to represent the specific oxidized and reduced forms. NAD is often considered to be used preferentially for oxidative catabolic processes that produce energy, whereas NADP is considered a source of reducing equivalents for biosynthesis. Dehydrogenases typically show a high selectivity for either NAD or NADP. The two molecules are thus in separate pools for cellular processes. The two pools are also separated for the most part in eukaryotes, with NAD in the mitochondria and NADP in the cytoplasm. Of course, exceptions to this generalization exist, and hydrogen equivalents can be transferred between NADH and NADPH by transhydrogenases.

Chemical properties of NAD(P)

NAD(P)H is the main carrier of molecular hydrogen equivalents in biologic systems. The redox potential of NAD(P)H is –340 mV; thus, the transfer of hydrogen from NAD(P)H to substrates is generally thermodynamically favorable and is often the physiologic reaction. In principle, hydrogen transfer from NAD(P)H could occur either by a hydride or by a radical mechanism, but the preponderance of mechanistic data collected to date with dehydrogenases indicates that hydride transfer is the preferred pathway. The two hydrogens at C-4 of the dihydro- nicotinamide ring of NADH and NADPH are diastereotopic and thus stereochemically inequivalent (Fig. 1). Elegant work by Fisher et al. (1) in the 1950s demonstrated that the pro-(R) hydrogen from C-1 of ethanol is transferred to the re-face of the nicotinamide ring of NADH and NADPH are diastereotopic and thus stereochemically inequivalent (Fig. 1). Elegant work by Fisher et al. (1) in the 1950s demonstrated that the pro-(R) hydrogen from C-1 of ethanol is transferred to the re-face of the nicotinamide ring of NAD(P)H.
NAD(P) Dependent Dehydrogenases

Figure 1: Structures of NAD⁺ (top) and NADH (bottom).

C-4 of the nicotinamide ring of NAD⁺ by yeast alcohol dehydrogenase, where it becomes HR of NADH (1), although the transfer was thought incorrectly at the time to take place at C-6 rather than C-4 of the nicotinamide. The correct structure for NADH, called DPNH (for Diphospho Pyridine Nucleotide) at the time, was determined by Pullman et al. in 1954 (2). A particular enzyme will be stereospecific for one or the other of these diastereotopic hydrogens, either HHR or HHS, on the dihydronicotinamide. In older literature, the re-face of the nicotinamide ring is called the "A-face" and the si-face is called the "B-face" of the nicotinamide ring.

Biologic properties of NAD(P)

NAD(P) is synthesized de novo from L-tryptophan in animals (3) and in some bacteria (4) by the kynurenine pathway through quinolinate (pyridine-2,3-dicarboxylate). In plants and in most bacteria, NAD(P) is biosynthesized from quinolinate by a different pathway, which starts from L-aspartate. Quinolinate is then converted to nicotinate mononucleotide by an unusual reaction with phosphoribosylpyrophosphate catalyzed by quinolinate phosphoribosyl transferase, with concomitant decarboxylation of the C-2 carboxylate. Amidation of the nicotinate and reaction with ATP to form the AMP dinucleotide completes the biosynthesis of NAD⁺. Subsequent phosphorylation at the 2'-OH of the adenosyl gives NADP⁺. Nicotinic acid (niacin) can also be converted to NADP⁺ by a salvage pathway in both procaryotes and eucaryotes. In addition to its use as a redox cofactor for dehydrogenases, NADP⁺ is a substrate for other biologically important reactions such as ADP-ribosylations and deacetylation of histones (5).

Reactions Catalyzed by NAD(P)-Dependent Dehydrogenases

NAD(P)-dependent dehydrogenases catalyze the oxidation/reduction of a wide range of organic substrates, which include alcohols, amines, alkanes, and thiols, as well as some inorganic substrates, such as nitrite, hydrogen, and phosphite (Table 1).

Alcohol dehydrogenases

Alddehyde dehydrogenases catalyze the oxidation of aldehydes to carboxylic acids (Eq. 2). Under physiologic conditions, this

NAD(P) Dependent Dehydrogenases

reaction is irreversible because of the subsequent ionization of the carboxylic acid.

\[
R \text{H} + \text{NAD(P)H} + \text{H}_2\text{O} \rightarrow R \text{O}^{-} + \text{NAD(P)H} + 2\text{H}^+ \quad (2)
\]

CH dehydrogenases and reductases

CH dehydrogenases form carbon–carbon double bonds by dehydrogenation (Eq. 3). Generally, these enzymes act on CH bonds activated by adjacent carbonyl or similar groups.

\[
R \text{H}_2 \text{O} \rightarrow R \text{O}^{-} + \text{NAD(P)H} + \text{H}^+ \quad \text{R}
\]

Primary amine dehydrogenases

These enzymes oxidize primary amines to form imines (Eq. 4). The most common substrates are alpha-amino acids.

\[
R \text{H} + \text{NAD(P)H} + \text{H}_2\text{O} \rightarrow R \text{O}^{-} + \text{NAD(P)H} + \text{H}^+ \quad \text{R}
\]

Secondary amine dehydrogenases and reductases

These enzymes oxidize secondary amines to imines (Eq. 5).

\[
R \text{H}_2 \text{O} \rightarrow R \text{O}^{-} + \text{NAD(P)H} + \text{H}_2\text{O} \quad \text{R}
\]

NAD(P)H dehydrogenases

These enzymes transfer H(2) from NAD(P)H to NADP+ (Eq. 6).

\[
\text{NAD(P)H} + \text{NAD(P)H}^{-} \rightarrow \text{NADP}^+ + \text{NAD(P)H} \quad (6)
\]

Other N-dehydrogenases and reductases

Most enzymes remove an oxygen from a nitrogen (Eq. 7), either sp(2), as in nitrate reductase, or sp(3), as in hydroxylamine reductase, or reduce an N-N double bond. Because the physiologic direction is reduction, most enzymes are called reductases.

\[
R \text{O}^{-} + \text{H}_2\text{O} + \text{NAD(P)H} \rightarrow R \text{O}^{-} + \text{NAD(P)H} + \text{H}^+ \quad \text{R}
\]

S-dehydrogenases and reductases

These enzymes catalyze the reversible oxidation of sulfur containing compounds. Most enzymes catalyze the interconversion of thiols and disulfides (Eq. 8), but a few enzymes can form or remove sulfur-oxygen or sulfur-carbon bonds.

\[
2R\text{SH} + \text{NAD(P)H} \rightarrow 2R\text{S}^{-} + \text{NAD(P)H} + \text{H}^+ \quad (8)
\]

Other miscellaneous dehydrogenases and reductases

NAD(P)-dependent dehydrogenases act on other types of substrates, such as H(2) (Eq. 9), diphenols, or phosphite.

\[
\text{H}_2 + \text{NAD(P)H} \rightarrow \text{NAD(P)H} + \text{H}^+ \quad (9)
\]

NAD(P)-dependent enzymes without net redox

Some NAD(P)-dependent enzymes require NAD(P) as a co-factor but they do not result in net oxidation or reduction in the product. In some cases, a reversible dehydrogenase reaction exists to form a catalytic intermediate (e.g., S-adenosyl homocysteine hydrolase or UDP-galactose epimerase). In catalase, the reduction occurs of tightly bound NADP+ by NADPH in solution without ligand exchange (6). The NADPH seems to be present to protect catalase against oxidation during turnover.
Structural Features of NAD(P)-Dependent Dehydrogenases

NAD(P)-dependent dehydrogenases exhibit a wide range of structures (Table 2). However, many have a common structural motif, called the Rossmann fold (7). This structure consists of a six-stranded parallel beta-sheet flanked by two alpha helices on each side of the sheet with the nucleotide bound at the COOH terminal end of the beta-sheet. A typical dehydrogenase structure that shows a Rossmann fold is presented in Fig. 2. The dehydrogenases can be grouped according to the presence of the Rossmann fold (Table 2). Most dehydrogenases are specific for either NAD or NAD(P), but not both, as coenzyme. The structural determinants for coenzyme specificity have been examined in many of these systems by site-directed mutagenesis. It has generally been found that an acidic residue exists, either aspartate or glutamate, in NAD-specific enzymes, and a basic residue exists, either lysine or arginine, in NADP-specific enzymes. These structures provide electrostatic interactions either to reduce NADP binding (aspartate, glutamate) or to increase NADP binding (lysine, arginine) (8, 9). In addition, NADP-specific enzymes have hydrogen bond donors like serine or tyrosine that can donate hydrogen bonds to the 2'-phosphate.

Alcohol dehydrogenases

Alcohol dehydrogenases are found in three major superfamilies that have no sequence or structural homology. The short chain dehydrogenases/reductases (SDRs) are the largest superfamily of alcohol dehydrogenases, with over 1600 members known to date (10). The SDRs have about 250 residues and are metal-ion independent. The medium chain dehydrogenases/reductases (MDRs) have about 350 residues and require a metal ion for activity, usually zinc (11). The MDRs form dimers or tetramers, and they contain one or two zinc ions per subunit. One zinc ion is always in the active site, whereas the other ion, if present, is held in a "structural site," remote from the active site. The active site zinc is coordinated by one or more cysteine thiolates, a histidine imidazole, carboxylates from glutamate or aspartate, and a water. Usually, the structural sites coordinate zinc with four cysteine thiolates. The MDRs include the canonical mammalian liver alcohol dehydrogenases. The structure of one subunit of a tetrameric alcohol dehydrogenase from a thermophilic bacterium, Thermoaerobium brockii, is shown in Fig. 2. The NADP⁺ can be seen as the ball and stick model between the Rossmann fold and the catalytic domain, which has the catalytic zinc shown as the large sphere. The third family of alcohol dehydrogenases is the smallest and is composed of ferrous iron-dependent dehydrogenases.

The 2-hydroxyacid dehydrogenases are found in two different superfamilies, which are stereospecific for their substrates. The D-2-hydroxyacid dehydrogenase superfamily (12) is larger and more diverse in reactions catalyzed than the smaller L-malate/lactate dehydrogenase superfamily. Neither of these 2-hydroxyacid dehydrogenases requires metal ions for activity.

Another group of alcohol dehydrogenases is the oxidative dehydrogenases, which include malic enzyme and isocitrate dehydrogenase. Malic enzyme, which catalyzes the reversible oxidation of L-malate to pyruvate and CO₂, is a tetrameric structure.

NAD(P) Dependent Dehydrogenases

Figure 2. Structure of one subunit of *Thermoanaerobium brockii* secondary alcohol dehydrogenase (RCSB PDB entry 1YKF). The Rossmann fold can be seen as the seven-stranded beta sheet capped with three alpha helices underneath the NADP⁺, shown as a ball and stick model. The catalytic zinc is the large sphere behind the NADP⁺.

Primary amine dehydrogenases

These enzymes are members of the Rossmann fold clan, but are distributed in several superfamilies within the clan. The glutamate/asparagine/asparaginase dehydrogenases form a family (12) that is related structurally and functionally, but alanine dehydrogenase is in a separate family. Another enzyme, diamino propionate dehydrogenase, is a member of the semialdehyde dehydrogenase family.

Secondary amine dehydrogenases

The secondary amine dehydrogenases are a small group of enzymes, most of which are involved in folate metabolism, such as dihydrofolate reductase, which has its own superfamily outside the Rossmann fold clan. Typically, the dihydrofolate reductases are monomers or dimers. The other members of the group, saccharopine dehydrogenase and 3-pyrroline-5-carboxylate reductase, have their own superfamilies within the Rossmann clan. 1-Pyrroline-5-carboxylate reductase has a dimeric catalytic unit but forms multimers as large as decamers.

NAD(P)H transhydrogenases

The transhydrogenases are members of the Rossmann fold clan and show similarity in the NAD(P) binding domain with alanine dehydrogenase. These enzymes are membrane bound and transfer reducing equivalents and protons across the membrane. Three subunits exist, an NADH binding subunit, an NADPH binding subunit, and a proton translocating subunit.

Other N-dehydrogenases and reductases

Another diverse group of enzymes includes the N-dehydrogenases and reductases. The reductases are dimeric flavoproteins that contain a Rossmann fold which transfer reducing equivalents from NAD(P)H. IMP dehydrogenase is a tetrameric enzyme in the GTP biosynthetic pathway that is a member of the triose phosphate isomerase (TIM) clan. Nitrate reductase contains a molybdenum cofactor. Nitrite reductase is a complex structure related to sulfitreductase (see below).

S-dehydrogenases and reductases

Several disulfide oxidoreductases form a separate superfamily within the Rossmann fold clan (16), which includes dihydrolipoamide dehydrogenase, glutathione reductase, mercuric reductase, and thioredoxin reductase. Dihydrolipoamide dehydrogenases are components of large enzyme complexes involved in oxidation of ketoacids, such as pyruvate and 2-oxoglutarate dehydrogenase. They contain FAD and NAD⁺ binding domains and transfer the reducing equivalents formed in the oxidative decarboxylation to NAD⁺. The disulfide reductases are in the same superfamily, and contain FAD, but they reduce disulfides with the consumption of NADPH. Mercapturic reductase, also in this family, is an NADPH-dependent flavoprotein that catalyzes the reduction of tertiary methyl mercapturates to sulfides.

CH dehydrogenases

These enzymes do not fall into a single superfamily, but they have members distributed throughout the other superfamilies of dehydrogenases. Some enzymes contain a catalytic flavin that mediates the transfer of hydrogen between substrate and NAD⁺.

Aldehyde dehydrogenases

Aldehyde dehydrogenases are found in a large superfamily distributed in many bacteria and archa as well as eucaryotes (14). Because of the distinctive mode of NAD(P) binding, the aldehyde dehydrogenases are not included in the Rossmann fold clan. These enzymes include highly substrate-specific members such as glyceraldehyde-3-phosphate dehydrogenase and non-specific aldehyde dehydrogenases for detoxification of toxic aldehydes. They may form either dimers or tetramers.

Primary amine dehydrogenases

These enzymes are members of the Rossmann fold clan, but are distributed in several superfamilies within the clan. The glutamate/asparagine/asparaginase dehydrogenases form a family (12) that is related structurally and functionally, but alanine dehydrogenase is in a separate family. Another enzyme, diamino propionate dehydrogenase, is a member of the semialdehyde dehydrogenase family.

Secondary amine dehydrogenases

The secondary amine dehydrogenases are a small group of enzymes, most of which are involved in folate metabolism, such as dihydrofolate reductase, which has its own superfamily outside the Rossmann fold clan. Typically, the dihydrofolate reductases are monomers or dimers. The other members of the group, saccharopine dehydrogenase and 3-pyrroline-5-carboxylate reductase, have their own superfamilies within the Rossmann clan. 1-Pyrroline-5-carboxylate reductase has a dimeric catalytic unit but forms multimers as large as decamers.

NAD(P)H transhydrogenases

The transhydrogenases are members of the Rossmann fold clan and show similarity in the NAD(P) binding domain with alanine dehydrogenase. These enzymes are membrane bound and transfer reducing equivalents and protons across the membrane. Three subunits exist, an NADH binding subunit, an NADPH binding subunit, and a proton translocating subunit.

Other N-dehydrogenases and reductases

Another diverse group of enzymes includes the N-dehydrogenases and reductases. The reductases are dimeric flavoproteins that contain a Rossmann fold which transfer reducing equivalents from NAD(P)H. IMP dehydrogenase is a tetrameric enzyme in the GTP biosynthetic pathway that is a member of the triose phosphate isomerase (TIM) clan. Nitrate reductase contains a molybdenum cofactor. Nitrite reductase is a complex structure related to sulfitreductase (see below).

S-dehydrogenases and reductases

Several disulfide oxidoreductases form a separate superfamily within the Rossmann fold clan (16), which includes dihydrolipoamide dehydrogenase, glutathione reductase, mercuric reductase, and thioredoxin reductase. Dihydrolipoamide dehydrogenases are components of large enzyme complexes involved in oxidation of ketoacids, such as pyruvate and 2-oxoglutarate dehydrogenase. They contain FAD and NAD⁺ binding domains and transfer the reducing equivalents formed in the oxidative decarboxylation to NAD⁺. The disulfide reductases are in the same superfamily, and contain FAD, but they reduce disulfides with the consumption of NADPH. Mercapturic reductase, also in this family, is an NADPH-dependent flavoprotein that catalyzes
the reduction of Hg₂⁺ to Hg₂⁺. Thioredoxin reductase also contains a catalytically essential selenocysteine residue. The sulfite reductases have a complex architecture, with an α4β4 quaternary structure in which the alpha subunit contains both FAD and FMN and the beta subunit contains an Fe₄S₄ cluster connected to a siroheme. An elemental sulfur reductase also exists from Pyrococcus furiosus, which is a dimeric flavoprotein that uses NADPH to reduce 50% to 72%.5

Other dehydrogenases
The NADH dehydrogenases are components of complex membrane-bound respiratory systems sometimes called Complex 1, found in mitochondria and chloroplasts. The NADH is used by an NADH-ubiquinone reductase subunit, which in turn transfers electrons from the reduced ubiquinone to the electron transport system. A similar enzyme is found associated with a NiFe hydrogenase in bacteria.

Chemical Mechanisms of NAD(P)-Dependent Dehydrogenases
As we have seen in the structural section, dehydrogenases may contain catalytic metal ions, most frequently zinc, but also iron, magnesium, or manganese. These metal ions may play a role as Lewis acids to facilitate the redox chemistry, or they may mediate electron transfer between coenzyme and substrate. Dehydrogenases without catalytic metal ions use general acid/base catalysis and/or other organic cofactors like FAD to facilitate the redox reactions.

Mechanisms of metal ion dependent dehydrogenases
The best-studied metal ion dependent dehydrogenase is horse liver alcohol dehydrogenase (H.LADH). Horse liver has a relatively high content of alcohol dehydrogenase, so it was a convenient source of alcohol dehydrogenase before recombinant technology became available. Two isozymes of horse liver ADH exist, the E-form that reacts rapidly with ethanol and the S-form that reacts faster with steroids. The reaction mechanism of horse liver ADH and related alcohol dehydrogenases is shown in Fig. 3 (17). The substrate oxygen becomes coordinated to the catalytic zinc, either by displacing the water or expansion of the coordination environment of the zinc. The polariza-tion of the substrate oxygen by the zinc-Lewis acid assists in alcohol deprotonation. The conserved serine-48/histidine-51 pair, together with the Zn²⁺ of the ribose of NAD, is believed to play a role in shuttling protons into and out of the active site. Mutation of serine-48 to alanine results in loss of activity, whereas mutation of histidine-51 to glutamine results in an 11-fold decrease in activity (18). Formation of the zinc alkoxide activates it for the hydride transfer to NAD⁺. Structural studies have shown that the dihydronicotinamide ring is puckered in some complexes (19). This finding may increase the reactivity of the nicotinamide for hydride transfer. The hydride transfer in the mechanism of H.LADH and related alcohol dehydrogenases has been studied in detail. Evidence exists to suggest that the hydride transfer proceeds with a significant amount of quantum mechanical tunneling in these enzymes (20).

In the case of the oxidative decarboxylase, malic enzyme, coordination of the substrate to the catalytic divalent metal ion M⁰₂⁺ helps to reduce the alcohol pKₐ so that the catalytic lysine-183 can form the alkoxide to initiate hydride transfer. The divalent metal ion then polarizes the carbonyl of the beta-ketoacid intermediate to facilitate decarboxylation (13).

Mechanisms of dehydrogenases without catalytic metal ions
The 2-hydroxy acid dehydrogenases such as lactate dehydrogenase generally carry a catalytic metal. The lactate dehydrogenase has an essential histidine residue that abstracts the proton from the alcohol concomitant with hydride transfer (21). The carboxylate of the substrate forms an ion pair with an essential active site arginine. The mechanisms of D-lactate dehydrogenase and malate dehydrogenase are very similar.

A dehyde dehydrogenases contain an essential active site cysteine thiol, which forms a hemithioacetal by nucleophilic attack on the aldehyde carbonyl of the substrate. The electron rich hemithioacetal is then activated for hydride transfer from the alkoxide to NAD⁺, giving a covalent thioester acyl intermediate, which undergoes hydrolysis, or phosphorolysis in the case of G3PDH, to provide the carboxylic acid product (22).

Amino acid dehydrogenases, such as glutamate dehydrogenase from bovine liver, use general acid/base catalysis to transfer hydride from an alpha-amino acid to NAD⁺. Glutamate dehydrogenase is one of the few dehydrogenases that use NAD⁺ and NADP⁺ equally. The formation of the free amino group by deprotonation of the ammonium of the amino acid zwitterion activates the substrate and has been shown to occur prior to hydride transfer (23).

Dihydrofolate reductase (DHFR) is the best studied of the dehydrogenases/reductases that act on secondary amines. The rate constants for each individual step in the mechanism have been determined by stopped-flow and rapid-quench kinetic analysis. Dynamics are important in the mechanism of hydride transfer in DHFR, as residues 25 A away from the active site can have a large influence on catalysis (24). As a result of both experimental and computational studies, the hydride transfer in DHFR has been proposed to involve long-range coupled motions driving hydrophobic tunneling.

In the reactions of enzymes with small inorganic substrates, such as sulfite or nitrite reductase, the reducing equivalents are not transferred directly from the NAD(P)H to the substrate. These structurally complex enzymes contain additional redox cofactors like flavins or iron-sulfur clusters, which are reduced by the NAD(P)H and interact with the substrate directly. Since NAD(P)H prefers to transfer a hydride ion with a pair of electrons, rather than stepwise single electron transfer, the flavin is necessary to split the hydride into single electrons. Some enzymes use an NADP⁺ as a cofactor to catalyze reactions without an overall redox change. In the case of
S-adenosylhomocysteine hydrolase, the bound NAD$^+$ converts the 3'-OH of the adenosine to a keto group, which increases the acidity of the CH bond at C-4', allowing for facile beta-elimination of the homocysteine (25). The 3'-ketoadenosine is reduced subsequently to adenosine by the bound NADH before release of product.

NAD(P)-Dependent Dehydrogenases—Applications in Biocatalysis

The ability of dehydrogenases to catalyze stereoselective transformations of carbonyl and related compounds has made them the object of considerable interest as biocatalysts. The major problem in the biocatalytic application of dehydrogenases is the regeneration of the NAD(P)H cofactor. It can be done in two ways. One way is to use a cheap sacrificial substrate to recycle the cofactor using the same enzyme. The other way is to add a second enzyme that uses a different substrate, for example, formate dehydrogenase for NADH, and glucose-6-phosphate dehydrogenase for NADPH. Mutant forms of phosphite dehydrogenase have been developed recently that can be used for recycling of both NADH and NADPH (8).

Alcohol dehydrogenases

The asymmetric reduction of ketones by horse liver ADH to produce optically active secondary alcohols was studied by Prelog (26), and a general rule was formulated, now commonly called “Prelog’s Rule” (Fig. 4). This rule states that reduction will usually occur by hydride transfer to the re-face of the carbonyl, resulting in the (S)-alcohol. Because of the commercial availability of horse liver ADH, the substrate activity and stereoselectivity for a wide range of ketones have been examined (27). However, several problems exist with the use of horse liver ADH in ketone reduction, including low activity with acyclic ketones, low stability, and sensitivity to organic solvents. Later work identified alcohol dehydrogenases with high activity for secondary alcohols and ketones in thermophilic bacteria, particularly *Thermoanaerobium brockii* and *Thermoanaerobacter ethanolicus*. These enzymes have high activity for ketone reduction, high stability, and are active in the presence of high concentrations of organic solvents. The secondary ADH from *Thermoanaerobacter ethanolicus* has been shown to be particularly effective in the asymmetric reduction of ketones.
T. ethanolicus exhibits low enantiospecificity for small alcohols like 2-butanol and 2-pentanol. A strong temperature dependence of the enantiomeric ratio, $E = R/S$, exists, with the preferred configuration for 2-butanol inverting from (S) to (R) as the temperature increases, with a racemic temperature at about 300 K (28). These results show that a large entropic contribution to the stereospecificity occurs, possibly because of differences in active site solvation for the enantiomeric substrates. Wild-type secondary ADH has no significant activity toward aromatic alcohols and ketones, but a mutant form, W110A, has high activity and stereoselectivity for reduction of 4-phenyl-2-butanone and 1-phenyl-2-propanone (29). The ketone substrates of interest are often sparingly soluble in water, which limits the scale of the reaction severity. However, recent studies that use biphasic systems and sol-gel immobilized alcohol dehydrogenases in organic media have shown high activity for ketone reduction, with comparable or increased stereoselectivity (30).

**Hydroxyacid dehydrogenases**

Hydroxyacid dehydrogenases are attractive catalysts for synthesis of 2-hydroxyacids because families are stereospecific for either D- or L-2-hydroxyacids. Despite this, few applications of these enzymes have occurred in synthesis. A microbial 2-hydroxyacid dehydrogenase has been used to prepare (S)-2-hydroxy-4-phenylbutanoic acid and (S)-phenyllactic acid in enantiomerically pure form (31).

**Amino acid dehydrogenases**

Amino acid dehydrogenases have been exploited to synthesize amino acids and analogs by reductive amination of α-ketocarboxylic acids. Glutamate dehydrogenase has been used extensively because of its commercial availability. Several glutamate analogs, such as 3-hydroxy and 4-methylglutamate, have been prepared with glutamate dehydrogenase. In addition, 6-OH-L-norleucine, which is an intermediate in the synthesis of the antihypertensive drug Omapatrilat, was prepared using glutamate dehydrogenase (32). Phenylalanine dehydrogenase has been exploited similarly in the synthesis of ring-substituted L-phenylalanine analogs. Some mutant phenylalanine dehydrogenases were found to be more tolerant of ring substituents than the wild-type enzyme. Leucine dehydrogenase has been used in oxidative resolution of DL-tert-leucine to provide enantiomerically pure D-tert-leucine (33).

**NAD(P)-Dependent Dehydrogenases as Drug Targets**

**Dihydropolate reductase**

Dihydropolate reductase (DHFR) has been the target for anticancer, antibacterial, and antiparasitic drugs because of its role in folate metabolism and in DNA biosynthesis (34). Methotrexate, a potent inhibitor of DHFR, has been used for many years to treat various cancers including leukemia, breast and lung cancers, as well as to treat arthritis and psoriasis. Trimethoprim is a DHFR inhibitor used for treatment of urinary infections, and it is sometimes used with sulfamethoxazole, a sulfonamide. Pyrimethamine with a sulfonamide is also given as an antimalarial. It is also interesting that a covalent adduct of NAD with isoniazid, which is the standard antituberculosis drug, is a potent inhibitor of DHFR in Mycobacterium tuberculosis. However, the main target of isoniazid in M. tuberculosis is the enoyl-acyl carrier protein reductase, which is strongly inhibited by the (4S)-adduct of isoniazid with NAD, whereas DHFR is inhibited by the (4R)-diastereomer (35).

**Inosine monophosphate dehydrogenase**

Inosine monophosphate dehydrogenase (IMPDH), which is an essential enzyme in the purine biosynthetic pathway, has been investigated as a potential target for anticancer drugs and immunosuppressants. A series of NAD mimetic drugs has been examined as inhibitors of IMPDH. Although it might be thought that NAD analogs would be rather non-selective for dehydrogenases in general, it was found that cofactor analogs with high affinity and specificity for IMPDH can be prepared by replacement of the nicotinamide ring with a heterocyclic ring that contains a carboxamide group. Tiazofurin is an analog that contains a thiazole ring, and it has been evaluated for antitumor activity (36). Unfortunately, high toxicity in clinical trials prevented tiazofurin from additional development. Non-nucleoside inhibitors of IMPDH include mycophenolic acid, which is a fungal natural product and is used as an immunosuppressant.

**17β-hydroxysteroid dehydrogenase**

Inhibitors of 17β-hydroxysteroid dehydrogenase (17β-HSD) have been of interest as potential anticancer agents because of the critical role of this enzyme in androgen and estrogen formation (37). Many common cancers, such as breast and prostate, exhibit a steroid dependency. 17β-HSD exists in several isoforms, which have different substrate specificity and tissue distribution. Isoform-specific inhibitors have been developed.
Aldose reductase/sorbitol dehydrogenase

The complications of diabetes include neuropathy, retinopathy, and nephropathy. These complications are caused by accumulation of sorbitol in cells from the reduction of glucose by aldose reductase, which produces osmotic stress on the cell and results in cell death. Thus, inhibitors of aldose reductase have been examined as potential therapeutic agents for diabetes (38). Aldose reductase and a similar enzyme, sorbinol dehydrogenase, which converts sorbitol to fructose, are also increased as a result of ischemia from myocardial infarction; thus, inhibitors of these enzymes may help in the treatment of heart attacks.

doi: 10.1002/9780470048672.wecb658

How to synthesize biologically active polypeptides chemically has long been an important challenge for many fields in chemistry and biology. In the past, the development of solution-phase and solid-phase synthesis techniques has made it possible to synthesize large molecules like peptides with molecular weights up to 10,000. The purpose of this review is to provide an overview of how to prepare natural bioactive peptides synthetically. Because of space limitations, this review concentrates on peptide hormones and neurotransmitters.

Abbreviations: Standard abbreviations as recommended by IUPAC-1:UB Commission are used in this review (1). Other abbreviations include: Acm, acetamidomethyl; Bn, benzyl; Boc, t-butyloxycarbonyl; Bom, benzyloxymethyl; BHA, benzhydrylamine; Cbz, benzyloxycarbonyl; cHx, cyclohexyl; DCC, N,N-dicyclohexylcarbodiimide; DCM, dichloromethane; DIC, N,N-disopropylcarbodiimide; DMF, N,N-dimethylformamide; DMSO, dimethyl sulfoxide; For, formyl; Fmoc, 9-fluorenylmethyloxycarbonyl; HMP, 4-hydroxymethylphenoxyacetyl; HOAt, 1-hydroxy-7-azabenzotriazole; HOBt, 1-hydroxybenzotriazole-benzotriazole; MBHA, 4-methylbenzhydrylamine; Mtr, 4-methoxy-2,3,6-trimethylphenylsulphonyl; Np, nitrophenyl; NSu, N-succinimide; ONsu, N-hydroxysuccinimide; Trt, triphenylmethyl; Pam, 4-(hydroxymethyl) phenylacetamidomethyl; PAL, 5-[4-(9-fluorenylmethyloxycarbonyl)aminomethyl-3,5-dimethoxyphenoxoy]valeric acid; Pcp, pentachlorophenyl; Pmc, 2,2,5,7,8-pentamethyl-chroman-6-sulphonyl; Tcp, trichlorophenyl; TFA, trifluoroacetic acid; TFAA, trifluoroacetic anhydride; Tos, p-toluenesulfonyl.

Peptide hormones and neurotransmitters are among the most important classes of natural products in living systems, including in humans. They modulate and regulate most major biological functions and behaviors that are necessary for the maintenance of life and health, including feeding behavior, reproduction, response to stress, pain, cardiovascular function, kidney function, energy homeostasis, aggression, maternal behavior, learning behavior, and many others. In addition, these hormones often are intimately involved in virtually all major diseases, including hypertension and other cardiovascular dysfunctions, diabetes, obesity, cancer, CFS diseases, and many others. The recognition that polypeptides played such a central role in health and disease is a relatively recent scientific development. The discovery of insulin as the principal modulator (along with glucagon—a later discovery) of glucose levels in the blood and the determination of the structure and total synthesis of the peptide hormone and neurotransmitter oxytocin, which controls uterine contractions, milk ejection, and later maternal behavior; socialization; and aspects of sexual behavior are milestones not only in peptide and protein chemistry, biology, and medicine, but also in modern drug discovery and design. Especially in the case of oxytocin immediately after its structure determination and total
synthesis by du Vigneaud and co-workers in the early 1950s, he and many others began to modify the "functional groups" and structure of oxytocin to determine those features important to biological activity. Of central importance in this regard was the development of increasingly efficient synthetic methods (if you cannot make it you cannot study it) and analytical methods for the preparation and purification of polypeptides. In this review, we will outline synthetic methods that have been developed for the synthesis of polypeptide hormones and neurotransmitters, and in the process we also point out the key analytical procedures that have been used in the synthesis and purification of these important biological natural products. See Table 1 for an overview of this article and its contents.

Peptide Hormones

Cardiac hormones

Atrial natriuretic peptide (ANP)

ANP is a 28-amino-acid peptide first discovered by de Bold et al. (2). It is released from heart atrial myocytes in response to a local arterial wall stretch. ANP acts on outer adrenal cells to decrease aldosterone production and blood pressure, increase salt and water excretion, and transudate plasma water to the interstitial (3).

The sequence of ANP is as follows: Ser-Leu-Arg-Arg-Ser-Arg-Ser-Leu-Arg-Arg-Ser-Val-Ser-Leu-Gly-Gly-OH.

The structure of ANP shows a disulfide ring at position 7 to 23, which is shared by the other two natriuretic peptides (brain natriuretic peptide and C-type natriuretic peptide). ANP has been prepared synthetically via solid-phase peptide synthesis using the N'-Boc strategy, von Geldern et al. (4) used a Biosearch Model 9500 automated synthesizer (Biosearch Technologies, Novato, CA) to assemble the amino acid sequence on a Merrifield resin preloaded with N'-Boc-Tyr. A standard protocol for solid-phase synthesis (DCM/CH2Cl2) with only a 5% yield from the fully protected peptide. The coupling of protected peptides with L-amino acid activated amino acid residues (WSCI-HOBT method) (6). The coupling of protected peptides with L-amino acid residues at the C-terminus was carried out using WSCI together with 2,4-dihydro-3-hydroxy-4-oxo-1,2,3-benzotriazaine (HOOBT), which is known to minimize racemization of activated amino acid residues (WSCI-HOBT method) (6). The side-chain protections were as follows: Asp was protected by a cHx group; Arg and His by Tos groups; Lys by a Cl-Cbz group; Tyr by a Boc group; Ser by a Pha group; Trp by a For group. The fully protected peptide thus obtained was deprotected by HF in the presence of arsine and MeEt. The Pha and For groups were not removed under these conditions. The Tyr residue was then sulfonated with 40 equivalents of sodium phenylsulfinate in TFA in an ice bath for 2 hours. After precipitation by adding water, the product was treated with 40 equivalents of sodium carbonate and 10% NaOH in DMSO in an ice bath for 10 minutes to remove the remaining Pha and For groups. The crude product was purified by CM-cellulose chromatography and then by reversed-phase HPLC to produce a homogeneous preparation of the final product with only a 5% yield from the fully protected peptide. The scheme for the synthesis is shown in Fig. 1.

Penke’s group has reported two successful solid-phase syntheses of this peptide. The first study was using the N’-Boc chemistry published in 1987, with an overall yield of 1%. In 1991, they announced another synthesis using the N’-Fmoc strategy, and the protected Tyr(SO3H)-OH was introduced into the peptide sequence during the chain assembly (8). A new solid support system, 4-succinylamido-2,2′,4′-trimethoxy-4-acetamido-benzophenone (SAMBA)-polystyrene resin, was also made for the synthesis to accommodate the acid-labile sulfate ester.

The anchor SAMBA was prepared through a five-step synthesis (Fig. 2). First, 2,4-dimethoxy-acetanilide benzenoic acid (0.03 mol) at room temperature for 25 minutes, followed by adding ice and ethylacetate and 10% sodium carbonate solution to neutralize the substance. The organic phase was washed three times with sodium carbonate solution and once with H2O and dried over sodium sulfate. After removing the solvents in vacuo, the oily residue was crystallized by triturating with ether, obtaining 2,4-dimethoxy-acetanilide benzene. The product was then dissolved in a mixture of 4N NaOH (30 mL) and methanol (30 mL) and refluxed for 1 hour. The mixture was then treated with 40 equivalents of ethyl acetate and 10% sodium carbonate solution at 0°C for 20 minutes. After washing with methanol (10 mL) and 2,4-dimethoxybenzene (0.035 mol), the solution was concentrated in vacuo, and 2,4-dimethoxybenzylidenecarbonylamine (SAMBA)-polystyrene resin, was also made for the synthesis to accommodate the acid-labile sulfate ester.

The anchor SAMBA was prepared through a five-step synthesis (Fig. 2). First, 2,4-dimethoxy-acetanilide benzenoic acid (0.03 mol) was dissolved in an ice bath for 2 hours. After precipitation by adding water, the product was treated with 40 equivalents of sodium carbonate and 10% NaOH in DMSO in an ice bath for 10 minutes to remove the remaining Pha and For groups. The crude product was purified by CM-cellulose chromatography and then by reversed-phase HPLC to produce a homogeneous preparation of the final product with only a 5% yield from the fully protected peptide. The scheme for the synthesis is shown in Fig. 1.

The first study was using the N’-Boc chemistry published in 1987, with an overall yield of 1%. In 1991, they announced another synthesis using the N’-Fmoc strategy, and the protected Tyr(SO3H)-OH was introduced into the peptide sequence during the chain assembly (8). A new solid support system, 4-succinylamido-2,2′,4′-trimethoxy-4-acetamido-benzophenone (SAMBA)-polystyrene resin, was also made for the synthesis to accommodate the acid-labile sulfate ester.

Naturally Occurring Peptide Hormones and Neurotransmitters, Synthesis of

Figure 1  Scheme for the synthesis of porcine CCK-33. Peptide coupling was done by the WSCI-HOBT method unless otherwise indicated. (a) Catalytic hydrogenolysis. (b) TFA. (c) Zn-acetic acid. (d) phenoxacyclic anhydride. (e) WSCI-HOBt. (f) WSCI-HOBUt. OPac = phenacyl. Taken from Kurano et al. (6).

dissolved in a mixture of pyridine (7.5 mL) and ethanol (50 mL), and it was refluxed for 45 minutes with hydroxyamine hydrochloride (0.067 mol). The solvent was then removed in vacuo, and the oily residue was triturated with 5% aqueous KHSO₄ solution. The resulting solid was filtered, washed with H₂O, and dried, obtaining 2,2',4,4'-trimethoxy-4-succinylamido-benzophenone oxime. The oxime (5 mmol) was suspended in glacial acetic acid (200 mL) and dissolved by warming. Then, 1 mL concentrated HCl and 0.2 g freshly prepared Pd-Catalyst were added, and the oxime was hydrogenated under pressure (1 M Pascal) for 5 hours. After filtering the catalyst and removing the solvents in vacuo, the oily residue was triturated with ether; the final product SAMBHA hydrochloride was crystallized as white solid. Four-mmol SAMBHA hydrochloride was then reacted overnight with Fmoc-OSu (4.4 mmol) in a mixture of H₂O (5 mL) and dioxane (15 mL) in the presence of sodium bicarbonate (670 mg) to get Fmoc-SAMBHA, which was used to couple with aminomethyl polystyrene suspended in DCM in the presence of DCC. The Nα-Fmoc group was cleaved by 10 minutes of treatment with 20% piperidine in DMF, and the SAMBHA resin was obtained with 0.33 mmol/g loading.

Nα-Fmoc-Tyr(SO₃Na)OH was prepared by reacting tyrosine with chlorosulfonic acid in TFA at −20°C for 5 minutes. Then Nα-Fmoc group was added by reacting with Fmoc-Cl in a mixture of 10% sodium carbonate solution and dioxane. The peptide was assembled using an Applied Biosystems 430A automatic peptide synthesizer (Applied Biosystems, Inc., Foster City, CA), and the SAMBHA-polystyrene resin was used as solid support. Amino acids were coupled as symmetric anhydrides using DCC in a 1:1 mixture of DCM-DMF or in pure DMF as coupling reagent, except that Nα-Fmoc-Asp(Ot-Bu) and Nα-Fmoc-Glu(Ot-Bu) were coupled as HOBt active esters and Nα-Fmoc-Tyr(SO₃Na) as a pentafluorophenyl ester. The side-chain protections were as follows: Asp and Ser were protected by t-Bu groups; His by a Fmoc group; Lys by a Boc group; Arg by a Pmc group. Coupling was repeated if a ninhydrin test was positive. After completion of the synthesis, the peptide resin was washed with a 1:1 mixture of DMF and DCM, and the coupling reaction was repeated with Fmoc-SAMBHA and DCC.
Naturally Occurring Peptide Hormones and Neurotransmitters, Synthesis of

Figure 2

Synthesis of 4-succinylamido-2,2',4'-trimethoxybenzhydrylamine (SAMBHA).

that contained 0.4 g of NaOH for 1 minute, methanol for 2 minutes, and ether (4 × 2 minutes). Then the resin was dried. The protected pCCK-33 sulfate ester resin was washed with DCM (4 × 2 min) and was treated two times with 12 mL of 50% TFA solution in DCM that contained 5% ethanedithiol and 2% dimethyl sulfoxide (1 × 1 min, 1 × 15 min, 1 × 1 min). The TFA-containing solutions were pooled, and solvents were evaporated in vacuo. pCCK-33 was precipitated by adding peroxide-free ether.

Crude pCCK-33 was dissolved in the mixture of acetonitrile and 0.05 M (pH = 6.5) ammonium acetate buffer and was purified by prep-HPLC on a C18 column. The synthetic peptide was identified by using the native pCCK-33 standard. Pure fractions were pooled and lyophilized three times.

Gastrin

In 1905, Edkins discovered a hormone from the stomach and named it gastrin. Different forms and fragments of gastrin have been reported since then. The characteristic forms include a 17-residue amide called little gastrin and a 14-residue amide called minigastrin, which were known for their abilities of stimulating acid, pepsin, and pancreatic secretions in response to food (9).

The sequence of human little gastrin is as follows: pyroGlu-Gly-Pro-Trp-Leu-Glu-Glu-Glu-Glu-Glu-Ala-Tyr-Gly-Trp-Met-Asp-Phe-NH2.

The sequence of human minigastrin is as follows: Trp-Leu-Glu-Glu-Glu-Glu-Glu-Ala-Tyr-Trp-Met-Asp-Phe-NH2.

Gastrins and gastrin analogs have drawn great interest from chemists, and many total synthesis studies have been reported. Solution-phase synthesis was achieved by Anderson et al. in the 1960s (10). In 1980, Brown and coworkers reported a solid-phase synthesis of these two peptide amides (11). Methoxycarbonyl-functionalized poly(dimethylacrylamide) resin was chosen as the solid support. It was converted into a primary amine by treating it with ethylenediamine and then the addition of the reversible-linkage agent [2,4,5-trichlorophenyl 4-(hydroxymethyl)benzoate] in the presence of HOBT. The peptide sequence was then assembled using initially N-Boc-Phe anhydride in the presence of catalyst (dimethylaminopyridine) to establish the peptide–resin ester bond, followed by 16 cycles of N-Boc amino-acid coupling. The symmetric anhydride method was used for coupling in all cases except for the last Gln, which was introduced as its p-nitrophenyl ester in the presence of HOBT. Deprotection of the N-Boc groups was done by treating with HCl-AcOH, whereas the Nα-Fmoc groups were removed by 20% piperidine in DMF. Gln was chosen as the N-terminal residue rather than pyroglutamic acid, which is present in little gastrin, so as to permit possible future extension into the prohormone series. Side-chain protections were as follows: Asp, Tyr, and Glu were protected by tert-butyl groups. After completing the synthesis, side-chain tert-butyl derivatives were removed by treatment with 90% aqueous TFA, and the free peptide was released from the resin by ammonolysis in saturated methanolic ammonia for 22 hours. Residual resin analysis indicated the removal of 91% of the peptide. At this stage, the product consisted of a mixture of the 17-residue N-terminal glutamine peptide amide and its cyclized pyroglutamyl analog (5:1). Cyclization was brought nearly to completion by treatment with 20% acetic acid (30°C, 64 hours under Argon).

HPLC analysis showed the crude peptide has three major impurity peaks (Fig. 3a). The residual glutaminyl peptide
GLP1 is a peptide hormone produced by the posttranslational processing of proglucagon secreted from L-cells in the lower gut. It has two forms: GLP1(7-36), which is a 30-residue glycine-extension peptide. It stimulates insulin secretion in response to the plasma glucose concentration change, and it is considered to have great potential in treating Type 2 diabetes.

Motilin is a 22-amino acid peptide first isolated from hog duodenal mucosa by Brown and colleagues in 1972 (18, 19). It is secreted from the duodenum and proximal jejunum in response to food. Two major physiological effects of GIP are inhibition of gastric acid secretion and stimulation of insulin release.

The sequence of porcine GIP is as follows: Tyr-Ala-Glu-Gly-Thr-Phe-Ile-Pro-Ile-Phe-Thr-Ser-Asp-Val-Ser-Ser-Tyr-Leu-Glu-Gly-Gln-Ala-Ala-lys-Glu-Phe-Ile-Ala-Trp-Leu-Val-Lys-Glu-Arg-NH₂.

The sequence of motilin is as follows: Phe-Val-Pro-Ile-Phe-Thr-Tyr-Gly-Glu-Leu-Gln-Arg-Met-Glu-Glu-Glu-Leu-Leu-Ala-Gln-Leu-Lys-Gly-Lys-Lys-Lys-Gln-

The total synthesis of GLP-1(7-36) was reported by A delhorrst et al. (12) in 1994 using the solid-phase peptide synthesis method. The peptide was synthesized on an ABI MED 422 multiple synthesizer. An N-\(\alpha\)-Fmoc strategy, which was modified according to Gauselv et al. (13), was used starting from a Rink-resin. The side-chain protections were as follows: Asn, Gin, and His were protected by Tt groups; Arg by a Pmc group; Asp, Glu, Tyr, Ser, and Thr by t-buty1 groups; and Trp and Lys by Boc groups. The peptides were cleaved from the residue and deprotected by a treatment of TFA/trimethylsilane/water (92.5:5:2.5) for 120 minutes and precipitated in t-butylmethyl ether and lyophilized from 10% acetic acid. The crude peptides were purified by reverse phase HPLC with Superpak Pep. S C2C18 column, obtaining a purity of >95%.

Glucose-dependent insulinotropic polypeptide (GIP)

Glucose-dependent insulinotropic polypeptide is originally known as gastric inhibitory polypeptide (GIP), which is a 42-residue peptide first isolated by Brown and Dryburgh (14). It is secreted from the duodenum and proximal jejunum in response to food. Two major physiological effects of GIP are inhibition of gastric acid secretion and stimulation of insulin release.

Gluconeogenic amino acids can be directly formed on HF cleavage of the final peptide residue 25 was introduced exceptionally by itself to the 26-42 or 26-43 peptide intermediate by the active ester method. The Cbz and Bn groups were removed by catalytic hydrogenation and the Boc and tBu groups by TFA treatment during the course of fragment condensation. After completing the synthesis, the crude protected peptide was treated with sodium in liquid ammonia to remove N-Cbz and N-Tos groups. The product was first purified by gel filtration on Sephadex G-25, followed by ion-exchange chromatography on CM-cellulose and HPLC with TSK-Gel LS-420K C-18 column.

Motilin was the first identified gut hormone to be a hormone that caused smooth muscle contraction. It was found to be released from enteroendocrine cells of the duodenal-jejunal mucosa to control gastrointestinal muscles by controlling the migrating motor complex.

The sequence of motilin is as follows: Phe-Val-Pro-Ile-Phe-Thr-Tyr-Gly-Glu-Leu-Gln-Arg-Met-Glu-Glu-Glu-Leu-Leu-Ala-Gln-Leu-Lys-Gly-Lys-Lys-Lys-Gln-

Ikeda (20) reported the first solid-phase synthesis of motilin in 1980, and the overall yield was 1.8%. Coy et al. (21) improved the synthesis and got a 12% yield. Coy’s synthesis was carried out on a Beckman model 990 automatic peptide synthesizer using N-\(\alpha\)-Boc chemistry. Motilin was assembled stepwise on a 1% cross-linked BHA resin with Boc-a-benzyl-Glu as the first amino acid to be incorporated. In this manner, C-terminal Gin could be directly formed on HF cleavage of the final peptide from the resin. The detailed coupling schedule is shown in Table 2 (22). The symmetric anhydride method was used for the synthesis of the peptide.

*Asn and Gln were dissolved in DMF, N$:^\alpha$-Boc-Arg(Tos) in 10% DMF-DCM. The extent of couplings were monitored by the ninhydrin test. Couplings, which were incomplete after 1 hour, were recoupled by using the appropriate symmetric anhydride procedure at room temperature in DMF.

After the completion of the solid-phase synthesis, 0.25 mmol of peptide-resin was treated with HF (30 mL) that contained 10% anisole for 30 minutes at 0$^\circ$C. After rapid removal of HF under a stream of nitrogen, free, deprotected peptide amide was precipitated by addition of ether, and then it was partially purified on Sephadex G-25. A further purification was done on an octadecylsilica column (5 x 45 cm) by elution with a linear gradient formed from 200 mL each of 15 and 30% 1-propanol in 10% acetic acid at a flow rate of 2 mL/min. Examination of the fractions by TLC and HPLC located the peptide in the third peak. Fractions were pooled for maximum purity to give 70 mg (10%) of motilin.

**Neuropeptide Y (NPY)**

NPY is a 36-amino acid peptide amide first isolated from porcine brain by Tatemoto et al. (23, 24) in 1982. It is found distributed in the central nervous system where it is involved in the control of blood pressure and appetite, and also in the
peripheral nervous system, where it is a potent vasoconstrictor and presynaptic inhibitor of neurotransmission.

The sequence of porcine NPY is as follows: Tyr-Pro-Ser-Lys-Pro-Asp-Asn-Pro-Gly-Glu-Asp-Ala-Pro-Ala-Glu-Asp-Leu-Arg-Tyr-Tyr-Ser-Ala-Leu-Arg-His-Tyr-Ile-Ala-Leu-Ile-Thr-Arg-Gln-Arg-Tyr-NH₂.

Krstenansky et al. (25) successfully prepared porcine NPY in 1987. It was synthesized by solid-phase techniques with an Applied Biosystems Inc. Model 430-A peptide synthesizer using MBHA resin. All residues were double coupled as the preformed symmetric anhydrides of the Nα-Boc amino acid derivatives except for Asn and Gln, which were coupled with the DCC/HOBT methodology (refer to the section on "Corticotropin-releasing factor synthesis" for details). The side-chain protections were as follows: Arg and His were protected by Tos groups; Asp and Glu by cHx groups; Ser and Thr by Bn groups; Lys by a 2,6-Cl-Cbz group; Tyr by a 2-Br-Cbz group. After completing the synthesis, deprotection and the resin cleavage were performed by a treatment with HF that contained 5% anisole for 50 minutes at 0°C. The HF was removed in vacuo at 0°C, and the crude peptide was precipitated with ether and extracted with 30% acetic acid. The extract was lyophilized. First-round purification was carried out on a 2.6 × 92-cm Sephadex G-15 column at 30 mL/h and 20 minutes per fraction (Fig. 6, top) (25). The fractions that contained the major peak detected by UV at 254 nm were combined and lyophilized. The residue was then purified for the second round by preparative HPLC on a 21.4 × 250 mm Rainin Dynamax C-18 column at 10 mL/min with 34% MeCN in 0.1% TFA at 0°C. The peptide was precipitated with ether and extracted with 30% acetic acid. The lyophilized residue was then purified using a reverse-phase HPLC column (MCI GEL ODS-1H4, 10 × 300 mm, Mitsubishi Kasei, Japan) with a linear gradient of 0.1% TFA/water and 0.1% TFA/acetonitrile in DMF at 0.1 mL/min. Taken from Krstenansky et al. (23).

Peptide tyrosine tyrosine (PYY)
PYY is a 36-amino-acid peptide originally isolated from porcine upper intestine by Tatemoto et al. (26, 27). It contains an N-terminal tyrosine and a C-terminal tyrosine amide and therefore is named peptide YY. It has a high degree of sequence homology (70%) with neuropeptide Y, and it strongly inhibits pancreatic exocrine secretion and jejunal and colonic motility as well as causes vasoconstriction.

The sequence of human PYY is as follows: Tyr-Pro-Ile-Lys-Pro-Glu-Ala-Pro-Gly-Glu-Asp-Ala-Ser-Pro-Glu-Glu-Leu-Asn-Arg-Tyr-Tyr-Ala-Ser-Leu-Arg-His-Tyr-Leu-Asn-Leu-V al-Thr-Arg-Gln-Arg-Tyr-NH₂.

Tatemoto et al. (28) also reported a solid-phase synthesis of PYY. Human PYY was prepared manually using Nα-Fmoc protection strategy on a 4-aminomethyl-3,5-dimethylphenoxyl resin (PAL resin). The coupling reaction was carried out using a five-fold excess of Nα-Fmoc amino acid and DIC in DMF. The u-amino group of the growing peptide was deprotected with 20% piperidine in DMF for 10 minutes. The side-chain protections were as follows: Asp, Glu, Ser, Thr, and Tyr were protected by t-Bu groups; Lys by a Boc group; His by a Trt group; Arg by a Mtr group. The peptide was deprotected and cleaved from the resin by a treatment with TFA/thioanisole/ethanedithiol/anisole (90/5/3/2) for 8 hours at room temperature. After filtration, TFA was removed in vacuo, and the peptide was precipitated by ether. The precipitate was redissolved in 0.1 M acetic acid and lyophilized. The crude peptide was purified using an reverse-phase HPLC column (MCI GEL ODS-1H4, 10 × 300 mm, Mitsubishi Kasei, Japan) with a linear gradient of 0.1% TFA/water and 0.1% TFA/acetonitrile. The synthetic

Figure 6 HPLC of synthetic porcine NPY. Top: after HF cleavage and Sephadex G-15 chromatography. Bottom: after preparative HPLC purification. Condition: Vydac 218TP54 (4.6 × 250mm) C-18 column with a linear gradient of 25–100% acetonitrile in 0.1% TFA over 25 minutes at 2 mL/min. Taken from Krstenansky et al. (25).
peptide obtained was found to coelute in HPLC with the natural peptide, and the results of amino acid and sequence analyses indicated that it was identical to human PYY.

Secretin
Secretin is a 27-residue peptide amide hormone produced by 5 cells of the duodenum. The primary effect of secretin is stimulating the release of bicarbonate from liver, pancreas, and duodenal tissues to inhibit gastrin-induced gastric acid release. It also enhances the effects of cholecystokinin and promotes normal growth and maintenance of the pancreas.

Several classic syntheses of secretin have been reported using either fragment condensation or repetitive coupling of single residues (29); one solid-phase synthesis has also been reported (30). However, a peptide-stability problem arose, and it caused difficulty in developing an efficient solid-phase synthesis of the peptide. Coy and Gardner (31) developed a two-stage rapid purification method to avoid traditional long purification routes, and this approach solved potential degradation problem of the peptide.

Coy’s synthesis was carried out on a Beckman model 990 automatic peptide synthesizer (Beckman Instruments, Fullerton, CA) using N-Boc chemistry. Secretin was assembled stepwise on a 1.0-mmol of 1% cross-linked BHA resin support using the synthesis schedule described in Table 2. The side-chain protections were as follows: Arg, Glu, Ser, and Thr were protected by Bn groups; Arg and His by Tos groups. Each amino acid was successively coupled in the presence of DIC and, in the case of Asn or Gln, 1 equivalent of HOBt was added. Couplings were monitored at each step by using the ninhydrin test. Couplings that were incomplete within 1 hour were recoupled by using the appropriate symmetric anhydride preformed at room temperature in DMF.

After the completion of the solid-phase synthesis, the peptide resin was treated with HF that contained 10% anisole for 30 minutes at 0°C. After rapid removal of HF under a stream of nitrogen, free, deprotected peptide was precipitated by addition of ether, and it was washed and extracted into 2 M acetic acid. The protected somatostatin tetradecapeptide was synthesized in a stepwise manner on chloromethylated resin prepared in a stepwise manner on a column (2.5 × 95 cm) of ODS silica LRP-1 (Whatman) (13–24 µm) with a linear gradient of 15 and 35% 1-propanol in 0.1 M ammonium acetate (pH 4) at a flow rate of 5 mL/min and pressure about 80 psi. Taken from Coy et al. (21).

Figure 7 Chromatography of crude synthetic secretin eluted on a column (2.5 × 45 cm) of ODS silica LRP-1 (Whatman) (13–24 µm) with a linear gradient of 15 and 35% 1-propanol in 0.1 M ammonium acetate (pH 4) at a flow rate of 5 mL/min and pressure about 80 psi. Taken from Coy et al. (21).

are secreted not only by cells of the hypothalamus but also by delta cells of the stomach, intestine, and pancreas. They inhibit the release of numerous gut peptides, like CCK, gastrin, secretin, motilin, GIP, and they also inhibit insulin and glucagon secretion from the pancreas.

The sequence of hypothalamic somatostatin 14 is as follows: Ala-Gly-c(Cys-Lys-Asp-Pro-Phe-Thr-Cys)-OH.

The sequence of hypothalamic somatostatin 28 is as follows: Ser-Ala-A s n-Ser-Ala-Asp-Pro-Ala-Met-Ala-Pro-Arg-Glu-Arg-Lys-

Somatostatin 14 was isolated, characterized, and synthesized by Guillemin’s group in 1973 (32, 33). Several independent studies of the peptide’s synthesis were reported immediately after that (34–37). Among those studies, River reported in detail the first solid-phase synthesis of the peptide in a highly purified form. The protected somatostatin tetradecapeptide was synthesized in a stepwise manner on chloromethylated resin prepared according to Stewart and Young (38). N-Boc chemistry was used for the synthesis: all amino acids were coupled as symmetric anhydrides using DCC as the coupling reagent except for Asn, which was coupled as Np active ester. The side-chain protections were as follows: Thr and Ser were protected by Bn groups; Lys by a 2-CI-Chz group. N'-Boc-Cys(p-OMe-Bn) was used because it is easily removed by HF. Ala and Gly were introduced as a Cbz-protected dipeptide (Cbz-Ala-Gly-OH) to have a reliable internal standard to evaluate the amino-acid analyses. TFA was used for cleavage of the N’-Boc protecting groups, and 1, 2-ethanediol/thiol was added for protection of the Thr residue from oxidation, which is a problem that has long been recognized in solid-phase synthesis. The completion of coupling was monitored by the ninhydrin test. The detailed schemes used for the synthesis are reported in Tables 3 and 4.

Cleavage and concomitant deprotection of the tetradecapeptide were achieved by HF in presence of anisole. After removing HF in vacuo and work-up, a white fluffy material that accounted for 60% of the calculated yield was obtained. A second HF treatment was applied to the resin, and 25% more of the peptide was obtained. The crude material was subjected to gel filtration. The main peak (Fig. 8, profile I) after lyophilization and...

routine handling was reapplied on the same column under the same conditions in an attempt to obtain one single symmetrical pattern (Fig. 8, profile I). A total yield of 28% in purified linear somatostatin was obtained.

Synthesis of somatostatin-28 has been reported by Nicolas et al. (39) in 1986. Nα-Boc protected amino acids were assembled on chlorosulfonyl/1% divinylbenzene resin by using solid-phase peptide synthesis techniques. The first amino acid was loaded by mixing the resin and Nα-Boc-Cys(3,4-dimethylbenzyl)-OH in DMF for 18 hours at 50°C in the presence of KI. The side-chain protections were as follows: Asp, Thr, Ser, and Glu were protected by Bn groups; Lys by a 2-Cl-Cbz group; Tyr by a 2-Br-Cbz group; Arg by a Tos group; Cys by a 3, 4-dimethyl-Bn group; Trp by a For group. The coupling was done using the symmetric anhydride method according to the protocol shown in Table 4 (40), except Asn was first coupled for 15 hours as its p-nitrophenyl ester in DMF and then by the use of HOBT as reported (41). After the coupling was completed, the peptide-resin was subjected to steps 1–10, washed with EtOH, and dried. The cleavage of the peptide was done by treating the peptide-resin with liquid HF in the presence of anisole for 30 minutes at −20°C and then 60 minutes at 0°C. After removal of HF by a stream of nitrogen, the residue was stirred in EidA.c, and the solid material was filtered off. The filtrate was purified on a Sephadex G-25 column (2.6 cm × 100 cm) equilibrated and run with degassed 10% AcOH saturated with nitrogen. The main peak was lyophilized, which yielded 665 mg product. Deformylation and formation of the disulfide bond were carried out by dissolving 100 mg material in water (25 mL) that contained 75% hydrazine and taken to pH 11.5 with 1 M NaOH. After 2 minutes, the solution was diluted to 1000 mL with distilled water, adjusted to pH 8 with glacial acetic acid, and allowed to stand at 24°C. After 22 hours, less than 1% free thiols remained as assessed by the Ellman’s method (42). After lyophilization, the material was dissolved in 5 mL of 10% AcOH and filtered through a Sephadex G-50F column (2.5 cm × 91 cm) in 10% AcOH. Isolation of material in the major peak gave 63 mg. This material was subjected to chromatography on CM-cellulose in a 1.5 cm × 35-cm column initially equilibrated with 10 mM NH₄OAc, pH 4.2. A gradient was applied through a 200 mL constant volume mixing chamber that contained the initial buffer by introducing 0.45 M NH₄OAc, pH 7. Material in the major peak was isolated to give 16.5 mg (a 6% overall yield) of somatostatin-28.
670–740 mL, 500 mg, 40%; profile II (employing the solid-phase technique using overnight with an excess of hydrochloride was neutralized with triethylamine and stirred with a mixture of Ac₂O and triethylamine in DMF overnight. The remaining unreacted amino groups of the resin were acetylated with 25% triethylamine-DCM. The remaining amino acid was used for coupling with a reaction time of 6 hours except for Gin, which was incorporated as a fivefold excess of its Np active ester with an 11-hour coupling time. Dry DCM was used as the coupling solvent except for Arg and Gin, which required purified DMF. N-Boc deprotection was accomplished by 50% TFA in DCM with neutralization by 10% Et₃N in DCM. The completion of coupling was monitored by the ninhydrin test, and recoupling was done when needed (refer to the sections on “Möllin synthesis” and “Secretin synthesis” for details). Cleavage of the peptide from the resin, with simultaneous removal of the protecting groups and formation of the carboxy terminal amide, was affected with 20 mL of dry HF in the presence of 2 mL of anisole for 1 hour at 0 °C. After removal of the excess HF in vacuo, the resin was washed with EtOH to remove anisole, followed by 0.5N H₂OAc to extract the peptide; 424 mg crude product was obtained and lyophilized.

Purification was done by gel filtration on a 102 × 2.5 cm column of Bio-Gel P2 eluted with 1.1% AcOH, with detection of the peptide peaks by UV at 256 nm. The main fraction (253 mg) was partitioned on a 100 × 1.5 cm column of Sephadex G-25 eluted with the system 0.1% AcOH-n-BuOH-Pyr (11:5:3) with detection of the peptide peaks by the Folin-Lowry procedure (45) at 700 nm, giving 90 mg (16.7%) of pure substance P. N-Fmoc synthesis of substance P also has been reported (46).

**Figure 8** Gel filtration of crude and purified synthetic reduced somatostatin. Column: 2.5 × 100 cm Sephadex G-25. 2 N AcOH, 10-2 M (mercaptoethanol). V₀ = hold-up volume; profile I (katharanth); 500 mg from I, yield 660–726 mg, 350 mg, 28%. Taken from Boxer et al. (57).

### Substance P

Substance P is an 11-amino-acid peptide amide hormone discovered by von Euler and Gaddum in 1931 (43) from certain tissue extracts, especially from intestinal plain muscles and brains of horses. It is involved in the transmission of pain impulses from peripheral receptors to the central nervous system. It is also involved in the vomit reflex, stimulates salivary secretions, and induces vasodilation. Antagonists seem to have antidepressant properties.

The sequence of substance P is as follows: Arg-Pro-Lys-Pro-Gln-Gln-Phe-Phe-Gly-Leu-Met-NH₂

This peptide was synthesized by Fisher et al. (44) in 1974 employing the solid-phase technique using N-Boc chemistry. BHA type resin was used for the synthesis on a Beckman Model 990 solid-phase peptide synthesizer. Dried BHA-resin hydrochloride was neutralized with triethylamine and stirred overnight with an excess of N-Boc-Met and DCI in DCM. The remaining unreacted amino groups of the resin were acetylated with Ac₂O and triethylamine in DCM overnight. Amino-acid analysis of the resin, after hydrolysis in 6 N HCl-propionic acid (1:1), gave a value of 0.2 mM/g of Met. The side-chain protections were as follows: Lys was protected by a Cbz group; Arg by a Tos group. A 2.5-fold excess of each amino acid was used for coupling with a reaction time of 6 hours except for Gin, which was incorporated as a fivefold excess of its Np active ester with an 11-hour coupling time. Dry DCM was used as the coupling solvent except for Arg and Gin, which required purified DMF. N-Boc deprotection was accomplished by 50% TFA in DCM with neutralization by 10% Et₃N in DCM. The completion of coupling was monitored by the ninhydrin test, and recoupling was done when needed (refer to the sections on “Möllin synthesis” and “Secretin synthesis” for details). Cleavage of the peptide from the resin, with simultaneous removal of the protecting groups and formation of the carboxy terminal amide, was affected with 20 mL of dry HF in the presence of 2 mL of anisole for 1 hour at 0 °C. After removal of the excess HF in vacuo, the resin was washed with EtOH to remove anisole, followed by 0.5N H₂OAc to extract the peptide; 424 mg crude product was obtained and lyophilized.

Purification was done by gel filtration on a 102 × 2.5 cm column of Bio-Gel P2 eluted with 1.1% AcOH, with detection of the peptide peaks by UV at 256 nm. The main fraction (253 mg) was partitioned on a 100 × 1.5 cm column of Sephadex G-25 eluted with the system 0.1% AcOH-n-BuOH-Pyr (11:5:3) with detection of the peptide peaks by the Folin-Lowry procedure (45) at 700 nm, giving 90 mg (16.7%) of pure substance P. N-Fmoc synthesis of substance P also has been reported (46).

### Vasointestinal peptide (VIP)

VIP is a 28-amino-acid residue peptide amide isolated in 1970 by Said and Mutt in the course of the purification of secretin from porcine duodenum (47). It was characterized 2 years later as a highly basic peptide related to gut peptides. It inhibits acid and pepsin secretion, acts as a neurotransmitter in peripheral autonomic nervous system, and increases secretion of water and electrolytes from pancreas and gut.

The sequence of porcine VIP is as follows: His-Ser-Asp-Ala-Val-Phe-Thr-Asp-Asn-Tyr-Thr-Arg-Leu-Arg-Lys-Gln-Met-Ala-Lys-Lys-Tyr-Leu-Asn-Ser-Ile-Leu-A sn-NH₂

Bolansky reported the first synthesis of VIP using solution-phase peptide synthesis (48). Several other syntheses, both solid-phase and solution-phase, also have been reported (49–52). Among these syntheses, Fourrier’s study is representative. N-Boc solid-phase synthesis techniques were used. Peptide syntheses were carried out with a Vega peptide synthesizer (Vega Biotech, Tucson, AZ) in the automatic mode following operations as described (53) (similar to Tables 3 and 4) except that 1% D,L-methionine was used in TFA instead of 5% thioanisole. The first amino acid was loaded to the BHA resin (0.21 meq/g) via the DCC-HOBt procedure after neutralization with triethylamine and thioanisole. The first amino acid was loaded to the BHA resin (0.21 meq/g) via the DCC-HOBt procedure after neutralization with triethylamine and thioanisole. The first amino acid was loaded to the BHA resin (0.21 meq/g) via the DCC-HOBt procedure after neutralization with triethylamine and thioanisole.

*In the case of N\(^\alpha\)-Boc-Val, -Leu, -Thr, 90 minutes of reaction time.

Bn groups; His by a Boc group; Tyr by a 2-Br-Cbz; Arg by a Tos group; Lys by a 2-Cl-Cbz group. Every coupling was monitored for completion using the ninhydrin test (refer to the sections on “Motilin synthesis” and “Secretin synthesis” for details). Excess amino groups were acetylated when the test showed slightly positive results (−1%). After the last amino acid was introduced, the cleavage and deprotection were executed in the K-F reaction vessels of a liquid HF apparatus. HF (8–10 mL/g) and a 5-molar excess D,L-methionine were added to the vessel that already contains anisole. The reaction proceeded for 30 minutes at \(−20\) °C and for another 30 minutes at 0 °C. The HF was rapidly evaporated in vacuo, and the resin was washed with ether. The crude peptide was extracted with 30% acetic acid \((\sim 200 \text{ mL})\), and the solution was lyophilized.

The crude peptide was dissolved in a minimal volume of 0.005-M ammonium acetate buffer at pH 6.0, and then it was applied to a column of Whatman CM-23 ion exchange resin equilibrated with the same buffer. The peptide was eluted with a pH and ionic gradient of adding 0.20 M pH 7.5 ammonium acetate buffer to the initial one at a flow rate of 700 mL/h. The elution was monitored by UV at 280 nm. Frations (12 mL) that corresponded to the major peak were collected and lyophilized twice to eliminate the volatile salt. A second chromatographic step on CM-23 resin was achieved with a pH and ionic gradient obtained by the addition of 0.12 M pH 7.5 to 0.005 M pH 5.2 at a flow rate of 700–1000 mL/h. In the third chromatographic step on CM-23 resin was achieved with a pH and ionic gradient obtained by the addition of 0.12 M pH 7.5 to 0.005 M pH 5.9 at a flow rate of 700–1000 mL/h. In the third chromatographic step, the semi-purified VIP was injected on a partition chromatography column packed with Sephadex G-50 resin and equilibrated with the solvent system 1-butanol, acetic acid, and 0.5%-pyridine (5:10:3). The flow rate was set to 20 mL/h, and 5-mL fractions were collected. Final purification (Fig. 9) was carried out on HPLC using a semi-preparative Waters µBondapak C-18 column under isocratic conditions: methanol ammonium acetate 0.10 M, pH 5.2 (70:30). The flow rate was adjusted to 1.2 mL/min, and the peptide was detected at 246 nm by UV. Two-hundred fifty µL of 40 mg/mL peptide solution were injected. The main peak was collected and lyophilized, which gave an overall yield of 4%.

Hypothalamic peptide hormones

Corticotropin-releasing factor (CRF or CRH)

CRF is a 41-amino-acid peptide first isolated from ovine hypothalamic extracts and characterized by Vale et al. (54) in 1981. It has a high potency for stimulating the secretion of corticotropin-like and β-endorphin-like immunoreactive substances.

Vale et al. (54) also synthesized the peptide, but they did not provide details of the synthesis. In 1982, Sueiras-Diaz and Coy (55) published the first detailed synthesis of ovine CRF using N-Boc solid-phase synthesis techniques. The amino acids were assembled on a 1% cross-linked BHA resin (0.1 g: 0.49 mmol amino groups) using a Beckman 990 automatic synthesizer (Beckman Instruments, Fullerton, CA). The symmetric anhydride procedure in DMF was used for the coupling of amino acids, and DIC was the coupling reagent. In the case of Asn and Gin, they were coupled with an equimolar amount of HOBt.

N-Boc protection was removed at each stage by two treatments with 39% TFA in DCM for 1 minute and 25 minutes. Reactive side-chains protections were as follows: Ser and Thr were protected by Bn groups, Gln by a Np group, Arg by a 2-Cl-Cbz group, His and Tyr by a 2-Ch-Orn group, and Lys by a 2-Cl-Cbz group.

The final purification was achieved by a preparative RP-HPLC procedure using a C-18, 10 µm, 300 Å (25 × 25 cm) Synchropack column loaded with 11.7 mg and eluted with a gradient of 25–35% isopropanol in 0.1% TFA developed over 30 minutes. Flow rate 1 mL/min, absorption at 215 nm, taken from Sueiras-Diaz et al. (55).

Gonadotropin-releasing factor (GnRF or GnRH)

GnRH, which was originally known as luteinizing hormone (LH) and follicle-stimulating hormone (FSH) releasing hormone, is a 10-residue polypeptide isolated from porcine hypophysis by Schally et al. (56) in 1971. It acts on the gonadotrope to control the release of LH and FSH.

Matuo et al. (57) also have prepared this peptide via solid-phase peptide synthesis. The protected decapeptide resin ester (N-Boc-Glu-His-Trp-Ser-D-Pro-Gly-Glu-Lys-Asp-Tyr-Gly-Leu-Arg-N(SO₂)-Pro-Gly-Pyr-H) corresponds to the amino acid sequence of LH-RH/FSH-RH was synthesized using N-Boc chemistry by the method described by Stewart and Young (38), which starts with N-Boc-Gly-resin ester (1.0 g; 0.35 mmol). The side-chain protections were as follows: Ser and Tyr were protected by Bn groups, Gin by a Np group, Arg by a Boc group.
NOC group. Coupling was achieved with DCC with the single exception that Gin was coupled by means of its p-nitrobenzyl ester. Stepwise synthesis was carried out in the DCM and/or DMF using a glass shaker at room temperature. The removal of the N-Boc groups in the first seven steps was performed by treatment with 50% TFA in DCM for 20 minutes. After the incorporation of the Trp residue, 1N HCl in acetic acid that contained 1% 2-mercaptoethanol was used for the removal of the N-Boc group as described by Marshall (58). The neutralization was carried out by shaking with 10% triethylamine in CHC13. In every DCC coupling step, 4 equivalents of N-Boc-amino acid (4 × 0.35 mmole) for every equivalent of the starting glycine resin ester was used in the presence of 4 equivalents of DCC for 5 hours. An additional reaction with the same reagents was performed for another 5 hours. For the incorporation of His, 5 equivalents of N-Boc-His were used, and the same reaction was carried out twice as above. Nitosopropyl ester coupling of N-Boc-Gln was performed with 10 equivalents of the active ester for 5 hours, followed by an additional treatment for 5 hours in the presence of 5 equivalents of imidazole. The yield of the protected decapeptide resin ester was 1.38g (about 78% based on dry weight and amino acid analysis).

To achieve cyclization of N-terminal glutaminyl group on the resin to the pyroglutamyl ring after removal of N-Boc group, the N-Boc-glutaminyl-peptide resin ester was treated with 1N HCl in acetic acid that contained 1% of 2-mercaptoethanol for 1 hour at room temperature. The peptide was cleaved by stirring in 20mL of absolute methanol saturated with ammonia for 3 days at room temperature. After filtration, evaporation of the methanolic filtrate yielded 368 mg of the corresponding amide as a yellow semi-solid material. All protecting groups were removed before 1g of the peptide-resin conjugate was treated with a mixture of 14mL of HF, 1.5mL of anisole, and 0.25mL of methylethyl sulfide at 0°C for 0.5 hour and at 0°C for 0.5 hour. The HF was removed in vacuo at 0°C, and the resulting peptide and resin mixture was washed twice with ether and twice with CHCl3 and ether alternately. The peptide was extracted five times with 2M CH3COOH, and the extract was lyophilized.

The first purification was done by loading the lyophilized product on a column of Sephadex G-50 developed in 30% CH3COOH to remove the truncated fragments and salt. The next step of purification was by CM-32 carboxymethyl cellulose cation-exchange chromatography developed with a gradient generated by adding 2.5 volumes of 0.4M NH4OAC at pH 6.5 to 1 volume of 0.01M NH4OAC at pH 4.5. Final purification was achieved by partition chromatography on Sephadex G-50 using the solvent system 1-butanol:ethanol:acetic acid:water (15:10:3:12). 

Growth hormone releasing factor (GRF or GRH)

GRF has been isolated and characterized from a human tumor of the pancreas (61) as well as from rat (62), porcine (63), bovine (64), caprine (65), ovine (65), and human (65) hypothalamic stalk-median eminence. It is a 40-44-amino-acid peptide hormone produced in the arcuate nucleus of the hypothalamus and released from neurosecretory nerve terminals of these arcuate neurons, and it is carried by the hypothalamo-hypophyseal portal circulation to the anterior pituitary gland where it stimulates growth hormone (GH) secretion (66).

Ling et al. (65) have described the synthesis of hGRH in 1984 after they isolated and characterized the peptide from human hypothalamic tissues. The peptide was prepared by solid-phase methodology on a Beckman model 990 peptide synthesizer (Beckman Instruments, Fullerton, CA) using N-Boc chemistry. The MβHA resin (6g, 0.6mmol/g) was used, and the side-chain protections were as follows: Ser, Glu, Asp, and Thr were protected by Bn groups; Arg by a Tos group; Lys by a 2-Cl-Cbz group; Tyr by a 2,6-Cl-Bn group. The N-terminal amino acid was loaded to the MβHA resin using the symmetric anhydride method, and DCC was the coupling reagent. The subsequent amino acids were coupled according to the schedule in Table 6. After the last amino acid had been incorporated, the N-Boc protecting groups were removed before 1g of the peptide-resin conjugate was treated with a mixture of 14mL of HF, 1.5mL of anisole, and 0.25mL of methyl sulfide at 0°C for 0.5 hour and at 0°C for 0.5 hour. The HF was removed in vacuo at 0°C, and the resulting peptide and resin mixture was washed twice with ether and twice with CHCl3 and ether alternately. The peptide was extracted five times with 2M CH3COOH, and the extract was lyophilized. The first purification was done by loading the lyophilized product on a column of Sephadex G-50 developed in 30% CH3COOH to remove the truncated fragments and salt. The next step of purification was by CM-32 carboxymethyl cellulose cation-exchange chromatography developed with a gradient generated by adding 2.5 volumes of 0.4M NH4OAC at pH 6.5 to 1 volume of 0.01M NH4OAC at pH 4.5. Final purification was achieved by partition chromatography on Sephadex G-50 using the solvent system 1-butanol:ethanol:acetic acid:water (15:10:3:12). The chromatographic fractions were monitored by UV at 280nm and TLC on 0.25-mm-thick precoated silica gel 60 plates with the solvent system 1-butanol:pyridine:CH3COOH:water (6:6:12:4:8), and the spots were detected with ninhydrin spray. Four hundred twenty-six milligrams of hGRF was obtained after final purification with an overall yield of 2.3%.

Thyrotropin-releasing factor

TRF was isolated from porcine hypothalamus by Schally et al. (67, 68) and from ovine hypothalamus by Galli et al. (69) It is a tripeptide amide with the structure of pyroGlu-His-Pro-NH2.
Classic synthesis of the peptide has been reported in 1970 (70); solid-phase synthesis was envisaged 1 year later, and Rivaille et al. claimed they successfully prepared the target with a better yield (71). N'-Boc chemistry was used in the synthesis, and N'-Boc was introduced into the amino acid by reacting amino acids with Boc-azide at a constant basic pH. The His side chain was protected with an α-N-Boc chemistry was used in the precipitation method. A 300-mg portion of the crude octapeptide was purged through the fritted disk of the reaction vessel at 25 °C. The suspension was filtered, and the resin was washed 3 times with 10 mL portions of TFA. The filtrates were evaporated in vacuo. The syrupy product was then dissolved in acetic acid and lyophilized to give 1.47 g.

Liver peptide hormones

Angiotensin II

Angiotensin II is an octapeptide derived from biologically inactive decapeptide angiotensin I, which comes from angiotensinogen through the cleavage by the kidney enzyme renin. It is responsible for essential hypertension through stimulated synthesis and for the release of aldosterone from adrenal cells. The sequence of horse Angiotensin II is as follows: Asp-Arg-Val-Tyr-Ile-His-Pro-Phe-OH.

Several syntheses of the peptide have been reported by solution methods (74–76). After the introduction of solid-phase peptide synthesis, Marshall and Merrifield conducted the first study of the synthesis of the peptide by using the new technique (77). N'-Boc chemistry was used, and Merrifield resin was selected as the solid support. The side chain protections were as follows: His, Arg, and Asp were protected by Bn groups; Arg by a NO2 group. The Phe was esterified onto the resin in ethanol with the presence of 1 equivalent of triethylamine. The symmetric anhydride method was used for the coupling of the amino acids, and DCC was the coupling reagent. The following cycle of reactions was used to introduce each new residue (Table 7): Amino acid analysis showed the average value of the eight amino acid residues to be 0.13 mmol/g of peptide resin or 0.16 mmol/g of unsubstituted copolymer. Removing the protecting groups was achieved by suspending the peptide resin in 20 mL anhydrous TFA and bubbling a slow stream of HBr through the fritted disk of the reaction vessel at 25 °C. The suspension was filtered, and the resin was washed 3 times with 10 mL portions of TFA. The filtrates were evaporated in vacuo. The product was redissolved in TFA and re-evaporated. The syrupy product was then dissolved in acetic acid and lyophilized to give 1.47 g.

Purification of the peptide was done by countercurrent distribution method. A 300-mg portion of the crude octapeptide was

* The symmetric anhydride was formed with one equivalent amount of DCC. ** In the case of Asn and Gln, a 1.2 equivalents of HOBt were included.

Table 6 Schedule of events for assembling the peptide p-MBHA resin
purified by 100 transfers in a 1-butanol-acetic acid:water (4:1:5) system. Over 80% of the Sakaguchi-positive material was located in one peak which matched closely a theoretical curve with distribution constant, k = 0.30. The material in the peak was collected and the organic phase was removed by evaporation. The residual aqueous phase was removed by lyophilization; 193 mg of product was obtained, which was equivalent to a yield of 56%.

Pancreatic peptide hormones

Amylin

Amylin is a 37-residue peptide hormone first discovered independently by two research groups in 1987 (78, 79). Amylin is secreted by pancreatic β-cells at the same time as insulin (in a roughly 100:1 ratio), and it is the major component of diabetes-associated islet amyloid deposits. It inhibits basal and meal-stimulated glucose uptake as well as glycogen synthesis by skeletal muscles (80). Thus, amylin is also known as a diabetes-associated peptide.

The sequence of human amylin is as follows: Lys-c(Cys-A sn-Thr-Ala-Thr-Cys)-Ala-Thr-Gln-Ala-Leu-Ala-Asp-Phe-Leu-Val-His-Ser-Ser-Ser-Leu-Ala-Asp-Phe-Gly-Ala-Val-Ser-Ala-Asn-Thr-Tyr-NH₂.

One solid-phase synthesis of amylin has been reported in 1991 by Balasubramaniam et al. (81). Standard N-Boc chemistry was used for the synthesis, and MBHA resin was selected as the solid support. The coupling was done by using the symmetric anhydride method except for Arg, Asp, and Gln, which were coupled as their HOBt esters (refer to the section on "Amylin synthesis" for details). After completing the chain elongation, the peptide was cleaved from the resin using HF at 0°C. The residue was then oxidized with K₂Fe(CN)₆ to form the disulfide bond, followed by purification on semipreparative reversed phase column. The overall yield of the synthesis was between 10–20%.

Glucagon

Glucagon is a 29-residue polypeptide secreted by pancreas α-cells. It increases lipid mobilization and glycogenolysis to increase blood glucose levels. It was first discovered by K. I. M. Martin and Murlin in 1923 (82) when studying pancreatic extracts, but the sequence was not determined until 1957 (83).

The sequence of mammalian glucagons is as follows: His-Ser-Gln-Gly-Thr-Phe-Thr-Ser-Asp-Tyr-Ser-Leu-Asp-Ser-Arg-Ala-Gla-Gln-Glu-Val-Leu-Met-Ala-Ser-Thr-OH.

Early attempts to synthesize glucagons proved to be difficult because of the unusual structure, and successful examples were not reported until Wünsch's classic solution-phase synthesis (84). M. B. Browning and M. Wünsch reported the first stepwise solid-phase synthesis of glucagon in 1981, in which they used bifunctional (Boc) amino acid derivatives and t-Bu based side chain protections, which were unstable. They improved the method by using a native Boc strategy and benzyl based side chain protections by using their newly developed PAM resin in 1984, which gave a rapid, convenient synthesis (86). The aminomethyl-resin was prepared according to Mitchel et al. (87, 88). The first amino acid Thr was loaded to the resin through 2 steps: 1) N-Boc-Thr(Bzl)-OH was treated with powdered K₂Fe(CN)₆ and [4-(bromomethyl)phenyl]acetic acid phenacyl ester to produce N-Boc-Thr(Bzl)-OCH₂C₆H₄CH₂COOH and 2) product was then dissolved in DCM and allowed to couple with aminomethyl-resin at the presence of 1 equivalent of DCC, and unreacted amino groups were blocked by acetylation. The peptide chain was then elongated by the symmetric anhydride coupling method. In all, 8 eq. of amino acid and 4 eq. of DCC were used for each coupling, except for Leu and Gly in 1.6 eq. and 1.2 eq., respectively. A side chain protection was coupled with HOBt: Arg at positions 17 and 18 were coupled twice each. The side chain protections were as follows: Seer and Thr were protected by Bn groups. His and Arg by Tos groups; Asp by a cBz group; Tyr by a Bn-Cbz group; Lys by a Cbz-Cbz group; Trp by a Fmoc group. One synthetic cycle consisted of the following steps: 1) DCM wash,

* For the im-benzyl-L-His and nitro-L-arginine cycles, step 8 was deleted, and DMF was substituted for DCM in steps 9–11.
1 minute, × 3; 2) deprotection with 50% TFA/DCM wash, 1 minute prewash + 20 minutes; 3) DCM wash, 1 minute, × 6; 4) neutralization with 5% iPr2EtN/DCM wash, 1 minute, × 3; 5) DCM wash, 1 minute, × 6; 6) performed symmetric anhydride coupling in DCM (4 eq.), 60 minutes; 7) DCM wash, 1 minute, × 6; 8) neutralization with 5% iPr2EtN/DCM wash, 1 minute, × 3; 9) DCM wash, 1 minute, × 6; and 10) repeat steps 6 and 7).

After the completion of the peptide assemblies, the final deprotection and cleavage of the peptide was done in a Teflon vessel using the HF procedure (80). The crude peptide was then purified by preparative HPLC using C-18 column, the eluant from the major peak was collected and desalted on Sephadex G-10, thereby obtaining pure synthetic glucagon with 48% overall yield.

The following 29 cycles of coupling were completed by using the HF procedure (94). Three grams of N-\text{Boc}-A\text{la esterified to 8 grams of the supporting cross-linked polystyrene resin. The shorter time was adequate for complete debenzylation of His and Cys and complete detosylation of Arg. The deprotected triacontapeptide was converted to the S-sulfonate. On electrophoresis, a major Pauly-positive spot existed with the same mobility as that of the B-chain S-sulfonate (BSSO₃) obtained by sulfidolysis of natural bovine insulin, and a minor contaminant probably caused by B₁-27. The overall yield from the first A₁a residue was 21%.

The A₁ chain was synthesized by the automated solid-phase procedure (94). Three grams of N-\text{Boc}-A₁a resin was carried through 20 reaction cycles as described for the B chain except that the reagents used for all deprotection and neutralization steps were 4 M HCl in dry dioxane and triethylamine in CHCl₃, respectively (95). The peptide was cleaved from the resin as described above (yield, 69%). The total time required was 8 days. The S-benzyl protecting groups were removed by treatment with sodium in liquid ammonia as described by Niu et al. (93), except that the stable light blue end point was limited to exactly 15 seconds to prevent excessive cleavage of the Thr–Pro bond. Under these conditions, this cleavage was only 20–25%, whereas 80% was lost during a 60-second treatment. The shorter time was adequate for complete debenzylation of His and Cys and complete detosylation of Arg. The deprotected triacontapeptide was converted to the S-sulfonate. On electrophoresis, a major Pauly-positive spot existed with the same mobility as that of the B-chain S-sulfonate (BSSO₃) obtained by sulfidolysis of natural bovine insulin, and a minor contaminant probably caused by B₁-27. The overall yield from the first A₁a residue was 21%.

After the completion of the peptide assembly, the final deprotection and cleavage of the peptide was done in a Teflon vessel using the HF procedure (80). The crude peptide was then purified by preparative HPLC using C-18 column, the eluant from the major peak was collected and desalted on Sephadex G-10, thereby obtaining pure synthetic glucagon with 48% overall yield.

Insulin
Insulin is a polypeptide hormone produced by β-cells of the pancreas; it contains two disulfide bonded peptide chains: an A chain of 21 residues and an intra-disulfide bridge and a B chain of 30 amino acids. Insulin is well known for regulating carbohydrate metabolism as well as increasing glucose uptake and utilization.

The structure of insulin is shown in Fig. 11. Insulin became one of the most demanded drugs after finding its power to treat Type 1 diabetes in the 1920s. However, it was thought almost impossible to be chemically synthesized at that time after the structure was elucidated by Sanger in 1955 because it involved three disulfide bridges, complicated higher-level structures, and so on. But these complications did not stop it from becoming one of the hottest targets for synthetic chemists. Several independent syntheses of insulin have been reported in the 1960s (89–91) using classic peptide-synthesis methods, which usually required several months to finish, and yields were low. Merrifield et al. (92) reported a fast and efficient synthesis later on by employing solid-phase peptide synthesis technique that only took several days with good yields. N-\text{Boc} chemistry was used for the synthesis. The assembling of the fully protected insulin B chain started with 1.9 mmol of N-\text{Boc}-A₁a esterified to 8 grams of the supporting cross-linked polystyrene resin. The following 29 cycles of coupling were completed by using the symmetric anhydride method and DCC as the coupling reagent. The side-chain protections were as follows: Glu, Cys, Ser, Tyr, and His were protected by Bn groups; Lys by a Cbz group; Arg by a Tos group. Cleavage of the peptide from the resin was done by firstly bubbling HBr through a liquid ammonia as described above (yield, 69%). The total time required was 8 days. The S-benzyl protecting groups were removed by treatment with sodium in liquid ammonia (96), and the four cysteine residues were converted to the S-sulfonate (A5SO₃⁺) (over all yield, 37%).

The synthetic A- and B-chain sulfonates (ASSO₃ and BSSO₃) were combined with each other and with the complementary natural chains. The mixtures were first reduced to the thiol derivatives with thioglycolic acid at 25 °C by a modification of the method of Du and colleagues (93, 97, 98). The reduced chains were precipitated together at pH 3.8, washed, and then oxidized in air at pH 10.0 to form insulin. The molar ratio of ASSO₃:BSSO₃ at the beginning of reductions was 4:1. The reduced insulin preparations appeared as Pauly-positive spots with the same mobility as standard bovine insulin, and both synthetic insulin preparations appeared as Pauly-positive spots with the same mobility as bovine insulin.

Pancreatic polypeptide
Pancreatic polypeptide is a peptide hormone secreted by pancreatic polypeptide-producing cells in the islets of Langerhans.

![Figure 11](image-url) The structure of insulin.
in the pancreas. It consists of 36 amino acids and has a molecular weight about 4200 Da. It suppresses the pancreatic secretion and stimulates gastric secretion.

The sequence of human pancreatic polypeptide (hPP) is as follows: Ala-Leu-Glu-Pro-Pro-Tyr-Pro-Gly-Asp-Asn-Ala-Thr-Pro-Glu-Gln-Met-Ala-Gln-Tyr-Ala-Ala-Asp-Leu-Arg-Arg-Tyr-Ile-Asp-Met-Leu-Thr-Arg-Pro-Arg-Tyr-NH₂

Regular solid-phase synthesis of hPP has been reported by Meyers and Czy (99). The peptide was assembled on BHA resin using N-BOC chemistry. Amino acids were coupled as symmetric anhydrides with DIC except for Asn and Gln, which were coupled as HOBT ester. The side-chain protections were as follows: Ser and Thr were protected by Bn groups; Glu and Asp by C1-Bn groups; Arg by a Tos group; Tyr by a 2-Br-Cbz group.

Deprotection of the N-BOC groups was done via treatment with 25% and 50% TFA in DCM. Couplings were monitored by the ninhydrin test, and they were repeated if not complete after 1 hour (refer to the sections on "Motilin synthesis" and "Secretin synthesis" for details). Free amino group found after double couplings were acetylated by acetylimidazole in DCM. After completing the synthesis, the peptide resin was treated with HF in the presence of 37% TFA to deprotect the resin and precipitate the peptide. The resulting peptide material was purified on a column of Sephadex G-50, which was followed by a column of CM-cellulose; fractions from the major peak were collected and lyophilized. The resulting peptide material was purified on a column of Sephadex G-25, which was followed by a column of CM-cellulose; fractions from the major peak were collected and lyophilized. The resulting peptide material was purified on a column of Dowex 1-X4 (acetate form), lyophilized, followed by chromatography on Sephadex G-10 in 1 N acetic acid in which only one peak of 346 mg peptide material was obtained. It was then applied on a column of Dowex 1-X4 (acetate form), lyophilized, followed by chromatography on Sephadex G-10 in 1 N acetic acid in which only one peak of 346 mg peptide material was obtained. It was then

Tyr-Ile-Asp-Met-Leu-Thr-Arg-Pro-Arg-Tyr-NH₂

Naturally Occurring Peptide Hormones and Neurotransmitters. Synthesis of

Adrenocorticotropic hormone (ACTH)

ACTH is a 39-amino acids polypeptide hormone cleaved from a precursor peptide called pro-opiomelanocortin, which is released from corticotropic cells of the anterior pituitary gland. ACTH acts through the stimulation of cell surface ACTH receptors, which are primarily located on the adrenocortical cells. It stimulates the cortex of the adrenal gland and increases the synthesis of corticosteroids. ACTH is also related to the circadian rhythm in many organisms.

The sequence of human ACTH is as follows: Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val-Gly-Lys-Lys-Arg-Pro-Val-Lys-Val-Tyr-Pro-Asn-Gly-Ala-Glu-Asp-Glu-Ser-Ala-Glu-Ala-Phe-Pro-Leu-Glu-Phe-OH.

The total synthesis of ACTH attracted many researchers in the 1960s and 1970s. Schwyzer and Sieber (100) first synthesized porcine ACTH by using a conventional solution-phase peptide synthesis method. After the development of solid-phase synthesis by Merrifield (92), Yamashiro and Li (101) extended the scope of how to prepare this important biomolecule. N-BOC chemistry was used throughout Yamashiro and Li’s synthesis. The remaining 37 cycles of couplings were accomplished by using a regular DCC coupling procedure, except that the deprotection of the Trp N-BOC group was achieved by treating with 25% TFA in DCM for 30 minutes followed by treating with 50% reagent for 6 minutes. The side-chain protections were as follows: Asp, Ser and Glu were protected by Bn groups; His by a Boc group; Arg by a Tos group; Lys by a 2-Br-Cbz group; Tyr by a 2,6-Cl-Bn group (refer to the sections on “Somatostatin synthesis” and “Angiotensin II synthesis" for details). After completing the synthesis, a portion (1.00 g) of the peptide resin was cleaved and deprotected with HF in the presence of anisole. The resulting peptide material was purified on a column of Dowex 1-X4 (acetate form), lyophilized, followed by chromatography on Sephadex G-10 in 1 N acetic acid in which only one peak of 346 mg peptide material was obtained. It was then

Figure 12 Carboxymethylcellulose chromatography of crude synthetic ACTH. Taken from Yamashiro et al. (101).
subjected to gel filtration on Sephadex G-25, which gave a major peak of 202-mg peptide material. The material was treated with dithiothreitol in 0.1 N acetic acid for 21 hours at 50°C to convert any Met-sulfoxide to Met and then chromatographed on carboxymethylcellulose (Fig. 12) to give a major peak of 68-mg peptide material, which was very similar to that of the natural ACTH. This 32 mg of the purified material was purified even more by partition chromatography on Sephadex G-50 with a solvent system of 1-butanol/pyridine:0.1% aqueous acetic acid (5:3:11) to give 12-mg highly purified synthetic hACTH with almost the same RF as natural hACTH (Fig. 13).

Melanocyte-stimulating hormones (melanotropins, MSHs)

MSHs consist of three peptide hormones: α-MSH, β-MSH, and γ-MSH, which are secreted by intermediate lobe of the pituitary gland. They are cleaved from the same precursor peptide as ACTH. Their basic function is stimulation of melanocytes to darken skin and stimulation of melanin synthesis to darken the skin and hair. They also have been found to be released in the brain affecting appetite, sexual arousal, and many other functions.

The sequence of α-MSH is as follows: N\(^{-}\)Acetyl-Ser-Tyr-Ser-Met-Glu-His-Phe-Arg-Trp-Gly-Lys-Pro-Val NH\(_2\).

The sequence of human β-MSH is as follows: Ala-Glu-Lys-Asp-Glu-Gly-Lys-Pro-Tyr-Arg-Met-Glu-His-Phe-Arg-Trp-Gly-Ser-Pro-Pro-Lys-Acetyl-OH.

The sequence of porcine β-MSH is as follows: Asp-Glu-Gly-Pro-Tyr-Lys-Met-Glu-His-Phe-Arg-Trp-Gly-Ser-Pro-Pro-Lys-Acetyl-OH.

The sequence of γ-MSH is as follows: Tyr-Val-Met-Gly-His-Phe-Arg-Trp-Asp-Arg-Phe-Gly-OH.

Solid-phase synthesis of α-β-MSH were achieved in our group in 1980 (103), both using N\(^{-}\)Boc chemistry. In the preparation of α-MSH, amino acids were coupled successively to valine-\(\text{BHA}\) resin with threefold excess of N\(^{-}\)Boc amino acid and 2.4-fold excess of DCC in 1-15 hours. Removal of the N\(^{-}\)Boc protecting group was achieved by a treatment of 45% TFA in DCM that contained 2% anisole. The side-chain protections were as follows: Ser and Asp were protected by Bn group, Tyr by a 2,6-Cl-Bn group; Lys by a 2,6-Cl-Cl2 group; Arg and His by Tos groups; Trp by a For group. After completing all coupling cycles, the amino terminal end of the peptide was acetylated with threefold excess of N\(^{-}\) acetylimidazole (refer to the sections on "Motilin synthesis" and "Secretin synthesis" for details). The peptide was cleaved from the resin, and all protecting groups were removed with anhydrous liquid HF with the exception of the For group on Trp. The residue was purified by gel filtration on Sephadex G-35, followed by deacylation with 4N NaOH at pH 11.5 for 3 minutes. The reaction was quenched by additional glacial AcOH to a final pH of 4.5. Cation exchange chromatography was used for the purification of α-MSH, followed by gel filtration on Sephadex G-25. Porcine β-MSH was prepared similarly but on Asp-Merrifield resin.

The total synthesis of γ-MSH was reported by Ling et al. (104). N\(^{-}\)Boc chemistry was used for the synthesis. The coupling was started from loading N\(^{-}\)Boc-Gly to the Merrifield resin. The rest of the amino acids were coupled subsequently to the resin using DCC as coupling reagent for 1 or 2 hours, except 8 hours for Asn, which was coupled as Np ester. After each coupling was done, the unreacted amino group was blocked by acetylation with Ac\(_2\)O. Peptide was cleaved and deprotected by a treatment of HF with presence of anisole and p-methoxyethyl sulfide. The residue was purified by cation-exchange chromatography on CM-32 carboxymethyl cellulose and followed by gel filtration on Sephadex G-25. The overall yield of the synthesis was 10.3%.

Oxytocin

Oxytocin holds a special place in the development of modern hormone and neurotransmitter chemistry and biology. It was the first peptide hormone (neurotransmitter) to be isolated, its structure determined, and prepared by total synthesis. Oxytocin is a 9-amino-acid poly peptide made in magnocellular neurosecretory cells of the hypothalamus, and is released into the blood from the posterior lobe of the pituitary gland. It causes uterine contraction and milk ejection in lactating women as well as facilitates birth and breastfeeding. It is also involved in social recognition and bonding, aspects of sexual function, and might be involved in the formation of trust between people.
The sequence of oxytocin is as follows: c(Cys-Tyr-Ile-Glu-Asp-Cys)-Pro-Leu-Gly-NH₂. The synthesis of oxytocin has drawn significant interest to chemists. It was first made by du Vigneaud et al. (105, 106), and many other syntheses have been reported since then in 1950s, 1960s, and beyond. One of the most high-yield and rapid syntheses was done by Manning (107). The protected nonapeptide was synthesized in a stepwise manner using N-Boc chemistry. The symmetric anhydride method was used for the couplings, and DCC was the coupling reagent, except that Asn and Gin were coupled as their p-nitrophenyl esters. The side-chain protections were as follows: Trp and Cys were protected by Bn groups. Final Cys was coupled as N-benzylcarbonyl-S-benzyl derivative. After completing the synthesis, the dried resin was weighed, giving a yield of 81%. The protected nonapeptide was cleaved from the resin by ammonolysis, which was achieved by suspending the resin in anhydrous methanol and bubbling with a stream of ammonia from a refluxing solution of dry ammonia for 2.5 hours, at 4°C for overnight, and at 23°C for 2 hours. The overall yield of the protected nonapeptide was 59% based on the amount of Gly originally esterified to the resin. Sodium and liquid-ammonia reduction was used to remove the Bn protecting groups on Cys and Tyr and the disulfide bond was formed by K₂Fe(CN)₆ oxidation (108). The residue was then purified by gel filtration on Sephadex G-15, and the pure oxytocin was obtained in an overall yield of 27%.

Vasopressin

The presence of vasopressin has been known for more than 100 years when people found pressor activity in extracts of the posterior lobe of the pituitary gland (109). However, it took almost a half-century before du Vigneaud and his colleagues figured out what it is (110, 111). Aagine vasopressin is a 9-amino-acid human hormone that is responsible of reducing plasma volume and increasing plasma osmolality by inducing the kidneys to conserve water.

The sequence of arginine vasopressin (porcine) is as follows: c(Cys-Tyr-Phe-Glu-Asp-Cys)-Pro-Arg-Gly-NH₂. The sequence of oxytocin is as follows: c(Cys-Tyr-Ile-Glu-Asp-Cys)-Pro-Leu-Gly-NH₂. The structure of human relaxin is shown in Fig. 14. Tregear and colleagues (115–119) have done many studies on the synthesis of relaxin, but results were mainly published in meeting papers, which do not provide synthetic details. An interesting total synthesis of human relaxin was reported by Bülesbach and Schwabe (120). The highlight of this synthesis was their use of cysteine-protecting groups in the selective synthesis of the three disulfide links. The most stable disulfide link, the intrachain disulfide loop between A10 and A15, was synthesized first. The liberation of the cysteine side chain in position A24 and the subsequent thiolysis of the S-activated cysteine in position B23 directed the formation of the interchain disulfide bond A24-B23. The third disulfide bond was formed by oxidative removal of the corresponding protecting groups in positions A11 and B11.

N-\textsuperscript{Fmoc} solid-phase chemistry was used for the synthesis of the K chain. HM P resin was selected as solid support, and standard DCC/HOBt coupling protocol was used to elongate the peptide chain. The side-chain protections were as follows: Glu, Asp, Tyr, Ser, and Thr were protected by iBu groups; His by a Trt group; Lys by a Boc group; Arg by a Fmoc group. The Cys side chains were protected by S-Trt groups in positions A10 and A15, by an Acm group in A11, and by a methyl-Bn group in A24. Deprotection of the N-\textsuperscript{Fmoc} groups was done in 20% piperidine in DMF. After finishing the peptide chains synthesis, the peptide was cleaved from resin and deprotected with TFA, using thiophenol as a scavenger to yield an A chain with two free thiol groups (A10, A15) and two differently...
protected cysteines. The formation of the intrachain disulfide loop was achieved by titration with iodine in 50% acetic acid. After purification with HPLC, the chain was stored in this form and the methyl-Bn group was removed prior to reaction with the corresponding B chain by HF, and the resulting A chain that contains one thiol group (A24), one disulfide link (A10/A15), and one Ac group (A12) was about 95% pure. The B chain was synthesized using N-Boc chemistry. PM resin was used as the solid support, and standard DCC/HOBt coupling protocol was used to elongate the peptide chain. The side chain protections were as follows: Glu, Ser, Thr, and Asp were protected by Bn groups; Arg by a Tos group, Lys by a Cl-Cbz group, Trp by a For group; Met was protected as a sulfoxide (refer to the section on "Glucagon’s synthesis"

details). Cys was protected by an Acm group in position B11 and by a 2-nitropyridinesulphonyl group in position B23. After completing the synthesis, the peptide was cleaved and partially deprotected with HF, followed by purification on Sephadex G-50. Trp(formyl) and Cys(Nou) remained untouched.

The formation of the interchain disulfide link A24/B23 was achieved in 8 M guanidinium chloride at pH 4.5 using monothiol-A chain and thiol-activated B chain in a molar ratio of 1:1.3 for 24 hours at 37 °C. The third disulfide bond was synthesized by oxidation with iodine in aqueous AOH. Final deprotection of the partially protected relaxin was achieved by reducing Met-sulfoxide in aqueous TFA that contained NH₄I for 24 hours at 37 °C. Met sulfoxide was also reduced during the cleavage (as Met was oxidized during the synthesis). The deprotected crude peptide was then oxidized with trans-[P(η5-C₅H₅)₂Cr₂]²⁺ to form the intramolecular disulfide bond and to obtain human calcitonin.

Calcitonin gene-related peptide (CGRP)

Human CGRP (hCGRP) is a 37-residue polypeptide isolated by Morris et al. (127) from human medullary thyroid carcinoma. It acts as a vasodilator and stimulates the formation of cAMP. The sequence of hCGRP is as follows: Ala-c(Cys-Asp-Thr-AlaThr-Cys)-Val-Thr-His-Arg-Leu-Ala-Gly-Leu-Leu-Ser-Arg-Ser-Gly-Gly-Val-Val-Lys-Ala-Asn-Phe-Val-Pro-Thr-Asn-Val-Gly-Ser-Ser-Lys-Ala-Phe-NH₂.

The peptide has been made using a conventional solution-phase method (128). Improved synthesis on solid support has been reported later by Smith et al. (129), who have prepared hCGRP using N-Boc chemistry and MBHA resin as solid support. All amino acids were coupled as HOBT active ester by using DCC/HOBt, the deprotection of the N-Boc groups was done by treating with 30% TFA in DCM. The side-chain protections were as follows: Asp, Thr, and Ser were protected by Bn groups; His by a Bom group; Arg by a mesitylene-2-sulfonyl group; Lys by a 2-CI-Cbz group. When the coupling yield was greater than 99%, the unreacted amino groups were acetylated with Ac₂O; when the yield was lower than 99%, another coupling cycle was performed before acetylation (refer to the section on "Corticotropin-releasing factor synthesis" for details). After completing the synthesis, the peptide was cleaved with TFA, and the disulfide bond was formed by oxidation with K₂FeCN₅ in NH₄OAc solution. The crude hCGRP was purified by gel filtration on a column of Bio-Gel P-6, followed by ion-exchange column chromatography on CM-Sephadex C25. Fractions that correspond to the hCGRP were collected and lyophilized, and final purification was achieved on HPLC using a Vydac C18 semi preparative column, obtaining pure hCGRP with 4.4% overall yield.

Peptide Neurotransmitters

Opioids

Dynorphin

Dynorphins are a class of endogenous opioid peptides produced by many different populations of neurons. They function primarily as µ- and δ-opioid receptor agonists; therefore, they may act as antidepressants in the brain. However, they also have µ- and δ-opioid receptor agonist activities. Dynorphin A, which is a 17-residue peptide, and Dynorphin B, which is a 13-residue peptide, are found in nature.

The sequence of dynorphin A (1-17) is as follows: Tyr-Gly-Gly-Phe-Leu-Arg-Leu-Arg-Pro-Lys-Leu-Lys-Tyr-Arg-Asp-Asn-Gln-OH.

The sequence of dynorphin B (1-13) is as follows: Tyr-Gly-Gly-Phe-Leu-Arg-Leu-Arg-Pro-Lys-Leu-Lys-Tyr-Arg-Asp-Asn-Gln.

Dynorphin A with a diiodotyrosine at position 1 was synthesized by using N-Boc solid-phase chemistry (130), and many other syntheses of the peptide and its analogs also were reported. An optimized N-Boc chemistry synthesis method by Lemr (131) achieved a 94% yield.
of [8-Ala]-dynorphin, which is a dynorphin-A analog particularly potent in an opiate receptor-binding assay (131), was reported by Solé and Barany (132). Fmoc-PAL-Nle-MBHA resin was selected as the solid support, which has a tris(alkoxy)-benzylamide linker that acts as side-chain anchor to prevent alkylation of the deprotected protecting groups to the peptide residues such as Cys, Met, Tyr, and Trp. Coupling was achieved by using DIC/HOBt as the coupling reagent, and the deprotection of the N'-Fmoc groups was done by treatment with 20% piperidine in DME. After completing the synthesis, several cleavage cocktails were tried, and the best one turned out to be TFA with phenol, water, and trisopropylsilane (88:5:5:2), which gave more than 95% cleavage yield. The crude peptide was then purified by RP-HPLC, giving pure [8-Ala]-dynorphin A in 58% overall yield.

Synthesis of dynorphin B also has been reported by using fragment condensation in solution-phase (133).

Endorphin

Endorphins are endogenous opioid peptides produced by the pituitary gland and the hypothalamus in vertebrates. They are known as "natural pain killers" because of their analgesic effect. The best-known endorphins are α-, β-, and γ-endorphin, of which β-endorphin seems to be most implicated in pain relief.

The sequence of β-endorphin is as follows: Tyr-Gly-Gly-Phe-Leu-OH.

The sequence of human α-endorphin is as follows: Tyr-Gly-Phe-Met-Thr-Ser-Glu-Ser-Gln-Thr-Pro-Leu-Val-Thr-Leu-OH.

The sequence of γ-endorphin is as follows: Tyr-Gly-Phe-Met-Thr-Ser-Glu-Lys-Ser-Gln-Thr-Pro-Leu-Val-Thr-Leu-Phe-Lys-Ala-Ile-Ile-Lys-Ala-Tyr-Lys-Gly-Glu-OH.

Many syntheses of β-endorphin have been achieved in the past, either in solution or on solid-phase. For example, an N'-Fmoc synthesis on solid-phase was reported by Atherton et al. (134). p-Alkoxybenzyl ester resin was selected as the solid support; coupling was done by using the symmetric anhydride and HOBt active ester method, except that Asn and Gin were coupled as p-nitrophényl esters. The N'-Fmoc groups were deprotected by 20% piperidine in DMF. After completing the synthesis, the peptide was cleaved from the resin, and the side-chain protection groups were removed with anhydrous TFA in the presence of excess Met. The peptide was purified by CM-S2 chromatography, with an overall yield of 43%.

α-γ-Ly-Endorphin have been synthetically prepared by Ling (135). An N'-Boc strategy was used for the synthesis. In the case of α-endorphin, N'-Boc-Thr(ΩBn) was loaded on a chloromethyl-resin. The rest of the amino acids were coupled to the resin by using DCC as coupling reagent, and the deprotection of the N'-Boc groups was done using 50% TFA in DCM. After incorporation of the Met, the TFA deprotection step was modified with the inclusion of 5% 1,2-ethanediol. The side-chain protections were as follows: Thr, Ser, and Gin were protected by Bn groups; Tyr by a 2,6-C1-Bn group, Lys by a 2-C1-Cbz group. After the completion of the chain elongation, the peptide was cleaved by HF with 10% anisole at -5°C. The crude peptide was purified by using a CM-32 carboxamidomethyl cellulose column first, followed by gel filtration on Sephadex G-25F column and partition chromatography on a Sephadex G-25F column. The pure α-endorphin was obtained with an 18% overall yield. γ-Endorphin was prepared in the same manner with a 30% overall yield.

Enkephalin

Enkephalins are endogenous opioid peptides that have analgesic effects. Met-enkephalin and Lys-enkephalin are found in nature, and they are pentapeptides that share the same first four residues.

The sequence of Leu-enkephalin is as follows: Tyr-Gly-Gly-Phe-Leu.

The sequence of human α-ENDorphin is as follows: Tyr-Gly-Phe-Met-Thr-Ser-Glu-Lys-Ser-Gln-Thr-Pro-Leu-Val-Thr-Leu-Phe-Lys-Ala-Ile-Ile-Lys-Ala-Tyr-Lys-Gly-Glu-OH.

Many syntheses of α- and β-endorphin have been reported. In addition, syntheses of these peptides have employed enzymatic methods, which could be done in low-water content systems on a preparative scale (138). N'-Cbz and N'-Boc protected Met-enkephalin and Leu-enkephalin were prepared by means of α-chymotrypsin, papain, thermolysin, and bromelain adsorbed on Celite. α-Chymotrypsin has a primary specificity for bulky and hydrophobic amino acids (Phe, Tyr, ...
Tripeptide Phe-Leu-Met, and it was selected for making the Tyr-Gly-Phe-Leu, and Phe-Met peptide bonds. Papain was selected for Gly-Gly and Gly-Phe peptide bonds. Bromelain is very similar to papain as far as its specificity. All these proteases are serine or cysteine type, and the peptide bond formation can be done under kinetically controlled conditions. Thermolysin is an aspartyl protease, and it was selected mainly for Phe-Leu and Gly-Phe bonds. MECN, EDTA, and metal caprate were used as solvents with a controlled amount of buffer or at fixed water amount.

The synthetic scheme is shown in Fig. 15 (138), which was based on 4 + 1 enzymatic fragment condensation. N -Cbz-Tyr-Gly-Gly-Phe-Leu-NH₂ and N -Boc-Tyr-Gly-Gly-Phe-Met-NH₂ were prepared in good yield.

**Leumorphin**

Leumorphin is a 29-amino-acid peptide first predicted by Yamanoto et al. (139, 140) when sequencing the cloned DNA complementary to porcine hypothalamic mRNA. They synthesized this peptide and found that it has potent opioid activity as predicted (140), and they also proved the existence of this peptide in humans (141).

The sequence of porcine leumorphin is as follows: Tyr-Gly-Gly-Phe-Leu-Arg-Ang-Gln-Phe-Lys-Val-Thr-Arg-Ser-Gln-Glu-Asp-Pro-Asn-Ala-Tyr-Tyr-Glu-Glu-Leu-Phe-Asp-Val-OH.

Portcine leumorphin was synthesized by a solid-phase technique with N -Boc strategy. The peptide chain was elongated on a chloromethylated resin with use of a peptide synthesizer (Beckman Model 990B). The side-chain protections were as follows: Asp, Glu, Thr, and Ser were protected by Bn groups; Tyr by a 2,6-Cl-Bn group; Lys by a 2-CI-Bz group; Arg by a Tos group. After the completion of the synthesis, the peptide was deprotected and cleaved from the resin with HF in the presence of anisole and ethane dithiol (refer to the sections on "Somatostatin synthesis" and "Angiotensin II synthesis" for details). The crude peptide was purified by gel chromatography on Sephadex G-10, followed by reverse-phase HPLC.

**Tachykinin**

Tachykinins are peptides characterized by the C -terminal amidated pentapeptide Phe-Gly-Leu-Met-NH₂

**Neurokinin A and B**

Neurokinin A and B are both decapeptides discovered by Kimura et al. (142) from the porcine spinal cord. Both have very similar amino acid composition and sequence homology to the mammalian mammalian bombesin as it has an identical C- terminal decapeptide with the exception of one residue as bombesin, which gives GRP similar biological activity as bombesin. It lowers body temperature and increases plasma levels of epinephrine and glucose (148).

The sequence of GRP is as follows: Ala-Pro-Val-Ser-Val-Gly-Gly-Gly-Thr-Leu-Ala-Lys-Tyr-Pro-Arg-Gly-Asn-His-Trp-Ala-Val-Gly-His-Leu-Met-NH₂.

Synthesis of this peptide has been achieved by Matki et al. (149). N -Boc solid-phase synthesis techniques were employed, and MBHA resin was selected as the solid support. All the amino acids were coupled as symmetric anhydrides using DCC as the coupling reagent except for Asn, which was coupled as N -Boc-Asn-OPfp ester with HOBt. After completing each residue for one or two coupling cycles, unreacted amino groups were acetylated. The side-chain protections were as follows: His and Arg were protected by Tos groups, Thr and Ser by Bn groups; Tyr by a 2,6-Cl-Bz group; Lys by a Cl-Cbz group. After the completion of the synthesis, the crude peptide was cleaved from the resin and the side-chain protection groups were deprotected by treating with HF (refer to the section on "Corticotropin-releasing factor synthesis" for details). Gel filtration on Sephaose G-25 was applied as the first purification of the peptide, followed by semi-preparative reverse phase HPLC and lyophilization to give the TFA-peptide salt in a 5% overall yield.

**Neurotensin**

Neurotensin is a tripeptide discovered by Carraway and Leeman (150) from bovine hypothalam in 1973. Neurotensin is distributed mainly in the central nervous system and in some regions of the digestive tract in various mammals. It has a broad spectrum of biological activities, including kinin activities such as a solid support, and the amino acids were coupled to the resin using the symmetric anhydride method; DCC was the coupling reagent. The side-chain protections were as follows: Asp, Ser, and Thr were protected by Bz groups; His by a Tos group; Lys by a C-Cbz group (refer to the sections on "Motilin synthesis" and "Secretin synthesis" for details). After the completion of the synthesis, the peptide was cleaved and deprotected by HF, and the crude peptide was purified by gel filtration on Sephaose G-25. HPLC elution was applied as the second purification, and followed by desalting on a column of Sephaose G-10, obtaining more than 98% pure peptides.

**Eledoisin, physalaemin, and kassinin**

These peptides have only been reported and prepared by traditional solution-phase synthesis (144–146). However, because their structures are not complicated, they can be readily prepared by modern solid-phase techniques.

**Others**

**Gastrin-releasing peptide (GRP)**

Gastrin-releasing peptide is a 27-amino acid-containing peptide first isolated and sequenced by McDonald et al. (147) from porcine gastric mucosa. As the name itself implies, it stimulates the release of gastrin from gastric mucosa. It is also called mammalian bombesin as it has a similar biological activity as bombein, which gives GRP similar biological activity as bombesin. It lowers body temperature and increases plasma levels of epinephrine and glucose (148).

The sequence of GRP is as follows: Ala-Pro-Val-Ser-Val-Gly-Gly-Gly-Thr-Leu-Ala-Lys-Tyr-Pro-Arg-Gly-Asn-His-Trp-Ala-Val-Gly-His-Leu-Met-NH₂.

Synthesis of this peptide has been achieved by Matki et al. (149). N -Boc solid-phase synthesis techniques were employed, and MBHA resin was selected as the solid support. All the amino acids were coupled as symmetric anhydrides using DCC as the coupling reagent except for Asn, which was coupled as N -Boc-Asn-OPfp ester with HOBt. After completing each residue for one or two coupling cycles, unreacted amino groups were acetylated. The side-chain protections were as follows: His and Arg were protected by Tos groups, Thr and Ser by Bn groups; Tyr by a 2,6-Cl-Bn group; Lys by a Cl-Cbz group. After the completion of the synthesis, the crude peptide was cleaved from the resin and the side-chain protection groups were deprotected by treating with HF (refer to the section on "Corticotropin-releasing factor synthesis" for details). Gel filtration on Sephaose G-25 was applied as the first purification of the peptide, followed by semi-preparative reverse phase HPLC and lyophilization to give the TFA-peptide salt in a 5% overall yield.

**Neurotensin**

Neurotensin is a tripeptide discovered by Carraway and Leeman (150) from bovine hypothalam in 1973. Neurotensin is distributed mainly in the central nervous system and in some regions of the digestive tract in various mammals. It has a broad spectrum of biological activities, including kinin activities such
as inducing hypotension, contraction of ileum and uterus, and relaxation of the duodenum; it also can cause a rapid increase of glucose levels in blood.

The sequence of neurotensin is as follows: Glu-Leu-Tyr-Glu-Asn-Lys-Pro-Arg-Pro-Tyr-Ile-Leu-OH.

Carrawy and Leeman also sequenced (151) and synthesized (152) this peptide. Standard solid-phase synthesis using N-\textit{Boc} chemistry was employed for the synthesis, and the Merrifield chloromethylated resin was selected as the solid support. Amino acids were coupled as symmetric anhydrides using DCC as the coupling reagent, except that Asn and Gln were coupled as \textit{p}-nitrophenyl esters. The side-chain protections were as follows: Glu and Tyr were protected by Bn groups; Lys by a \textit{Boc} group; Arg by a \textit{NO2} group. The deprotection of the N-\textit{Boc} groups was achieved by 50% TFA in DCM. After completing the synthesis, the peptide was cleaved and partially deprotected by treatment with HBr-TFA, and the remaining NO2 group was removed by hydrogenation (refer to the sections on "Somatostatin synthesis" and "Angiotensin II synthesis" for details). The crude peptide was first purified on Sephadex LH-20 column, followed by cation exchange chromatography on sulfoethyl-Sephadex column. Pure neurotensin was obtained with 7% overall yield.

**Bradykinin**

Bradykinin is a 9-residue peptide discovered by Silva et al. (153). It is found to be a potent endothelium-dependent vasodilator, to cause contraction of nonvascular smooth muscle, and to increase vascular permeability; it also is involved in the mechanism of pain.

The sequence of bradykinin is as follows: Arg-Pro-Pro-Gly-Asp-Val-Pro-Phe-Arg-Asp. Bradykinin has been prepared synthetically many times in the 1960s (154-156). The first solid-phase synthesis was achieved by Merrifield (157) using N-\textit{Boc} chemistry. More recent modifications of bradykinin synthesis were reported by Khar et al. (158), who also used N-\textit{Boc} solid-phase synthesis technique. Amino acids were coupled as active esters to the preloaded N-\textit{Boc}-Arg(\textit{NO2})-OCH2-resin. Phe and Gly were coupled as O-Tcp esters, Pro was coupled as O-Pro ester, and Ser was coupled as an O-N\textit{Ns}u ester. The side-chain protections were as follows: Ser was protected by a Bn group, Arg by a \textit{NO2} group. After completing the synthesis and before removing the last N-\textit{Boc} protecting group, the peptide resin was submitted to hydrogenation using Pd(OAc)2 as catalyst, which resulted in only the N-\textit{Boc} protected crude peptide. Deprotection of the N-\textit{Boc} groups with TFA followed by purification on carboxymethyl-cellulose column gave bradykinin in 20% overall yield.

**Summary and Conclusions**

The total synthesis of peptide natural products, especially hormones and neurotransmitters, is a highly developed area of organic synthesis. A plethora of peptides with numerous \(\beta\)-substituted amino acids, highly constrained peptides, highly hydrophobic peptides, and \(\text{N}-\text{alkyl substituted amino acids can present synthetically challenging, numerous synthetic strategies have been developed to overcome these problems. Furthermore, despite all the mythology about the applications of peptides as drugs for a wide variety of diseases, peptide drugs are becoming increasingly important in medicine because of their general lack of toxicity and their high efficacy especially for hormones and neurotransmitters. These trends are likely to accelerate into the future as numerous alternative methods of drug delivery are developed and optimized even more. This trend will be especially true for hormones and neurotransmitters, in which oral delivery is often a very poor choice for numerous reasons. Furthermore, the cost of peptide synthesis has decreased dramatically in recent years, and several companies have been developing increasingly efficient syntheses of peptides for use as pharmaceutical reagents in up to metric ton quantities.**

**As outlined in this article, several very effective solution- and solid-phase synthetic methods have been developed for the total synthesis of peptides. We have covered most synthetic strategies and tactics that have been developed and found to be useful. In general, successful peptide synthesis depends on careful attention to the details of the synthesis and careful analytical monitoring of the progress of the synthesis. If this care is taken, then successful synthesis of most peptides can readily be accomplished by a competent synthetic chemist.**

A detailed readings about peptide synthesis and its practical and mechanistic considerations can be found in many books, chapters in books and reviews. A good starting point for the interested person includes the items listed within the Further Reading section.

Oxygen-Activating Enzymes, Chemistry of

Corinna R. Hess*, Richard W. D. Welford* and Judith P. Klinman†, Departments of Chemistry and Molecular Cell Biology, University of California, Berkeley, California
doi: 10.1002/9780470048672.wecb431

Aerobic organisms derive the energy required for cellular processes from the conversion of dioxygen to water, which highlights the importance of dioxygen chemistry in biologic systems. The biochemistry of dioxygen is far from simple and has been the subject of intense study in a range of chemical and biologic disciplines. The reduction of dioxygen is energetically favorable; however, dioxygen is a ground state triplet, kinetically unreactive with singlet organic molecules. Nature has developed a diverse array of catalysts to overcome this kinetic barrier. These dioxygen-activating enzymes are divided into two classes: oxygenases and oxidases. Oxygenases incorporate directly at least one atom from dioxygen into the organic products of their reaction. Oxidases couple the reduction of dioxygen with the oxidation of substrate. Typically, enzymes that react with dioxygen contain transition metal ions and/or conjugated organic molecules as cofactors. The reaction with dioxygen is initiated by electron transfer from the cofactor to O₂. The subsequent chemistry varies depending on both the nature of the cofactor and the protein scaffold. Here we review the fascinating chemistry of the dioxygen-activating enzymes and identify some of the common strategies and themes that have emerged from over half a century of research.

Biological Background

The introduction of an oxygen-rich atmosphere led to the evolution of enzymes capable of exploiting this diatomic gas for a variety of different chemistries. Viewing life today, we can conclude that the use of dioxygen ultimately turned out to be advantageous. Dioxygen is required by all aerobic forms of life for a variety of chemical transformations and biological processes, which are catalyzed by a rich and diverse set of protein catalysts (1). In addition to its crucial function in the respiratory chain, dioxygen also is involved in biosynthesis, signaling, xeno-biotic metabolism, DNA repair, and biodegradation. However, a darker side exists to dioxygen biochemistry. The reactive oxygen species (ROS) formed by reduction of dioxygen species have been linked to several detrimental processes such as aging and cancer (2). These ROS can damage proteins, cell walls, and DNA. One key area of interest is how dioxygen-activating enzymes use ROS without damaging their own peptide backbone in the process.

Dioxygen Chemistry

The full four-electron, four-proton reduction of O₂ to two molecules of H₂O is strongly exothermic (Table 1). However, most redox processes involve sequential one or two-electron transfer pathways. The first electron transfer to dioxygen is the most difficult step (Table 1) because of the loss in O–O bond strength associated with formation of superoxide (3). Most organic molecules do not possess enough reducing power to facilitate this initial reduction, and as a consequence, their one-electron oxidation by dioxygen is thermodynamically unfavorable. Moreover, dioxygen is a triplet in its ground state, whereas most organic molecules possess singlet ground states. Consequently, the direct reaction of dioxygen with organic molecules necessitates a spin conversion to the singlet excited state of O₂, which has 22.5 kcal/mol more energy.
strength upon reduction of O$_2$. The rich spectroscopy associated with metal–oxygen bonds compensate partly for the loss of bond torsion present in dioxygen and its many reduced forms. The resultant active sites, such as Mn, have been documented. Metallocofactor electrons to yield the final enzymatic products. Dioxygen products are highly reactive and readily accept additional electrons to yield the final enzymatic products.

Cofactors used in Dioxygen Activation

Practically all known oxygen-activating enzymes employ a cofactor in the form of a metal center, a highly conjugated organic molecule, or both. Ultimately, the reactions involve the reduction of O$_2$ by two or four electrons to generate hydrogen peroxide or water. Metallocofactors and flavin molecules are powerful redox centers, able to overcome the large potential associated with the formation of superoxide (Table 1), and with comparatively stable one-electron oxidized forms. The activated dioxygen products are highly reactive and readily accept additional electrons to yield the final enzymatic products.

Dioxygen activation by metalloenzymes is dominated by Fe and Cu, although a few examples of other transition metal active sites, such as Mn, have been documented. Metallocofactors bind dioxygen and its many reduced forms. The resultant metal-oxygen bonds compensate partly for the loss of bond strength upon reduction of O$_2$. The rich spectroscopy associated with metal sites has advanced our understanding of the chemistry of dioxygen-activating enzymes. Methods such as electron paramagnetic resonance spectroscopy (EPR), X-ray absorption spectroscopy (XAS), and M$\text{O}$$\text{S}$bau have been used to obtain structural information regarding the metallocofactors at various stages in the catalytic mechanisms (4).

Dioxygen-activating enzymes can be categorized according to the type of cofactor(s) employed. Although similar types of cofactors can catalyze different reactions, common structural features and reaction intermediates often exist for a given type of cofactor, as discussed below.

Iron-containing motifs for dioxygen activation

Iron-containing proteins are classified as heme, mononuclear non-heme, and binuclear non-heme enzymes. The Fe center in heme proteins is ligated by four nitrogens of a porphyrin molecule, in addition to one or two axial ligands (Fig. 1a). The reaction of Fe$^{II}$ with O$_2$ generates an Fe$^{III}$-superoxide, in which the reduced O$_2$ is coordinated at an axial position of the heme unit in a bent, end-on fashion.

Mononuclear non-heme iron centers with several different types of coordination environments have been identified (5–6). The most prevalent coordination is an octahedral or square pyramidal site with a 2His-1carboxylate ligand set coordinated to one face of an Fe$^{II}$ center (Fig. 2a). In the resting state, the other positions are occupied by water molecules, which can be readily substituted during the reaction cycle by the substrate, the co-substrate, or O$_2$. A notable group of mononuclear non-heme iron enzymes activate their organic substrate for direct reaction with dioxygen. These enzymes contain an Fe$^{II}$, in which the coordination environment differs by subfamily. For example, intradiol dioxygenases contain a trigonal bipyramidal Fe$^{III}$ ligated by 2His, 2Tyr, and a hydroxide in the resting state (Fig. 3a). The active sites of binuclear non-heme enzymes consist of two Fe atoms, separated by 3–4 Å and bridged by O-atoms derived from hydroxide or carbonylate residues (Fig. 3b). The iron centers can adopt 4-, 5-, or 6-coordinate geometries, with the bridging ligands bound via one or two O-atoms. The remaining coordination sites are occupied by His and Asp/Glu residues.

The reactions of iron-containing enzymes with O$_2$ often involve high oxidation states of the metal. Generally, the initial reaction of dioxygen with both heme and mononuclear non-heme ferrous enzymes results in the formation of Fe$^{III}$-superoxide intermediates. Highly reactive Fe$^{IV}=O$ intermediates often are employed often for C–H activation. The mechanism of substrate oxidation by binuclear non-heme enzymes involves high valent, o xo-bridged species, with Fe in the +3 or +4 oxidation state.

Copper-containing motifs for dioxygen activation

The copper-containing enzymes can be classified as mononuclear, binuclear, or multicopper proteins (9). Unlike iron, copper cannot readily access high oxidation states and the formation of Cu$^{III}$ in biological systems remains controversial. Generally, Cu$^{II}$ centers undergo one-electron oxidations to activate dioxygen. Thus, the Cu-containing enzymes tend to employ multiple copper atoms or an additional cofactor for the final two or four-electron oxidation of their substrates.

Mononuclear copper enzymes capable of dioxygen activation contain a Type 2 copper center (Fig. 1b). Generally, Type 2 copper sites have a tetragonal geometry in the Cu$^{II}$ state and can be identified by their EPR spectra (10). Reduction of the Cu site is accompanied by a loss of water molecules and a change in coordination geometry; trigonal or tetrahedral geometries are common for Cu$^{II}$ (11). Dioxygen is thought to bind to the reduced copper site in an end-on or side-on fashion, to yield a Cu$^{II}$-superoxide intermediate.

A Type 3 active site, which consists of two antiferromagnetically coupled Cu atoms, ~3 Å apart, is found in binuclear copper enzymes (10). Each copper is coordinated by three histidine residues and by one or two water molecules that serve...
as $\eta^2$ bridging ligands (Fig. 1f). These enzymes all bind to O$_2$ in an $\eta^2$ fashion, where each O atom is bound by the two copper atoms. Each copper atom transfers one electron to dioxygen to yield a CuII$_2$-peroxide intermediate (for example, “oxy state” in Fig. 3g). Proteins with Type 3 copper centers include dioxygen transport and dioxygen-activating enzymes.

The multicopper enzymes contain a binuclear metal cluster that consists of a Type 2 copper site and a binuclear, Type 3 copper site (10). The Type 3 site of multicopper enzymes is distinct from the active site of the coupled binuclear copper enzymes described above. Although the Type 3 Cu centers are antiferromagnetically coupled, the centers are separated by ~ 5 Å and are bridged by a hydroxide ligand. The multicopper oxidases also contain at least one mononuclear, Type 1, blue copper site in addition to the binuclear Cu cluster. The Type 1 Cu site is ligated by two histidines, a cysteine, and often a weakly coordinating axial 4th ligand. Blue copper sites also are found commonly in electron transfer proteins and are defined by their intense Cys-to-metal charge-transfer transition at ~ 600 nm (11).

**Dioxygen activation by flavins**

A large group of enzymes react with O$_2$ by using an organic flavin cofactor (Fig. 1g) (12, 13). The reactions can be divided into two half-reactions. First the flavin is reduced by substrate, and then the reduced flavin reacts with an electron acceptor, such as dioxygen. When O$_2$ is the electron acceptor, the first step in the oxidative half-reaction is the rate-limiting electron transfer, which leads to the formation of a caged radical pair of superoxide anion and flavin semiquinone. The fate of the radical pair depends on whether the enzyme is an oxidase or an oxygenase and will be discussed below. The second-order reaction of a reduced free flavin with O$_2$ in solution proceeds at a rate of $2.5 \times 10^2$ M$^{-1}$ s$^{-1}$. For an enzyme-bound flavin, the rate can vary between 2 M$^{-1}$ s$^{-1}$ and 10$^6$ M$^{-1}$ s$^{-1}$. It is not fully understood how enzymes with extremely similar active sites can access such a range of rates for reaction with O$_2$.

The following sections describe specific examples of oxygenase and oxidase chemistry catalyzed by the cofactors described above. It is by no means an extensive list, but it should offer the reader a flavor of the diverse mechanisms of dioxygen activation by enzymes.
Oxygenases

The enzymes in this section can incorporate either one or two atoms from dioxygen into the organic product(s) of their reaction. It is of note that many oxygenases also can catalyze oxidation-like reactions, such as deamination and ring closure. Figure 2 illustrates the reactions catalyzed by some of these enzymes, whereas Figure 3 shows partial reaction mechanisms, including key intermediates.

Iron oxygenases

Heme-Fe: The cytochromes P450

The cytochromes P450 are some of the most well-studied oxygenases enzymes; their oxidation reactions, typically hydroxylation, are important for xenobiotic metabolism and biosynthesis (18, 19). Several notable differences exist between P450s, which catalyze oxygenations, and the O2 transport globins, which simply bind O2 reversibly. P450s have an axial cysteine thiolate iron ligand on the proximal side of the heme, whereas the transport globins have a histidine residue (20). Additionally, P450s have a conserved GX(E/D)T sequence motif on the distal side of the heme, which is thought to be involved in the proton donation required for cleavage of O2. In the resting state, the P450s contain a heme-ligated FeII. Typically, the electrons for the reduction of O2 are supplied by NADPH via protein redox partners. Extensive spectroscopic work has led to the observation of several of the peroxo intermediates involved in the conversion of the Fe–oxygen complex, FeIII–O–O, to the compound I + H2O (Fig. 3a). Most recently, elegant one-electron cryo-reduction and EPR spectroscopy allowed the detection of the FeII–O–O− and FeII–O–OH− intermediates. The loss of water from the latter generates the highly oxidizing compound I, which is believed to be an FeIV=O species with radical character localized on either the porphyrin ring or thiol ligand. Compound I can abstract a hydrogen atom from an organic substrate. The substrate radical combines rapidly with the iron-ligated hydroxyl in a "radical rebound" mechanism (21). Several facets of P450 catalysis are underlying themes for some other oxygenase enzymes.

Mononuclear non-heme oxygenases

The mononuclear, non-heme iron enzymes can be divided into subfamilies, which differ in the cosubstrate that provides the electrons for the reduction of O2 and the relative positions of the 2His-1Carboxylate residues in the protein sequence (7). Even among members of the same subfamily, the only conserved residues are the 2His-1Carboxylate, which indicates the use of this motif for activation of O2. Despite the conserved ligand set, the chemistry can vary greatly. In the reaction cycle of the a-ketoglutarate (a-KG) dependent subfamily, it is the a-KG co-substrate that ligates the Fe, whereas the prime substrate occupies a second sphere position. The counter substrate is observed for the extradiol catechol dioxygenases where the "prime" substrate ligates directly to the iron. The largest subfamily in the 2His-1Carboxylate group of non-heme FeII-dependent enzymes depends on a-KG as a co-substrate (6). The substrate binding is ordered. First a-KG ligates the FeII, then the prime substrate binds adjacent to the metal site, and finally O2 binds to the metal (Fig. 3b). The ternary complex reacts intramolecularly to yield the oxidizing species. This was characterized recently as an FeIV=O by Møssbauer, Raman, and EXAFS spectroscopy, which is the first enzymatic example of a non-heme FeIV (14). As with P450s, the FeIV=O is thought to be the oxidizing intermediate in a variety of reactions, including hydroxylation, desaturation, and oxidative ring closure (6). The multifaceted, highly controlled nature of this chemistry is exemplified brilliantly by the enzyme clavaminate acid synthase, which uses a single active site to catalyze a hydroxylation, desaturation, and a ring closure at different stages in a single biosynthetic pathway. The a-KG-dependent enzymes, like other oxygenases, can hydroxylate amino acid side chains in the vicinity of the active site under certain conditions (7). This illustrates the enzymes' need to control the oxidizing intermediate to minimize such deleterious side reactions. In fact, mammals are thought to require vitamin C for the reduction of FeIII, generated as a by-product of unproductive reaction cycles of a-KG enzymes.

The extradiol dioxygenases, similar to their intradiol counterparts, cleave aromatic compounds, but the position of ring opening differs (Fig. 2, 17). In the resting state, the extradiol dioxygenases contain a 2His-1Carboxylate, five-coordinate FeII. Bidentate binding of the catechol to the Fe activates the metal for O2 binding. This process is analogous to the a-KG enzymes.
Oxygen-Activating Enzymes, Chemistry of

*Figure 2* Some common reactions carried out by oxygenase enzymes. A * represents an oxygen atom derived from O₂. The reactions listed are those thought to be the enzyme’s biologically relevant reaction. Where appropriate the name of the enzyme catalyzing the example reaction is given.

except an additional substrate is not required to make the center five-coordinate. The Fe³⁺ superoxide formed on dioxygen binding can induce radical character in the catechol that leads eventually to ring opening.

Another subgroup of the 2His-1carboxylate family is dependent on a reduced pterin cofactor (5). They catalyze hydroxylations at the aromatic positions of amino acids in phenylalanine catabolism and hormone biosynthesis (*Fig. 2*). Unlike the α-KG-dependent enzymes, the pterin co-substrate does not ligate to the iron directly. In the reaction cycle, the pterin co-substrate supplies two electrons for the heterolysis of O₂ to give a yet to be characterized iron-oxygen hydroxylating species.

X-ray crystallography and magnetic circular dichroism spectroscopy have shown that, for the α-KG- and pterin-dependent mononuclear non-heme iron enzymes, the binding of the penultimate substrate promotes a change to a five-coordinate iron center. As with the P₄₅₀, this finding implies that dioxygen will not bind in the absence of an organic substrate, which prevents the build up of potentially damaging intermediates (23).

**Binuclear non-heme iron oxygenases**

Soluble methane monoxygenase (sMMO) is the best studied binuclear non-heme iron oxygenase enzyme, largely due to its remarkable ability to hydroxylate the stable C-H (440 kJ/mol) of methane (15). sMMO is a three-component enzyme system, which consists of the di-iron hydroxylating protein, a flavin-Fe⁵₇₃ protein, and a third regulatory protein that does not contain a cofactor. The role of the flavin-Fe⁵₇₃ protein is to provide two electrons from NADPH to form the active Fe⁴⁺-Fe²⁺ form of the di-iron hydroxylating protein. Although incompletely understood, the regulatory protein seems to coordinate the interaction of the other two components such that uncoupled reaction cycles do not occur. The intermediates in the sMMO reaction cycle accumulate in the absence of methane, which is a feature that has allowed their spectroscopic characterization (14). Studies on the Mössbauer suggest that O₂ binds initially to the binuclear Fe site forming a μ-1,2-peroxo-Fe⁴⁺ intermediate, which then decays to form the highly oxidizing intermediate termed Q (*Fig. 3c*). EXAFS and Mössbauer have indicated collectively that Q is a bis(μ-oxo)-Fe⁵⁺, with a short Fe-Fe separation of 2.46 Å. A strong consensus on how this intermediate compound hydroxylates methane has not yet been reached despite a wealth of studies using isotopically labeled and radical clock substrates (15). Currently, a radical rebound mechanism or a nonsynchronous concerted rearrangement remains possible.
Copper oxygenases

Copper-containing oxygenases are less common than their iron counterparts, perhaps because of the greater difficulty in obtaining more reactive, higher oxidation states. Examples include dopamine β-monooxygenase (DβM), tyramine β-monooxygenase (TβM), peptidylglycine α-hydroxylating enzyme (PHM), tyrosinase, and a membrane bound form of MMO (16, 17, 24). The membrane bound form of MMO contains both a Type 3 binuclear Cu site and a mononuclear Type 2 Cu site (25). At the moment, its mechanism has not been studied in detail and will not be discussed additionally here.

Figure 3 Illustration of possible partial reaction cycles of some oxygenase enzymes. Water molecules and protein ligands have sometimes been omitted for clarity. (a) P450 (18); (b) intradiol dioxygenase (7); (c) lipoxygenase (7); (d) α-KG-dependent non-heme iron enzymes (14); (e) soluble methane monooxygenase (15); (f) uncoupled binuclear copper (16); (g) coupled binuclear copper; (h) flavin monooxygenases (17).
Uncoupled binuclear copper oxygenases

DyM, TmM, and PHM all employ two uncoupled, Type 2 copper sites in the biosynthesis of neurotransmitters and of hormones (16). The reaction entails the hydroxylation of unactivated carbon centers, similar to the chemistry of the Fe(II) and u-FeG-dependent non-heme iron enzymes. The two metal sites of the uncoupled binuclear Cu monooxygenases are separated by more than 11 Å, which is a feature that distinguishes this family of enzymes from the binuclear Type 3 copper proteins. Each Cu site has a discrete coordination environment and serves a unique function in the hydroxylation reaction. The CuM site functions as the dioxygen activation site, whereas CuM serves as the electron transfer site, providing the additional electron required for substrate oxidation. Evidence suggests that the reaction of dioxygen with the reduced CuIIM generates a CuIIM-superoxide intermediate (Fig. 3f), which subsequently abstracts a hydrogen atom from the substrate (26, 27). A methionine ligand to CuM is believed to stabilize the reduced enzyme form, such that oxygen activation is coupled strongly to the ensuing C-H activation step. The steps following C-H activation are still unresolved. A CuII-oxyl radical (CuII\(\cdot\)) is a postulated, short-lived intermediate along the reaction pathway. This high energy intermediate is unprecedented in copper chemistry, but it could provide the driving force for the requisite electron transfer from CuIIM to CuII.

Coupled binuclear copper oxygenases

A characteristic Type 3, binuclear Cu site is found in tyrosinase (10). Tyrosinase catalyzes the conversion of monophenols to ortho-quinones, the formation of which is coupled to the two electron reduction of \(\text{O}_2\) and proceeds in two steps. The first step occurs via electrophilic attack on the phenol ring of the substrate and is followed by the oxidation of the di-hydroxybenzene to yield the quinone product. Thus, tyrosinase functions as both an oxygenase and an oxidase. Much of the structural information pertaining to the tyrosinase active site and various Cu-dioxygen intermediates was derived by comparison to several spectroscopic studies on model complexes (10). The resting form of tyrosinase assumes two forms: 15% of the enzyme exists in the met state, which is dehydrated to regenerate the resting state. Each Cu site has a discrete coordination environment and is dehydrated to the active conformation. The Baeyer-Villiger monooxygenases and mammalian flavin monooxygenases use an alternative strategy. The flavin is reduced readily by NADPH in the absence of substrate, but the (hydro)peroxyflavin intermediate is stabilized by the bound NADP until a suitable substrate binds.

Flavin oxygenases

Several types of flavoprotein monooxygenases exist. One group catalyzes electrophilic aromatic substitution or heteroatom oxidation reactions, whereas the other group catalyzes Baeyer-Villiger-type oxidations of ketones (Fig. 2) (13, 17). In the well-studied, single-component flavoprotein monooxygenases, the flavin is reduced by a hydride delivered from a single molecule of NADPH (Fig. 3h). The reduced flavin then reacts with \(\text{O}_2\) producing a peroxyflavin intermediate, which is in equilibrium with the hydroperoxyflavin form. For electrophilic substrates, as in the Baeyer-Villiger-type oxidation, it is the peroxyflavin intermediate that reacts with substrate. For hydroxylation of aromatic rings, the more electrophilic hydroperoxy intermediate is the reactive species. In the final step, the flavin is dehydrated to regenerate the resting state.

In the Baeyer-Villiger-type oxidations, the flavin is reduced by a hydride delivered from a single molecule of NADPH (Fig. 3h). The reduced flavin then reacts with \(\text{O}_2\) to form the peroxyflavin intermediate, which is in equilibrium with the hydroperoxyflavin form. For electrophilic substrates, as in the Baeyer-Villiger-type oxidation, it is the peroxyflavin intermediate that reacts with substrate. For hydroxylation of aromatic rings, the more electrophilic hydroperoxy intermediate is the reactive species. In the final step, the flavin is dehydrated to regenerate the resting state.

Oxidases

Oxidases couple the oxidation of an organic substrate to the two- or four-electron reduction of \(\text{O}_2\), producing \(\text{H}_2\text{O}_2\) or two molecules of \(\text{H}_2\text{O}\), respectively. Oxygen atoms from dioxygen are not incorporated into the product, unlike reactions catalyzed by oxygenases. Oxidase reactions may proceed via inner-sphere or outer-sphere mechanisms.

Iron oxidases

Non-heme mononuclear iron oxidases

As mentioned, many non-heme iron enzymes also catalyze oxidase-type reactions, such as desaturation, in biological systems (7). Similar to the non-heme iron oxygenases, the reactions are thought to proceed through an \(\text{Fe}^{3+}\text{O}^2-\) intermediate. Two examples of enzymes that catalyze biologically interesting oxidase reactions are isopenicillin N-synthase (IPNS) and 1-amino-2-cyclopropane-1-carboxylate oxidase (ACCO). IPNS catalyzes a double ring closure in the formation of isopenicillin concomitant with the four-electron reduction of dioxygen to two molecules of water, without the use of any cofactors or cosubstrates other than the \(\text{Fe}^3+\) (Fig. 4e). Ligation of the substrate thiolate activates the \(\text{Fe}^3+\) for reaction with dioxygen by converting the active site from a five-coordinate to a six-coordinate metal center. The first ring closure is believed to occur with heterolytic cleavage of \(\text{Fe}^{3+}\text{O}-\text{OH}\) forming \(\text{Fe}^{3+}\text{OH}\), which then closes the second ring.
ACCO breaks down 1-aminocyclopropane-1-carboxylate (ACC) in plants to form the growth hormone ethylene, hydrogen cyanide, and CO₂. In the initial stages of catalysis, ACC ligates the iron, priming the system for reaction with dioxygen. Electrons for the reduction of O₂ are derived from ascorbate, leading to formation of the reactive iron oxygen intermediate, possibly an FeIV=O. Although the later steps from ascorbate, leading to formation of the reactive iron oxyanion, ultimately generating a tyrosyl radical, which transfers an electron, are poorly characterized, it is thought that an FeIV=O may remove a hydrogen atom from ACC, generating a substrate radical, which breaks down to generate the gaseous product molecules.

Binuclear non-heme iron oxidases: Class I ribonucleotide reductases

Ribonucleotide reductases (RNRs) catalyze the conversion of nucleotides to deoxynucleotides and can be found in all organisms. RNRs are categorized into three classes and employ different cofactors for this process. The Class I RNRs contain a binuclear iron cofactor (29). The iron active site is located on the R2 subunit, one of two homodimeric subunits that compose the Class I RNRs, and is very similar structurally to the active site of sMMO (Fig. 1d). The resulting Cys radical abstracts a hydrogen atom from ACC, generating a substrate radical, which breaks down to generate the gaseous product molecules.

Oxygen-Activating Enzymes, Chemistry of

Copper Oxidases

Mononuclear copper oxidases

Most copper-containing oxygenases and oxidases use multiple metal centers to conduct their biotransformations. Copper amine oxidases (CAO) and galactose oxidase (GalO), instead, employ posttranslationally derived amino acid side chains as cofactors to supply additional electrons (24). CAOs use a quinone cofactor to catalyze the oxidation of primary amines to aldehydes (Fig. 5a) (30). The metal cofactor of CAO is a binuclear Cu(II) center ligated by three histidines and by two water molecules (Fig. 5a). A distance of ∼3 Å separates the copper site and the organic cofactor. Although its catalytic function is as an oxidase, CAO also functions as an oxygenase in the self-processing mechanism of quinone cofactor biogenesis (33). The biogenesis reaction requires two equivalents of molecular oxygen for the six-electron oxidation of an active site tyrosine to 2,4,5-trihydroxyphenylglycol one (TPQ). The catalytic oxidase reaction of the CAOs can be separated into two half-reactions. In the oxidative half-reaction, the amine substrate is oxidized to the corresponding aldehyde. Concurrently, TPQ is converted to the reduced aminoquinol form.
Dioxygen subsequently reacts with the reduced amino group, generating TPQ and one equivalent of hydrogen peroxide. Reduction of the copper center has not proven essential for oxidase activity. In selected CAOs dioxygen has been shown to be activated via direct electron transfer from the reduced TPQ (30). Kinetic studies suggest that the metal center in the oxidase reaction contributes primarily to charge stabilization of the activated dioxygen (Fig. 5a).

GalO contains a unique cofactor, which is composed of a cysteine-cysteine ligand, Tyr-cysteine, ligated to a copper center, derived from posttranslational crosslinking of the two amino acids (Fig. 5b, 32, 33). A second Tyr, two His residues, and water molecule comprise the remaining ligands of the square pyramidal CuII site. Cofactor formation is catalyzed by the enzyme itself, in a dioxygen and CuII-dependent reaction. The Tyr-Cys residue is oxidized during the posttranslational process to yield the active form of GalO, which is a CuII-Tyr-Cys cation radical. The reaction catalyzed by GalO is the oxidation of primary alcohols to their corresponding aldehydes. The oxidation of substrate is coupled to the two-electron reduction of dioxygen to H2O2. Kinetic studies support the oxidation of alcohols via a ping-pong mechanism. In the reductive half-reaction, a hydrogen atom is abstracted from the C-H position of the metal bound alcohol to produce CuI and the reduced cysteinyl-tyrosine. In the oxidative half-reaction (Fig. 5b), dioxygen is believed to bind directly to the reduced Cu site, displacing the water molecule. The Tyr-Cys ligand supplies the additional electron that is required for the two-electron reduction of dioxygen to peroxide, and for the regeneration of the cofactor radical.

Binuclear copper oxidases

The active site of the catechol oxidases is virtually identical to the Type 3 binuclear Cu site found in tyrosinasess (vide infra) (10, 34). In contrast to the tyrosinases, catechol oxidases do not exhibit monooxygenase activity and are capable only of the second reaction, the oxidation of diphenols to quinones. The resting form of catechol oxidases lies exclusively in the met state. According to the accepted mechanism, two molecules of catechol are oxidized on binding to either the reduced, deoxy form or the oxy form. Dioxygen reacts with the reduced form after product release to yield the CuII-oxy-educto adduct and allow binding of the next substrate molecule (Fig. 5c). The difference in reactivity toward O2 for the Type 3 copper centers in tyrosinasess, catechol oxidases, and hemocyanins has been attributed to the partial or the complete occlusion of the substrate binding site in the latter two enzyme families. The degree of flexibility around the copper active site has also been cited as a possible factor (35).

Multicopper oxidases

The multicopper oxidases couple the one-electron or two-electron oxidation of their substrates to the four-electron reduction of dioxygen to water (36). The reaction with substrate can proceed via an outer-sphere or an inner-sphere mechanism, and as a result, the substrate specificity varies substantially among the enzymes. The best-characterized enzymes are laccase, ascorbate oxidase, and ceruloplasmin. Radical phenol and amine species formed by laccase and ascorbate oxidase react further via polymerization reactions with other organic molecules, or disproportionate to generate the final biological products. The substrate for ceruloplasmin is FeII, which is oxidized to FeIII. Four substrate molecules transfer electrons sequentially to the Type 3 Cu site, which shuttles three electrons to the trinuclear cluster to generate the fully reduced enzyme form. Dioxygen is activated by the trinuclear copper cluster, which obtains two electrons from the Type 3 site (Fig. 5d). The Type 2 center is required for dioxygen activation but remains reduced at this stage in the reaction. The hydoperoxide is bound to the trinuclear cluster near the Type 3 binuclear Cu center, but both the Type 2 and the binuclear copper centers contribute significantly to the reduced oxygen molecule (37). The bound peroxide is reduced further by two electrons, one from the Type 2 Cu center and one from the distant Type 1 Cu site, forming the native intermediate. The native intermediate is believed to contain an oxo coordinated by the three Cu atoms of the trinuclear cluster. This species reacts with the substrate in the catalytic cycle.

Flavin Dependent Oxidases

Flavoprotein oxidases can conduct a variety of oxidation reactions, such as the conversion of alcohols and amines to aldehydes (12). Typically, the organic substrate provides an equivalent of hydride to reduce the flavin. As mentioned previously, the rate-limiting step in the reaction of the reduced flavin with dioxygen is the initial electron transfer to form a superoxide anion (30). Unlike the flavin oxygenases, a hydperoxylflavin intermediate has never been detected for the flavin oxidases during catalysis. Instead, the mechanism is thought to proceed by a sequential one-electron transfers forming H2O2 (Fig. 5e). The lack of a solvent deuterium isotope effect in kcat/Km(O2) for glucose oxidase has provided evidence that proton transfer is not rate-limiting for the reduction of dioxygen.

Cytocrome c Oxidase

Cytocrome c oxidase is a vital enzyme in the respiratory pathway of most aerobic organisms (38, 39). The enzyme couples the four-electron reduction of dioxygen to the generation of a proton gradient and the resulting synthesis of ATP, which is the primary source of energy for all cellular processes. Cytocrome c oxidase contains two iron-porphyrin units (heme a and heme a3) and two mononuclear Cu sites (CuB and CuA). Heme a and CuA serve as electron transfer sites, whereas heme a3 and CuB form a binuclear metal site that activates dioxygen. CuB is coordinated by three His residues and is located 5 Å from the Fe center of heme a3. A tyrosine residue is bound covalently to one CuB-His ligand and is believed to be critical to the four-electron reduction of O2. The first intermediate generated upon the reaction of dioxygen with the reduced CuA-FeIIa3 center has been identified, based on resonance Raman spectroscopic studies, as an FeIIa3-O2, although a peroxide bridged FeIIa3-O2–CuIIa3 species has not been ruled out entirely (Fig. 5f) (38). The heme-bound dioxygen molecule is reduced rapidly by four electrons, two of which are obtained from the iron center and one each obtained from CuB and the active site tyrosine. The resultant intermediate P.0 consists of
an $Fe^{II}=O$, Cu, and a tyrosyl radical, as deduced from Raman and EPR spectroscopy (40, 41). A series of proton and electron transfer events regenerates the resting, fully oxidized form of cytochrome $c$ oxidase. The electrons for this process are derived from cytochrome $c$ and shuttled through the CuA and heme $a$ sites, during which protons are pumped across the cell membrane. Thus, cytochrome $c$ oxidase functions as an electron-coupled proton pump.

Figure 5 Illustration of possible partial reaction cycles of some copper- and flavin-dependent oxidase enzymes. (a) Copper amine oxidase 30, 31; (b) galactose oxidase (32); (c) catechol oxidase (10); (d) multicopper oxidases (10); (e) flavin oxidases (30); (f) cytochrome $c$ oxidase (38).

Conclusions

The mechanisms of the oxygenases and oxidases detailed here represent some of the numerous strategies employed by enzymes to overcome the kinetic barrier for reaction of organic molecules with dioxygen. This list is far from exhaustive; new reactions are discovered continually, and many intermediates in more established systems have not yet been characterized. A
key feature of the dioxygen-activating enzymes is their ability to form highly ROS using carefully tuned cofactors. The en-
zymes prevent the release of ROS at a stage in the catalytic cycle when damage to the protein or the wider cellular environ-
ment could occur as a consequence. Efforts to mimic nature’s dioxygen chemistry with synthetic inorganic complexes often are only partially successful (7, 42). Many biomimetic com-
plexes will react with dioxygen, but the resultant M–O bonds are either too stable to catalyze the subsequent chemistry or the products are too unstable and lead to undesirable side reactions.

Although great strides have been made to understand dioxy-
gen activation by enzymes, many questions remain. The rela-
tion between protein structure and enzyme catalysis is not well understood. Changes in the active site, beyond the primary coordination sphere, lead to altered cofactor reactivity. An identical cofactor is often employed by different enzymes to carry out dissimilar chemistry. The protein fold tunes the reactivity of these sites through electrostatic effects, control of solvent and substrate access, and by carefully organizing the orientation of substrates around the active site. The role of pro-
tein dynamics in tuning enzyme reactivity has become the focal point of recent studies, as well. These aspects of enzyme catal-
ysis present the primary difficulties in the design of synthetic complexes that function as protein mimics.

Oxygen-Activating Enzymes, Chemistry of
Pyridoxal phosphate-dependent enzymes catalyze a wide variety of reaction types on amines and amino acids, generally by stabilizing carbanionic intermediates, which makes them very common in both primary and secondary metabolism. A fundamental mechanism by which reaction specificity is enforced is stereoelectronic effects; the bond to Cα that gets broken in the universal external amine intermediate is that which is aligned parallel to the p-orbitals of the conjugated, electron-deficient π system. When a bond to Cα has been broken, enzymes must also carefully control the fate of the resulting carbanionic intermediate. Structurally, all known pyridoxal S'-phosphate (PLP)-dependent enzymes are separated into five groups. The largest of these, Type 1, is the aminotransferase group, of which aspartate aminotransferase is the prototype. The prototypes for the other groups are as follows: Type 2, tryptophan synthetase; Type 3, alanine racemase; Type 4, D-amino acid aminotransferase; and Type 5, glycogen phosphorylase.

Biological Background

Pyridoxal S'-phosphate (PLP, the active form of vitamin B6) is an enzyme cofactor in amine and amino acid metabolism. Vitamin B6 was first identified as pyridoxine, which is a catalytically inactive form, in 1938, whereas the catalytically active aldehyde (pyridoxal) and amine (pyridoxamine) forms and their phosphorylated derivatives (pyridoxal S'-phosphate and pyridoxamine S'-phosphate) were discovered in the early 1940s (1). Snell discovered that heating pyridoxal and amino acids yielded the amino form of the coenzyme, and he proposed, based on these observations, that pyridoxal, or a derivative thereof, was the amino form of the coenzyme, and he proposed, based on these observations, that pyridoxal, or a derivative thereof, was the amino form of the coenzyme, and he proposed, based on these observations, that pyridoxal, or a derivative thereof, was the mediator of transamination reactions (1). These three decades observed the demonstration of the involvement of PLP and pyridoxamine S'-phosphate in a wide variety of both enzymatic and nonenzymatic reactions. The enzyme-catalyzed reactions that correspond to the nonenzymatic reactions were shown to follow the same basic chemical mechanisms, in which the enzymes enforce substrate and reaction specificity as well as enhance catalytic power.

PLP-dependent enzymes are ubiquitous; it has been estimated that 1.5% of genes encoded by free-living prokaryotes are PLP-dependent (2). PLP-dependent enzymes are central to nitrogen metabolism, commonly catalyzing racemization, transamination, decarboxylation, retro aldol cleavage, 3-elimination, as well as several other types of chemistry. Figure 1 outlines these mechanisms, with the “Others” group composed of 3-elimination, 3-decarboxylation, radical-based rearrangements, cyclopropyl ring formations and openings, and combinations of different individual activities into single enzymes. Indeed, 4% of all activities classified by the Enzyme Commission are catalyzed by PLP-dependent enzymes (2).

The biosynthesis and degradation of amino acids is the most prominent realm of PLP enzymes. Other metabolic arenas in which they are central include the biosynthesis and degradation of biogenic amines (e.g., histamine and dopamine), heme and chlorophyll, amino sugars, sphingolipids, vitamins (e.g., biotin and folate), antibiotics, polyamines, neurotransmitters (e.g., GABA), and ethylene. These examples include several pathways that are directly affected in or generate pathophysiological conditions. Understanding the fundamental mechanistic bases for the multifarious capabilities of this class of enzymes has both medical and basic science importance.

Despite the diversity of chemistry that PLP-dependent enzymes catalyze, the chemistry of the PLP is based nearly universally on the formation of stabilized carbanions. Without PLP, the Cα proton of amino acids is simply not reactive enough for reaction to take place under physiological conditions. For example, the pKₐ for loss of the Cα proton from an amino acid in the absence of PLP is ~30 (3), and the half-life for the uncatalyzed decarboxylation of an amino acid is estimated to be 1.1 billion years (4). However, by resonance stabilizing negative charge that develops at Cα in the transition state, as well as the...
fully formed carbanion (Fig. 2), PLP makes possible the wide variety of reaction types that PLP-dependent enzymes catalyze. Professor William Jencks once wrote... it must be concluded that pyridoxal phosphate was created to provide satisfaction and enlightenment to those enzymologists and chemists who enjoy pushing electrons, for no other coenzyme is involved in such a wide variety of reactions, in both enzyme and model systems, which can be reasonably interpreted in terms of the chemical properties of the coenzyme. (5)

PLP is used in a remarkable number of reaction types. The first and common step for most PLP-catalyzed reactions is the formation of the “external aldimine” intermediate (Schiff base between PLP and the substrate amino group) from the “internal aldimine” (Schiff base between an active site lysine and PLP) and the free-amine substrate. From this common external aldimine intermediate, the various reactions diverge mechanistically (Fig. 1).

The external aldimine intermediate is poised to undergo facile heterolytic bond cleavage to generate a carbanion next to the amino group, because it is strongly resonance stabilized by the extended conjugation of the Schiff base/pyridine ring $\pi$ system. The occurrence of distinct carbanionic intermediates in PLP enzymes is accepted commonly in the literature.

The chemistry of free PLP has been investigated in great detail and provides a strong foundation for work in enzyme systems. Free PLP is an effective catalyst of many reactions in solution. Early studies with PLP model systems found catalysis of racemization, transamination, and other types of chemistry in solution. In enzyme active sites, the intrinsic properties of PLP account for a large fraction of catalytic power. For example, it has been found that nearly half of the rate acceleration in alanine racemase is caused by PLP ($\sim 10^6$ fold), whereas the active site environment contributes another $10^6$-fold increase in the reaction rate (6). However, the protein environment does not just contribute to an increase in the rate of reaction. Model studies show that PLP can catalyze multiple types of chemistry with a single substrate in solution. For example, serine undergoes racemization, transamination, and retro aldol cleavage in the presence of PLP. However, PLP-dependent enzymes are specific for a single reaction type, which reduce potential side reactions to levels that are barely detectable.
Structural Relationships Among PLP-Dependent Enzymes

All PLP-dependent enzymes that have X-ray crystallographic structures solved to date are categorized into five-fold types (7–9). Each structural class contains representatives of multiple reaction types; the classes are unified not by the chemistry that is catalyzed but instead by three-dimensional structure.

The Type 1 or aspartate aminotransferase family includes many well-studied PLP-dependent enzymes, which include its namesake as well as GABA aminotransferase and diaminopimelate decarboxylase. Enzymes in this group function as homodimers or higher-order oligomers. Each monomer of the Type 1 enzymes has a large and a small domain. The active sites are at the dimer interface, with each monomer contributing residues. Four subgroups exist within the aminotransferase superfamily.

Enzymes in the Type 2 or tryptophan synthase family also generally function as homodimers or higher order oligomers. However, in Type 2 enzymes, the active site is composed of residues from a single monomer. In addition, these enzymes differ from Type 1 enzymes in that they often contain a regulatory domain.

The Type 3 or alanine racemase family contains its founding member, alanine racemase, as well as eukaryotic ornithine decarboxylase and diaminopimelate decarboxylase. Structurally, this family is significantly different from the other fold types. Enzymes in this family consist of an αβ barrel and a second β-strand domain. Despite these gross structural differences, PLP binding in this family is very similar to what is observed in the other fold types, in which the PLP phosphate acts as an anchor and the lysine Schiff base is present. The enzymes are dimers with each monomer contributing residues to the active site.

The Type 4 or D-amino acid aminotransferase family is similar to Types 1 and 2 because they also function as homodimers, and each monomer is composed of a small and a large domain. However, the cofactor is bound in a nearly perfect mirror image of the Fold Types 1 and 2 binding sites, such that the α rather than the β face is solvent exposed.

Finally, the Type 5 or glycogen phosphorylase family is completely different from all other fold types. These enzymes are mechanistically different as well; they use the phosphate group of the cofactor for catalysis.

Mechanisms of Common PLP-Dependent Enzymes

Figure 1 illustrates the breadth of reaction specificity enabled by PLP using serine as an example substrate. The first and common step for all PLP-dependent enzyme-catalyzed reactions is a Schiff base exchange reaction (transamination). All known PLP enzymes exist in their resting state as a Schiff base (internal aldimine) with an active site lysine residue. The incoming, amine-containing substrate displaces the lysine α-amino group from the internal aldimine, in the process forming a new aldimine with the substrate (external aldimine). This process involves many steps, which include several facile steps; it is frequently very rapid compared with the central steps in the reaction mechanism (e.g., deprotonation of Cu). The external aldimine is the common central intermediate for all PLP-catalyzed reactions. Divergence in reaction specificity occurs from this point. Most pyridoxal phosphate-catalyzed reactions depend on the formation of a carbanionic intermediate, whereas some 1,2-aminomutases employ PLP in radical-based reactions (10, 11).

From the external aldimine intermediate, carbanions formed by heterolytic cleavage of any one of the three potentially labile bonds to Cu can be stabilized. Dunathan proposed that enzymes determine which bond to Cu will be cleaved by orienting it parallel to the π orbitals of the conjugated x system (12). In this way, the developing negative charge in the transition state for heterolytic cleavage will be best stabilized, and the bond will be more labile.

Proton abstraction is the most common forward step that external aldimines undergo since racemization, transamination, and β-elimination, which are three common reaction types, all require it. Loss of CO2 gives a carbanion that is commonly protonated on Cu to give the corresponding amine as the product. Less commonly, for example with diaminoglycine decarboxylase (discussed below), the resulting carbanion is protonated on C4 of the coenzyme to give oxidized substrate and the reduced, amino form (PMP) of the coenzyme. Retro-aldol cleavage of serine, which is central to one-carbon metabolism, is initiated by abstraction of a proton from the β-hydroxyl group followed by Cu-Cδ bond cleavage. Other known reaction types include β-decarboxylation of aspartate, β-elimination and replacement, γ-elimination and replacement, ω,ω′-elimination, cyclopentyl ring opening, radical-based 1,2-amino migrations, and others. This wide range of reaction types makes PLP enzymes extraordinarily useful to cells. The enzyme commission (EC) has more than 140 EC numbers assigned to PLP enzymes (2).

The mechanism for stabilization of the resulting carbanion is resonance delocalization within the extended conjugated x system, which is illustrated in Fig 2 where the three most significant resonance forms are shown. The rightmost resonance structure is referred to as the “quinonoid” because its structure resembles that of a quinone. It has strong absorption at ~500 nm (ε500 ~ 40,000 M⁻¹cm⁻¹) and is sometimes spectroscopically observable in enzyme-catalyzed reactions. This quinonoid resonance structure commonly is considered the major species responsible for the catalytic power of PLP because the electrons from Cu are neutralized by the protonated pyridine nitrogen.

Aspartate aminotransferase is the prototype of the large aminotransferase family. The catalytic cycle of all transaminases is composed of two reversible half-reactions. These reactions comprise the same chemical steps but employ substrates with different carbon backbones. For example, the a-amino acid/α-keto acid pairs aspartate/oxalacetate and glutamate/β-ketoglutarate in the two half-reactions of aspartate aminotransferase. The mechanism of the transamination half-reaction with
aspartate/oxalacetate is shown in Fig. 3. The transamination cycle is completed by the reverse reaction of α-ketoglutarate with the amino form of the cofactor through the same series of chemical steps.

In decarboxylation, the external aldimine formed from the internal aldimine and amine acid substrate loses CO₂ and forms the quinonoid intermediate. The quinonoid is usually protonated at Cα, which results in nonoxidative decarboxylation, to generate the imine between the amine product and PLP. In the next step, the product imine undergoes transamination with the active site lysine residue to regenerate the internal aldimine and give free product. Most PLP-dependent decarboxylases catalyze nonoxidative decarboxylation (i.e., amine formation) as their primary reaction. For these enzymes, oxidative decarboxylation that results from protonation at C4′ is a side reaction that results in an inactive enzyme.

Many PLP-dependent decarboxylases studied have been shown to facilitate decarboxylation using ground-state destabilization achieved by placing the charged carboxylate in a hydrophobic environment. Examples include ornithine decarboxylase (13, 14), dopa decarboxylase (15), and arginine decarboxylase (16). DGD is an interesting exception that has a hydrophilic active site with residues stabilizing the carboxylate.

A common feature of PLP-dependent decarboxylases is the stereochemistry of the catalyzed reaction. All PLP-dependent decarboxylases studied that act on an L-stereocenter have been found to decarboxylate with retention of configuration, that is, the carboxylate is removed from one face of the molecule and the proton is placed on this same face. The only known exception is diaminopimelate decarboxylase, which decarboxylates a D-stereocenter with inversion of configuration (17, 18).

Dialkylglycine decarboxylase (DGD) is an interesting and unusual PLP-dependent decarboxylase that catalyzes decarboxylation-dependent transamination. In the first half-reaction catalyzed by DGD, a small dialkylglycine, such as aminoisobutyric acid, is decarboxylated oxidatively to give the ketimine between acetone and PMP. DGD is highly specific for oxidative decarboxylation (19). The ketimine formed is hydrolyzed to give free acetone and the PMP form of the enzyme. The second half-reaction is a classic transamination half-reaction, in which a ketimine forms between PMP and an α-keto acid, such as pyruvate, followed by a 1,3-prototropic shift from C4′ to Cα to give the external aldimine between PLP and L-alanine.

In the DGD active site (Fig. 4), PLP is bound covalently to the enzyme via a Schiff base linkage to Lys272, as observed in all PLP-dependent enzymes studied to date. Modeling of the L-isovaline and L-alanine external aldimines into the DGD active site allowed development of a functional active site model that is consistent with the previously observed reactivity and the idea of stereoelectronic control of reaction specificity proposed by Dunathan (20). Additional work with alternate substrates has validated this model (19).

In the functional active site model for DGD, three subsites exist (Fig. 4). The A subsite is near Q52 and K272 and is the position in which all bond breaking and making occurs, because it is here that the bond is aligned parallel to the π system of the PLP ring and is activated stereoelectronically. When decarboxylation occurs, the carbonyl is proposed to bind in the activated A subsite, which interacts with Q52 and K272. X-ray crystallographic studies with aminophosphonate...
inhibitors provide support for this proposition, which show the phosphonate near the A subsite (21). When transamination occurs, as with L-alanine, Dunathan’s hypothesis predicts that the Cα-phosphonate near the A subsite is lost, which produces the carboxylate near the B subsite. X-ray crystallographic structures show that the B subsite residues R406 and S215 interact well with a carboxylate in this position (21, 22). Thus, studies on DGD have allowed the experimental confirmation of Dunathan’s stereoelectronic hypothesis for control of reaction specificity.

Tryptophan synthase is representative of the Type 2 PLP-dependent enzymes. It catalyzes the replacement of the L-serine hydroxyl group with indole in the final step of tryptophan biosynthesis. In this reaction, the Cu ion is removed to give the carbinol, which eliminates hydroxide from Cu. This step is followed by addition of indole to the resulting aminoacyl-carbinol intermediate. This enzyme is an \( \alpha_2 \beta_2 \) heterodimer. The \( \alpha \) subunit catalyzes the release of indole from indole-3-glycerolphosphate, but this indole is not released into solution. Instead, the enzyme has a molecular tunnel that leads from the active site of the \( \alpha \) subunit to that of the \( \beta \) subunit (23, 24). The activities of the two active sites are regulated by allosteric interactions. This allosterism also regulates the channeling of indole between the active sites.

The Type 3 prototype is alanine racemase. This enzyme provides bacteria with D-alanine for cell wall biosynthesis. It catalyzes perhaps the simplest reaction of all PLP-dependent enzymes: the removal of the Cα proton from one stereochmical face and its replacement on the other. Lys39 and Tyr265 are the two bases that deprotonate/reprotonate Cα on opposite stereochmical faces (6). The Type 4 prototypes are D-amino acid aminotransferase, whose mechanism follows that outlined above for all aminotransferases (25). The Type 5 prototype is glycogen phosphorylase. This class of PLP-dependent enzymes is unique in that the phosphoglucone group and not the aldehyde group is involved directly in catalysis of polysaccharide phosphorylation.

Vitamins, Chemistry of
Proteins are biological macromolecules synthesized with genetically determined sequences of amino acids by the formation of peptide bonds through the removal of water molecules. The chemical nature of amino acids is important for the folding and stability of protein structures. In this article, we give an overview of the computational analysis of protein structure and function from the viewpoint of chemical biology. The biological insights obtained from the analysis of known protein structures and their applications to protein structure prediction and folding rates are outlined. The computational analysis needed for understanding the functions and stability of proteins and for predicting the functionally important residues is described. The methods developed for understanding the factors that influence the stability of proteins and predicting protein stability during mutation are explored. Furthermore, the current status of computational protein design and the approaches to understanding the recognition mechanism of protein complexes are discussed.

The formation of stable secondary structures and a unique tertiary structure of proteins are dictated by the interactions between constituent amino acid residues along the polypeptide chain and by their interactions with the surrounding medium. During the process of protein folding, the hydrophobic force drives the polypeptide chain to the folded state and overcomes the entropic factors while hydrogen bonds, ion pairs, disulfide bonds, and van der Waals interactions define the shape and keep it from falling apart. The structure of a protein mainly dictates its function, and the attainment of stable conformation is essential for proper function. Hence, many methods have been developed to determine the three-dimensional structures of proteins experimentally.

X-ray crystallography, nuclear magnetic resonance (NMR) spectroscopy, and electron microscopy are widely used to determine the structures of proteins and their complexes. These structures have been deposited in Protein Data Bank (PDB) and are available at http://www.rcsb.org/ (1). Currently, the PDB has nearly 50,000 structures, and the wealth of data provide valuable information on relating the structures of proteins with their functions, interactions, and evolution. For example, the structure of a protein explicitly reveals the presence of various interactions, cavities, clefts, active sites, binding regions, and so forth.

Figure 1 shows the crystal structure of X-linked inhibitor of apoptosis (XIAP) binding with small-molecule inhibitor, which helps to restore apoptosis and offset the cancerous state. The availability of many protein structures has enabled researchers...
to perform various computational analysis from different perspectives such as structure, function, and stability.

The applications of the chemistry of amino acids to the biological problem, protein structure and function, and folding and stability are the main focus of this article. The article is divided into five main sections that include the biological insights on protein structures, chemical applications including protein functions, thermodynamics of proteins, protein interactions, and computational protein design.

### Biological Insights

The computational studies on protein structures have been carried out from different perspectives in biology. These perspectives include 1) comparison of protein structures, 2) structural analysis, and 3) protein structure prediction. Table 1 lists the online resources that are providing such services.

### Comparison of protein structures

The function of a protein mainly depends on its structure, and proteins of similar structures perform similar functions. Structure comparison is the process of analyzing two or more structures to evaluate the extent of similarity in their three-dimensional structures. The comparison of protein structures is very important in the design of algorithms that predict protein function and is expected to play a major role in structural genomics projects. The comparison also enables one to classify the protein structures into different structural classes, folds, families, and superfamilies. Typically, the structures being compared are superposed, and the measure, root mean square deviation (RMSD), is widely used to characterize structural relatedness among the proteins being compared. It has been reported that the method PRIDE (2), based on the distribution of amino acid Cα atoms, is fast and can handle large amounts of data and vast structural databases. However, it has many...
false positives and negatives. Yet, the method combinatorial extension (3), based on aligned fragment pairs, is an accurate one, but it is slow for comparison. In addition, comparison of protein structures is helpful to get the biological information in distinctly related protein structures to detect the similar and dissimilar regions between protein structures.

Analysis of protein structures

The computational analysis of unrelated protein structures (nonredundant set) enables one to identify the fundamental principles that govern their folding and stability. Different types of computational analyses such as solvent accessibility; surrounding hydrophobicity, flexibility; thermodynamic parameters; average medium- and long-range contacts; preference of amino acid residues in α-helical, β-strand, and coil regions; and so forth have been carried out. In these calculations, either the coordinates of α-carbon atoms or all atoms in protein structures have been used. Solvent accessibility is a measure to identify the location of amino acid residues (inside the protein core or on the surface) in protein structures (4). It is defined as the locus of the center of the solvent molecule (usually a sphere of water with a radius 1.4 Å) as it rolls over the van der Waals surface of the protein (Fig. 2). The concept of solvent accessibility is used to compute the hydrophobic or solvation free energy. Surrounding hydrophobicity of a residue in protein structure is the sum of the experimental hydrophobic indices of the residues that are located within a distance of 8 Å (5). The short-, medium-, and long-range contacts are computed with the information about the contacting residues in space (less than 8 Å) and their respective locations with the intervals of 1–2, 3–4 and > 4 residues, respectively in the sequence (Fig. 3). The conformational parameters have been derived by the ratio between the frequency of occurrence of a specific amino acid residue (say A→A) in a particular conformation (say α-helix) and the occurrence of the same residue in the whole protein (6). These parameters derived from the computational analysis of protein structures have been used extensively to predict the secondary structures, solvent accessibility, and residue contacts from amino acid sequence.

Furthermore, the parameters derived from protein three-dimensional structures characterize the topology of proteins, which play an important role in kinetics of protein folding. For example, contact order (7) and long-range order (8) are derived from the information about residue contacts in protein structures. Contact order reflects the relative importance of local and nonlocal contacts to the native structure of a protein, whereas long-range order accounts for the contacts between two residues that are close in space and far in the sequence in protein structure. These parameters have shown a strong correlation with protein folding rates, which is a measure of slow/fast folding of proteins from the unfolded state to their native three-dimensional structures. The amino acid properties and the topological parameters are successfully used to predict protein folding rates from amino acid sequence and structure, respectively.

Prediction of protein structures

Predicting the three-dimensional structure of a protein from its amino acid sequence, known as the protein folding problem, is a challenging task. Considering the rapid growth of amino acid sequences against known structures, prediction of protein structures from sequences is necessary in structural and functional genomics. As an intermediate step, several methods have been proposed for predicting protein secondary structures and solvent accessibility. These methods are based on statistical
Proteins: Computational Analysis of Structure, Function, and Stability

Valencia's group (14) proposed a method based on structural templates in the form of multiple alignments with structures and local conservation of residues for predicting the functionally important residues (e.g., catalytic sites and residues that are involved in substrate or cofactor binding). Generally, a database will set up the functional residues, and their characteristic features will be analyzed based on available sequence and structure analysis tools. These parameters are used for predicting the functionally important residues. Fisher et al. (15) analyzed the conservation of functional residues and their neighboring residues, the distribution of amino acid residues, and the predicted secondary structure and solvent accessibility and developed a method for predicting functionally important residues.

Chemistry

Protein function

The functions of proteins are dictated with the importance of specific amino acid residues that are acting as catalytic site residues and binding site residues, which are capable of binding small molecules (ligands) and interacting with macromolecules. The chemistry of amino acids plays a major role in developing computational models for characterizing the functionally important residues in proteins. Thornton's group (13) collected the catalytic site residues in protein structures and developed a database, Catalytic Site Atlas (CSA), which is available at http://www.ebi.ac.uk/thornton-srv/databases/CSA/. The catalytic site residues have been analyzed with the pattern of hydrogen bonding, location of amino acids in proteins, conservation of residues, ability to possess binding pockets, and so forth. Furthermore, the catalytic mechanisms of hydrolysis and transfer reactions have been compared with the aid of a database of enzyme catalytic mechanisms (http://mbs.cbrc.jp/Ecatal/).

Functional residues identified by site-directed mutagenesis

The site-directed mutagenesis experiments provided a large amount of data about the functional importance of amino acid residues in a protein. Systematic studies on p53 tumor suppressor protein showed that the mutation of each residue leads to different kinds of tumors. Furthermore, several residues are identified as important for drug resistance, protein translocation, substrate binding, increased affinity and activity, and so forth. The information about human genes, genetic disorders, and the effects of mutation has been collected in the form of databases, Online Mendelian Inheritance in Man (OMIM) and Human Gene Mutation Database (HGMD). The combined information about the mutational effects of protein stability and diseases along with sequence and structural details is available at http://pbk26.bse.kyutech.ac.jp/puhou/3dinsight/disease.html. These resources will be helpful in predicting the functionally important residues, which is eventually useful for protein engineering experiments.

Prediction of functionally important residues

The functionally important residues are dispersed in a protein, which makes it difficult to map them on structures. However, the comparison of protein structures provides useful information for predicting protein function. Valencia's group (14) proposed a method based on structural templates in the form of multiple alignments with structures and local conservation of residues for predicting the functionally important residues (e.g., catalytic sites and residues that are involved in substrate or cofactor binding). Generally, a database will set up the functional residues, and their characteristic features will be analyzed based on available sequence and structure analysis tools. These parameters are used for predicting the functionally important residues. Fisher et al. (15) analyzed the conservation of functional residues and their neighboring residues, the distribution of amino acid residues, and the predicted secondary structure and solvent accessibility and developed a method for predicting functionally important residues.

Protein Thermodynamics

Protein stability is the free energy difference (ΔG) between the folded and unfolded states at physiological conditions, and it is in the range of 5–25 kcal/mol. Site-directed mutagenesis experiments provided a wealth of data for understanding the importance of chemical interactions for the stability of proteins during amino acid substitutions. Protein stability is experimentally measured with differential scanning calorimetry, circular dichroism, fluorescence spectroscopy, and so forth. The availability of such data in an electronically accessible database would be a valuable resource for the analysis and prediction of protein mutant stability.

Thermodynamic database for proteins and mutants

ProTherm (16) is a large collection of thermodynamic data on protein stability, which has information on 1) protein sequence and structure (2) mutation details (wild-type and mutant amino acid: hydrophobic to polar, charged to hydrophobic, aliphatic to aromatic, etc.), 3) thermodynamic data obtained from thermal and chemical denaturation experiments (free energy change, transition temperature, enthalpy change, heat capacity change, etc.), 4) experimental methods and conditions (pH, temperature, buffer and ions, measurement and method, etc.), 5) functionality (enzyme activity, binding constants, etc.), and 6) literature.
Amino acid properties and protein stability

Analysis of the relationship between amino acid properties and protein stability showed that hydrophobicity is the major factor for the stability of proteins during substitution of amino acids in the interior of the protein. The stability of protein mutants is attributed to the number of carbon atoms, which shows the direct relationship between hydrophobicity and stability.

For the mutations on the surface of the protein, the classification based on the chemical nature of amino acids, such as hydrophobic amino acids (Ala, Cys, Phe, Gly, Ile, Leu, Met, Val, Trp, and Tyr), amino acid side chains that can form hydrogen bonds (Asp, Cys, Glu, His, Lys, Met, Asn, Gin, Arg, Ser, Thr, Trp, and Tyr), and so forth, improved the correlation between amino acid properties and protein mutant stability. Furthermore, the inclusion of neighboring and surrounding residues remarkably improved the correlation in all the subgroups of mutations. This result indicates that the information from nearby polar-charged amino acid residues and the aliphatic and aromatic residues that are close in space is important for the stability of exposed mutations.

Empirical potentials and protein stability

The information about the preference of amino acid residues for contact with each other in protein three-dimensional structures has been used to derive empirical potentials for understanding protein folding and stability. The most widely used approach is the computation of the frequencies of sequence and structure features and the conversion of the frequencies into free energies (17). The potentials based on torsion angles and conformation features and the conversion of the frequencies into free energies (17) have also been used to estimate the stability change between wild-type and mutant proteins by Serrano’s group (19). In this method, all contact residues have been used for predicting protein mutant stability (18). Furthermore, free energy approach has also been used to derive empirical potentials for understanding protein stability (18). Furthermore, free energy approaches have been systematically considered to compute the stability, especially the van der Waals contributions of all atoms, solvation energies (17), amongst others.

Furthermore, free energy approaches have been systematically considered to compute the stability, especially the van der Waals contributions of all atoms, solvation energies (17), amongst others.

Stabilizing residues in protein structures

The key residues that are important for the stability of protein structures have been delineated from a consensus approach (20). This method includes the concept of long-range interactions, hydrophobicity, and conservation of amino acid residues in homologous sequences. It shows good agreement with experimental thermodynamic data of globular proteins, and the consensus method could be used to identify potential candidates for protein engineering.

Protein Interactions

Protein–Protein Interactions

Protein interactions play a key role in many cellular processes. Despite the fact that protein interactions are remarkably diverse, all protein interfaces share certain common properties (21). The structural analysis of protein–protein complexes showed that a specific preference for amino acid residues is found at the interface, and most interfaces consist of completely buried cores surrounded by partially accessible rims. The binding sites consist of a few highly packed regions, which contribute significantly to the free energy of binding. In protein–protein complexes, contacts between hydrophobic residues were favorable, pairs of hydrophilic and polar residues were unfavorable, and the charged residues tended to pair subject to charge complementarity. The buried interface is mainly created by nonpolar (carbon-containing) groups followed by polar (N-, S-, and O-containing) groups. Furthermore, hydrogen bonds and salt bridges are found to be important for protein–protein interactions.

Protein–protein interactions represent a highly populated class of targets for drug discovery (22). Integrins are cell surface receptors and are the first example of drug-like protein–protein inhibitors. They bind various protein ligands, such as fibronectin and vitronectin, which possess an Arg-Gly-Asp motif. Furthermore, inhibitors of integrin receptors from various chemical
Regarding the interacting pairs of protein–protein interactions. Protein interaction databases provide a wealth of information used to predict interaction networks in other species, which is networks. The interaction maps obtained for one species can be has enabled the construction and analysis of protein interaction networks. However, the fast development of mass spectroscopy and other experimental techniques for studying protein interactions has enabled the construction and analysis of protein interaction networks. The interaction maps obtained for one species can be used to predict interaction networks in other species, which is useful for identifying the functions of unknown proteins. The protein interaction databases provide a wealth of information regarding the interacting pairs of protein–protein interactions.

Protein–nucleic acid interactions

Protein-nucleic acid interactions play a key role in many vital processes, including regulation of gene expression, DNA replication and repair, and packaging. The remarkable specificity with which proteins recognize target DNA sequences is of considerable theoretical and practical importance, and its basis has been demonstrated through structural analysis of many protein–DNA complexes. The structural analysis of protein–DNA interactions showed that hydrogen bonds are the most frequent interactions followed by van der Waals, hydrophobic, and electrostatic interactions. The electrostatic interactions between the atoms in amino acids and the bases of DNA make many hydrogen bonds in the major groove of DNA, whereas hydrophobic interactions are dominant in the minor groove. The protein–DNA recognition is characterized by both nonspecific and specific interactions via the contacts between the atoms in amino acids and the phosphate/sugar chains of DNA and between the side chains of amino acids and the bases of DNA. In specific interactions, the positive-charged amino acids, Arg and Lys, are dominant in the binding sites of proteins. The main contributor from DNA is thymine with Lys and guanine with Arg for specific interactions; nonspecific contacts are mainly coordinated with phosphate groups of DNA. In addition, the weak interactions including CH...π contacts that involve the thymine methyl group and position C5 of cytosine are comparable to the number of protein–DNA hydrogen bonds. Furthermore, the chemical and physical properties, such as polarity, size, shape, and packing; conformational changes in DNA (bending and flexibility); and water molecules bridging amino acids and bases, are important for the specificity of protein–DNA complexes.

The free energy of binding is a measure for understanding the importance of specific residues/bases for binding, and the experimentally measured specificities of protein–nucleic acid interactions have been compiled in PDBbind database (http://pdb2bind.bse.kyutech.ac.jp/pdb2pocket/pronit.html). The binding of protein with DNA is also characterized by the preference of secondary structures in proteins as well as specific motifs, such as helix-turn-helix, leucine zipper, zinc finger, helix-loop-helix, and so forth. Recently, for the first time, the thermodynamic characterization of the stability and specific DNA binding of a full-length gene product of the MyoMadMax family, namely, Max protein isoform p21 (p21) with helix-loop-helix-leucine zipper motif, have been reported (23). They showed that the association is driven by a large exothermic effect, which is partly compensated for by entropic factors.

In protein–RNA interactions, the recognition frequency occurs in noncanonical and single-strand-like structures that allow interactions to occur from a much wider set of geometries and make use of unique base shapes and hydrogen-bonding ability. Although it forms a glove-like tight binding pocket around RNA bases, the size, shape, and nonpolar binding patterns differ between specific RNA bases. A dinucleotide is distinguishable from guanine based on the size and shape of the binding pocket and steric exclusion of the guanine N2 exocyclic amino group. The unique shape and hydrogen-bonding pattern for each RNA base allows proteins to make specific interactions through a very small number of contacts. Furthermore, knowledge-based potential functions are shown to be useful for predicting the specificity and binding free energy of protein–RNA complexes.

Protein–ligand interactions

The biological functions of proteins depend on their direct physical interactions with other molecules. Specificity of such interactions is crucial so that each protein must interact only with the appropriate molecule and not with any others present in the cell. A molecule of any type that interacts with a protein is designated as a ligand. The affinity between a protein (P) and a ligand (L) is measured by the association constant (K_a), and for the binding reaction at equilibrium, K_a = [P•L]/[P][L]. The inverse of K_a is dissociation constant (K_d), and the free energy of binding, ΔG_bind = −RT ln K_a = RT ln K_d.

Protein–ligand interactions are important for finding new pharmaceuticals, industrial compounds, and functional molecules for food products. It has been shown that a ligand’s partial charges are critically important for estimating the electrostatic interactions in ligand–receptor interactions. Furthermore, the van der Waals energy between proteins and ligands and solvation energy based on the interactions of chemical groups with aqueous medium are used to identify the ligand binding sites.

Prediction of ligand binding sites is an essential part of the drug discovery process. Generally, the binding sites are predicted with bioinformatics approaches, whereas the binding free energy of binding can be determined experimentally using isothermal titration calorimetry or fluorescence polarization.
Computational Protein Design

Computational protein design is a practical option for solving problems in protein engineering. Several advances have been made in this area that include the development of new potential functions, efficient ways of computing free energies, flexible treatments of solvent and solvent-mediated effects (pairwise approximation to continuum electrostatics implemented with the finite-difference Poisson–Boltzmann model), energy function approximations, ensemble-based approaches for inclusion of entropic effects, improvements to stochastic search techniques, and methods to design combinatorial libraries for screening and selection. These new approaches have several applications such as the successes in the design of specificity for protein folding, binding, and catalysis, in the redesign of proteins for enhanced entropic effects, improvements to stochastic search techniques, and methods to design combinatorial libraries for screening and selection. These new approaches have several applications such as the successes in the design of specificity for protein folding, binding, and catalysis, in the redesign of proteins for enhanced entropic effects, improvements to stochastic search techniques, and methods to design combinatorial libraries for screening and selection.

Computational protein design is also applied for redesigning a whole protein. Mayo’s group (25) redesigned a protein, Drosophila melanogaster engrailed homeodomain, which has a sequence of 51 amino acid residues. They used dead-end elimination theorem to overcome the complexity of calculations including the energy functions for simultaneously modeling the residues in solvent-exposed protein surface and in hydrophobic core. Two of the designed sequences were evaluated experimentally, and those two sequences differ by 11 mutations and share 22% and 24% sequence identity with the wild-type protein. Interestingly, computation effectively to design stable proteins and protein engineering.

Conclusions

The chemical nature of amino acids mainly dictates the contacts between them in protein structures in terms of hydrophobic, electrostatic, hydrogen bonding, disulfide bonds, and van der Waals interactions, which are key determinants for the structure, folding, stability, and functions of proteins. The computational analyses of protein structures, such as comparison, prediction, and development of structure-based parameters, can identify the structurally similar regions, functionally important residues, and modeling and folding rates of proteins. The functionally important residues have been identified with catalytic sites and substrate binding sites and are important to protein transport, signaling, channels, enhance activity, affinity, and so forth. These residues are predicted with structurally similar regions, conservation of residues, and physico-chemical properties.

The relationship between amino acid properties and protein stability revealed that the number of carbon atoms (methyl and methylene groups) that reflects the property hydrophobicity has a strong relationship with protein stability for the mutations in the interior of the protein. Yet, hydrophobic, hydrogen bond, electrostatic, and other polar interactions are important for the stability of mutation at the surface of the protein. The atom pair potentials set up on the basis of chemical nature and connectivity successfully could predict protein stability during amino acid substitution.

The structural analysis of protein complexes showed that the chemical behavior of the interacting partners is important for understanding the recognition mechanism. The binding of small molecules with proteins provides deep insights for drug discovery. In addition, computational approaches have been used effectively to design stable proteins and protein engineering.

Protein bioconjugation is a critically important tool for the elucidation of enzyme mechanisms, the tracking of biomolecules in living systems, the improvement of pharmacokinetic properties, and the construction of new materials. All these applications rely on a continually expanding set of chemical reactions that can modify native protein functionality in aqueous solution under mild pH and temperature conditions. To survey these techniques, this article provides an introduction to the chemical reactivity of the amino acid side chains, with an emphasis on the selectivity that can be achieved using a particular reactive strategy. Site-selective techniques that target the unique reactive properties of N-terminal residues are also reviewed, as are native chemical ligation methods for the modification of the C-terminus. Whenever possible, the mechanistic aspects of the reactions are discussed, as these considerations provide the foundation for future reaction development. The article concludes with a brief description of labeling reactions that selectively target unnatural functional groups in the presence of native protein functionality.

Our understanding of the chemical reactivity of proteins lies at the very heart of chemical biology. In concert, the chemical behavior of the amino acid functional groups provides the basis for enzyme catalysis, and the differences between their reactive properties allow chemoselective protein labeling techniques to be developed. The ability to attach new functionality to a protein of interest allows the rich diversity of biomolecular function to be expanded to the limits of one’s imagination, which affords hybrid structures that can enhance our understanding of and interactions with living systems. For example, the biological role of many proteins has been clarified by tracking their cellular localization with attached fluorescent probes (1, 2). In many cases, chemical cross-linking strategies have then facilitated the identification of their binding partners. Radiolabels are commonly introduced to assess protein biodistribution in vivo, and polymers have been attached to improve circulation behavior (3, 4). Surface immobilization offers exceptional promise for the generation of microarrays for proteomic studies, and chemically modified proteins have been used to build new materials that use biological structure to template inorganic crystal growth (5, 6).

At the core of these studies is the expanding set of chemical reactions that can modify biomolecules in buffered aqueous solution. These techniques push organic reactivity to the limits of efficiency and chemoselectivity, often with the ability to modify a single functional site among hundreds of spectator groups. This article focuses on the reactive principles that have led to the development of these strategies, with a particular emphasis on the site selectivity that can be achieved for each. It is hoped that this survey can serve as a useful guide for those individuals wishing to modify a protein of interest and that it can facilitate the design of new strategies for modifying proteins with ever-increasing levels of precision and yield.

General Reactivity and Stability Considerations

Proteins have evolved to catalyze a remarkably diverse set of chemical transformations, largely by employing general acid/base chemistry and radical pathways (7). Although this range of reactivity provides the very reason for our interest in the chemical behavior of proteins, it also limits our ability to make general predictions about how specific reagents and conditions will affect a biomolecular target. As long as we remember that each protein has a unique reactivity “personality,” however, we can formulate a few guidelines that can serve as logical starting points for protein analysis, purification, and modification protocols.
The amide linkages of proteins are generally stable under both acidic and basic conditions, as are the native amino acid functional groups. However, changes in pH will alter the conformation state of many side chains (Fig. 1), which will result in changes in their reactivity and the overall folding state of the protein. To maintain higher-order structure, most modification techniques are conducted at a pH between 6 and 8.5, although many proteins will remain folded outside this range. The three-dimensional structure of most proteins is stable in aqueous solution between room temperature and 37 °C, and many proteins (such as those isolated from thermophilic organisms) can be heated to temperatures that are significantly higher before unfolding occurs. Large fractions of organic cosolvents (such as methanol, DMSO, and DME) are generally disruptive to protein structure, whereas small amounts are often used to solubilize the organic reagents that are used for protein modification. Although it is sometimes possible to refold proteins into their native conformation after denaturation occurs, this refolding can be difficult to achieve in practice because of unwanted aggregation or the absence of chaperones that facilitate the correct folding pathway. Thus, unless a refolding protocol is available or anticipated, it is recommended that proteins be processed under the mildest conditions possible if more biochemical studies are to be pursued.

The side chain functional groups contain a wide range of nucleophiles, including amines, thiolates, carbonylates, phenolates, and electron-rich aromatic rings, but disulfide bonds represent the only appreciably electrophilic functional groups. Therefore, the bulk of protein modification reagents are themselves electrophilic in nature. Amino acid side chains in the active sites of enzymes often show distinct nucleophilicity because of the alteration of their pKₐ values or other forms of activation. This nucleophilicity allows these positions to be targeted by less-reactive electrophiles that are ineffective for the modification of “ordinary” residues. An excellent review of this technique for the activity profiling of enzymes has recently appeared (8).

Many side chain groups are prone to oxidation, including thiolates, thioethers, and indole rings, but proteins are relatively nonreactive toward reducing agents (disulfide bonds again being the one exception). Although several proteins are known to catalyze reactions through radical pathways, proteins themselves are often unreactive toward radical species in solution (such as polymerization initiators (9)). The lack of alkene functional groups also precludes the direct participation of proteins in most electrocyclization reactions.

A critical consideration for any protein labeling experiment is the level of site specificity that can be achieved. Largely, the inherent selectivity is dictated by the abundance of the targeted amino acid in the protein sequence. As listed in Fig. 1, the commonly modified amino acids occur with average frequencies ranging from 1.4% (tryptophan) to 6.3% (glutamic acid) of the amino acids overall (10). However, significant variations are commonly observed, as tabulated for the soluble cellulase domain in Fig. 1 (11). The hydrophobicity of the amino acids also influences their relative surface accessibility and, thus, their ability to participate in a particular reaction. The best strategy for the modification of a particular protein, therefore, varies on a case-by-case basis, which makes it important to have a range of modification techniques that can target several different amino acids.

These considerations form the basis for the numerous techniques that are now available for the chemical modification of proteins. The sections that follow will examine these techniques and the reactive principles by which they function. A section describing reactions that display orthogonal reactivity to native protein functional groups has also been included because of the growing importance of these reactions as tools to label proteins in complex mixtures. Because it is not practical to summarize all protein bioconjugation methods here, this information instead is intended to serve as an introduction to the concepts that drive the development of these reactions. Several additional reviews and books on protein modification have been listed in the Further Reading section.

### Chemical Reactivity of Amino Acid Residues in Proteins

It should be stressed that proteins are more than just the sum of the amino acids that comprise them. Surprises abound when predicting the chemical modification behavior of a particular protein, largely because of the complex interplay between the individual functional groups and the local environments in which they reside. Nevertheless, the first step to understanding the chemical behavior of proteins is to characterize the reactive properties of the individual side chain groups. The following sections describe these aspects, with an emphasis on the chemical techniques that are commonly used to modify these residues for applications in chemical biology.

#### Chemical reactions of lysine residues

The amino groups of lysine residues are highly nucleophilic in aqueous solution, which makes them the most commonly targeted sites for covalent protein modification. As they must be deprotonated to react, these reactions are typically run at slightly elevated pH (often 8–9). However, many lysine modification reagents undergo competing hydrolysis under alkaline conditions, and thus a balance must be struck to obtain optimal modification yield. Although the average pKₐ of lysine amino groups is 10.5, this value can be altered significantly by interactions with other charged groups on the protein surface. A recent review has described an analysis technique to evaluate these effects (12).

The most common reagents for lysine modification are NHS-esters, which react with amines at rates that are significantly greater than background hydrolysis, Fig. 2a (13). These reagents are most commonly prepared from carboxylic acids and isolated before exposure to the protein substrate. Because of the popularity of this method, dozens of premade NHS-esters are now commercially available. In cases where aqueous solubility is problematic, sulfonated NHS-esters can be used. Because virtually all proteins have many lysine residues on their surface, this reaction affords the most reliable and general method...
for protein modification, although initial screens are still recommended to determine the required amount of reagent and optimal buffer conditions. It should be noted that the abundance of lysine residues also renders this technique inherently non-site selective, which leads to mixtures of products that vary in both the number and location of the modifications. Although lysine acylation is the principal reaction that occurs with these reagents, the N-terminal can also be acylated, as can a variety of other nucleophilic side chains. In the latter case, the transient species that result are often cleaved by exposing the protein to hydrazineamine before isolating the product by gel filtration.

Several related reagents are also available for lysine modification, including isocyanates, which are often prepared from acyl azides using the Curtius rearrangement (Fig. 2b), and isothiocyanates (Fig. 2c), which are more stable for long-term storage. Amine arylation can also be accomplished using 2,4-dinitrofluorobenzene (Sanger’s reagent, Fig. 2d). The products of this reaction are fluorescent, which assists their detection in sequencing applications. All of these reactions proceed under similar conditions and are often selected based on the convenience of reagent preparation from the compounds on hand.

As an alternative strategy, lysine residues can be modified through reductive alkylation, Fig. 2e. This method is most frequently carried out by exposing the protein to aldehydes in the presence of hydride-containing agents that reduce the transiently formed imines. NaB(CN)H3 and NaB(OAc)3H are commonly used for this purpose. As an alternative, transfer hydrogenation can be carried out in the presence of an Ir(III)[Cp*]2(bipyridyl) catalyst, which allows imine reduction to occur under mild conditions using buffered formate as the hydride source (14). Relative to acylation strategies, modification via reductive alkylation preserves the overall charge state (and thus the solubility) of the protein. In general, this technique also suffers from poor site selectivity.

**Chemical reactions of cysteine residues and disulfides**

By far the most widely used methods for site-selective protein modification target cysteine residues. In contrast to lysine, cysteine is one of the rarest amino acids (10), and it is unusual to find it in the reduced form on protein surfaces. Thus, it is often possible to introduce a uniquely reactive cysteine residue using genetic methods. Similar to lysine-modifying reagents, many cysteine-reactive small molecules are commercially available because of the success of this overall strategy.

In the reduced state, the sulfhydryl group of cysteine can be deprotonated (pKa ∼8) to generate a potent thiolate nucleophile. This species then can be intercepted by "soft" electrophiles, such as iodoacetamides (Fig. 3a), maleimides (Fig. 3b), acrylamides, and vinyl sulfones (Fig. 3c), to result in the formation of a new carbon-sulfur bond. Although lysine residues can also be modified using many of these reagents, cross-reactivity can often be minimized by running the reactions at relatively low pH to encourage protonation of the amine groups. Varying amounts of cysteine-alkylating reagents (from 1 to 1000 equivalents) are used to reach the desired level of modification. Although possible, the acylation of cysteine residues is not commonly used as a modification strategy because the resulting thioesters hydrolyze over time in solution.

Figure 1: Tabulated data for amino acid side chains commonly targeted in chemical modification reactions. As a specific example, a space-filling model of a soluble cellulase domain from C. cellulolyticum (PDB ID 1IA7) shows the relative abundance and surface accessibility of these residues. Examples of commonly used modification reagents are also listed.
Cysteine-alkylating groups have been coupled to small molecules that bind to specific sites on a protein to gain an additional level of labeling selectivity. As one example, a weakly reactive fluoromethyl ketone was fused to pyrrolopyrimidines known to inhibit a series of kinases. When binding to two kinases (RSK1 and RSK2), selective alkylation was observed for a cysteine residue adjacent to the binding site (15). Ligand-receptor interactions have also been implicated in the modification of ion channels. In these studies, maleimides bearing channel-blocking groups were used to alkylate genetically introduced cysteine residues. After modification, the activity of the ion channel could be controlled by the photoisomerization of an attached azo moiety (16).

A second method for the modification of cysteine residues involves the formation of disulfide bonds (Fig. 3d). In this method, reduced cysteine residues exchange with exogenous disulfides, which leads to the formation of new disulfides on the protein surface. This reaction can be driven to completion by mass action using a large excess of disulfide, or its efficiency can be improved by using asymmetric disulfides that possess good leaving groups. Disulfides of 2-thiopyridone (17) and 3-carboxy-4-nitrothiophenol (Ellman’s reagent) are commonly used for this purpose. To assist with the thermodynamic considerations of these reactions, a helpful table of disulfide reduction potentials has been published (18). A unique aspect of this class of cysteine modification reactions is that they are reversible, which is a feature that could be exploited for drug delivery applications (19).

Disulfides themselves are often modified during protein analysis. Most commonly, this modification is accomplished by reducing them with dithiothreitol, mercaptoethanol, or tris (2-carboxyethyl)phosphine (20) and following this reduction by a subsequent alkylation step using any of the reagents listed above, Fig. 3e (21). An interesting version of this procedure has been developed to link both of the cysteines that result from the reduction step through two consecutive alkylation reactions (22). The ability of this technique to replace a disulfide bond with a more robust link could be used to improve the stability of proteins, hormones, or antibodies for in vivo applications. To distinguish reduced cysteines from disulfides in proteolytic digests, a biotin-based affinity capture strategy has been developed (23).

Chemical reactions of aspartic and glutamic acid residues

The surface of most proteins displays many aspartic and glutamic acid residues, which provides an additional set of locations for protein modification. The carbohydrate groups are predominately deprotonated at neutral pH ($pK_a = 3.5–4$), which makes it generally difficult to distinguish between the many copies that are present. In cases where site selectivity is not a concern, the carbohydrate functional groups can be activated through the use of water-soluble carbodiimides, such as N-$\text{N'}$-$\text{N'}$-dimethylaminopropyl carbodiimide (EDC), Fig. 4. This reagent forms an $\text{O}$-acylisourea intermediate that can react with amines to form amides. This intermediate can also hydrolyze to regenerate the carboxylate anion, and in some cases it will undergo an acyl shift to yield an $\text{N}$-acyl urea. This latter pathway results in a permanent modification of the protein and in the deactivation of the carboxylate group toward more modification. Nucleophilic catalysts (such as NHS and HOBT) make it generally difficult to distinguish between the many copies that are present. In cases where site selectivity is not a concern, the carbohydrate functional groups can be activated through the use of water-soluble carbodiimides, such as N-$\text{N'}$-$\text{N'}$-dimethylaminopropyl carbodiimide (EDC), Fig. 4. This reagent forms an $\text{O}$-acylisourea intermediate that can react with amines to form amides. This intermediate can also hydrolyze to regenerate the carboxylate anion, and in some cases it will undergo an acyl shift to yield an $\text{N}$-acyl urea. This latter pathway results in a permanent modification of the protein and in the deactivation of the carboxylate group toward more modification. Nucleophilic catalysts (such as NHS and HOBT)
have been shown to suppress this pathway (24). When lysine side chains supply the amino groups, this reaction results in protein cross-links that can be used for topology mapping purposes. As one example, this technique has been used to determine the number of individual protein subunits in an ion channel, which affords information about its multimeric state (25).

**Chemical reactions of tyrosine residues**

Although the chemical modification of tyrosine residues has enjoyed a long history, this residue remains an underused target for bioconjugation reactions. It is typically modified through electrophilic aromatic substitutions (EAS), which makes its reactivity distinct from other amino acid side chains. This reaction complementarity is particularly useful in cases when cysteine chemistry cannot be used or in combination with cysteine chemistry when multiple labels need to be introduced in specific locations. Although tyrosine is a relatively common amino acid, it is often buried in the interior of the protein. This placement effectively reduces the number of phenolic side chains that can participate in reactions, which often leads to higher site selectivity than can be expected for lysine modification strategies. In general, EAS reactions are selective for the positions adjacent to the phenolic hydroxyl group, and in some cases (such as iodination) two additions can be observed for a single ring. When increased reactivity is needed, reactions are often run at elevated pH (pH 8–10) to access an appreciable population of the more nucleophilic phenolate anion.

The oldest method for the modification of tyrosine residues occurs through the use of diazonium salts, as reported in 1904 (26). This reaction results in the formation of azo compounds that are brightly colored. Both tyrosine and histidine participate in these reactions, and it has been reported that aliphatic amino groups can react to form unstable triazenes (27, 28). Thus, it should not be assumed that tyrosine is the only modified amino acid without additional confirmation.

In the case of tyrosine, these reactions typically require the participation of the phenolate anion and thus are carried out at pH 8-10 at 4°C (26). In most cases, the diazonium salts are generated through the reaction of anilines with sodium nitrite under acidic conditions and are used immediately. This reaction has been used to produce antigens (30) and to elucidate the requirements of tyrosine and histidine in enzyme active sites (31). The azo products have also served as probes of amino acid surface accessibility (29), thus providing an indirect method to determine protein conformation. One recent example has used this reaction to immobilize pig liver esterase on silica to prepare a reusable catalyst for the hydrolytic kinetic resolution of racemic esters (32).

Diazonium coupling reactions have also been applied to the modification of protein assemblies, reaching nearly quantitative conversion for the modification of tyrosine residues that are displayed on M S2 (33) and TMV (34) viral capsids. These proteins are particularly good targets for this reaction, as each capsid monomer possesses a single solvent-exposed tyrosine residue and contains no histidines. In these studies, it was found that electron-withdrawing substituents in the 4 position of the diazonium salt significantly enhanced the efficiency of the reaction. These modification reactions have been used to introduce hundreds to thousands of ketone and aldehyde groups for the subsequent attachment of MRI contrast enhancement agents (35) and water-solubilized carbon nanotubes (36).

Phenol nitration with tetranitromethane (37) (TNM) is typically run at pH 8 at room temperature and is selective for tyrosine residues under these conditions (although some oxidation of cysteine residues has been reported) (38). The product of this reaction could be thought to develop through an electrophilic aromatic substitution reaction, but the mechanism instead has been shown to proceed through a radical coupling pathway (39). The degree of nitration is easily quantified by measuring the absorbance of nitrotyrosine at 428 nm. If the reaction is performed under more rigorous conditions, such as with increased equivalents of TNM, then histidine, tryptophan, and methionine can also react.

The in vivo nitration of tyrosine by peroxynitrite and other reactive nitrogen species is implicated in many disease states and is an area of active research (40). It has recently been proposed that tyrosine nitration, mediated by nitric oxide and superoxide, is a regulated cell signaling pathway that provides quick response to the microenvironment of the cell (41–43).

The iodination of proteins has proven to be invaluable in the area of biomedical research. These techniques allow the biodistribution of biomolecules to be tracked after they have been labeled with radioisotopes, such as iodine-131. Although early studies used molecular iodine and bromine for this purpose (37), more efficient reagents have since been developed to make better use of small quantities of radioisotopes. An improved iodination method that uses iodine monochloride (ICl) has been exceptionally useful for protein radiolabeling, with efficiencies as high as 60–70% being reported, Fig. 5b (44). Since its original disclosure, several modifications of this reaction have been reported to improve efficiency and reduce handling hazards (45–47). An alternative Chloramine-T based method has also been developed to achieve both low and high levels of specific radioactivity, with iodine use as high as 60–75% (48).

Formaldehyde-induced cross-linking is commonly used for many biochemical applications, from studying protein-protein interactions to immobilizing whole cells on surfaces. Although a detailed early review of the effect of formaldehyde on proteins (49) implicated tyrosine as one residue responsible for cross-linking, a few reports have been written regarding the rigorous chemical characterization of this mechanism with modern analytical techniques. A recent investigation into the nature of these cross-links used extensive enzymatic degradation and MS/MS analysis of insulin that had been exposed to formaldehyde to determine the relative level of participation of different residues and the yield of specific modifications (50).
In follow-up studies, it was demonstrated that nickel-catalyzed irradiation times of less than one second. In this reaction, the acceptor, effectively cross-links tyrosine-containing proteins with persulfate, which generates Ru (III) as the one-electron oxidant.

In a more recent advance in tyrosine modification chemistry has been the development of a Mannich-type reaction that involves the condensation of an amine derivative with aldehydes, followed by the nucleophilic addition of tyrosine to generate a new carbon–carbon bond, resulting in peptide bond cleavage. This procedure thus provides a useful tool for the study of pro-enzyme activation.

Chemical reactions of tryptophan residues

Several features of tryptophan residues render them strategic targets for chemical modification. Tryptophan is the most fluorescent of the native amino acids, and the emission wavelength and intensity of this residue are often used to assess changes in the folding state of the protein or to detect ligand binding. Through the chemical alteration of this residue, these properties could be enhanced, shifted, or abrogated to determine the environment of a single tryptophan residue in the presence of others. As tryptophan residues are often hydrophobic contributors in binding sites, the modification of this residue could offer a way to modulate substrate binding.

The electron-rich indole ring of tryptophan is susceptible to attack by electrophilic reagents. Although the 3-position is typically the most nucleophilic site of the aromatic ring, the alkyl substituent present in tryptophan residues can direct reactions to occur at the 2-position instead. Electrophilic halogen species, such as N-bromosuccinimide (NBS) (63) and in situ-generated dimethylchlorosulfonium ions (64) have been used for some time to effect the oxidation of tryptophan residues through the intermediary of halohydrins. As it is the rarest of the amino acids (particularly on protein surfaces), its selective modification could provide a strategic handle for bioconjugation when cysteine chemistry cannot be used. Because of its importance, a growing number of techniques are becoming available for the modification of this residue.

3-bromo-2-(2-nitrophenylsulfonyl)-3-methylindole (BNPS-skatole) is often used (66). It was recently reported that the tryptophan residues of proteins could be nitrated by the action of peroxynitrite (67). This reactive nitrogen species (RNS) is generated from the reaction of nitric oxide with superoxide at a rate that is ten times greater than the destruction of superoxide by dismutases. The authors propose that the nitration of tryptophan, although less common than tyrosine nitration, could serve to modulate the function of some proteins. However, at this time there is no in vivo evidence for tryptophan nitration by RNS, and this has yet to be reported. One common way to modify tryptophan residues occurs through the addition of 2-hydroxy-5-nitrobenzyl bromide (HNB). Also known as Koshland’s reagent (68), this compound first alkylates the 3-position of the ring and eventually leads to the formation of a product mixture through subsequent intramolecular cyclization pathways, Fig. 6c. This reagent exhibits good tryptophan selectivity, although some levels of cysteine cross-reactivity (about fivefold less) are sometimes observed. Multiple additions to a single tryptophan residue have also been reported (69). Nonetheless, this compound has long served as the reagent of choice to estimate the tryptophan content of proteins (70, 71), and it has been used extensively to probe the role of tryptophan in the active sites of enzymes (72–74).

As an alternative reaction pathway, a recent report has shown that the nitrogen atom of the indole ring can be modified using malonyl dialdehyde derivatives with quantitative conversion, Fig. 6d (75). When carried out under strongly acidic conditions, such as 50% aqueous trifluoroacetic acid, competing Schiff base formation and arginine modification can be avoided. Although the strongly acidic conditions required for this reaction will undoubtedly denature protein substrates, this reaction offers a convenient method for the identification of tryptophan-containing peptides for proteomics applications. The aldehyde group remaining in the product can be derivatized through hydrazine...
formation, which allows enrichment of tryptophan-containing peptides through solid-phase capture (76).

A transition metal catalyzed reaction has been developed to modify tryptophan residues on proteins with high chemoselectivity, Fig. 6c (77). This reaction involves metallocarbenoid intermediates generated in situ through the degradation of vinyl diazo compounds by sodium carbonate salts. The resulting species react with indole rings to form a mixture of N- and 2-substituted products, likely proceeding through direct N-H insertion and cyclopropanation/ring opening pathways, respectively. Although no organic cosolvent is required for the reaction to occur, the addition of small amounts of ethylene glycol can be used to achieve solubilization of the diazo compound. Hydroxyamine hydrochloride was found to promote this reaction significantly, presumably by binding the catalyst and attenuating the reactivity of the metallocarbenoid species. However, the use of this additive requires that the reaction be carried out under low pH conditions (pH 3.5) that would be expected to denature most proteins. A subsequent study has reported that diazido-1,6-heptadiene-3,5-dione derivatives can be used at neutral pH without the use of this additive (78). This report demonstrated the use of this approach for the attachment of fluorescent probes to a tryptophan residue on beta-lactoglobulin.

Chemical reactions of other amino acid residues

Several other amino acids are known to react selectively with chemical reagents. Although they are less commonly targeted for bioconjugation, the modification of these residues is often used for the purposes of analysis or to annihilate catalytic activity. As one example, histidine residues can be acylated using diethylpyrocarbonate (Fig. 7a), a commonly used strategy to deactivate RNase when intact RNA molecules are required. Methionine residues react selectively with cyanogen bromide (CNBr) (79), which results in the formation of cyclic imidates that can be cleaved during acidification (Fig. 7b). This method has long been used to degrade full-sized proteins into smaller peptides for sequencing analysis. Methionine residues are reactive toward oxidants, such as periodate, yielding sulfoxides. Arginine residues can be modified selectively using dicarbonyl compounds (Fig. 7c) (80). Both single- and double-addition products are obtained in these reactions. Serine and threonine residues are generally difficult to modify in aqueous solution unless they are present in the active sites of proteases (8) or at the protein N-terminus, as described below.

Modification of the N- and C-Terminal

As multiple copies of even the rarest amino acids are often present, cases exist in which none of the chemical modification strategies described above can be used to functionalize a single site. To address this challenge, many groups have developed reactions that take advantage of the unique chemical reactivities of the polypeptide termini. In addition to providing improvements in site selectivity, these methods have been used to form native-like peptide links in some instances.

Historically, the most important technique to target the N-terminus has been the Edman degradation, Fig. 8a (81). In this sequencing method the N-terminal amino group is first reacted with phenylisothiocyanate to form a thiourea. During subsequent acidification, the sulfur atom attacks the proximal amide bond, which results in the removal of the first amino acid from the polypeptide chain. The initially formed thiazolidine quickly rearranges under the acidic conditions to form the more stable thiohydantoin. HPLC analysis then is used to identify the liberated residue. The remaining polypeptide chain bears a new N-terminal amino acid that can be analyzed in a subsequent sequencing round. Peptides up to 50 amino acids in length can be analyzed in this fashion.

The N-terminal amino group is less basic (pKₐ = 6–8) for the protonated form (82) than lysine amino groups, which makes it possible to achieve a degree of selective acylation by using NHS-esters at relatively low pH. However, this strategy usually does not yield absolute site selectivity because of the large number of competing lysines that are present. More selective N-terminal modification reactions also involve the side chain functionality of the first amino acid. A common example is the oxidation of beta-aminoo alcohols of N-terminal serine and threonine residues to yield aldehyde groups for subsequent modification (Fig. 8b) (83, 84). N-terminal serine and cysteine residues can also be condensed with aldehydes to form oxazolines and thiazolines, respectively (Fig. 8c) (85). Both of these links are stable at high pH, but display varying hydrolysis rates in acidic media. Aldehyde groups are known to react readily and irreversibly with N-terminal tryptophan residues, yielding high yields of Pictet-Spengler products (Fig. 8d) (86). Finally, N-terminal cysteine residues can participate in native...

Figure 8 Reactive strategies targeting the N-terminus.

chemical ligation with thioesters, as detailed in the next section (see Fig. 9). As an alternative to these techniques, reactive functionality can also be introduced at the N-terminus using biomimetic strategies. Early reports by Dixon indicated that reactive functionality can be accomplished by exposing proteins to aldehydes (such as glyoxylic acid) and Ni$^{2+}$ or Cu$^{2+}$ ions (87, 88). More recently, a metal-free version of this reaction has been reported using pyridoxal phosphate (PLP) to effect the transamination reaction (89). This method proceeds in buffered aqueous solution at pH 6.5 at 22–50°C. Several N-terminal amino acids, such as glycine and aspartic acid, have been shown to be compatible with this method, whereas tryptophan can react with the aldehyde of PLP through other pathways, as described in the previous paragraph. This technique provides a convenient method for the site-specific modification of several protein targets and has been demonstrated for the attachment of polymerization initiators (9) and surfaces to proteins through well-defined links (90). This method has also been applied to the modification of monoclonal antibodies in sites that are adjacent to the antigen binding regions (91).

Modification of the C-terminus

The native chemical ligation (NCL) has enjoyed tremendous success as one of the few methods for C-terminal protein modification. In its most general form, this approach is a ligation between a peptide that contains a C-terminal thioester and a peptide that contains an N-terminal cysteine, which results in a “native” amide bond (Fig. 9) (92). The full power of this protein synthesis technique is realized in the expressed protein ligation (EPL), a variant of the NCL in which the thioester-containing peptide is produced recombinantly (93). In EPL, the N-terminal portion of the desired peptide is expressed contiguous with an intein domain. The intein catalyzes an N-to-S acyl shift to form a thioester between the peptide target and a cysteine thiol at the end of the intein sequence. During the addition of a functionalized N-terminal cysteine, a transthioesterification occurs to join the two coupling partners and release the intein. A final S-to-N acyl shift forms the native peptide bond to yield the desired product. A addition small-molecule thiols are often added to accelerate this reaction.

A wide variety of biologically relevant molecules have been linked to the C-terminus of proteins using the EPL approach, ranging from naturally occurring biomolecules, such as lipids and polysaccharides, to non-natural probes like fluorophores, affinity tags, and metal chelating agents (94). In combination with solid-phase peptide synthesis (SPPS), EPL has made valuable contributions to proteomics by enabling the synthesis of proteins containing posttranslational modifications that are difficult to introduce (95). This approach has been used to attach fluorophores to proteins for the detection of protein–protein interactions by emission wavelength shifts (96) or through FRET (97). The site-specific incorporation of stable isotopes has been used also to facilitate NMR structural studies. In one example, two intein-splicing events were used to 15N-labell an internal
Bioorthogonal Methods for Protein Labeling

Although this review has focused on the reactivity modes that can be used to modify the amino acids directly, it is equally important to be able to predict what will not react with the native functional groups of proteins. Reactions that can proceed in aqueous solution while ignoring the natural amino acids are exceptionally useful for the development of secondary labeling strategies. In these approaches, one reaction described above is used to attach a chemically distinct functional group to a particular amino acid. A second reaction is then used to install a desired label that might have interfered with the chemistry of the first step. The targeting of unique chemical functional groups is also important for the labeling of a single biomolecule that is present among many others, as is the case in cell lysates, living cells, or entire organisms (101).

In particular, the development of “bioorthogonal” labeling reactions has been propelled by the availability of new tools for the direct incorporation of artificial functional groups into biomolecules. For proteins, powerful techniques have been developed for the introduction of new amino acids on the translational level, both through stop codon suppression (102) and amino acid codon reassignment (103). Metabolic engineering techniques have also been developed for the incorporation of artificial groups into carbohydrates (104, 105), and sequence-selective enzymatic labeling techniques have been used to introduce lipids (106) and cofactors (107, 108) that are substituted with new functionality.

The purpose of this section is to provide a brief list of the new chemical strategies that have been developed to target these artificial functional groups because the importance of these techniques will undoubtedly grow in the coming years.

Methods targeting carbonyl groups

The first methods that were used to label non-native functional groups on proteins targeted aldehydes and ketones. These groups can be introduced directly through the periodate oxidation of N-terminal serine residues (83), transamination (89), or carbohydrate oxidation with periodate (100). They can also be installed using metabolic engineering (104) or translational techniques (110). Aldehydes and ketones condense selectively with hydrazine and alkoxyamine derivatives to form hydrazine- and oxime-type derivatives, respectively (Fig. 10a) (110, 104).

Both reactions are carried out in aqueous solution using an excess of the ketone-reactive reagents. Early mechanistic studies determined that the rate-limiting step in the reaction is the dehydratation of the tetrahedral intermediate that is formed after nucleophilic attack on the carbonyl group (111). Therefore, mild acidic conditions (e.g., pH 6.5) are typically used to accelerate the dehydration step without fully protonating the nucleophilic reagents. This reaction exhibits excellent chemoselectivity and works well for protein labeling with a diverse array of functional groups. However, the presence of competing ketone and aldehyde metabolites limits its use for protein labeling in crude cell lysates.

Methods targeting azides

More recently, azide groups have emerged as popular targets for chemoselective protein modification. They seem to be ignored completely in a variety of biological settings (112), and yet they possess a favorable thermodynamic reaction potential through the loss of nitrogen gas (113). They are also small in size and thus can be incorporated using a variety of enzymatic, metabolic, or translational techniques. The azide group also provides a unique IR chromophore for spectroscopic characterization convenience.

The first technique that was used to modify azide groups in a biological setting was a modified Staudinger ligation (105),

which used a pendant ester group to capture the iminophosphorane intermediate. The resulting amide bond served to link additional functionality on the phosphine to the protein permanently (Fig. 10b). Although the original version of this reaction incorporated the triarylphosphine oxide into the coupling product, more recent "traceless" versions have appeared (114, 115). When used in conjunction with native chemical ligation techniques (see above), this reaction can serve as a means to synthesize full-sized proteins (99). A version of this technique has also been developed for the fluorescent detection of azido groups (116). Perhaps the ultimate testament to the bioorthogonality of this method is its reported use in living animals (112), which renders it a uniquely useful approach for the study of glycans using in vivo imaging techniques (117). A detailed mechanistic investigation of this reaction has appeared (118).

A second mode of reactivity for azide groups occurs through a [3 + 2] cyclization reaction with alkynes, as originally described by Huisgen (119). Although this reaction occurs thermally in the absence of additional reagents, a critical advance for the targeting of azide groups on biomolecules was the observation that Cu(I) salts catalyzed the formation of the triazole products in aqueous solution at ambient temperature (120, 121) (Fig. 10c). This technique has been used for the labeling of viral capsids (122, 123) and the surface of bacterial cells (124), and it has been used to attach proteins to surfaces (125). Both azide and alkyne groups have been introduced on the translational level to provide the appropriate coupling partners (124, 126). This reaction has been used with particular success as a detection method for the identification of new proteases, which were labeled with azides at active sites (127). The monumental success of this reaction for the facile construction of diverse molecules in organic synthesis suggests that it will have a very bright future ahead for biomolecule labeling. The mechanism of the copper-catalyzed reaction has been described (128).

For situations in which copper ions are observed to interfere with protein function or to exhibit toxicity, a metal-free version of this reaction has been developed. This strategy uses a strained cyclooctyne as the alkyne component, which readily undergoes the Huisgen cyclization with azides at room temperature (Fig. 10d) (129). Although unsubstituted cyclic alkynes participate in the reaction with relatively slow rates, a subsequent report has shown that the presence of electron-withdrawing fluorine substituents can accelerate the cycloaddition significantly (130). Taken together, this set of reactive pathways renders the azide group one of the most promising targets for bioconjugation reactions in which complete functional group tolerance is required.

Modification through oxidative coupling reactions

An alternative method has been developed for the modification of proteins through the oxidative coupling of aniline groups (131) (Fig. 30c). This method targets aminophenylalanine, which is one of the most successful amino acids to be introduced into protein sequences using the stop codon suppression technique (132). In the presence of oxidants, such as periodate or cerium (IV), this group reacts rapidly with phenylamine derivatives to afford adducts that are highly stable toward hydrolysis, reduction, or oxidation. The reaction displays very high chemoselectivity, although the reliance on periodate leads to varying levels of methionine oxidation in addition to the desired products.

Conclusion

Although protein bioconjugation has enjoyed a long and successful history, recent years have witnessed a dramatic increase in the number of available techniques for chemical modification. This increase has developed largely because of the availability of high-resolution mass spectrometry and NMR characterization techniques, which have accelerated the rate with which detailed chemical information can be obtained for the modification products. With the addition of each new reaction, previously inaccessible protein bioconjugates of ever-increasing complexity can be realized. The chemical underpinnings of these reactions also form the basis for future modification strategies and expand our understanding of protein reactivity in living systems.

The Chemistry of Metallo-Enzymes and Metallo-Proteins

Robert J.P. Williams, Oxford University, Oxford, United Kingdom
doi: 10.1002/9780470048672.wecb327

Metallo-enzymes and metallo-proteins are a combination of a metal ion or several metal ions in which the metal ion is strongly held in a protein. Hence, before describing their properties and functions, it is necessary to appreciate which metal ions bind strongly to proteins and exchange slowly. The biological significance of metallo-enzymes is that they are essential catalysts, especially for the metabolism of small molecules such as H₂, CH₄, CO, N₂, and O₂ as well as for long-range electron transfer. The control of uptake and the synthesis of their proteins rest with feedback in a series of metallo-proteins.

Before describing these enzymes (see the examples in Table 1), it is necessary to make a broad division of metal interactions in enzymes. In one case, the metal ion is firmly attached to the protein so that like a nonmetal of an amino acid it does not exchange within days. In such a situation, the isolation of the metallo-protein, correctly named, can be followed through all steps of purification until further purification procedures fail to alter the stoichiometry of the metal/protein, and this is a whole number. At the same time, if the metallo-protein is an enzyme, activity will become optimal. This approach to metallo-enzymes was first developed by Professor B. L. Vallee of Harvard. A different extreme is one in which the metal ion is loosely attached to the protein when isolation procedures may well result in an apoprotein, and if it was an enzyme, it would then be devoid of activity. The problem in such a case is to know which metal ion was intrinsically involved in activity in vivo. Now a great number of metal ion/protein interactions are intermediate in character between extremes so that purification results in the discovery of 'fractional stoichiometry' and can be beset by contamination. Confusion is increased because many enzymes have several metal ion centers when it may require astute experimentation to reveal the nature of the original metal ion complement. We must be aware of both binding constants of metal ions to proteins of different kinds and of their rates of exchange so as to establish their nature correctly as it is related to function (1–4).

Binding Constants

Over many years orders of binding strengths of metal ions have been established. Some general features are that the ions of sodium and potassium bind very weakly if at all, those of magnesium and calcium bind more strongly, and certain transition metal ions bind with very considerable strength. In more detail, the binding of divalent ions to virtually all ligands follows the Irving-Williams order and the metal ions toward the end of the series are those that form stable metallo-enzymes.

\[
\text{Mg}^{2+} < \text{Mn}^{2+} < \text{Fe}^{2+} < \text{Co}^{2+} < \text{Ni}^{2+} < \text{Cu}^{2+} > \text{Zn}^{2+}
\]

Binding strength of the monovalent Cu⁺ is large like that of Cu²⁺, but binding of trivalent ions may also be very strong, especially Fe³⁺ and Mn³⁺. (Changes of oxidation state can occur during isolation when the properties of interest may be hidden.) A further specific difficulty is that the binding of Ca²⁺ is extremely variable in magnitude relative to that of Mg²⁺. Although the above sequence is roughly that of increasing electron affinity and hence of binding constant strength, as the ions do not differ greatly in size, the size of Ca²⁺ is very different so ligands can be devised for it that are of greater binding strength than Mg²⁺ by using structural constraints on ligand conformation, creating a disadvantage for Mg²⁺ binding.

The fact that so many metal ions are available and that they vary in availability in environmental waters means that specifically separating each one with a given ligand, assuming at first that equilibrium is attained (i.e., that is, binding constant orders are obeyed), make for a problem of selection. It is largely solved in cells as follows; see Fig. 1.

A cell can limit the free concentration of a metal ion in a given compartment by using energized pumps either inwardly or outwardly directed in the containing membrane of the compartment (Fig. 1). It can also use selective reagents outside the cell, siderophores, or proteins to scavenge for metal ion,

NOTES: Organic side chains and metal ions can be substituted. The organic side-chain substitution is usually done by gene mutation, but metal ion substitution is done by direct exchange and, in fact, can be done for S and Se.  

In these cases, the metal ion is in a metal complex.

particularly iron, bringing them into the cell where they may be reduced (3). In this manner, the concentration of ions in a cell can be fixed; for example, Mg²⁺ at about 10⁻³ M in the cytoplasm greatly exceeds that of all other ions. The cell has certain binding agents, potential ligands (L) that, although they bind in a given order of strength, Mg²⁺ < Mn²⁺ < Fe²⁺ < Cu²⁺ < Ni²⁺ < Co²⁺ < Zn²⁺, show only a modest change from Mg²⁺ to Cu²⁺ (e.g., the pyrophosphate of ATP). Given that concentration of the ion bound depends on the product K[M²⁺][L] = [ML], the high value of [M⁺] for Mg²⁺ makes it the only ion able to bind to a very weak-binding ligand L, which has a general binding constant between 10³ M⁻¹ and 10⁴ M⁻¹. In fact, only Mg²⁺ is found in many enzymes using ATP, where Mg²⁺ ATP is the substrate. No other metal ion is observed in these metal/ligand/protein complexes (e.g., the kinases).

Now consider the opposite extreme of binding strength Cu²⁺(Cu⁺). Its concentration in a cell is limited to around 10⁻¹⁵ M by pumps, so a very strong binding ligand is required to retain copper. A Cu²⁺(Cu⁺) has such a strong binding constant, it alone can still form its Ml complex so long as the free concentrations of the other metal ions in the product K[M][L] are weaker than for Cu²⁺, which then links Cu to a given L, but if excess [L] over [CuL] were allowed, then the excess of [L] above that of [CuL] would let this ligand, L, bind other metal ions. This possibility is prevented as the free [Cu] binds to a transcription factor for the synthesis of its L (Fig. 1), with equal strength such that when free [Cu] is at a specific

![Figure 1](image-url)  
Figure 1: An example of the way metallo-enzymes are under controlled formation through both controlled uptake (rejection) of a metal ion and controlled synthesis of all the proteins connected to its metabolism and functions. The example is that of iron. Iron is taken up via a molecular carrier by bacteria but by a carrier protein, transferrin, in higher organisms. Pumps transfer either free iron or transferrin into the cell where Fe²⁺ ions are reduced to Fe⁰ ions. The Fe⁰ ions form heme, aided by cobalamin (cobalt B₁₂ control) and a zinc enzyme for α-laevulinic acid (ALA) synthesis. Heme or free iron then goes into several metallo-enzymes. free Fe⁰ also forms a metallo-protein transcription factor, which sees to it that synthesis of all iron carriers, storage systems, metallo-proteins, and metallo-enzymes are in fixed amounts (homeostasis). There are also iron metallo-enzymes for protection including Fe SOD (superoxide dismutase). Adenosine triphosphate (ATP) and H⁺ gradients supply energy for all processes. See References 1–3.
value, say $10^{-15}$ M, the production of L ceases; hence, $[\text{CuL}]$ alone is formed. No other metal ion has a sufficient $K[M][L]$ to form such complexes. The transcription factors bind to promoter regions of DNA. By a subtle combination over such controls of both free $[M]$ and free $[L]$, specific combinations can be obtained for all divalent ions. In fact, very little cross contamination of $M$ and $L$ is observed in vivo (see the cases in Table 1). (In all these considerations we must remember that $K$ is an effective binding constant in cells dependent on pH and the presence of other interacting ions or molecules. It is the size of the effective constant $K$ that makes certain that binding is selective.) We estimate the free ion concentration, molarity, in the presence of other interacting ions or molecules. It is the size of the effective constant $K$ that makes certain that binding is selective. We estimate the free ion concentration, molarity, in cells to be in the inverse order to binding strength $K$.

In contrast, the effective constant $K$ can be looked upon as a simple ratio of the rate of ligand, $L$, binding, $k_{on}$, relative to the rate of leaving $K_{eq}$ (i.e., $K = k_{on}/k_{off}$). As $k_{off}$ is limited by loss of water from around the ion, which cannot exceed $10^9$ s$^{-1}$, $k_{off}$ is always less than 1 second for $K > 10^6$ M$^{-1}$, and for $K > 10^{12}$ M$^{-1}$ the off-rate is close to or more than 1 hour. For slower on-rates, the off-rate for a given $K$ is correspondingly slower. It is these rates, often related to equilibrium binding constants, that decide whether an enzyme containing a metal can be separated in pure bound form, a true metallo-enzyme, that is in slow exchange, (8), or will need a metal ion to be added to an isolated apo-enzyme to form a metal ion protein complex that is a fast exchange (9-12). Now certain ions always have relatively fast exchange rates. Examples are Na$^+$, K$^+$, Mg$^{2+}$, Mn$^{2+}$, and sometimes Ca$^{2+}$. Examples of metal ions that have slower exchange rates and readily form metallo-enzymes are Cu$^{2+}$, Co$^{2+}$, Zn$^{2+}$, Ni$^{2+}$, Mo$^{6+}$, Fe$^{3+}$, Mn$^{3+}$, and possibly Co$^{3+}$. In an intermediate group is Fe$^{2+}$, the enzymes of which are usually included in the class of metallo-enzymes. We must also remember that some metal ions are trapped not bound directly to protein side chains but to complex ligands such as porphyrins, for example, Fe, Mg, Co, and Ni (see Fig. 2) or special dithiols such as M or see Fig. 2 and W from which exchange is slow and the metal ions are frequently in low-spin states. The bindings of these complexes is often very tight and in slow exchange, and we include their enzymes in the class of metallo-enzymes. It is generally found that these ions are inserted into the complex...
ligand by selective processes. Slow exchange is also observed for Fe₅S₄ centers, but certainly some Fe₄S₄ centers exchange at intermediate rates.

To transfer or insert the cations that are in slow exchange with aqueous cations or are very dilute in solution demands special transporting proteins (Fig. 1). The first of these to be discovered was the protein for calcium transport across cells, calbindin, a member of the S-1 class of proteins. More recently, transporters have been discovered for Ni, Cu, Mo, and for molecules such as vitamin B₁₂ (Co). In essence, a transport metallo-protein, T, with only very slow loss of the metal ion, carries the ion and delivers it from a pump to an apoprotein, A, which becomes an enzyme and implies that the transporter, sometimes called a chaperone, and the apoprotein form a complex TMA, which by exchange becomes TMA. TM must also exchange with a pump, P, in the same way PM:T becomes P:M:T. It is interesting that the genes for T, P, and A often lie close together under one promoter and transcription factor F (Fig. 1), which senses either the CM or that of the free M concentration giving F:CM, and all these metallo-proteins have rather similar binding constants and selective functional groups.

We have now described the intracellular movement leading to the synthesis of a metallo-enzyme and we see that the control of synthesis rests with the supply of M to the cell from the environment, with its genetic system, which controls synthesis of the apoprotein, with its carrier and its pumps. All must be in a tight feedback circuit so that each metal has its selected proteins and its free concentration in homeostasis, which implies that all their binding constants are closely related to the Irving-Williams series and that to obtain selectivity the binding groups of the proteins are such that thiols are common for binding Cu²⁺, Zn²⁺, Mo⁶⁺, W⁶⁺, and Fe³⁺; N-donors are more common for Fe⁴⁺ and Mn²⁺; whereas O-donors are observed to bind Mg²⁺, Ca²⁺, and K⁺. We need to go forward to the properties of these proteins as isolated and then return to their cellular functions. We shall take it that clear-cut metallo-proteins are those containing simple Cu, Zn, Ni, and Mo (W) ions including the cases of heme (Fe), some Fe₅S₄, B₁₂ (Co) and F-430 (Ni), as well as some mixed metal ion proteins of Fe²⁺/Fe³⁺, of Mn²⁺, or of NiFe and MnFe.

**Properties Of Isolated Metallo-Proteins**

Metallo-proteins have been studied by a great range of physical methods, which have revealed that frequently the metal ion is held in a constrained (sometimes called entatic) state (Figs. 3 and 4 (B-28)). The simplest explanation of this state is that the binding energy of the metal ion in the resting state of the enzyme is such as to lower the activation energy required for it to function in a catalytic act relative to that energy required for free ion activity, which is most easily understood if we refer to a free energy diagram for a reaction pathway. In the course of the reaction the substrate is transformed while the catalyst cycles. Referring to the discussion of substrate activation in a catalyst, Pauling proposed that its binding energy was used in part to distort its structure to match as far as possible the transition state for the reaction presuming the structure of the catalyst was fixed. Turning now to the metal ion, or any other part of a catalyst that acts in the catalytic act, we can examine its
bonding relative to that normally observed in the ground state of its simple compounds where its bonds are relaxed to optimal free energy binding conditions. As examples, the bond angles and bond lengths of amino acids and of metal ions in simple aqueous complexes (no steric hindrance or other constraint) are well known and the corresponding physical-chemical properties are understood. It is now known that in a protein complex the binding of any group can be strained by the need for the overall structure to have as great an activity as possible. It is usually found that a metal ion in a metallo-protein has distinctly unusual bond properties. The observed structural consequence is that the bonding geometry of any single unit, here a metal ion, can be seen to match the catalytic requirement. Some ways in which catalytic properties are achieved are for the metal ion 1) to have a small number of ligating atoms giving the metal ion an enhanced electron affinity for acid attack (Fig. 4) or 2) to have a ligand geometry matching its redox properties with those required for redox catalysis (Fig. 3). In addition, if during the catalytic cycle the metal ion has to change coordination number or oxidation state, then the constrained condition of the metal ion ensures that the relaxation energies between states in the cycle remain small. Note immediately that strong binding and non-exchanging ions are most likely to show these properties. In addition, it may be helpful if the metal ion has an open-sided structure and has a disposition of ligands to repel product while accepting substrate. Examples illustrate these generalities (see Table 2).

NOTES: The constraints have been shown to be related to function in many cases.

The case of Lewis acid function of metallo-enzymes is given by many a zinc enzyme (Fig. 4). Taking the case of zinc in carbonic anhydrase, the ground state structure shows it to be open sided with easy access for H_{2}O and CO_{2} but not larger substrates. Moreover, these neutral molecules bind more readily than the product HCO_{3}-. The zinc ion is known to be open sided and to go readily between 4- and 5-coordination, which is extremely useful in the required catalytic cycle. Moreover, the pK_{a} of attached water is close to 7.0, an exceedingly low value for Zn^{2+}(H_{2}O) complexes. The reason for the selection of zinc as a biological Lewis acid catalyst is now clear. Functionally, it has optimum properties by being readily constrained in the ground state and it easily passes through different coordination...
states all the time in fast exchange internally with substrate intermediates in the site. If we look at other available Lewis acid cations, we observe that of the metal ions with possible similar advantages are 1) Mg2+, but it binds weakly and is a weak acid; 2) Ni2+, but it does not change geometry easily; and 3) Cu2+, but it would readily react with oxygen that can access the site. Only Co2+ is an ideal substitute, but it is a somewhat weaker acid than Zn2+. However, in confirmation that Co2+ is the only obvious substitute, it is found that the catalytic power of the M2+ ions in carbonic anhydrase follows the order

\[
\text{Zn}^{2+} > \text{Co}^{2+} > \text{Mn}^{2+} > \text{all other cations} \quad (0.0)
\]

Notice that this order is not the relative Lewis acid strength or binding strength to the site as demonstrated in simple aqueous complexes that follow the order

\[
\text{Cu}^{2+} > \text{Zn}^{2+} > \text{Ni}^{2+} > \text{Co}^{2+} = \text{Fe}^{2+} = \text{Mn}^{2+} > \text{Mg}^{2+}
\]

but is a result of the similar coordination geometries of Zn2+ and Co2+. In addition, Fe2+, Mn2+, and Mg2+ are used in enzymes for certain acid catalyses; however, these enzymes are not true metallo-enzymes but are metal/enzyme complexes from which the metal ion dissociates relatively easily, and hence these ions function both as a catalyst and as a free unbound regulatory ion (Fig. 1). Probably the tightly bound ions Zn2+, Cu2+, and Ni2+ only act as regulators while bound to proteins.

We turn next to a simple example of a redox metallo-enzyme—azurin, which is a copper electron-transfer protein and, as the electron has no volume, it is best if the metal ion is enclosed in a chelate from which it can escape (Fig. 2). Very well-known examples of such metallo-enzymes are provided by porphyrin and its derivatives as in Fe2+/heme, Co2+/B12, Ni/F-430, and even Mg2+ chlorin, although the last is only found in electron-transfer enzymes of photo-centers. For the three transition metal ions, the placing of them in the strong ligands of the porphyrin series generates low spin states in contrast with all the examples we have given so far where metal ions are high spin. Low spin states are more common among second and third rows of transition metal ions such as of elements Rh, Pd, and Pt, and Mn has made great use of these ions as catalysts, but they are not environmentally available to organisms, hence the resort to porphyrins. A big advantage of porphyrin is that it induces low spin states in its Fe, Co, and Ni complexes where redox change is usually of small relaxation energy so that relaxation is usually easy as various oxidation states can be held in or closely in the porphyrin plane. Of course the binding of additional ligands above and below the plane or just below it tunes the function and once again the protein can create constrained advantageous conditions. With two ligands bound, the heme iron is an excellent electron-transfer metallo-enzyme known in the series of cytochromes a, b, and c. The metal ions Cu2+/B12 and Ni2+/F-430 by contrast are naturally open sided. They, together with open-sided Fe-heme, readily bind ligands but of very different kinds. Open-sided Fe2+/heme is

\[
\text{O}_2 \quad \text{H}_2\text{O}
\]

for certain acid catalyses; however, these enzymes are not true metallo-enzymes but are metal/enzyme complexes from which the metal ion dissociates relatively easily, and hence these ions function both as a catalyst and as a free unbound regulatory ion (Fig. 1). Probably the tightly bound ions Zn2+, Cu2+, and Ni2+ only act as regulators while bound to proteins.

Transient State Enzyme Kinetics

Kenneth A. Johnson, Department of Chemistry and Biochemistry, Institute for Cellular and Molecular Biology, University of Texas at Austin, Austin, Texas
doi: 10.1002/9780470048672.wecb609

Transient-state kinetic analysis defines the elementary steps along the pathway of an enzyme-catalyzed reaction. The methods rely on rapidly mixing a substrate with a sufficient concentration of enzyme to allow a direct observation of intermediates and products formed at the active site during a single enzyme cycle. Stopped-flow methods afford observation of reactions by monitoring changes in optical signals (i.e., absorbance, fluorescence, and light scattering) as a function of time after mixing. Analysis of the substrate concentration dependence of the rates and the amplitudes of observable species can define the sequence of events that occur after substrate binding. Rapid-chemical quench-flow methods require two sequential mixing events: one to start the reaction and a second to stop the reaction by the addition of a quenching agent. One then quantifies the amount of product formed, often by chromatography, to resolve radiolabeled substrate from the product. Because one can observe the conversion of substrate to product directly on a known concentration scale, rapid quench experiments can be interpreted directly.

In the final analysis, the most rigorous interpretation relies on global analysis fitting both stopped-flow and rapid quench-flow data simultaneously to establish a reaction pathway and the rates of interconversion of kinetically significant intermediates. Accordingly, transient-state kinetic methods allow a definition of a reaction sequence by direct measurement of each step to establish the kinetic and thermodynamic basis for enzyme specificity and efficiency.

Structural and kinetic methods provide a powerful combination of related data to explore the remarkable efficiency and specificity of enzymes. Each method fills in details left out from the other. Structural studies provide a static picture, whereas kinetic studies bring the structure to life by providing the data to define the dynamics that underlie catalysis. To relate kinetic studies directly to structure, it is crucial to examine the reactions that occur at the active site of the enzyme, namely, after substrate binding and before product release. Unfortunately, steady-state kinetic methods cannot reveal details regarding the conversion of substrate to product at the active site of an enzyme. Therefore, we turn to rapid-transient kinetic methods in which we examine the enzyme as a stoichiometric reactant rather than as a trace catalyst. We can thereby observe enzyme-bound species formed during catalysis by examining the time scale of a single enzyme turnover. The reactions that govern enzyme specificity and efficiency can then be defined by quantifying the rates of substrate binding, enzyme isomerization, chemical conversion of substrate to product, and product release.

Measurable Kinetic Parameters

Traditional steady-state kinetic studies rely on indirect observation of catalysis by monitoring the accumulation of product or consumption of substrate as a consequence of many reaction cycles with a trace of catalyst. Conclusions are limited to inference of the possible pathways for the order of addition of multiple substrates and release of products and quantification of two bulk kinetic parameters, $k_{cat}$ and $k_{cat}/K_m$. The parameter $k_{cat}$ defines the maximum rate of conversion of enzyme-bound substrate to product released into solution, but it cannot be used to establish whether the maximum rate of reaction is limited by enzyme conformational changes, rates of chemical reaction, or rates of product release per se. It does, however, set a lower
limit on the magnitude of any rate constant in that sequence. The term \( k_{cat}/K_m \) is known as the specificity constant because it quantifies which enzyme or substrate wins in a competition. Moreover, \( k_{cat}/K_m \) defines the rate of substrate binding multiplied by the probability that once bound, the substrate is converted to product and released. As such, \( k_{cat}/K_m \) sets a lower limit on the second-order rate constant for substrate binding, and it also provides a measure of enzyme efficiency relative to the diffusion-limited substrate-binding rate. The term \( K_m \) is best understood as the ratio between the two primary parameters, \( k_{cat} \) and \( k_{cat}/K_m \), and it is generally not equal to the dissociation constant for substrate binding. These steady-state kinetic parameters form the minimal background to design experiments than can define the sequence of individual steps along the reaction pathway.

Transient-state kinetic analysis allows definition of a minimal reaction sequence of kinetically significant intermediates responsible for the conversion of substrate to product at the enzyme active site. Resolution of how individual rate constants lead to a given value for \( k_{cat}/K_m \) provides an understanding of the reactions that govern enzyme specificity and efficiency. Direct measurement of events that occur at the active site of the enzyme fills the void of information left by steady-state kinetic studies, namely, the steps that occur after substrate binding through to the point of product release. Using transient kinetic methods, the rates of a single reaction cycle are measured using an enzyme as an observable reactant often at concentrations approximately equal to the substrate. For example, given the pathway shown in Scheme 1, all eight rate constants can be measured by a combination of equilibrium, steady-state, and transient-state kinetic experiments. Moreover, these kinetic studies lay the foundation for the identification of enzyme-bound intermediates (EI).

Comprehensive kinetic analysis defines the mechanistic basis for enzyme specificity and efficiency in ways that can be directly related to enzyme structure. In this article, the rationale will be described for design and interpretation of experiments to define the pathway of enzyme-catalyzed reactions using transient kinetic methods. These principles will be illustrated with three examples of biologically important reactions, none of which could have been solved with steady-state kinetic methods alone. This article is by no means a comprehensive survey of this extensive field, but rather, selected examples from the author’s laboratory will be used to illustrate the methods to provide a flavor for what is possible.

### Transient Kinetics of Biological Reactions

Enzyme catalysis is the basis for life. Enzymes accelerate desired reactions so they occur on a time scale requisite for living organisms. Moreover, enzymes can synthesize complex biological macromolecules that exist long enough to sustain life by coupling desired synthetic reactions to thermodynamically favorable catabolic reactions. Kinetic analysis allows us to decipher the pathway by which enzymes carry out these biologically important reactions with incredible speed, efficiency, and specificity. Traditional steady-state kinetic methods provide estimates for the kinetic constants, \( k_{cat} \) and \( k_{cat}/K_m \), which govern the flux through metabolic pathways. Transient-state kinetic methods allow definition of the kinetically significant reaction sequence and can provide estimates for each intrinsic rate constant along the pathway, including rates of formation and breakdown of enzyme-bound intermediates. Thus, transient-state kinetic analysis is essential to understanding how enzymes bring about catalysis. Here, three examples of biologically important reactions are provided.

#### DNA polymerase fidelity

As one example, we have long been fascinated by the incredible speed and accuracy of DNA polymerases that can replicate DNA at a rate of 300 base pairs per second while introducing errors only 1 out of a billion times. Kinetic analysis has revealed how these enzymes use information from both hydrogen bonding and shape of the base pair to discriminate correct base pairs from the three possible competing mismatches at any DNA template position. The most important step in which specificity is determined is during a change in enzyme structure after nucleotide binding, in which substrate binding energy is used to alter the enzyme conformation. After the conformational change, a correct substrate (deoxynucleotide) becomes tightly bound in a state that slows release of the bound substrate and organizes the active site residues to promote catalysis. In contrast, an incorrect substrate (a mismatched deoxynucleotide) disorganizes the active site residues leading to a state that promotes release of the substrate and slows the chemical reaction. Thus, it is the kinetic partitioning of the conformational isomer formed after substrate binding that establishes substrate specificity. Transient-state kinetic analysis has revealed how these structural dynamics endow the polymerase with the ability to replicate DNA with sufficient accuracy and speed to sustain a living organism.

#### Detection of enzyme intermediates

Enzymes often catalyze conversion of a substrate to product through a sequence of intermediate states. In many instances, the intermediates must be inferred because they are not sufficiently stable kinetically or thermodynamically to be observed directly. However, in several instances, transient-state kinetic analysis has allowed identification of enzyme-bound intermediates. Rigorous kinetic analysis is essential to distinguish intermediates from the side products of the reaction. As one example, excitatory postsynaptic potential (EPSP) synthase, which is the target of the herbicide glyphosate, catalyzes the reaction of shikimate-3-phosphate (S3P) with phosphoenolpyruvate (PEP) through a tetrahedral intermediate to form the product, EPSP.

\end{array}
\]

**WILEY ENCYCLOPEDIA OF CHEMICAL BIOLOGY © 2008, John Wiley & Sons, Inc.**
for more effective herbicides. Transient-state kinetic studies revealed the rapid formation and breakdown of the intermediate in less than 100 milliseconds. In contrast, structural studies by nuclear magnetic resonance suggested another species (EPSP ketal) as an intermediate, but subsequent kinetic analysis showed that its rate of formation at the active site was a million-fold too slow to account for catalysis (9, 10). Thus, kinetic competence is a critical criterion for the identification of intermediates; the intermediate must be formed and broken down at rates sufficient to account for the net conversion of substrate to product at the enzyme active site (11). Single-turnover transient-state kinetic studies provide the crucial data to identify enzyme intermediates.

**Force production by motor proteins**

Motor proteins such as myosin, dynein, and kinesin, produce a force for movement by coupling the hydrolysis of ATP to conformational changes in protein structure that are linked to the cyclical interaction of the motor with a filament (actin or microtubule). Initial characterization of actin-stimulated myosin ATPase kinetics using steady-state methods led to the puzzling observation that actin fully stimulated ATP turnover while associating with only small fraction of the myosin (12). In a set of simple and direct experiments using transient kinetics, Lymn and Taylor (13) showed that actin associates with myosin for a very brief time and then rapidly dissociates as part of the myosin crossbridge cycle. ATP binding to the actomyosin complex stimulates rapid release of the myosin from the actin, whereas the binding of actin to the myosin-ADP-P complex stimulates the release of products (ADP and Pi). Conformational changes that occur with nucleotide binding and release are then coupled to force production. A motor protein, which is called kinesin, walks along microtubules in a hand-over-hand fashion because of an alternating-site ATPase pathway (14, 15). Strain in the linkage between the two motor domains of this dimeric protein distinguishes leading from lagging ATPase sites when they are both bound to the microtubule surface. This strain leads to rapid dissociation of ADP from the leading motor domain while stimulating ATP hydrolysis on the lagging motor domain. Moreover, ATP binding to the lagging head stimulates the release of ADP from the leading head. Transient kinetic analysis established this alternating site ATPase cycle by showing directly that ATP binding to one site stimulated the rate of ADP release from the other site (14).

**Kinetic and Structural Basis for Catalysis**

Structural analysis is often the basis for discussions of enzyme specificity and mechanism. However, structural studies alone cannot establish mechanism or define the origins of enzyme specificity. In the three examples cited above, structural studies were critical to illustrate the active site residuum, but could not by themselves address the most pressing questions. In particular, enzyme specificity is a kinetic phenomenon which is quantified by $k_{cat}/K_m$ but the underlying origins of specificity are not revealed by pondering the magnitude of $k_{cat}/K_m$ or by inspecting the three-dimensional arrangements of amino acids. Rather, in combination with transient-state kinetic studies, the structures and steady-state kinetic parameters take on new meaning and can be interpreted to reveal fascinating details of enzyme dynamics and specificity.

**The chemistry of DNA polymerization**

The structure of the active site of a DNA polymerase with bound DNA and an incoming substrate, dCTP, is shown in Fig. 1a (16). In this structure, the DNA is terminated with a deoxyribonucleotide that lacks the 3'-OH so that catalysis is prevented, and so this structure is thought to represent a close approximation to the closed enzyme state immediately preceding catalysis. The chemistry of the reaction is well established in that the reaction is catalyzed by a two metal ion mechanisms, in which one Mg$^{2+}$ increases the nucleophilic reactivity of the 3'-OH while the other Mg$^{2+}$ stabilizes the developing negative charge on the $\beta$-phosphate during the transition state (17). However, this model does not explain the extraordinary efficiency and specificity of the reaction. This polymerase copies DNA at a rate of 300 base pairs per second and makes a mistake approximately one out of a million times. After making a mistake, the polymerase stalls, which gives time for the DNA primer strand to melt away from the template strand and migrate to an exonuclease site 25 Å away to remove the mismatched base. The primer then rapidly renatures and polymerization continues so that the overall error frequency is only one in a billion (15). Efficiency and specificity are kinetic properties of the enzyme that can be addressed directly by transient kinetic analysis to define the kinetically significant intermediate and thereby establish the kinetic and thermodynamic basis for nucleotide selectivity. Detailed kinetic studies have revealed that although the metal ions mechanism accounts for a base level of catalysis, the alignment of positively charged amino acids on the O-helix (Fig. 1a) plays a critical role in specificity by their involvement in recognition of a correct base pair.

**The chemistry of EPSP synthase**

EPSP synthase catalyzes the synthesis of EPSP by an addition-elimination reaction through the tetrahedral intermediate shown in Fig. 2a. This enzyme is on the shikimate pathway for synthesis of aromatic amino acids and is the target for the important herbicide, glyphosate, which is the active ingredient in Roundup (The Scotts Company LLC, Marysville, OH). Transient-state kinetic studies led to proof of this reaction mechanism by the observation and isolation of the tetrahedral intermediate. Moreover, quantification of the rates of formation and decay of the tetrahedral intermediate established that it was truly an intermediate species on the pathway between the substrates (S3P and PEP) and products (EPSP and Pi) of the reaction. The chemistry of this reaction is interesting in that the enzyme must first catalyze the formation of the intermediate and then catalyze its breakdown, apparently with different requirements for catalysis. Quantification of the rates of each step of this reaction in the forward and reverse directions has afforded a complete description of the free-energy profile for the reaction and allows
has been the topic of research for more than a half century. Studies in the light microscope established a sliding filament model for muscle contraction, which was subsequently shown to be caused by the cyclical interaction of the myosin ATP-Pase with actin filaments. A major revelation came with the realization that the largest changes in free energy are associated with the binding of ATP and the release of ADP and Pi, whereas the actual chemical step involving hydrolysis had an equilibrium constant of only 4 at the active site of the enzyme (13). The very tight binding affinity \( K_a \sim 10^{-11} \text{M} \) of ATP to myosin is used in the cycle to induce a change in enzyme structure that breaks the otherwise tight interaction of myosin with actin in the so-called rigor complex. After dissociation of the myosin-ATP complex from the actin, the hydrolysis of ATP converts the myosin to a myosin-ADP-Pi state that can reassociate weakly with actin. Subsequent conformational changes coupled to the sequential release of Pi and then ADP drive the swinging of a lever arm during force production (18, 19). The key to understanding coupling is to recognize that the myosin motor cycles between tight- and weak-nucleotide-binding states in reactions that are opposed and therefore coupled to cycling between tight- and weak-filament-binding states. The details of this energy transduction cycle are derived from a combination of structural, spectroscopic, equilibrium, and kinetic measurements; transient-state kinetic analysis has played a central role in defining the pathway.

The coupling of ATP hydrolysis to force production by kinesin is different, but it relies on similar principles in that the binding of substrate and release of products are coupled to conformational switching between tight- and weak-filament-binding states (14, 15, 20). Like myosin, cycling between two nucleotide-binding states is coupled to cyclical changes in the affinity of the kinesin motor domain for binding to the microtubule surface. However, the pathway is complicated by the negative cooperativity between the two ATPase domains of the dimeric motor. It is believed that strain induced when simultaneously binding both motor domains to the microtubule surface causes the leading head into a weak-nucleotide-binding state stimulating the release of product ADP. In contrast, the trailing head binds ATP tightly, and the tight association with the microtubule surface also stimulates ATP hydrolysis. The subsequent release of Pi is then coupled to the dissociation of this trailing head from the microtubule that allows it to leapfrog forward, thereby being converted from the trailing to a leading motor. As this motor domain then binds to the microtubule surface in its new role as leading motor, it reaches a weak-nucleotide-binding state and rapidly releases the bound ADP. Unlike myosin in which one step of the cycle can be attributable to the force-producing step, net displacement of kinesin along the microtubule occurs with a complete cycle of the ATPase shown in Fig. 3a, which is rate limited by the release of Pi from the trailing head. This complex pathway was derived by a relatively small set of simple and direct experiments using transient kinetic methods to measure the rate of each reaction and to provide definitive evidence for this alternating site ATPase pathway. For example, Fig. 3b shows the effect of increasing ATP concentrations in stimulating the release of ADP from kinesin bound to a microtubule.

**Figure 1** Mechanism of DNA polymerization. (a) The structure of T7 DNA polymerase in a complex with DNA and an incoming nucleotide is shown with a fluorescent label attached to C314. Changes in the fluorescence allow quantification of the nucleotide-induced change in structure and its role in selectivity. Residues 235-411 and 436-454 have been removed to reveal the active site. Shown also are the 52-Nbs and key catalytic residues from PDB 1T7P (17). (b) The time dependence of the fluorescence change induced by nucleotide binding is shown at three concentrations of dCTP. **The chemistry of energy transduction by motor proteins**

The free energy available from the hydrolysis of ATP to form ADP and Pi in solution is generally in the neighborhood of 15 kcal/mol, depending of course, on the intracellular concentrations of ATP, ADP, and Pi. The means by which an enzyme can couple this free energy to produce a force for movement...
Transient State Enzyme Kinetics

Transient-Kinetic Tools and Techniques

Transient-kinetic techniques most often rely on the rapid mixing of reactants with enzyme to initiate the reaction. This mixing is essential so that all enzyme molecules start reaction in synchrony with one another; therefore, the time dependence of the observable reactions defines the kinetics of interconversion of enzyme intermediate states. Because mixing requires a finite amount of time, conventional methods are limited in their ability to measure very fast reactions. For example, a typical value for the "dead time" of a stopped-flow instrument is approximately 1 ms, which is because of the time it takes to fill the observation cell. Thus, reactions with a half-life of less than 1 ms (rate > 700 s⁻¹) are difficult to observe depending on the signal to noise ratio. With a favorable signal to noise ratio, rates on the order of 2000 s⁻¹ can be measured, but it is rare. Other transient kinetic techniques have been devised to break this time barrier. Both temperature-jump and pressure-jump experiments can approach the 1-µs limit, but both only allow observation of relaxation of a system of reactants from one equilibrium position to another and therefore have less widespread use. Modern microfluidic methods have also achieved mixing times in the microsecond range and offer the promise of more widespread use. In addition, recent efforts have succeeded in combining rapid mixing followed by mass spectrometry analysis to detect enzyme intermediates.

Stopped-flow methods

The two prominent transient-kinetic mixing methods are stopped flow and rapid chemical quench flow. In the stopped flow, the

Figure 2 Intermediate in the EPSP synthase pathway. (a) The mechanism of the reaction catalyzed by EPSP synthase is shown. The reaction proceeds by an addition-elimination mechanism via a stable tetrahedral intermediate. (b) A single turnover reaction is shown in which 100-µM enzyme was mixed with 100-µM S3P and 3.5-µM radiolabeled PEP. Analysis by rapid-quench kinetic methods showed the reaction of PEP to form the intermediate, which then decayed to form EPSP in a single turnover. The smooth lines were computed from a complete model by numerical integration of the equations based on a global fit to all available data. Reproduced with permission from Reference 7.
instrument mixes and then forces reactants through a flow cell. After an abrupt stop of the flow, the observation cell contains reactants that were just mixed within the previous millisecond. One can then trigger a computer to collect data to measure changes in optical signals such as absorbance, fluorescence, or light scattering as a function of time after mixing. Other spectroscopic methods such as electron paramagnetic resonance have been employed, but many traces must be collected and averaged to improve the signal-to-noise ratio. Stopped-flow methods have a distinct advantage in that one can often obtain data of high quality (high signal-to-noise ratio) over a series of concentrations of substrate with a modest investment of time and materials. These data can then accurately define the concentration dependence of observable rates of reaction; this information is critical in developing a model for the enzyme pathway. However, stopped-flow signals are sometimes difficult to interpret uniquely, especially when fluorescence data scheme multiple exponentials, as described below. An important solution to the problem can be achieved by correlating stopped-flow data with measurements of the chemical conversion of substrate to product using rapid quench-flow methods.

Figure 1b illustrates the analysis of substrate binding and dissociation using stopped-flow fluorescence methods. The concentration dependence of the binding rate defines a two-step sequence that involves a weak rapid-equilibrium binding followed by isomerization to tighter binding. The inset to Fig. 1b shows an experiment to measure the substrate dissociation rate. Combined, the two experiments accurately define the kinetic parameters that govern the two-step binding sequence.

Rapid quench-flow methods

Rapid chemical-quench-flow methods are employed to measure the chemical conversion of substrate to product without necessarily relying on an optical signal. Often, radiolabeled substrates are used, and the substrate and product are resolved chromatographically to allow quantification of the conversion of substrate to product. The reaction is started by mixing the enzyme with substrate and then stopped by mixing with a quenching agent, such as 2 N acid or base. In a quench-flow apparatus, reactants are driven through loops of tubing at defined speeds to control the timing and to achieve reaction times as short as 2 ms. Longer reaction times, up to approximately 100 ms, are achieved by using longer loops of tubing. Even longer reaction times, greater than 100 ms, require a push-pause-push mode in which the first push forces the reactants into a reaction loop and after a pause of known duration, a second push forces the reactants to mix with a quenching agent and then out into a collection tube. The method can be time consuming and tedious compared with stopped-flow, but rapid quench-flow methods have two distinct advantages. First, they provide a direct measurement for the rate of conversion of substrate to product at the active site; second, they allow one to assess the extent to which dead ends are present. This can be interpreted more easily in evaluating a given model. In addition, they allow one to assess the extent to which dead enzyme or microheterogeneity in the enzyme and/or substrate might influence interpretation of the data.

Figure 2b shows the results of a rapid-quench single-turnover experiment performed with EPSP synthase with enzyme in excess over the radiolabeled substrate, PEP. The data show the transient formation and decay of the tetrahedral intermediate, which led to its subsequent isolation and structure determination.

When transient kinetic methods fail

Conventional transient-kinetic methods are not always applicable to every enzyme system. In particular, enzymes that have
very fast turnover rates such as carbonic anhydrase are not amenable to single-turnover kinetic methods and may require the use of stopped-flow methods just to observe reactions in the steady state. In addition, enzymes with very high $K_w$ values are sometimes difficult to study because the high substrate concentrations needed to saturate the rate of reaction increase the background in attempts to observe product formed at a concentration equal to only one per enzyme site. However, these limitations are being challenged constantly by the development of better instrumentation, new methods, and better signals. If one is lucky or wise enough to choose an enzyme with $K_w$ values in the micromolar range and $k_{cat}$ less than several hundred per second, then a large range of experiments is possible.

Experimental Design and Interpretation of Data

The overall goal of a comprehensive kinetic study is to provide estimates for each step in the pathway and to identify enzyme-bound intermediates. The time dependence of an enzyme-catalyzed reaction can be rather complex for even a simple reaction sequence that contains only one substrate, one product, and one enzyme-bound intermediate such as the reaction illustrated in Scheme 1. Nonetheless, careful design and rigorous interpretation of a combination of equilibrium and kinetic data can define all eight rate constants under favorable circumstances; in particular, definition of the reverse rate constants usually requires that the reaction be measurable in the reverse direction. In those cases in which rates cannot be defined with certainty, the degree of uncertainty must be stated. For example, in some cases the data may only indicate that $k_2$ and $k_4$, for example, must be greater than $1000 \text{s}^{-1}$, but no data define an upper limit. In either case, the data could show that the formation of the intermediate is the kinetically significant step and that the intermediate breaks down at a fast rate. Given the very nature of the reaction, this method may be the best possible and perhaps all that is important mechanistically.

Equilibrium measurements

Steady-state and equilibrium measurements are extremely important to place constraints on the interpretation of more complex kinetic experiments. For example, measurement of the overall equilibrium constant for the reaction defines the product of equilibrium constants for all four steps, $K_{eq} = K_1K_2K_3K_4$. In addition, it is often possible to measure the two internal equilibria, $K_2$ and $K_3$, if concentrations of enzyme can be attained that are higher than the dissociation constants for substrate and product. Finally, dissociation constants for substrates and products can be measured in some instances, particularly with multiple substrate reactions when one of the reactants can be left out to allow the binding but not reaction of the other substrate. Whatever information can be obtained will facilitate the design of subsequent experiments (i.e., what concentrations of substrate are needed to saturate the enzyme) and in their interpretation (i.e., knowing that $k_{cat}/K_w = K_2$ provides an important constraint in globally fitting data).

Binding kinetics

It is useful to approach the solution of an enzyme pathway from both ends and work inward. Measurement of the substrate-binding kinetics is a good first start, but it will depend on a useful signal. Often, changes in protein fluorescence occur that reflect changes in protein structure induced by substrate binding; these signals can be monitored to measure the kinetics of binding and isomerization. In other cases, a fluorescent analog of a substrate or a fluorescently labeled protein can provide a useful signal. In either case, definition of rate constants that govern binding assist in the design and interpretation of subsequent experiments to measure rates of substrate to product conversion at the active site. Figure 1b illustrates the measurement of substrate binding kinetics.

Pre-steady-state burst kinetics

Important results are obtained in an experiment where enzyme is mixed with an excess of substrate and then the formation of product is monitored over the time period of a few enzyme turnovers and with an enzyme concentration high enough to allow quantification of one product per enzyme site. Under conditions in which substrate binding and chemical conversion to product are faster than the release of product, one observes a “burst” of product formation equal to one product per enzyme site, followed by steady-state turnover. The mere observation of a burst implies that a step after chemistry is at least partially rate limiting for steady-state turnover. In addition, if no observable burst occurs, then the data imply that chemistry is largely rate limiting. When a burst can be observed, quantitative fitting of the amplitude and rate of the burst phase relative to the steady-state phase affords estimates for three rate constants: $k_2$, $k_{-2}$ and $k_4$ in the pathway shown above (Scheme 2).

Single turnover kinetics

If enzyme can be obtained at concentrations approaching the $K_w$ or $K_v$ for substrate, then experiments can be performed with enzyme in excess of substrate. In these experiments, one can observe the net conversion of substrate to intermediate and form product in a single enzyme cycle. The real advantage of the method is in the signal-to-noise (or background) ratio of the data. While in a pre-steady state burst experiment, one might be looking for the appearance of an intermediate in the background of 100-fold higher concentration of substrate; in a single turnover experiment, that same intermediate might appear as 30% of the total substrate. This finding was the case in studies on EPSP synthase, in which single-turnover experiments revealed the presence of the tetrahedral intermediate, which led to its isolation and structure determination (Fig. 2b).
Interpretation of transient kinetic data

Unlike the standard protocols for steady-state kinetic analysis, transient kinetic analysis is dependent on the availability of signals to measure individual steps of the reaction. Moreover, the observable kinetics can change and be complex or deceivingly simple depending on the relative magnitudes of sequential steps in a pathway. The rule of thumb is that one exponential phase exists in the time dependence of a reaction for each step in the pathway. For example, the time dependence of signals observable according to Scheme 2 will follow a triple exponential function: $Y = A_1 e^{-\lambda_1 t} + A_2 e^{-\lambda_2 t} + A_3 e^{-\lambda_3 t} + c$. Moreover, it is important to note that the observed rates ($i$ values) do not translate directly to rate constants for individual steps except in the rare case where each step is irreversible. Rather, the observable rates are a function of all rate constants that are reversibly linked (1, 21, 22). In general, the observed rate approaches the sum of the rate constants for all steps that contribute to the observable transient. A complete discussion of this is beyond the scope of this review, but some simplifying concepts are important to note. For example, if the binding of substrate is a rapid equilibrium or the experiment is conducted at sufficiently high substrate concentration, then the exponential term that governs the formation of ES is so fast that it is dropped from the equation. In addition, in a pre-steady-state burst experiment, the last exponential term is lost because the release of products renders the formation of ES so fast that it is dropped from the equation. For example, in a pre-steady-state burst experiment, the last exponential term is lost because the release of products generates free enzyme, which blunts the time dependence of the reaction into the steady-state phase. Thus, it is common that for this three-step pathway, the observed rate of formation of product during a pre-steady-state burst experiment follows a single exponential with a rate constant provided by the sum, $k_{observed} = k_2 + k_2 + k_3$ (followed by linear steady-state turnover).

Under some conditions, the kinetics of the reactions simplify, but the validity of such simplifying assumptions is limited. Moreover, as a reaction becomes more complex, the mathematical modeling of the data becomes intractable. For these reasons, methods have been developed for modeling and fitting kinetic data by computer simulation based on numerical integration of the full rate equations without simplification. The data shown in Fig. 3b, for example, can only be analyzed by simulation to obtain meaningful information because of complexities in the experiment. However, in fitting the data by simulation, the rate constant for ATP binding is defined accurately by the observed increase in rate of the slow reaction phase as a function of ATP concentration.

Computer simulation and global data fitting

Kinetic data can be fitted directly to a given model without invoking simplifying assumptions needed to solve mathematical equations. Rather, by numerical integration of the rate equations, complex models can be examined in fitting data over a wide range of concentrations and differing starting conditions. When fitting data by computer simulation, one bypasses mathematical modeling entirely and fits data directly to the model. Moreover, many experiments can be fitted simultaneously to a single unifying model. Several computer programs are currently available including Dynafit (BIoK, Ltd., Watertown, MA), Copasi (EML Research, Heidelberg, Germany), and KinTek Global Kinetic Explorer (KinTek Corporation, Austin, TX), and all are available on the internet. The major difficulty in using these programs occurs because of the ease with which one can propose overly complex models in attempting to explain kinetic data. Understanding which kinetic constants are actually constrained by the data becomes extremely difficult when fitting multiple parameters to several data sets. KinTek Explorer addresses this problem by allowing the user to scroll through each rate constant, starting concentration, or output factor and watch the curves change in shape. This dynamic simulation immediately reveals whether a given constant has a significant effect on the fit to the data and shows when a model is overly complex.

The future of kinetic analysis lies in the use of these powerful computer simulation methods to design experiments and to fit data rigorously to extract mechanistic information. Ongoing work is directed toward the development of more robust algorithms to address the confidence intervals with which individual parameters can be obtained from modeling a given set of data. With these tools, one can accurately establish a given reaction mechanism and provide estimates for the rates and free-energy changes for each kinetically significant step in the pathway.

Water plays multiple roles in biological electron transfer (ET): energy bath, polarizable medium that defines the reaction coordinate, electronic coupling bridge, and intimate participant in molecular recognition. This article explores these many faces of water in ET. Links are drawn to reactions in photosynthesis, oxidative phosphorylation, proton-coupled ET, and DNA damage and repair.

Biological Background: The Many Roles of Water in Biology

Biological electron transfer (ET) reactions are ubiquitous in nature. They define the fundamental reactions of bioenergetics, biocatalysis, and nucleic acid synthesis and repair. These reactions occur both in membranes and in aqueous environments. In both settings, water plays multiple roles in the ET reaction kinetics and dynamics (1–5). The roles of water are diverse. Its roles vary from establishing a high dielectric screening medium to supporting the solvation of counterions to establishing hydrogen-bonded relays to providing electron tunneling pathways and proton wires for key transport reactions. Our aim is to review the influence of water on biological ET and, as such, examine some of the many roles of water in these reactions.

Chemical Roles of Water in Biomolecular ET

The last 50 years have witnessed the establishment of a truly molecular-level description of electron transfer chemistry. From the Marcus description of how solvent polarization defines the ET reaction coordinate, to fully quantum treatments that describe electron and nuclear tunneling contributions to the kinetics, to atomistic simulations of reaction coordinate motion, a comprehensive view of biological ET is emerging (1–5).

Inner-and outer-sphere ET

Electron transfer reactions are categorized as outer or inner sphere. In outer-sphere processes, structural changes during ET largely involve solvent reorientation (polarization). Inner-sphere reactions involve changes in the bonding to the redox unit and are more difficult to describe using the ET theory as it is explained here.
Outer-sphere biological redox reactions occur between cofactors beyond van der Waals contact distances, and they occur mostly via electron tunneling. The ET rate is proportional to the product of an electron tunneling probability and an Arrhenius-like activation factor (1–5). The electron tunneling probability is proportional to the square of the donor-acceptor electronic coupling, and the Arrhenius-like factor is given by $\exp[-\Delta G^*/k_B T]$, where $\Delta G^*$ is the activation free energy, $k_B$ is Boltzmann’s constant, and $T$ is the temperature. The activation factor arises from changes in nuclear polarization coupled to the electron transfer event.

The activation free energy $\Delta G^*$ is defined by two terms. One term is the reaction free energy $[\Delta G(0)]$, which is derived from the redox potential difference of the donor and acceptor. The second term is the medium reorganization energy ($\lambda$), which is the energy stored in the solvent internal degrees of freedom when the electron is shifted suddenly from donor to acceptor (1–5). Marcus theory predicts the activation free energy:

$$\Delta G^* = [\Delta G(0) + \lambda^2/4\lambda]$$

(1)

Because $\Delta G^*$ enters the rate expression in the argument of an exponential, changes in driving forces and reorganization energies sweep ET rates over many orders of magnitude. In photoinduced electron-transfer reactions (as in the photosynthetic reaction center and photosystem II (2, 7)), the thermodynamic driving force for charge separation and charge recombination reactions are very different. Indeed, this difference is believed to enhance the efficiency of photosynthetic charge separation (1).

The reorganization energy $\lambda$ in Equation 1 has contributions from “inner-sphere” and from “outer-sphere” (i.e., solvent) motion. The outer-sphere reorganization energy ($\lambda_{\text{out}}$) often dominates the activation free energy. The activation free energy for ET depends on the match between $-\Delta G(0)$ and $\lambda$. That is, the reaction rate is maximized (for a fixed donor-acceptor distance) when $-\Delta G(0) \approx \lambda$. In the regime where $-\Delta G(0) < \lambda$, the “normal” regime, the reaction rate increases with increasing thermodynamic driving force. When $-\Delta G(0) > \lambda$, the reaction is “inverted” and its rate slows with additional increases in driving force. A great achievement of the 1980s was to access both of these regimes (1, 3), which validated the most dramatic prediction of the Marcus theory. Polar solvents like water have larger $\lambda_{\text{out}}$ than nonpolar solvents ($\lambda_{\text{out}}$ for water is typically a few electron volts and for nonpolar solvents is typically tens of electron volts). Therefore, the inverted regime of ET in aqueous solvent is accessed at larger driving forces than ET in low-polarity solvents, and aqueous ET reactions are more likely to be in the “normal” regime. As such, docking or association processes that exclude water would decrease $\lambda_{\text{out}}$ and accelerate the kinetics. This simple observation explains a possible advantage for carrying out the charge separation reactions of biomembranes of nonpolar transmembrane proteins rather than in aqueous media. Membranes also play a second and important role by defining a simple directorality for electron and proton transport.

Inner-sphere ET reactions are of great interest in chemistry and biology (8). However, the kinetics of these reactions are rather complex as they involve bond breaking and formation with the redox group. For inner-sphere processes, electron transfer need not be rate limiting and the reaction coordinate may not be determined as described above for pure ET events. ET kinetics may also be gated by conformational charges or ion motion (9, 10).

When inner-sphere motion is coupled to ET but does not control the reaction mechanism, it adds to the outer-sphere reorganization energy to define a total $\lambda$ value for Equation 1. Changes in bond lengths and vibrational frequencies contribute to the reorganization energy and are known as inner-sphere components. Inner-sphere reorganization energies routinely are computed with quantum chemical methods and are typically on the scale of tenths of electron volts; outer-sphere reorganization energies can be larger than this size and frequently are computed using continuum dielectric methods (20).

In addition to bulk water, which contributes to $\lambda_{\text{out}}$, buried water molecules can make significant contributions to the overall reorganization energy of biological ET reactions. The magnitude of the buried-water contribution depends on the location of the waters relative to the D and A moieties and on their number. Finite-difference Poisson-Boltzmann calculations for the R. viridis photosynthetic reaction center, which contains more than 100 buried waters, show that the buried water contribution to the total reorganization energy varies from 0.05 to 0.27 eV for different PRC ET reactions (Reference 11 and references therein). The largest contribution (0.27 eV) is for the cytochrome to the special pair ET reaction and constitutes 25% of the total computed reorganization energy (total meaning bulk and buried water, protein, and membrane). The effect of water on $\Delta G^*$ strongly depends on the ET system considered, for example, on how deeply the D and A moieties are buried inside the protein (which screens the bulk solvent) and on the positions of internal waters relative to the D and A molecules.

### Water-mediated molecular interactions

Water has $C_2$ symmetry. In the gas phase, the measured O–H bonds are 0.957 Å, and the H–O–H angle is 104.5° (12). Liquid water and ice have structures controlled by the formation of hydrogen bonds. These bonds make it possible for hydrogen ions to exchange among water molecules on the millisecond to picosecond time scale (13), depending on pH. The extensive and dynamic hydrogen bond networks account for many unusual properties of water and hydrated biomolecules (12).

Water-mediated molecular interactions, including hydrogen bonding, hydrophobic effects, ion pairing, and cation–π interactions, play a central role in biomolecular structure and function (5). In soluble proteins, most nonpolar residues that cannot form hydrogen bonds with water are located in the protein core, whereas polar and charged residues form most of the protein surface, which increases the protein-solvent stability (14). Cation–π interactions, which involve electrostatic attraction between a cation and the negative electrostatic potential associated with the face of a π system, influence both the protein structure and the ion distribution in solvents (5). These factors play a central role in protein-protein and protein-ligand binding, particularly influencing the structure of the thin water layers between biomolecules in an encounter complex and thereby influencing intermolecular ET reactions (15).
Water and nonequilibrium solvation

Water also influences the nature of the motion along the ET reaction coordinate (donor, acceptor, and solvent degrees of freedom that are coupled to ET). A measure of the short timescale nonequilibrium solvation dynamics is the Franck-Condon time \( \tau_{FC} \). This time is the time it takes for the ET system to move away from the crossing point of the electron donor and acceptor potential surfaces where the activation complex is formed. For temperature \( T \) and reorganization energy \( \lambda \), \( \tau_{FC} \) is \( \tau_{FC} \approx \hbar/\sigma \Delta U \), where \( \sigma \Delta U = \sqrt{\lambda T} \) is the root mean square fluctuation in the donor to acceptor energy gap (16) and references therein). For biological ET, \( \tau_{FC} \) was computed for azurin ET (Ru\(^2+\)–Ru\(^3+\)) (17) using a semiclassical molecular dynamics (MD) methodology (18). The computed \( \tau_{FC} \) was 2.47 fs with significant protein and solvent (water) contributions. For protein alone, it was \( \tau_{FC} \approx 4.3 \) fs, and from solvent alone, it was \( \tau_{FC} \approx 3.0 \) fs. Water solvation dynamics are equally important for excited-state ET, in which the formation of the D excited state by photoexcitation may induce a large dipole moment change of the D moiety that is followed by rapid protein matrix and solvent response. Excited-state ET from (FADH\(^2\)) to DNA in DNA photolyase is an example of an ET reaction in which the change in dipole moment of the D moiety induced by photoexcitation [(FADH\(^2\)) \( \rightarrow \) DNA] has shown very fast and significant solvation dynamics induced by photoexcitation with relaxation timescales ranging from 2 to 60 picoseconds (20). This solvation dynamics, which is much faster than the ET rate, is partially attributed to water molecules in the DNA photolyase active site (20). Solvent relaxation can limit rates that are fast compared with the solvent relaxation timescale (21). This water is characterized by a broad distribution of relaxation timescales (subpicosecond and slower) and may therefore act as a rate-limiting solvent for ET reactions (21).

Tunneling mediation

The tunneling characteristics of biological ET have placed considerable recent focus on protein and solvent (3, 22). The energetic proximity of solvent and protein orbitals to the redox active states of the donor and acceptor cofactors provides supereexchange pathways for tunneling (23). That is, the energy cost of tunneling via these protein states is much lower than the cost of tunneling through “pure” empty space. As such, the intervening medium facilitates weak tunneling propagation of the electron from donor to acceptor via coupling pathways (24). The tunneling probability through this medium multiplies the Marcus factor described above. Early models for protein-electron tunneling predicted that rates would drop by about a factor of 10 for a 1 Å decrease in the 1980s and 1990s, approaches were introduced to explore the influence of the specific medium structure on the tunneling. In recent years, the influence of medium dynamics was added to complete the models (14, 25–29, and references therein).

The role of disordered water as a tunneling medium has been the subject of several electronic-structure computational studies. Early calculations focused on the Fe(H\(_2\)O)\(_{6}\)\(^{3+}/2+\) self exchange reaction (30–32). These calculations concluded that disordered water is not a very effective electron-tunneling medium. More recently, one-electron pseudopotential analysis of electron tunneling through water layers placed between electrodes indicated that water is a modest tunneling mediator (33). A further computational study of aqueous ET between ion pairs used MD simulations with INDO/S and CAS-SCF calculations of the electronic coupling (34). This study showed that water can be an essential tunneling medium. The computed INDO/S tunneling matrix element decay parameter was 2.0 Å\(^{-1}\) and the anisotropy values ranged from 1.5 to 1.8 Å\(^{-1}\). Experiments in aqueous glasses give average decay of 1.8 Å\(^{-1}\) (22).

Of particular interest is how oriented water in confined spaces contributes to tunneling. Several experiments indicate a special role for bridging waters (22, 35–37). Recent studies of interprotein ET reveal details of how the ensemble of docked structures contributes to the observed rate. The “dynamic docking” paradigm for ET between weakly associated proteins suggests that minority population configurations dominate the electron tunneling mediation (38). It seems likely that water can contribute to dynamic docking by influencing donor-acceptor coupling pathways or by modifying the reorganization energies as the proteins approach a docked structure. Newer developed experimental methods enable the study of electron transfer kinetics between co-crystallized proteins. These experiments are likely to provide direct answers to some of the questions of how specific waters at protein-protein interfaces may influence ET kinetics (22, 39).

The fleeting nature of water structures in proteins makes it extremely challenging to study their influence on ET by direct means. Indications that a few key bridging waters seem to accelerate protein ET reactions motivated a theoretical simulation of the presence of explicit bridging water molecules (35–37). Pathway studies indicate that waters at cytochrome c\(_o\) and the photosynthetic reaction center serve as key mediators (Fig. 1) (40) Quantum studies of water mediation in protein-protein systems indicate that spatially confined waters between proteins may enhance electronic coupling in a regime just beyond protein-protein contact (Fig. 2) (41). In this regime, the distance permits entry of a few intervening waters and the coupling is enhanced by constructive interference among multiple coupling pathways. At larger distances, the effect rapidly dissipates. These studies are motivating small-molecule studies of water-mediated electron transfer in systems with well-defined cavities that may bind water molecules (D. Waldeck, private communication).

Proton-coupled ET reactions

In bioenergetics, electron transfer drives proton transfer, proton gradients in turn power ATP synthesis. In addition to coupling to medium polarization, biological ET reactions may also couple strongly to proton transfer. As such, rates may be limited by proton transfer or electron transfer or may fall into an intermediate regime. Rapid advances are being made in both the theoretical and experimental investigation of these coupled rate processes (42, 43, and references therein).
Electron Transfer, Chemical Roles of Water in

Figure 1  Water-mediated ET pathways between cytochrome c2 and the photosynthetic reaction center in an encounter complex (left panel) and the more fully docked state (right panel) (40). The pathways are shown for 50 conformations obtained by MD sampling. Cofactor-mediated pathway fragments are shown in green, protein-mediated fragments are shown in purple, and water-mediated fragments are shown in orange.

Figure 2  Dependence of the mean square electronic coupling on distance between two porphyrin rings in the cytochrome b5 self-exchange ET reaction (41). For each distance, system conformations were sampled using MD and the coupling was computed for each conformation at the extended Hückel level. The black line marked XH(P, W) shows the water-mediated coupling; for comparison, the red line marked XH(P) shows the coupling computed for the same protein conformation in vacuum. Conformational snapshots typical for the three coupling regimes are shown.

Isotope effects on ET reactions

Substitution of H2O solvent by D2O generally leads to a change in ET kinetics (44, 45, and references therein). In the simplest model of ET coupled to a single solvent vibration involving H, substitution of H by D lowers the frequency of the vibration and increases the localization of the vibrational wave functions. These changes influence the Franck–Condon factor for the ET reaction in a way that depends on the temperature and on reaction energetics. For example, at low temperatures, when the vibrations are in their ground states, the increased localization (for deuteration) of the vibrational wave functions is expected to speed up an activationless reaction by enhancing the probability of being at the crossing point between D and A potential energy surfaces. In contrast, for an activated ET reaction at low temperature, the increased localization will reduce the probability of reaching the crossing point by nuclear tunneling, which, thus, slows down the ET reaction.

Protein ET systems have large and somewhat flexible macromolecule assemblies with folded structure and motion strongly coupled to the surrounding solvent. In these systems, isotopic substitution of the solvent may affect multiple factors that influence the ET rate, and, generally, the overall isotope effect on the ET rate is system-dependent. For example, D2O changes protein solvation because the solvent–solvent hydrogen bonds are stronger in D2O compared with H2O, which leads, therefore, to an increased hydrophobic effect. Changes in the fold and volume of a protein may alter the donor–acceptor distance, the redox potentials, and the tunneling-pathway networks, which all influence the ET rate.

The strengthened hydrogen bond networks in D2O, which lower molecular and solvent flexibility, produce larger reorganization energies and affect nuclear fluctuation timescales, which are especially important in gated and solvent-controlled ET. For proton-coupled ET reactions, D2O solvent substitution changes the proton transfer–electron transfer equilibria and kinetics. The literature on the isotope effect on ET is large and growing (44, 45, and references therein).

ET reactions controlled by conformational transitions and solvent viscosity

Because of the rapid decay of the electronic coupling with distance, very long-distance (>40 Å) ET reactions rarely occur in a single step. Instead, extremely long range ET involves an array of multiple redox centers, mobile electron carriers, or large-scale motion of redox-active domains (46). All intermolecular ET reactions require either protein–protein docking or formation of an encounter complex in which the two protein cofactors are

\[
\begin{align*}
\text{direct contact} & \quad \text{structured water} & \quad \text{bulk water} \\
10^{-14} & \quad 10^{-12} & \quad 10^{-10} & \quad 10^{-8} & \quad 10^{-6} & \quad 10^{-4} & \quad 10^{-2} & \quad 10^0 & \quad 10^2 \\
\text{XH(P)} & \quad \text{XH(P, W)} & \quad \text{XH(P)} & \quad \text{XH(P, W)} & \quad \text{XH(P)} & \quad \text{XH(P, W)} & \quad \text{XH(P)} & \quad \text{XH(P, W)} & \quad \text{XH(P)} & \quad \text{XH(P, W)}
\end{align*}
\]
within a few angstroms (40, 41). In these cases, protein diffusion in solvent, influenced by solvent viscosity, pH, and other factors, can be rate limiting if the formation of an encounter complex is slower than the ET reaction itself.

In unimolecular ET, the rate can be controlled by large-scale cofactor motion, such as the quinone motion in the photosynthetic reaction centers, the Rieske subunit motion in the cytochrome bc₃ complex (47), or the cytochrome bc₁ domain in sulfite oxidase. Theoretical models for conformationally controlled ET reactions have been suggested by Hoffman and Ratner (48) and Brunschwig and Stuiv (49). Large-scale protein or domain motions are themselves linked to the movement of water molecules.

**Experimental and Theoretical Methods**

**Experimental methods**

Ultrafast ET reaction kinetics usually is measured using transient absorption or luminescence spectroscopy. ET reactions are initiated by exciting the native or modified ET cofactor or by injecting an electron or hole by a flash-quench technique (22). Slower ET reactions can be studied by using a variety of methods, including calorimetry, stopped flow, dipole relaxation, and other techniques (4). Recent experiments on the structural relaxation of water provide intriguing observations of its structure and dynamics. For example, the coexistence of ordered surface water and crystallite-like ice structures following exposure to a femtosecond-range infrared laser pulse was observed with ultrafast electron diffraction methods (50). Studies of the first hydration shell of a water molecule in liquid water using X-ray absorption spectroscopy and X-ray Raman scattering reveal that water molecules typically form only two hydrogen bonds (one donor and one acceptor bond), contrary to predictions of MD simulations that suggest three or four hydrogen bonds (51). Theoretical calculations find the optimal combination of bonded and non-bonded links from the donor to the acceptor cofactors using an X-ray-determined protein structure (24). Intriguingly, with essentially one parameter (the ratio of through bond to through space coupling decay), the Pathways model qualitatively described the nature of ET rates in several redox proteins, facilitating an early phase of mapping structural effects on protein ET reactions (24).

**Theoretical methods**

Theoretical methods for estimating the reorganization energy have to account for its large variations in different environments. The Marcus model for ϵ_loxp assumes spherical donors and acceptor moieties embedded in a dielectric continuum that represents the solvent. ϵ_loxp is proportional to (1/ϵ_loxp - 1/ϵ_in), where ϵ_loxp is the optical dielectric constant and ϵ_in is the static dielectric constant of the medium. The dependence of ϵ_loxp on ϵ_loxp explains why ϵ_loxp is higher in water and highly polar solvents compared with nonpolar solvents. In low dielectric media like membranes, ϵ_loxp and ϵ_in are nearly matched, thus lowering the reorganization energy. The simple continuum model cannot be used to compute accurate reorganization energies in complex molecular environments. More sophisticated numerical approaches have been developed for the computation of ϵ (e.g., References 11, 56, 57, and references therein). Numerical approaches permit the computation of reorganization energies for cofactors of arbitrary shape (e.g., Reference 24). They can be combined with MD simulations to compute the reorganization energy for different MD conformations of the ET system to assess the influence of fluctuations. Different methods have also been developed for computing λ (e.g., References 11, 56, and references therein).

A variety of theoretical descriptions of hydrogen-bonding water networks has been proposed, including flickering clusters, percolation networks, fluctuating charges, random networks, continuum models, and so forth. (58), yet many structural aspects of liquid water remain open to debate (59, 60). Since the first explicit (atomic) model for water was proposed by Bernal and Fowler in 1933, a variety of water potential functions have been developed (61, 62). These water potential functions typically include noncovalent interactions, for example, Coulombic interactions among partial charges assigned to each atom (and to each electron lone pair in some models) and van der Waals interactions among atoms. Some force fields include elastic terms, namely O–H bond stretch and H–O–H angle deformations. Two force fields common in biomolecular simulations are the SPC model and the TIP3P model (61, 62). Both force fields are rigid, three-site descriptions that were parameterized to reproduce the bulk liquid water phase structure and thermodynamics. However, none of these (and similar) force fields accurately predicts the temperature dependence of liquid water’s density (60). Later force fields incorporated intramolecular flexibility (e.g., the TIP4P model (62)).
Electron Transfer. Chemical Roles of Water in

Other improvements include adding fourth and fifth sites, polarizability, and quantum effects (62). Although models like TIP4P and TIP5P provide a more accurate description of homogeneous bulk water, they perform poorly in describing gas-phase clusters and nonpolar solutes in polar solvents (62). In biomolecular simulations, these models cannot correctly account for situations when a nonpolarizable moiety is exposed to different electrostatic environments, either within a static structure or during simulations. Another problem with nonpolarizable models is that of including the average bulk polarization in the potential. Whereas polarizable force fields, such as the fluctuating charge and related models, attempt to address these problems with varying success, SPC and TIP3P remain the most appropriate force fields for simulations of large biomolecular systems (61). Sampling of the biomolecular conformations is usually performed using MD simulations or Monte Carlo methods (61, 62). The protonation state of titratable amino acids can be treated with constant pH dynamics, QM/MM calculations, or continuum electrostatics methods (61, 62). Formation of a protein–protein encounter complex is often studied using Brownian dynamics (63). Studies of protein–protein docking involve electrostatic potential analysis, and more recently, protein flexibility models, for example, normal mode analysis (64).

Frontiers in Biomolecular ET Reactions

Protein-mediated ET reactions

The photosynthetic cytochrome b6f complex is an integral part of the oxygenic photosynthetic electron–proton transport chain. It transfers electrons from photosystem II to photosystem I and moves two protons per electron transferred across the photosynthetic membrane to build a transmembrane proton gradient. The solution of the crystal structure of the cytochrome b6f complex (65) revealed the relative positions of its redox-active subunits, cytochrome f, cytochrome b, and the Rieske 2Fe–2S protein, as well as the structural similarities with the respiratory cytochrome bc1 complex. In the cytochrome b6f complex, a lipid-soluble quinol transfers an electron to the Fe2S2 center of the Rieske protein, an electron to the heme b6 of cytochrome b6 and two protons to the aqueous side of the thylakoid membrane. The Rieske 2Fe–2S protein subsequently reduces the heme c center of cytochrome f that extends into the aqueous side of the membrane. Cytochrome f reduces the Cu center of water-soluble plastocyanin that in turn transfers the electron to photosystem I. Cytochrome f contains a buried chain of five water molecules inside its heme-binding large domain. The water chains are hydrogen bonded to surrounding residues that are highly conserved in cytochrome f sequences (66). It was shown that mutations that affect this water chain impair electron transfer and photosynthetic function (67). The mutations also affected the redox potentials of cytochrome f (Fig. 3). It is possible that the water chain interacts with the Rieske 2Fe–2S protein when the latter approaches the hydrophilic edge of cytochrome f to transfer an electron to the heme (67). Water chains (as long as 10–12 water molecules) and smaller water clusters are also present in bacterial photosynthetic reaction centers. They connect the secondary quinone to the cytoplasmic surface and are thought to participate in proton transfer from the cytoplasm to the secondary quinone (6, and references therein; Fig. 4). Water molecules seem to play a more complex role in cytochrome c oxidase, the terminal component of the mitochondrial and to other bacterial respiratory chains. The protein performs the four-electron reduction of O2 to water and couples it to transmembrane proton transport. The mechanism of function for this enzyme is not fully understood and is the subject of ongoing studies (6, and references therein; Fig. 1).

Apart from the role of the water molecules as proton wires, it has also been suggested (although not demonstrated experimentally) that internal waters are involved in redox-linked switching of the proton wires. Electron transfer from the heme a of cytochrome c oxidase to the binuclear Cu–heme a3 site may invert the local electric field between the redox sites and thus cause restructuring of internal waters and the switching of the proton pathways (6, and references therein).
DNA-mediated ET reactions

DNA is a polyelectrolyte with a tightly bound spine of water. Both DNA damage and repair mechanisms involve ET (10). Water is an important determinant of DNA structural stability, both in the form of organized water that occupies the major and minor grooves of the DNA double strand and as bulk solvent (10).

The mechanism of DNA-mediated ET remains poorly understood. Theoretical and experimental studies are consistent with a mechanism of superexchange (tunneling) mediation at short distances and multistep hopping at longer distances. Intensive investigations are exploring the degree of delocalization of “holes” in the DNA stack and the polaronic nature of the transport (10). Water may influence DNA charge transport in a variety of ways. Bulk and structured water around DNA and specific water molecules in the minor groove (70) and ordered water chains surrounding and internal water molecules (71) mediate hole transfer by acting as a superexchange bridge (Fig. 4). DNA decamer duplexes determined the hydrogen and deuterium atomic positions of the water molecules that hydrate the DNA (69). These experiments show that the water network in the DNA minor groove can form interstrand and intrastrand bridges that connect different parts of the duplex by hydrogen bonds. Density functional electronic structure calculations using the hydrated duplex structure identified in these experiments showed that the structure has three nearly degenerate highest occupied molecular orbitals, each spatially distributed over the G bases, and specific water molecules in the minor groove (70). These results suggest that hydrating water molecules in DNA not only influence the electronic structure of the polaron hole (10) but also mediate hole transfer by acting as a superexchange bridge (Fig. 4).

Conclusions

A unified view of how water influences biological ET is yet to emerge. Many qualitative effects are apparent: Water produces large reorganization energies, and structured water may produce favorable electron and proton transport pathways. Water at protein–protein interfaces can perturb docking energetics and influence both the coupling mechanisms and ET reaction coordinate. Structured water chains provoke intriguing questions regarding electron and ion communication, coupling, and switching. In nucleic acids, water and DNA counter ions influence both the structure of “holes” and the kinetics of their transport.

Force measurements on a wide variety of biologic macromolecules indicate that the perturbation of water structuring as hydrated surfaces closely approach can dominate interaction energetics. Forces with remarkably similar characteristics are observed for the repulsive interactions of charged polymer surfaces, of uncharged polymer surfaces, of charged solutes with uncharged surfaces, and of uncharged solutes with charged surfaces stressing the universality of the hydration force in aqueous solution. Repulsive interactions are caused by a disruption of the hydrogen bonding network of the intervening water between surfaces. The available measurements of forces between macromolecules that spontaneously assemble are consistent with an attractive hydration interaction. A water-order parameter theory has been developed that is successful for predicting force curve behaviors. The direct involvement of water structuring in the interaction between macromolecules has important consequences for recognition, assembly, and conformational transitions that underlie biologic function.

In the simplest representation, hydration forces reflect the energetic consequences of perturbing the water structure as two hydrated surfaces approach. The concept developed as a result of direct measurements of interactions between macromolecules or surfaces in water that were unlike the forces commonly considered important (1-14). As is amply described elsewhere in previous articles, polar or charged surfaces bind and structure water strongly. Hydration contributes substantially to structure and stability. Water is a highly associative liquid because of its strong hydrogen-bonding ability; the structuring of water in direct contact with the macromolecular surface will alter the structure of subsequent water layers in solution. As two hydrated surfaces approach, the intervening water must accommodate both surfaces. Depending on the nature of the opposing surfaces, the hydrogen-bonding network of water can be disrupted, resulting in repulsion, or reinforced, causing attraction. Ample evidence from infrared or Raman spectroscopy, neutron scattering, and dielectric relaxation shows that the structuring of water in confined spaces, as in zeolites, inverse micelles, or very small droplets, can be different from bulk water (15-22) and references therein). In practice, hydration forces are observed between macromolecules only over the last 1–1.5-nm separation between surfaces, which corresponds to about the two last water layers on each surface. Although the energy perturbation per water molecule can be relatively small, the force can be large when summed over all the water molecules that must be reorganized. An order parameter theory has been developed to formalize the treatment of hydration forces and has been surprisingly insightful.

Force Measurements
We present the force measurements that led to the hypothesis of hydration forces, focusing on the osmotic stress measurements of several very different biologically important assemblies: lipid bilayers, DNA, collagen, and several different polysaccharides. The measurement of repulsive hydration forces between macromolecules at close approach has now been supplemented by similar measurements for the exclusion of small solutes from macromolecular surfaces. Atractive hydration interactions are more difficult to probe, but the available evidence indicates that the polycation-mediated assembly of DNA and the temperature-favored assemblies of collagen and hydrophobically modified cellulose are examples of attractive hydration forces. Lastly, the magnitude of the observed hydration forces means that polar surfaces will avidly cling to the hydration waters in the absence of a stringently complementary surface that can replace the favorable water interactions. This has profound consequences for recognition and assembly reactions in the cell that are typically characterized by both binding strength and specificity. Water structuring forces or energetics have
be sensitive to salt, solutes, pH, temperature, and so on. Along the macromolecule, the partial derivatives in the above expression represent the forces acting to push \( N(CH_3)_4^+ \)-DNA helices to touching, for example, in a DNA helix-DNA helix interaction. The same kind of force is observed to dominate the interactions of small solutes with macromolecular surfaces. The osmotic stress approach has also been used to map the distribution function for the exclusion of small nonpolar solutes from DNA and of polar solutes from hydrophobically modified cellulose. The partial derivatives in the above expression remind us that forces between macromolecules can be sensitive to salt, solutes, pH, temperature, and so on.

Hydration Repulsion

Figure 1 shows osmotic stress force curves, \( \log(\Pi_{\text{osm}}) \) versus the surface separation between macromolecules, for several different macromolecular assemblies that are charged, zwitterionic, or completely uncharged. Unlike hard materials such as mica or clays that show oscillating forces as surfaces approach \( 3–4 \AA \) exponentially, biologic macromolecules have forces that decay as \( 3.5–4 \AA \) exponentials with a 3.5–4-Å decay length \( \lambda \).

Order Parameter Theory for Hydration Forces

A phenomenologic theory has been developed to account for hydration forces (42–45). Water organized by surfaces is characterized by an order parameter. The linearized theory is mathematically equivalent to the Debye-Hückel formulism for electrostatic double-layer interactions. Homogenous surfaces that contain salt and other small solutes that equilibrate between the backbone phosphate neutralized by \( N(CH_3)_4^+ \), for egg phosphatidyl choline that has a \( CH_3 \) \( H_2 \) \( CH_2 \) group covalently linked to the phosphate of the lipid head group and didodecyphosphosphate in \( N(CH_2)_4^+ \) is shown scaled to the same phosphate surface area. The surface hydration is dominated by the phosphate group with an additional weak contribution from the tetraalkylamine counterion. The macromolecular surfaces with the same hydrated chemical groups show similar force amplitudes. The common unifying theme is that all the macromolecular systems are hydrated. Within the hydration force framework, the 3–4-Å exponential decay length \( \lambda \) reflects a water-water correlation length. Such a correlation has been observed by X-ray scattering for density fluctuations in pure water (38). The force amplitude or pre-exponential factor is caused by the structure of water in direct contact with apposing surfaces. In all cases exclusion is characterized by a 3.5–4-Å decay length associated with the pre-exponential factor for the exclusion of simple nonpolar alkyl alcohols from DNA and of polar solutes from hydrophobically modified cellulose. The pre-exponential factor for the exclusion of simple nonpolar alkyl alcohols from DNA varies linearly with the difference between the number of alkyl carbons and hydroxyl oxygens (43) in the solute, which further emphasizes the connection between molecular hydration and force magnitude.
Figure 1 Osmotic stress force curves are shown for several biological assemblies: schizophyllan (a triple helical polysaccharide composed only of glucose) in water (\(\bullet\)), \(\iota\)-carrageenan (a double helical charged polysaccharide) in 0.4-M NaCl (\(\square\)), hydroxypropyl cellulose in water at 5°C (\(\circ\)), DNA in 0.4-M NaCl (\(\triangle\)), DNA in 0.4-M \(\text{N(CH}_3\text{)}_4\text{Cl}\) (\(\triangleleft\)), DNA in 0.25-M \(\text{N(CH}_3\text{)}_4\text{Cl}\) scaled to the same phosphate surface density as DDP and egg PC. Those biomacromolecular assemblies measured in water are net neutral, either zwitterionic (egg PC) or wholly uncharged (schizophyllan and HPC). Forces between charged surfaces are insensitive to salt concentration over the last 10–15 Å, but they do depend significantly on the counterion identity. The X-ray spacings have been adjusted to give approximate surface separations from either gravimetric measurement of spacing as dependent on water content (the lipid bilayers), fiber dimensions determined by X-ray scattering (DNA, schizophyllan, and \(\iota\)-carrageenan), or the spacing between polymers when dried (HPC). Even though force amplitudes span a range of \(\sim\)1000 in pressure, the decay lengths, \(\lambda\) of the apparent exponential are similar for all these systems; the fits to the schizophyllan and DDP forces give 3.4 and 3.5 Å, respectively. The overlap of the force data for egg PC, \(\text{N(CH}_3\text{)}_4\text{Cl}\)–DDP, and \(\text{N(CH}_3\text{)}_4\text{Cl}\)–DNA scaled to the same phosphate surface area indicates that force amplitudes are determined by the hydration of groups on the surface. Data for DDP and egg PC are from Leikin et al. [2].

Organize water symmetrically, as illustrated in Fig. 3a, are repulsive since the hydrogen-bonded network between surfaces will become increasingly disrupted as surfaces move closer.

The order parameter theory gives for the osmotic pressure between two planar surfaces with a separation D and water–water correlation length \(\lambda_w\),

\[
\Pi^{\text{homo}}_\text{water} = \frac{C_r}{\sinh^2(D/2\lambda_w)} \sim C_r e^{-D/\lambda_w}, \text{ for } D \gg \lambda_w
\]

Similarly, two homogeneous surfaces with a complementary water structuring, as illustrated in Fig. 3b, will be attractive, as the hydrogen-bonding structure of the intervening water is strengthened,

\[
\Pi^{\text{homo}}_\text{water} = -\frac{C_a}{\cosh^2(D/2\lambda_w)} \sim -C_a e^{-D/\lambda_w}, \text{ for } D \gg \lambda_w
\]

The coefficients \(C_a\) and \(C_r\) are measures of the strength of water ordering on the surface.

Of course, biological surfaces are not homogeneous. Real surfaces typically can have both opposing attractive and repulsive patches. In such a case, the osmotic pressure can be represented by (2, 9, 13, 46, 47),

\[
\Pi = \frac{C_a}{\cosh^2(D/2\lambda_w)} + \frac{C_r}{\sinh^2(D/2\lambda_w)} \sim -(C_a - C_r)e^{-D/\lambda_w} + (C_a + C_r)e^{-2D/\lambda_w}, \text{ for } D \gg \lambda_w
\]

In the case, \(C_a \gg C_r\), repulsions dominate and the purely repulsive exponential form \(\Pi \sim -C_a e^{-D/\lambda_w}\) is recovered. If the attractive and repulsive patches are balanced, then the second-order term of the approximation dominates with an apparent decay length that is only half that of \(\lambda_w\), or \(\sim 2\) Å. This second-order term is always repulsive and reflects the loss of favorable water–water interactions that are caused by the presence of the other surface. Its magnitude is only dependent on the overall surface water structuring whether attractive or repulsive.

Often decay lengths do not divide so neatly into two classes of value. Three complications can cause significant variability in observed decay lengths. Surface periodicities or the separation length scale of hydrated groups on the surface must necessarily contribute to decay lengths (2). This effect will decrease the
Hydration Forces

Figure 2. The distance dependence characterizing exclusion of small solutes from macromolecular surfaces follows the same exponential behavior as the hydration force between macromolecules. The extent of exclusion can be extracted from the dependence of forces on solute concentration. \( \Pi_{\text{excess}} \) is the effective osmotic pressure applied by the solute in the bulk solution on the macromolecular phase, and \( \Pi_{1} \) is the maximal pressure from complete exclusion. \( \Pi_{\text{excess}}/\Pi_{1} = 0 \) then corresponds to complete exclusion and \( \Pi_{\text{excess}}/\Pi_{1} = 1 \) then indicates full inclusion. The distance dependent exclusion of the polar polyol adonitol (a) and glycerol (g) from hydrophobically modified hydroxypropyl cellulose (HPC) and of the nonpolar alcohols i-propanol and methyl pentanediol (MPD) from spermidine3 alkyltriamine spermidine is shown. As in Fig. 1, interaxial spacings are converted to surface separations. The apparent exponential decay length varies between 3.5 and 4 Å (solid lines indicate fits to the data).

Hydration Attraction

If \( C_{s} \gg C_{1} \), in Equation 4, then attractive forces can result. Forces measurements on DNA double helices spontaneously assembled by polycations provide evidence for attractive hydration forces (12, 13). The binding of several polycations result in spontaneous condensation of DNA. Packaging of genetic material in vivo and compaction of DNA for use in nonviral gene therapy exploit this attraction. The equilibrium spacing between helix surfaces in the condensed state varies between 6-12 Å depending on the nature of the condensing counterion indicative of both attractive and repulsive forces acting on DNA as implicit in Equation 4. Figure 4 contrasts the osmotic stress curves for DNA in the +3 alkyltriamine spermidine that results in spontaneous precipitation of DNA, in the +2 alkylamine putrescine, and in the +1 alkylamine tetramethylammonium, \( \text{N(CH}_{3}\text{)}_{4}^{+} \). Neither putrescine2- nor \( \text{N(CH}_{3}\text{)}_{4}^{+} \) condenses DNA. The \( \text{N(CH}_{3}\text{)}_{4}^{+} \)-DNA curve shows a 4-Å single exponential characteristic of purely repulsive hydration forces dominated by the first-order term of Equation 4. The putrescine2- -DNA force curve also shows a single exponential force at high osmotic pressures but with a \( \sim 2 \)-Å decay length indicative of a balance between attractive and repulsive patches that leaves the second-order term of Equation 4 dominant. The force curve in the presence of spermidine3- is different. At \( \Pi_{1} = 0 \), there is a balance between the attractive first-order term and the repulsive second-order term that results in a finite equilibrium spacing (arrow). This spacing leaves \( \sim 9.5 \) Å of water-filled space between DNA molecules. The curve eventually merges with the single exponential, \( \sim 2 \)-Å decay length observed with putrescine2- as the interhelical spacing decreases, which aligns with the prediction of the order-parameter formalism for the emergence of a second-order repulsive term in the presence of hydration attractions. The merging of spermidine and putrescine forces at high osmotic pressures is expected for DNA surfaces with chemically homologous bound cations. The second-order repulsion is simply determined by the overall water structuring on a single helix, not on the specific mixture of attractive and repulsive patches. Determining the decay length for attractions is more difficult because there are currently no experimental techniques to directly measure attractive forces between molecules. Combining single-molecule force measurements of net attraction with the osmotic stress...
The temperature-favored assembly of hydrophobically modified cellulose, hydroxypropyl cellulose (HPC), has also been probed (31). At temperatures below ~40°C, exponential repulsive forces are observed with an approximate 3-4 Å decay length. At very close spacings (~2 Å surface separation), the force amplitude increases rapidly, which is likely caused by steric interactions between hydroxypropyl groups on the surface. The force amplitude of the 3-4 Å decay length exponential decreases linearly with temperature extrapolating to 0 at ~40°C very close to the temperature at which the polymer precipitates from dilute solution, ~42°C. Above 40°C, the equilibrium spacing between HPC polymers in the absence of applied osmotic pressure continuously decreases with increasing temperature. Since the very short-ranged steric force does not change observably with temperature, this change in equilibrium spacing must result from an attractive force with an amplitude that increases with temperature. Force data above 40°C can be well fit by the sum of the rapidly changing short-ranged force and an attractive 4 Å decay length exponential. Remarkably the temperature dependence of the fitted attractive force amplitude is a linear continuation of the repulsive force amplitudes directly observed at lower temperatures. Since hydrophobic forces have long been considered to be caused by the release of water structured around nonpolar surfaces, a connection with hydration forces should not be surprising. The strengthening of attraction or weakening of repulsion as the temperature increases is caused by a difference in the temperature dependence of water structuring around polar hydroxyl groups and nonpolar methyl groups. A confounding aspect, however, is that the 2 Å second-order repulsion observed with condensed DNA is completely absent with HPC. This hydrophobic polymer simply acts as a homogeneous surface that smoothly transforms from repulsive to attractive as the temperature is increased.

Hydration Linked to Recognition Reactions and Protein Transitions

The important lesson from the direct force measurements for biology is that polar or charged surfaces will avidly retain their hydration waters in preference to other surfaces if those surfaces are not closely complementary. A key difference, therefore, between specific and nonspecific binding of proteins, for example, should be in the water sequestered by the complexes (53, 54). Differences in water between specific and nonspecific recognition complexes can be readily determined from the dependence of the relative equilibrium constant or ligand binding constant on osmotic pressure or water activity. For osmotic pressures expressed as an osmolar concentration, a standard linkage relation is applied to water in a same way it is traditionally applied to salt, ligands, or pH is,

\[
\frac{d \ln (K_{eq})}{d [\Pi_{w}]} = -\frac{\Delta N_{w}}{55.56}
\]

where \(K_{eq}\) is the equilibrium constant between two complexes and \(\Delta N_{w}\) is the difference in bound water between them.
We have focused on differences in hydration among specific, noncognate, and nonspecific complexes of three sequence specific DNA binding proteins. DNA binding proteins will typically bind to nonspecific DNA or indeed to polyanions in general with binding constants in the range from $10^2$ to $10^7$ M$^{-1}$ and to their recognition sequence with constants typically in the range $10^3$ to $10^5$ M$^{-1}$.

The water release accompanying the transfer of the type II restriction nuclease BambhI from a nonspecific sequence to the recognition sequence was measured in order to validate the osmotic stress approach (55). Crystal structures of both the specific (56) and the nonspecific (57) complexes are known. The nonspecific structure shows a gap between the protein and DNA surfaces that can accommodate $\sim$150 waters. The two interfaces are in direct contact in the specific complex (Fig. 5). Relative nonspecific-specific binding constants can be determined from the loss of specific binding as the concentration of nonspecific competitor DNA is increased, using either a gel mobility shift or a self-cleavage assay (58). Relative binding constants vary significantly with the concentration of added osmolytes. The linear dependence of $\ln(K_{rel})$ on the osmotic pressure of the added solutes observed in Fig. 5 indicates that about 135 ($\pm$15) extra water molecules are retained in the nonspecific versus specific BamHI-DNA complex in good agreement with the structural data. The insensitivity of $\Delta N_w$ to the osmolyte used set water activity indicates that this water is likely sequestered at the protein-DNA interface of the nonspecific complex. This number of waters corresponds to about one-two hydration layers at the interface.

EcoRI is another type II restriction endonuclease that recognizes the DNA sequence GAATTC. As is typical for these restriction nucleases, sequence recognition is exquisitely stringent. The change of even a single base pair is sufficient to reduce the binding constant by a factor of $10^4$ to a value more characteristic of completely nonspecific binding (59). The osmotic pressure dependence of the relative specific-nonspecific binding constant indicates that the nonspecific EcoRI-DNA complex sequesters $\sim$110 more waters (60, 61). EcoRI complexes with DNA sequences that have even one wrong base pair ("star"-sites) also sequester $\sim$110 more waters than the specific complex. This water, however, can be removed from complexes with a single wrong base pair by increasing the osmotic pressure (62). The osmotic work required to remove almost all of the water from a complex of EcoRI with the sequence TAAACCT was estimated as 3–4 Kcal/mole complex. Water could not be removed from complexes with more than one wrong base pair even at the highest osmotic pressures examined. The loss of water from the "star" sequence complexes provides a natural link between enzymatic "star" activity of EcoRI and osmotic pressure.

The binding of the Cro repressor protein to DNA is more typical of specific-DNA-protein interactions. Unlike BamHI and EcoRI, changes in the DNA recognition sequence result in gradual decreases in the binding free energy of Cro protein. This bacteriophage $\alpha$ repressor recognizes two 6 base pair regions separated by a 5-bp spacer. An examination of a set of 5 binding sequences that span a range of $\sim$2200 in relative binding constants shows that for every 10-fold decrease in binding constant about eight to nine more water molecules are incorporated by the complex (63). Water and binding energy are strongly coupled. There are also marked differences in the extent of hydration between specific and nonspecific protein-protein interfaces. In a survey of crystal structures in the Protein Data Bank, the average number of crystallographically resolved waters in specific binding interfaces (for instance, between dimers) was compared with the number of waters in nonspecific "crystal contacts" (protein crystal contacts not normally involved in biologic interactions) (64, 65). With an average of 10 waters per 1000 Å$^2$, the biologically specific interfaces are 50% less hydrated than the crystal packing interfaces. These numbers represent waters sufficiently immobilized to be visible by X-ray and underestimate the actual amount of water at protein-protein interfaces. Although neither interface is dry, the displacement of interfacial waters at the protein-protein interface was a distinguishing characteristic of specific binding.

Allosteric conformational changes are a hallmark of protein structure and function. Small changes in the structure of a binding pocket can often trigger large conformational changes elsewhere in the protein. Hydration forces are reasonable candidates for this amplification of small structural perturbations since small rearrangements of the chemical groups on surfaces can result in large changes in the hydration force between them. Once again a coupling between water and conformation should be expected if hydration forces underlie the structural change. The T-R transition of hemoglobin that accompanies oxygenation is the best known and most extensively studied allosteric reaction. The binding of 4 O$_2$ molecules is linked to the binding of $\sim$50–60 extra water molecules by the protein as surfaces that were complementary are slightly perturbed and now prefer interactions with water (66).

Conclusions and Prospectives

Although it is almost universally acknowledged that water plays an important role in biologic assembly and recognition processes (67), defining its role quantitatively, however, has proven more difficult. It has long been known that the unfavorable interaction of water with nonpolar groups underlies the hydrophobic interaction. The observation of a common force at close separation among nonpolar, polar, and charged macromolecules that can be interpreted as resulting from water structuring greatly broadens the scope of hydration-driven interactions. The observed force is unlike that expected for double-layer electrostatics or van der Waals interactions that are more commonly considered important. Removing the last one or two layers of water between macromolecules is energetically costly if the apposing surfaces are not closely complementary. The force characteristics observed, particularly the observed decay lengths, seem remarkably simple and robust. The transmission of surface water structuring into the solution through correlated water-water interactions can account for the decay lengths. The order parameter theory provides a satisfactory initial framework for understanding and calculating hydration.

Hydration Forces

Figure 5  The nonspecific DNA complex of the restriction nuclease BamHI retains significant water at the protein-DNA interface compared with the specific complex. Neutral osmolytes (triethylene glycol, α-methyl glucoside, and glycine betaine) are added to the solution to change water activity. Increasing the osmotic pressure of the bulk solution increases the free energy difference between specific and nonspecific binding. The linear dependence corresponds to 135 more water molecules sequestered by the nonspecific complex compared with the specific complex. The insensitivity to the nature of the osmolyte indicates the water is sterically sequestered. The inset shows the structures of the nonspecific (pdb identification-1esg) and specific (1bhm) complexes of BamHI looking down the DNA axis. The DNA is in tan, and the BamHI protein in blue. The nonspecific complex has a gap at the DNA-protein interface large enough to accommodate ∼150 water molecules that is not present in the specific complex. 

forces. The frustrating gap in our understanding is in connect-
sing surface water structuring with the pre-exponential factors, C0 and C1 of Equation 4. Making this link is necessary to de-
velop predictive tools for calculating hydration forces, but it will
require the combined contributions of theory, careful character-
ization of surface water structuring, and further measurement of intermolecular forces.

Water is an integral part of DNA structure, and it plays an important role in dictating conformational preferences and binding properties of nucleic acids. Although in recent years a wealth of information on the physical properties of water in the vicinity of nucleic acids has accumulated, our understanding of how water interacts with nucleic acids and how it mediates DNA recognition by small ligands and DNA-binding proteins remains limited. In this article, we review the current state of DNA hydration research. In particular, we discuss structural, dynamic, and thermodynamic aspects of nucleic acid hydration. We also present an overview of the structural and thermodynamic role of water in modulating protein–DNA recognition and highlight the importance of hydration as a major contributor to the energetics of nucleic acid recognition. We emphasize the need for additional physico-chemical studies of DNA hydration by experimental and theoretic scientists.

**Liquid Water**

Water is the least understood liquid with respect to its macroscopic properties; yet, because of those same properties, it is also the only milieu known to support life (1). Some of the more important properties of water that make life possible are the negative change in volume associated with the ice-to-water transition, the density maximum at 4 °C, the anomalously high melting and boiling points, the high mobility of H3O+ and OH− ions, and its translucency to visible light. The ability of a water molecule to engage in hydrogen bonding is the key to understanding the macroscopic anomalies of liquid water. A water molecule can act simultaneously as both donor and acceptor of hydrogens, which leads to the formation of extensive hydrogen-bonded networks in liquid water. In crystalline ice, each water molecule is hydrogen bonded to four nearest neighbors that are arranged spatially with local tetrahedral symmetry. A comparison of the enthalpies of fusion and sublimation of ice reveals that liquid water at 0 °C is only ~15% less hydrogen bonded than ice. At 100 °C, liquid water still retains half of its hydrogen bonds.

The current view of liquid water is that of highly dynamic, random, three-dimensional networks of hydrogen-bonded water molecules with a local preference for tetrahedral geometry but with a large proportion of strained and broken hydrogen bonds (1). The abnormal properties of water are thought to result from the competition between bulky water structures networked by strong hydrogen bonds and more compact arrangements of water molecules with a prevalence of strained and broken hydrogen bonds (1). The distribution of water structures can be described by a pressure- and temperature-dependent partition function that takes into account the free energy differences between the various hydrogen-bonded arrangements. This distribution is altered locally under the influence of a solute; however, the change in distribution is paid for by respective changes in free energy, entropy, and enthalpy. These thermodynamic changes depend on the chemical nature of the solute (charged, polar, nonpolar) and, correspondingly, the nature of solute-solvent interactions.

**Hydration as a general phenomenon**

Water is not just a medium that dissolves a solute. Interactions between solute and water also dictate the conformational preferences of macromolecules, simultaneously guiding and actively participating in all aspects of molecular recognition. The modifying effect of hydration can have both structural and thermodynamic components. The structural effect is exerted by ordered waters that serve as localized hydrogen donors or acceptors for polar and charged groups of a macromolecule or their complexes and may be conceptualized as a structural extension of the macromolecule. The thermodynamic contribution of hydration is caused by solute-induced changes in the energetics of all affected waters. In this context, structural waters
Water of hydration is chemically identical to water in the vicinity of a solute. From a thermodynamic standpoint, hydration can be viewed as binding of water molecules to the hydration sites of a solute. The energetics of this association is modulated by the type of solute-solvent interactions (electrostatic, hydrogen bonding, van der Waals) and by solute-induced solvent reorganization. The latter occurs even in the absence of appreciable solute-solvent interactions because the equilibrium distribution of hydrogen-bonded water networks of the bulk becomes disrupted at the solute surface.

Water represents an integral part of DNA structure with the energetics of hydration being an important determinant of the conformational preferences of nucleic acids and the affinity and specificity of DNA interactions with other molecules. In the sections that follow, we discuss the current state of knowledge on the impact of hydration on nucleic acid structure and recognition.

Physical properties of DNA hydration

Water of hydration is chemically identical to water in the bulk. The differences between these two populations of water involve only their physical properties. Consequently, many physical methods have been employed to characterize water of DNA hydration.

Gravimetric measurements, in which the weight of water adsorbed by DNA films is determined as a function of relative humidity, have a long and venerable history (2, 3). Falk et al. (2) have concluded that, at 92% humidity, double-stranded DNAs are hydrated with about 20 water molecules per nucleotide. More recently, a comparative gravimetric investigation of the poly(dA)poly(dT) duplex and the poly(dT)poly(dA)poly(dT) triplex revealed that, at 98% humidity, the duplex and the triplex are hydrated by 21 ± 1 and 17 ± 2 waters per nucleotide, respectively (3). These findings are in quantitative agreement with the results of infrared spectral studies of DNA films performed as a function of relative humidity (3-5). Results of a detailed infrared study suggest that the initial hydration of the sugar-phosphate backbone and heterocyclic bases (at 64% relative humidity) includes about six water molecules (5). At this stage, the less-hydrated A-conformation DNA begins to form. An increase in humidity leads to additional binding of four to five more water molecules. At this level of hydration, formation of A-DNA is complete. Finally, above 95% humidity, the number of water molecules in the hydration shell of DNA becomes equal to ~20 per nucleotide, which results in the final stabilization of B-DNA.

One manifestation of strong solute-solvent interactions is the inability of affected waters to freeze when the temperature falls well below the freezing point. Nuclear magnetic resonance (NMR), infrared spectroscopy, and low-temperature calorimetry have been employed to characterize the number of nonfreezing waters in the hydration shell of DNA (6-9). Based on their infrared measurements of DNA films, Falk et al. (6) have concluded that about 10 water molecules per nucleotide are incapable of freezing with an additional 3 waters that show a tendency to supercool at a high cooling rate. Subsequent low-temperature NMR measurements in dilute DNA solutions have revealed a significantly greater number of nonfreezing water molecules that ranges from 27 to 29 molecules per nucleotide (7). The observed discrepancy may reflect partially a higher sensitivity of NMR over the early infrared spectroscopic techniques for characterizing water states.

Systematic differential scanning calorimetric measurements have revealed the sequence and conformation dependences of the number of nonfreezing waters in DNA hydration shells (8, 9). These studies have suggested that duplex DNA contains 11. CsCl density gradient ultracentrifugation of genomic DNA have concluded that, at 92% humidity, double-stranded DNAs have revealed a significantly greater number of nonfreezing waters per nucleotide than the single strand (10 vs. ~7 waters), whereas AT-rich domains of DNA are more hydrated than GC-rich domains (14 vs. 8 nonfreezing waters per nucleotide). These calorimetric results seem to be in qualitative agreement with the results of ultracentrifugation and osmotic stress studies (10, 11). Results of osmotic stress measurements have suggested that the triplex-to-duplex plus a single-strand transition of poly(dT)poly(dA)(poly(dT)) is accompanied by releasing one water molecule per triplet, whereas the duplex-to-single strand transition of E. coli DNA and poly(dA)poly(dT) causes the release of four water molecules (10). It has been noted, however, that at reduced humidity, GC base pairs exhibit a greater predisposition to adopt the A-conformation than do AT base pairs (12, 13). Consequently, the results of these low water activity studies may predominantly reflect reduced hydration of A-relatives to B-DNA rather than the differential hydration of GC and AT base pairs.

Volumetric investigations have provided a wealth of information on the sequence-, composition-, and structure-dependent hydration of nucleic acids and their low-molecular-weight analogs (14). The partial molar volume, V′, and adiabatic compressibility, K′, have proven to be sensitive to solute hydration (14). Generally, when comparing solutes that are structurally and compositionally similar, lower values of V′ and K′ (less positive or more negative) correlate with stronger and/or more extensive hydration of the solute. The partial molar volumes, V′, and adiabatic compressibilities, K′, of lithium, sodium, potassium, rubidium, cesium, ammonium, and tetramethylammonium salts of various polymeric nucleic acids have been determined at 25 °C with rigorous consideration of the Donnan membrane equilibrium effect (15). These measurements have revealed that, for any salt, the poly(dIdC)poly(dIdC) duplex is the most hydrated B-form DNA duplex followed by the poly(dGdC)poly(dGdC) and poly(dAdT)poly(dAdT) DNA duplexes. Furthermore, it has been observed that B-DNA generally exhibits lower values of V′ and K′ than A-RNA, with the latter including poly(rA), poly(rU), poly(rG), poly(rC), and poly(rU)poly(rC). Finally, single-stranded poly(U) is more hydrated than double-stranded poly(A)poly(rU) (normalized per base), an observation consistent with an increase in hydration accompanying the helix-to-coil transition. This notion is in agreement with a decrease in compressibility accompanying helix-to-coil transitions of polymeric DNA and RNA.
duplexes (16), although it contradicts the results of osmotic stress and low temperature calorimetric investigations (9, 10). The discrepancy may reflect differential probing of hydration by different techniques, which emphasizes again that hydration is defined operationally and it depends on the experimental observable.

In summary, the picture emerging from these studies suggests that DNA is an extensively hydrated macromolecule; the very structure of DNA is dictated by its interactions with water. The aggregate results suggest that 10 to 38 waters per phosphate interact with DNA and that these waters can be distinguished from bulk water by various physical observables. DNA hydration, as characterized by physical methods, has been shown to be sequence-, composition-, and conformation-dependent. However, different physical parameters are sensitive to different subpopulations of waters of hydration. As such, different parameters may be complementary but not directly comparable with each parameter providing its own unique window into a particular aspect of DNA-solvent interactions.

**Structural Aspects of DNA Hydration**

Information about ordered waters around nucleic acids comes predominantly from single-crystal X-ray studies of DNA and RNA oligonucleotides, although fiber diffraction data also have provided valuable insights. X-ray crystallography enables one to detect a subpopulation of the more localized water molecules predominantly from the first hydration shell of a biopolymer. Less localized waters or waters from more distant hydration shells are bound less tightly and generally do not contribute to measurable electron densities. Analysis of X-ray diffraction patterns in terms of hydration requires a combination of high quality data and reliable methods of refinement. Waters of hydration are in dynamic equilibrium with bulk water and generally exhibit low site occupancies and high temperature factors. Consequently, X-ray crystallography detects not solvent molecules themselves but loci that are occupied frequently and that are referred to commonly as hydration sites. The presence of cations in the vicinity of DNA may cause electron densities to be mistaken easily for those of water molecules.

With these notes of caution, X-ray crystallographic studies have provided important insights into the patterns of hydration of the A-, B-, and Z- conformations of DNA. In a seminal work, based on 15 B-DNA, 22 A-DNA, and 22 Z-DNA structures, Schneider et al. (17) have determined the average number of water molecules located in the first hydration shells of phosphates and bases of A-, B-, and Z-form DNA. It has been found that the sum of the waters in the hydration shells of phosphates and bases coincides with the net number of ordered waters in A- and B-DNA. This agreement is consistent with a picture in which the hydration shells of phosphate groups and bases in DNA do not overlap. By contrast, the sum of phosphate and base waters in Z-DNA (6.8) is larger than the total number of ordered waters (5.3), which suggests an overlap between the hydration shells of the backbone and the bases. The latter reflects the presence of continuous water networks that bridge phosphates and bases, which is a hydration signature of Z-DNA; Z-DNA is favored by low water activity conditions.

In agreement with conventional wisdom, in all three forms, water exhibits the highest affinity for the anionic O3P and O2P oxygens (see Fig. 1) (17, 18). The next highest affinity is observed for the hydrophilic exocyclic and endocyclic nitrogens of the bases (17, 18). Each of the two partially charged phosphate oxygens, O1P and O2P, has three hydration sites in the first layer, which form a so-called “cone of hydration.” By contrast, O3P and O5P phosphate ester oxygens and the ring oxygen O4′ are hydrated poorly. No ordered water molecules exist within 3 Å from O3P and O5P oxygens. In the right-handed A- and B-DNA, O5P is excluded sterically from water. All water contacts to O3P are longer than 3.1 Å, which suggests only weak hydrogen bonding of waters that are bound primarily to the partially charged oxygens O1P and O2P.

The O4′ oxygen of the furanose ring, which is often shielded by the attached base or by stacking on a neighboring base, can participate in hydration networks, although its involvement depends on its accessibility to water (18, 19). In A- and B-DNA, O4′ usually shares water molecules with the minor groove hydropathic base atoms from a previous residue. In the Z- form, only the guanine sugar O4′ atom is accessible for hydrogen bonding, because the O4′ atoms of cytosine sugars are oriented toward the guanine ring of the next residue.

In B-DNA, water molecules that solvate neighboring phosphate groups can be linked only through second-layer waters (17, 19). By contrast, in A- and Z-DNA, water molecules frequently bridge anionic phosphate oxygen atoms of different residues (17-19). In A- and Z-DNA, water molecules that bridge anionic phosphate oxygens form apparent strings of water along the duplex backbone. In fact, it has been proposed that the more economical hydration of phosphate oxygens in A- and Z-DNA relative to B-DNA is the driving force behind the B-to-A and B-to-Z transitions observed in conditions of reduced water activity (20).

The periodic order of double-stranded nucleic acids facilitates arrangement of water molecules into regular hydration networks in and at the grooves. Except for B-DNA with its strong, sequence-dependent pattern of minor groove hydration, polar atoms in the DNA grooves are well hydrated at about half the level of the O1P and O2P oxygen atoms (17-19). In the minor groove of AT-rich domains of B-DNA, water molecules that bridge the adenine N3 and thymine O2 atoms are, in turn, connected via other waters, there by creating the spine of hydration. A similar spine of hydration has been reported for the minor groove of Z-form d(GCCCGC), where water molecules form hydration networks that bridge O2 cytosine atoms on opposite strands (19, 22). The major groove of A-DNA is narrower than that of B-DNA. This disparity is in inverse proportion to minor groove hydration, polar atoms in the A-DNA octamer d(GGTATACCC), and decamer d(GGGTGATACCC), the water molecules in the major groove are arranged in fused pentagons and hexagons that connect the phosphate backbone with the bases (18).
The spine of hydration in the central AA TT part of d(CGCGAATTCCGG)\(_2\) is, perhaps, the most distinctive feature of the Dickerson-Drew B-DNA dodecamer (see Fig. 2) (22). The spine represents a string of waters at the floor of the minor groove spanning O2 of thymine and N3 of adenine, which are brought into close proximity by helix rotation. The spine of hydration is stabilized additionally by hydrogen bonding to the sugar O4' atoms at the bottom of the minor groove (23). These first hydration shell waters are coordinated tetrahedrally and interconnected by second layer waters. A more recent high-resolution X-ray crystallographic structure of the Dickerson-Drew dodecamer revealed a third hydration layer that consists of a second spine that runs parallel to the inner spine at the periphery of the minor groove (24, 25). With the outer spine, the zigzag-shaped inner spine represents the lower part of four nearly planar fused hexagons that dissect the minor groove along the central hexamer portion of the dodecamer duplex (25). The spine of hydration is disrupted sterically in GC-rich domains of B-DNA because of the presence of the guanine N2 amino group in the minor groove.

**Dynamics of DNA Hydration**

Water molecules in the solvation shell of DNA are able to exchange with the bulk solvent with relative ease with the rate of exchange depending on the nature of DNA-water interactions. Insight into the kinetics of solvent exchange and the dynamics of water of hydration is derived from NMR and time-resolved fluorescent techniques. These techniques are mutually reinforcing; they are sensitive to different time domains, different subpopulations of water, and different physical characteristics related to water motion. NMR methods are most effective to characterize water molecules with lifetimes of 0.1 ns and longer. These relatively long-lived waters may play important structural roles. On the other hand, time-dependent fluorescent techniques are sensitive to short-lived, nonstructural waters of hydration with lifetimes in the femtosecond to picosecond range.

The use of NMR in hydration studies is based on two complementary approaches. In one approach, nuclear Overhauser effect (NOE) cross-peaks between DNA protons and hydration water are used to gain insight into the dynamics of localized water...
molecules near nonexchangeable DNA protons. The second approach uses the nuclear magnetic relaxation dispersion (MRD) spectrum of DNA to characterize the relaxation properties of perturbed waters without specifying their relative positions. Intramolecular magnetization relaxation and fast proton exchange by labile DNA protons may complicate interpretation of DNA water cross-peaks in NOE measurements and also may affect interpretation of \( n^2 \) MRD results. Such complications are avoided in \( \text{O}^1 \) and \( \text{H}^2 \) MRD measurements that are uniquely related to water relaxation (26).

Most NMR studies on DNA hydration have investigated the spine of hydration in the minor groove of the Dickerson-Drew dodecamer and related sequences (27). NOE studies have revealed the presence of long-lived water molecules in the minor groove of AT-rich domains of B-DNA with residence times of \( \sim 1 \text{ ns} \) (26–28). Consistent with these results, MRD measurements with and without the minor groove binding agent netropsin also have located long-lived waters with a residence time of 0.9 ± 0.1 ns in the minor groove of the Dickerson-Drew dodecamer (26, 28). NOE measurements also have detected waters with lifetimes in excess of 0.5 ns in oligonucleotides with a central 5′-TTAAN-3′ domain, when \( N \) is either T or C (29, 30). By contrast, no long-lived waters in the minor groove are detected when the flanking nucleotide \( N \) is G or A (29, 30). These observations suggest subtle sequence-dependent effects of minor groove hydration that may correlate with the groove geometry.

NMR studies of water dynamics in the major groove of B-DNA are sparse. Although NOE cross-peaks between water and thymine methyl protons and guanine 8H and adenine 8H protons in the major groove of the Dickerson-Drew dodecamer have been identified, the estimated lifetimes on the order of 200 to 500 ps are short compared with that of water in the minor groove (26, 28). MRD measurements at 4\(^\circ\)200 to 500 ps are short compared with that of water in the minor groove. Most experimental techniques provide an average residence time for the entire population of fast-lived DNA water molecules.

**Computer Simulations**

Theoretical approaches have emerged as a powerful means to characterize nucleic acid hydration at a level not restricted by the limitations of experimental techniques. In particular, molecular dynamics (MD) computer simulations have provided a wealth of information on the structure and dynamics of water in the vicinity of nucleic acids (12). Recent advances also identified short-lived water molecules with residence times of \( \sim 30 \text{ ps} \) that are not associated with the minor groove of B-DNA (28). Surprisingly, this MRD-based estimate is in good agreement with fluorescent-detected hydration lifetimes discussed below. It represents an average residence time for the entire population of fast-lived DNA water molecules.

Time-resolved emission spectroscopy (TRES), also referred to as time-resolved Stokes shift spectroscopy, enables one to derive information about the dynamics of biopolymer-solvent interactions on the femtosecond to nanosecond time scales, provided that suitable solvatochromatic fluorescent probes have been identified. Such probes should exhibit significant Stokes shifts that change with solvent polarity and should have fluorescent lifetimes on the order of the dynamic solvent exchange process or longer. TRES detects solvent dynamics that influences the energy difference between the excited and the ground states of the fluorophore and is insensitive to dynamic processes that are significantly slower than the fluorescence lifetime.

The fluorescence lifetimes of the four natural DNA bases within the femtosecond range are too short to be useful as spectroscopic probes to characterize the solvation dynamics of DNA (31). The minor groove binder Hoechst 33258, the fluorescent adenine analog 2-Aminopurine (2A.p), and the base pair mimic coumarine 102 abasic site are better probes because they exhibit longer lifetimes and better solvatochromatic properties. Of the two base pair analogs, the coumarine 102-abasic site base pair mimic disrupts the native DNA structure more than the adenine analog 2A.p. However, the spectroscopic characteristics of the former are superior to those of 2A.p for probing solvation dynamics.

Using 2A.p and Hoechst 33258 as probes, Pal and Zewail (32) have identified two groups of weakly bound water molecules in the vicinity of DNA with residence times of \( \sim 1 \text{ ps} \) and 12 to 19 ps. Subsequently, the Berg group (33) using the coumarine 102-abasic site base pair mimic has discovered power law solvation dynamics that range over six orders of magnitude from the low femtoseconds to the high nanoseconds. The 1-ps and 19-ps solvation dynamics detected by Pal and Zewail represent a part of the overall solvation dynamics detected by the Berg group (33). These studies provided unique insights into the ultrafast solvation dynamics at the site of the modified base. However, it is yet to be understood how these results relate to the hydration dynamics of unperturbed DNA. A large body of evidence suggests that even minor chemical modifications, such as the adenine to 2A.p replacement, may impact significantly the structure and thermodynamics of DNA. By implication, it is not unreasonable to anticipate that the solvation dynamics at the probe site may also be perturbed by the chemical modification.
Nucleic Acid Hydration

A- and B-conformations contain, respectively, 17.7 and 19.3 tightly bound waters. GC base pairs in A- and B-conformations interact with water more strongly than A-T base pairs in both A- and B-conformations. In B-DNA, this disparity reflects partially the wider minor groove of GC base pairs and their weaker interaction with DNA. B-DNA contains in its hydration shell one more water molecules in the first hydration layer interact weakly with DNA. GC base pairs interact with water more strongly than AT base pairs in both A- and B-conformations. In B-DNA, this disparity reflects partially the wider minor groove of GC base pairs and their more extensive hydration (three solvation sites per base pair). This sequence-dependent pattern of hydration agrees with the more extensive hydration (three solvation sites per base pair).

Protein–DNA Recognition

Water plays a major role in modulating DNA recognition by drugs and proteins. In protein-DNA recognition, water plays a structural role in addition to its thermodynamic role. In fact, it has been suggested that water is a critical element of the recognition code, mediating interactions that would be less favorable in its absence (33). Interfaces of specific and nonspecific protein-DNA complexes can be significantly hydrated, often with water molecules that form bridges between amino acid residues and nucleic acid bases. These water molecules mediate the specificity of protein-DNA recognition by screening unfavorable electrostatic interactions and by facilitating formation of water-mediated networks of protein-DNA hydrogen bonds. For example, the crystal structure of the paired homeodomain dimer complexed with DNA displays 18 ordered waters that mediate contacts between the protein and the DNA major groove (36). Molecular dynamics simulations of the estrogen receptor binding to consensus and nonconsensus DNA sequences have indicated that binding specificity and stability is conferred by a network of direct and indirect (water mediated) protein-DNA hydrogen bonds (37). Significantly, the fluctuating network of hydrogen bonds between the receptor and the nonconsensus DNA facilitates penetration of water molecules to the protein-DNA interface.

The trp repressor represents a striking example of the structural aspect of hydration: all but one interaction between the protein and the operator DNA are mediated by water molecules (38). A comparison of high-resolution structures of the free and bound states of the trp operator DNA has revealed that the hydration sites in the two structures are the same (39). Thus, conserved water molecules mediate trp repressor-operator contacts, consistent with a picture in which protein and DNA recognize each other’s hydration patterns. A subsequent analysis of 11 protein-nucleic acid complexes has shown that the positions of polar protein atoms hydrogen bonded directly to DNA groups generally correspond to hydration sites that would normally be occupied by water molecules in unbound DNA (40). This observation is consistent with a picture in which the hydration sites of free DNA mark the protein binding sites at the protein-DNA functional interface. A similar conclusion has been reached based on grand canonical Monte Carlo simulations of the BamHI complexes with noncognate and cognate DNA sequences (41). Based on these results, it has been concluded that interfacial waters can serve as a “hydration fingerprint” for a given DNA sequence that guides its recognition by DNA-binding proteins.

Hydration has been suggested to play a functional role in which it facilitates discrimination by a DNA-binding protein between the specific and the nonspecific sites by linear diffusion or “sliding” (42, 43). This possibility was emphasized by von Hippel who wrote, “Can one really think of the protein-DNA interface of a nonspecific complex as retaining full hydration, and what role does the expulsion of water bound to polar groups at the interface play in stabilizing the specific complexes that form when the DNA target site is reached?” (42). A partial answer to this question stems from the fact that little, if any, dehydration accompanies the formation of a nonspecific protein-DNA complex as suggested by near-zero changes in heat capacity $\Delta C_H$ (43–45). By contrast, very large and negative changes in $\Delta C_H$ that accompany specific protein-DNA association suggest extensive dehydration of specific protein-DNA complexes (42, 44, 45).

Differential changes in hydration associated with the binding of several DNA-binding proteins to cognate and noncognate sites have also been detected by osmotic stress measurements. For example, the binding of the restriction endonuclease EcoRI to its specific DNA sequence is accompanied by a release of $\sim$110 more waters than binding to a nonspecific sequence (46). Based on the independence of this number on the osmolyte type, it...
has been proposed that the nonspecific complex sequencers 110 waters in a space between the interacting protein and the DNA surface that is sterically inaccessible to solutes. More recently, osmotic stress measurements have been used to detect ordered (crystallographically detectable) and unordered (crystallographically undetectable) waters in a space between the interacting protein and the DNA surface that is sterically inaccessible to solutes. From the time of the discovery of the double-helix structure of DNA, it has become increasingly clear that solute–solvent interactions represent the very foundation of the conformational preferences, stability, and biological functions of nucleic acids. In recognition of this fact, many experimental and theoretic studies explore the hydration properties of nucleic acids. The structural picture of DNA and RNA hydration that is emerging from X-ray and NMR studies is robust. However, hydration is not limited to structurally ordered water molecules; it involves a large number of unordered waters. The latter population of water molecules is more challenging to detect and to characterize, although their thermodynamic impact on nucleic acid structure and recognition may be as important as, or even exceed that, of ordered waters. More concerted experimental and theoretic studies are required to fully understand the role of water in fine tuning the structure and recognition of nucleic acids. The emerging insight may well be the key to understanding the molecular mechanisms of gene expression and control.

Concluding Remarks

From the time of the discovery of the double-helix structure of DNA, it has become increasingly clear that solute–solvent interactions represent the very foundation of the conformational preferences, stability, and biological functions of nucleic acids. In recognition of this fact, many experimental and theoretic studies explore the hydration properties of nucleic acids. The structural picture of DNA and RNA hydration that is emerging from X-ray and NMR studies is robust. However, hydration is not limited to structurally ordered water molecules; it involves a large number of unordered waters. The latter population of water molecules is more challenging to detect and to characterize, although their thermodynamic impact on nucleic acid structure and recognition may be as important as, or even exceed that, of ordered waters. More concerted experimental and theoretic studies are required to fully understand the role of water in fine tuning the structure and recognition of nucleic acids. The emerging insight may well be the key to understanding the molecular mechanisms of gene expression and control.

Roles of Water in Biological Recognition Processes

Martin F. Chaplin, London South Bank University, London, United Kingdom

doi: 10.1002/9780470048672.wecb636

Water is central to biology, providing much more than the means to allow the movement of biologic molecules. It is an excellent solvent, a substrate and facilitator for reactions, and it provides a means for ionizations and extends the intricate three-dimensional surface geometry and complex charge distribution of biomolecules out towards the bulk solution. Water’s hydrogen bonds and dipoles are strong enough to present structural information concerning surfaces to distant diffusing molecules and to fine tune their orientation to match potential recognition sites, but they are weak enough to break to make way for direct binding processes. Water occupies potential interaction sites until they are recognized by suitable molecules, with the release of the water providing free energy to help compensate for the entropy loss on binding. Also, water molecules may determine the conformation of the biological molecule and directly assist and take part in the recognition process. Among the techniques available, X-ray crystallography has provided the most information on these roles for water.

Aqueous Hydrogen Bonding in Biology

Water is suited highly to its role as the medium of life and clearly has guided molecular evolution. It is the third smallest molecule known, and so it can penetrate the smallest of structural crevices. It is polar and capable of hydrating and shielding ions and dissolving a wide range of materials, both polar and small nonpolar. It can bind and release hydrogen ions to create a rich ionic environment with long-range interactions. Most importantly, water can form highly directional hydrogen bonds that allow interactions with electronegative atoms and link together to form chains and clusters. All biomolecules function within this aqueous environment; with much of biology being guided by water that facilitates highly specific recognition processes (1).

The water molecule

The water molecule (H₂O) consists of an electronegative oxygen atom holding tightly to the electrons from two hydrogen atoms, which leaves their positively charged nuclei partially exposed (Fig. 1a). Thus, water has a dipole that will interact with charged molecules and ions to solvate and to shield them from other charged species. Water ionizes to give hydrated protons and hydroxide ions. Importantly it can also carry excess protons and act as a proton wire to transfer protons rapidly from one site to another in biomolecular systems (2).

The disparity in the mass of the oxygen and hydrogen atoms allows the hydrogen nuclei to vibrate with considerable movement, which takes them closer to interact with other atoms and endows them with more freedom of movement. Because of water’s small size, a high density of water molecules exists in solutions that produce a high density of molecular interactions, which make large and important enthalpic and entropic contributions. In many circumstances, the free energies of interactions are relatively small because of the compensation between these terms; stronger binding to water is associated with both lower enthalpy and lower entropy (3). In other cases, such interactions can provide substantial entropic or enthalpic drive to direct a recognition process.

Hydrogen bonding

Water molecules interact with each other and with electronegative atoms by means of roughly, tetrahedrally positioned hydrogen bonds (Fig. 1b). These are modest, mainly electrostatic, directed interactions. Individually, they are strong compared with thermal fluctuations, although far weaker than covalent bonds, giving water its powerful hydration properties. The small molecular size and the extensive vibration of the hydrogen nuclei in water causes individual hydrogen bonds to have only short lifetimes (À ps), although they often will reform after...
breaking. Thus, water possesses significant thermodynamic hydration power sufficient to affect the structure of the hydrated biomolecules, but the rapid kinetics for hydrogen bond formation and breakage causes the hydrating water molecules to exchange rapidly, which otherwise might be taken for weak binding. This counterintuitive behavior is key to much of the use and the properties of water within biomolecular interactions. In particular, it allows water to orient molecules strongly according to neighboring surface characteristics but to move rapidly out of the way when required to allow biomolecular binding.

The heterogeneous nature of water is responsible for local correlations between the orientations of the molecules. In turn, it endows liquid water with its high dielectric and its consequent ability to shield electrostatic interactions. Also, it allows water molecules to transfer information concerning the structure of surfaces outward towards the bulk of the solution. The strength of water’s hydrogen bonds depends on the strength and the direction of the other hydrogen bonding that involves the same water molecules. The preference of water molecules for balanced numbers of donor and acceptor hydrogen bonds results in both cooperative and anticooperative effects: an accepted hydrogen bond strengthening a water molecule’s hydrogen bond donating ability but weakening its ability to accept a second hydrogen bond (Fig. 1b) (4). Some strong hydrogen bonds in biological systems are formed when water donates a hydrogen bond to charge-dense oxygen atoms in carboxylate and phosphate groups, or when water accepts a hydrogen bond from positively charged amino groups or oxonium ions.

The high density of hydrogen bonding sites in liquid water, together with their flexibility, allows water to act as a lubricant for translational movement between biomolecular surfaces while retaining hydrogen bonding and consequent control over the orientation of the moving molecules.

The heterogeneous nature of water

Under circumstances that favor hydrogen bonding, the density of water expands toward that of fully tetrahedral hydrogen-bonded ice (5). Such a structure has more negative enthalpy and lower entropy. When ice melts, this expanded structure collapses somewhat to the liquid state, but it still contains much of its hydrogen bonding. Liquid water is heterogeneous with fluctuating volumes of lower density, in which more hydrogen bonds are changing back and forth, into volumes of higher density where more broken hydrogen bonds and greater van der Waals interactions exist (3). Thus, aqueous systems are in constant flux with the local equilibria between the low-density and high-density states shifted by different surfaces, groups, and ions (6). Where the less dense structuring is found, water is more structured and viscous, whereas denser patches with greater dangling hydroxyl groups are more reactive, less viscous, and contain more rapidly diffusing molecules. The characteristics of the biomolecular structure are responsible primarily for controlling the structuring in the surface water layers. Thus, the ease of diffusion for visiting molecules is controlled both toward and away from areas of biomolecular surfaces.

The hydrophobic effect

When water lies next to hydrophobic surfaces, it cannot form as many hydrogen bonds as when it is in the bulk of the liquid. It can maximize its van der Waals contacts and hydrogen bonding to itself and to the bulk by forming loose, transient networks of pentagonal rings over some areas. Otherwise, these surfaces are energetically unfavored. Water molecules next to such surfaces can translate sideways and away from the surface more easily than they can rotate, and many hydroxyl groups will be left without hydrogen-bonding partners. Hence, biomolecular hydrophobic-binding sites usually are hydrated poorly, with the water molecules they contain unable to form their optimum number of hydrogen bonds, and often they possess moderately high entropy when compared with bulk water molecules. When displaced by a complementary-shaped hydrophobic ligand, the entropy loss on binding between the biomolecules will be compensated by the binding free energy due to the complementary surface dispersion enthalpy and both enthalpic and entropic contributions from the released water.

Figure 1 (a) The structure of an H2O molecule in liquid water, which shows the average bond length and angle, the approximate outline shape, and the surface electrostatic potential. (b) A typical tetrahedral water cluster found in liquid water that shows typical dimensions of its hydrogen bonds. Donating (d) and accepting (a) hydrogen bonds are indicated. Individual bond lengths and angles vary considerably around those given.
Water binding

The strength of binding of water to and between biomolecules is difficult to determine because of the complex nature of hydration interactions and the static and dynamic effects of the local environment. Binding consists of enthalpic and entropic terms and includes the effects of the rearrangement, removal, or addition of water within its surroundings. Entropy changes include hydrogen bonds, electrostatic terms, and dispersion terms, whereas entropy changes include conformational restrictions in the biomolecules and changes in both the rotational and the translational freedom of the water molecules reflecting differences in the organization between the bulk and interfaces. The process of binding (as exemplified by protein–ligand binding) can be described by the following equilibria:

\[ P + H_2O_{bulk} = Paq_1 + H_2O_{aq1, aq2} \]  
\[ L + H_2O_{bulk} = L_{aq1} + H_2O_{aq1, aq2} \]  
\[ Paq_1 + L_{aq1} = PL_{aq2} + H_2O_{aq2, aq3} \]

where the subscripted terms “bulk” and “aq” represent different amounts of water. Although the organization of the water at the interfaces differs on binding, most remaining interfacial water molecules retain their original anchoring hydrogen bond(s). The last equation (Equation 3) determines the binding free energy, which in turn differentiates recognition in terms of the specificity of different ligands. As a clearly an entropic cost (\( T \Delta S \) is negative) exists in binding \( P \) to \( L \), then compensation must exist in terms of any combination of entropy gain (\( T \Delta S \) is positive) by the water released, entropy gain by remaining water at the interfaces (but usually entropy is lost here), enthalpy gain (\( \Delta H \) is negative) in the water released, enthalpy gain by remaining water at the interfaces, and enthalpy gain in the interactions between \( P \) and \( L \). It should be noted that apart from carboxylate and phosphate oxygen atoms, water energetically prefers to hydrogen bond to itself rather than to biomolecules, if it can.

It is known that water mediates protein folding by orienting the polypeptide strands and manages their interactions as they move from being solvent separated to forming the direct peptide hydrogen bonds found in their secondary structures (7). Although it has not been shown with the same degree of proof, it is likely that similar processes operate in macromolecular binding. Water has both dynamic and structural roles. The ease with which the water molecules move relative to each other and the biomolecular surfaces determines the dynamics, whereas the strength of the hydrogen bonding linking areas on this surface and between surfaces determines its structural effects. Dynamically, it can control and guide the process by its proof, it is likely that similar processes operate in macromolecular binding. Water molecules coat biomolecular, ionic, and solute surfaces in aqueous solution, minimizing the system free energy using van der Waals contacts, electrostatic interactions, and hydrogen bonds to compensate partially for the entropic and enthalpic cost of their removal from the bulk phase. They even enter hydrophobic spaces, which maximizes their van der Waals surface contacts and hydrogen bonds as far as possible.

Water molecules hydrogen bond to several biomolecular groups. Of particular note are the donated hydrogen bonds to the oxygen atoms in carboxylate, phosphate, and peptide carbonyl oxygen atoms and the accepted hydrogen bonds from peptide amines, other neutral and positively charged amines, and alcohol groups. When binding within or between biomolecules, water usually forms three or four hydrogen bonds and rarely (if ever) forms just two hydrogen bonds of the same form, accepting or donating, because of their anticooperativity (4).

Usually, only bridges that consist of single water molecules are considered, because bridging by chains of water molecules are more difficult to determine in structural studies because of their kinetic instability. However, such extensive bridges are important in the overall thermodynamics and stereospecificity of binding. Together, these aqueous interactions probably are decisive in guiding conformational rearrangements, differentiating potential binding sites, and selecting those eventually chosen (8). Normally, a mixture of direct and water-mediated links exist in about equal amounts with the direct links between the biomolecules being relatively more directed and inflexible and kinetically more difficult to reverse without the help from neighboring hydration.

The role of water in mediating binding differs between the biomolecules because of variations in the strength of the natural hydration of the interfaces, which approximates roughly to DNA > proteins > ligands.

Protein–protein recognition

The protein surface is varied in shape, structure, and charge, so it is no surprise that its hydration is varied equally with both static interactions and weak interactions in about equal measure. Water molecules form an extensive network around proteins, which extend its surface characteristics out into the bulk. Often, this extended network seems rather thin to many analytical methods and current modeling, but it is thought likely that its influence extends somewhat further to several water layers. The amount of structured water around a protein controls the protein’s dynamics, which in turn may control its binding to other biomolecules. Water is important for the structure of individual proteins, their linking to form quaternary structures, and binding to form molecular clusters. Although

Biological Recognition

Our appreciation of biological recognition is different today from that of a few years ago. Then, the focus was concerned primarily with the complementary molecular surfaces (e.g., the lock-and-key mechanism), together with appropriately placed hydrogen bonding and electrostatic interactions between hydrophilic groups. Water was assumed simply to make way for the binding. Today, we know that water controls the kinetics and thermodynamics totally and must be included in any accurate description of these processes.

Biomolecules and water

Water molecules coat biomolecular, ionic, and solute surfaces in aqueous solution, minimizing the system free energy using van der Waals contacts, electrostatic interactions, and hydrogen bonds to compensate partially for the entropic and enthalpic cost of their removal from the bulk phase. They even enter hydrophobic spaces, which maximizes their van der Waals surface contacts and hydrogen bonds as far as possible.
Roles of Water in Biological Recognition Processes

such structuring may help recognition by hydrophilic sites, it will mask complementary structures where dehydration is required. In general, the hydrogen bonding to hydrating water molecules in binding sites is poor so that it may be removed easily both kinetically and thermodynamically.

Proteins may make specific links through their side chains or less specific links of the nature of peptide linkages. Using water molecules to connect these groups, rather than having direct interactions, gives a greater degree of freedom in terms of the relative protein–protein interaction. This analysis indicated that water molecules contributed to the close packing of atoms that ensured complementarity between the protein surfaces and that provided suitably situated polar interactions. Both studies showed that some interfaces were essentially dry with water molecules distributed around the periphery of the contact, whereas others were hydrated within the central region of the interfaces. As an example, the E9 deoxyribonuclease (DNase) and immunity protein Im9 protein–protein complexes, including 24 protease–inhibitor, 19 antibody–antigen, and 11 that are involved in signal transduction. This analysis indicated that water molecules contributed to the close packing of atoms that ensured complementarity between the protein surfaces and that provided suitably situated polar interactions. Both studies showed that some interfaces were essentially dry with water molecules distributed around the periphery of the contact, whereas others were hydrated within the central region of the interfaces. As an example, the E9 deoxyribonuclease (DNase) and immunity protein Im9

Protein–ligand recognition

The binding sites of proteins are, or are surrounded by, relatively rich areas for binding water. Many biological ligands, on the other hand, contain relatively few groups that can hydrogen bond to water. An extreme example of these ligands is phosphothioate A7 (13), which has a hydrophobic catalytic site held some distance from the substrate phospholipid surface and requires rigidly ordered water molecules to surround the active site and to maintain this interface of binding.

A network of 392 crystal ligand–protein structures (14) showed an average of 4.6 ligand-bound water molecules, with 76% of them bridging between the ligand and the protein. On average, three interactions existed that involved each of these linking water molecules with the protein–ligand complex: two to the protein and one to the ligand. A separate analysis of 251 protein–ligand active-site complexes gave an average of 34 water molecules and 118 aqueous hydrogen bonds per active site, with average coordination of just over two strong hydrogen bonds per water molecule (15). In addition, these water molecules were found to lie close to carbon-bound hydrogen atoms, which increased their van der Waals contacts. Most aqueous hydrogen bonds were to the protein rather than to the ligand, with an intermediate number of water–water hydrogen bonds. Using water to link the ligand and the protein can broaden the specificity due to the extra stereochemical flexibility. Thus, the peptide–binding protein OsP4A uses several flexible adaptively water molecules to hydrogen bond and to shield charges when binding lysine frayed tripeptides KXX, where K represents lysine and X is any one of the 20 common amino acids (16). Before such binding, these bridging water molecules are held by two or more hydrogen bonds to the unliganded protein, and they are conserved generally in the liganded protein crystals.

The hydrophobic interaction is an important factor in molecular recognition (17). Thus, the streptavidin–binding site for biotin contains a five-membered cyclic pentameric ring of water molecules stabilized by additional hydrogen bonds to coplanar amino acid side chains from the streptavidin and enclosed top and bottom by hydrophilic groups. When these highly ordered water molecules are expelled to make way for biotin, there is an entropy gain that more than compensates for the entropy loss on the strong streptavidin–biotin binding.

Peptide inhibitors are used in highly active antiretroviral thera-

DNA–DNA recognition

Although the structure of the DNA double helix is well known to be caused by base pairing and base stacking, the form of the helix is also highly dependent on its state of hydration. Hydration is crucially important for the conformation and use of nucleic acids and for its recognition by itself and other molecules (21). The strengths of many aqueous interactions are greater than those for proteins because of their highly ionic character. The DNA double helix can take up several conformations with differing hydration. The predominant natural DNA, B-DNA, has a wide and deep major groove as well as a narrow and deep minor groove and requires the greatest hydration. Partial dehydration converts it to A-DNA (with a narrow and deep major groove)
by decreasing the free energy required for A-DNA deformation and twisting, which is employed usefully by encouraging supercoiling but eventually leads to denaturation.

Hydration is greater and is held more strongly around the phosphate groups that run along the inner edges of the major grooves, but it is more ordered and more persistent around the bases with their more directional hydrogen-bonding ability and restricted space. Because of the regular structure of DNA, hydrating water forms chains along the double helix in both the major and the minor grooves. The cooperative nature of this hydration aids both the zipping (annealing) and unzipping (unwinding) of the double helix. Water motion within the grooves is slowed down compared with the bulk water, with the greatest reduction within the more restricting minor groove (22). On separation of the double helix (i.e., melting), about four water molecules per base pair are released despite extra hydration sites being released by the previously hydrogen-bonded base pairing (23), which confirms the importance of the cooperative nature of the water binding within the grooves.

**DNA–protein recognition**

The major problem in DNA protein recognition is how the protein can rapidly find a particular DNA base sequence from the enormous choice available when the specificity of the bases is somewhat hidden by the hydrogen bond linked and stacked base pairs. In an analysis of 109 protein-DNA complexes, an average of about nine water molecules per complex were bridged between the protein and the DNA, with another 125 linking to one or the other (24). Most water molecules were useful in screening unfavorable electrostatics from phosphates to allow binding (Fig. 3). The most common link found was where the water molecule donated hydrogen bonds to both a side chain and accepting phosphate oxygen atoms (25). Another analysis of 39 crystallographically characterized protein-DNA complexes indicated that 46% of bridging waters (32 per complex) linked the protein to the nucleotide bases and the remainder was useful in screening out the unfavorable electrostatics, being linked very strongly to the DNA phosphate groups (25).

Figure 2  Cartoon that shows water-assisted asparagine recognition and aspartate discrimination by asparaginyl-tRNA synthetase. (a) Among the bound water molecules in the unliganded enzyme, one (Wat1) is bound between the Gin259 peptide carboxyl and the Gin230 carboxylate and another (Wat4) between the side chains of Tyr333 and Arg364. (b) These water molecules link to the amide group on the asparagine-AMP substrate on binding and two water molecules are released (Wat2 and Wat3). Aspartate-AMP cannot bind at the same site as the Wat1 water molecule is not able to donate three hydrogen bonds. Some hydrogen atoms have been added to clarify the hydrogen bonding. Figure partially redrawn from Reference 17 with permission.

The restriction endonuclease MspI makes specific contacts between donating protein-charged amino or guanidinium groups and accepting phosphate oxygen atoms. A further analysis of 39 crystallographically characterized protein-DNA complexes indicated that 46% of bridging waters (32 per complex) linked the protein to the nucleotide bases and the remainder was useful in screening out the unfavorable electrostatics, being linked very strongly to the DNA phosphate groups (25).

Water-mediated links are also important in nuclear hormone receptors such as the estrogen receptor-DNA complex. A major question concerns how a protein detects speedily a specific DNA sequence-binding site from the many closely related sites available. Restriction endonucleases have to find rapidly their specific hydrolytic sites in DNA molecules among the many similar sites, which differ by as little as a single base pair. They do this first by scanning the DNA rapidly at a distance, held at low affinity by favorable electrostatic interactions but separated by a significant but lubricating hydration layer. This process is then followed by partial dehydration and binding at their specific sites (27). Thus, the complexes of the restriction endonucleases BamHI and EcoRI with nonspecific sections of DNA have about 100-150 more bound water at the interface than the specific complexes (28, 29), which distances the protein from the DNA. The large amount of these water molecules released subsequently to the bulk liquid on specific binding contributes favorably to the binding thermodynamics. The specificity is almost total with a single substitution of thymine at the beginning of the specific nucleic acid sequence GAAATTC (to give TAATTC) removing nearly all binding (5000 × less) by EcoRI (29).

The restriction endonuclease MspI makes specific contacts with all eight bases in the four base pair recognition sequence (CCGG), by six direct and five water-mediated hydrogen bonds and 13 water-mediated links to the phosphates (30). Number...
Roles of Water in Biological Recognition Processes

Figure 3 Cartoon that shows how water molecules shield the phosphate charges from the protein by donating hydrogen bonds (shown as dashed lines) to acceptor atoms on both the DNA and the protein, to attenuate their electrostatic repulsion. A need exists for these water molecules to accept hydrogen bonds from other water molecules (as shown) or for protein groups to stabilize such links.

van der Waals contacts exist as water molecules contribute to the close packing, which mediates shape complementation. A key feature of direct protein DNA links in bound complexes is that they can change to and from water-mediated links to allow movement within binding cleft (31) while retaining contact information.

Investigative Methods

No clear-cut method exists that gives complete or unambiguous information concerning the biomolecular binding processes in aqueous solution. The main problem is that although water’s hydrogen bonds are significant thermodynamically, water molecules are very mobile individually, as described earlier. Water molecules, therefore, have significant thermodynamic effects on recognition that are difficult to pin down by diffraction or NMR, because of their constant movement. A hydrogen bond only has a lifetime measured in picoseconds, and even an individual H₂O molecule exists for less than a millisecond. In addition, explicit hydration is not included easily within molecular simulations because of the complexity of the inter–water and water–surface interactions. Many computer models for water have been developed, but they have very limited use in forecasting accurately the properties of bulk water. However, their predictions are probably more accurate close to surfaces than at intermediate distances where greater complexity exists because of the bulk aqueous milieu. Therefore, if care is taken, simulations can be used to help determine the structure and the properties at biologic interfaces (32).

The most useful data in many of the above studies is from X-ray and neutron diffraction, which provides the average positions of some water molecules in the free and the bound complexes. Although the structural information concerns crystals only, it is believed that the stereochemistries of many biomolecules within crystals are often close to those found in biological situations. Both methods detect water molecules in favored sites but fail to detect exactly where the most water molecules are present at any given time. Also, X-ray data cannot provide direct information that concerns the hydrogen bonding as the hydrogen atoms cannot be observed. The data does, however, provide a solid foundation and can be used as a starting point in molecular simulations.

NMR can be used to determine the presence and the movement of water molecules next to biomolecular surfaces (33). Sometimes it is particularly useful to detect the links to buried water and to water molecules that mediate between biomolecules.

Occasionally, vibrational spectroscopy can provide information that concerns specific water molecules or clusters when they are distinct sufficiently from the wide range of such structures found in the bulk liquid (34).

Calorimetry determines the heat generated (ΔH) during binding and solvation processes. Together with the binding constant for the binding equilibrium (providing ΔG), the entropy changes during binding (ΔS) can also be determined. These values are interesting and useful but fail to provide precise or accurate molecular details concerning the binding even when a range of similar molecules are compared.

Determination of the osmotic pressure of solutions in the presence of other solutes and biologic-binding processes can indicate clearly changes in the amount of water bound or, more exactly, the amount of water that can no longer interact freely with the solutes. Such methods have been useful particularly to determine the DNA–protein interactions (39).
Conclusion: Knowns and Unknowns

The more information is discovered concerning the role of water in biological recognition processes, the more its importance is confirmed. Where diffraction data is available we have, or can get, a good appreciation of the biological recognition process and the importance of the water molecules at the interface. However, currently we lack the means to determine the importance of water molecules removed slightly from the interface or details of how they guide the binding process, if indeed they do. While retaining the structural base from diffraction studies, the development of more accurate molecular simulations together with more powerful computers and concentrating on the interfaces and neighboring water without washing too much resource on inconsequential distant bulk water (for example, Reference 35) is clearly a way forward.

Water is well known for its unusual properties, which are the so-called “anomalies” of the pure liquid, as well as for its special behavior as solvent, such as the hydrophobic hydration effects. During the past few years, a wealth of new insights into the origin of these features has been obtained by various experimental approaches and from computer simulation studies. In this review, we discuss points of special interest in the current water research. These points comprise the unusual properties of supercooled water, including the occurrence of liquid–liquid phase transitions, the related structural changes, and the onset of the unusual temperature dependence of the dynamics of the water molecules. The problem of the hydrogen-bond network in the pure liquid, in aqueous mixtures and in solutions, can be approached by percolation theory. The properties of ionic and hydrophobic solvation are discussed in detail.

It is widely assumed that during the 4 billion years of evolution on our planet, life has adjusted to all properties of water and has taken advantage of any of the numerous unusual features of this liquid, which has been called “life’s matrix” (1–3). Water is made of the two most abundant cosmic elements besides the inert helium (4), and it has served as one of the initial compounds for the energetically induced reactions to form the first organic molecules. This reaction may have happened like in the Miller-Urey primordial earth atmosphere under the influence of electric discharge (5) or in the porous interior of icy comets under the influence of cosmic radiation (6). The abundance of water in our galaxy has been estimated as several ten-thousand earth oceans per sun, and it is distributed on planets, moons, comets, and dust grains mostly in the form of crystalline and amorphous ice. In the past few years, many new aspects of the microscopic structure, dynamic behavior, and role of water in biologically relevant molecular processes were obtained from computer simulation studies, which have been performed to understand various new experimental observations. Therefore, in this short review, we will strongly focus on the picture of water that developed from such computational studies. This review can by no means be complete but lists some points of special interest in the current water research. Because of the importance of water, numerous reviews and monographs on different aspects of water can be found (7–13).

Water appears in various condensed forms; 15 different crystalline ice structures are reported, as well as at least three amorphous (noncrystalline) ices and a similar number of metastable liquid water forms (14). This structural diversity has its origin in the elementary building blocks of water: the hydrogen bonds and the tetrahedral arrangement of H-bonded neighbors [which is often called the “Walrafen pentagon” (15)]. Both building blocks provide large structural flexibility. The strength as well as the directionality of the H-bonds is intermediate between van der Waals interactions and covalent bonds, which allows easy distortion of the perfect tetrahedral local arrangement and a versatile adjustment of the water structure to the changing thermodynamic conditions or the presence of solutes.

As we largely refer in this short review to simulation results, the following should be noted beforehand: The first molecular dynamics simulation studies of water by Rahman and Stillinger (16, 17) were received by the community of water researchers with great enthusiasm, as they demonstrated that the structural, dynamic, and thermodynamic properties of this complex liquid could be reproduced simultaneously to an astonishingly high degree by the use of a simple pair interaction potential, which was made up from Lennard-Jones and Coulombic contributions. This finding offered an unprecedented opportunity to study structural and dynamic details on the molecular level. To improve the reliability of the obtained simulation results by a better quantitative agreement between simulation model and real water, many different interaction potentials were developed since then. Numerous comparative studies have been published. A recent compilation can be found in Reference 18; other examples, which focus on special properties, are given in the following sections. Despite these efforts, no current model is fully satisfactory, but the interpretation of simulation results in comparison with real water can be improved by taking into account the shift of the phase diagram between model liquid and real water.
Anomalies of Water and Polyamorphism

The exceptional rank of water is manifested by its unusual properties compared with most other liquids, the so-called "anomalies." These anomalies comprise thermodynamic as well as structural and dynamic properties, especially their pressure and temperature dependence. The key to understanding these properties lies in two competing influences on the local structure: the attempt to build low-density tetrahedral structures (with low energy) versus the tendency toward closer packing (with higher entropy) (19).

The density maximum at 4°C and the decrease of volume on melting of ice are well-known anomalies. More aspects of the extraordinary behavior of water have been brought into the focus of many researchers by the seminal articles of Angell on supercooled water (20, 21). In contrast to "ordinary" liquids, the isothermal compressibility and the heat capacity of water increase drastically during supercooling. This finding indicates strongly increasing volume and entropy fluctuations during cooling. A spectacular explanation for this behavior was delivered by a computer simulation study, which gave evidence for the existence of a (second) critical point of water buried in the deeply supercooled liquid region (19, 22) [see also the reviews by Stanley and Debenedetti (23, 24)]. This second critical point is considered the endpoint of an equilibrium line between two forms of (metastable) liquid water: a low- and a high-density liquid.

The two different liquids have their counterparts in the amorphous solid state: the experimentally well-studied high-density amorphous (HDA) and low-density amorphous (LDA) ice forms (25). However, it is still unknown exactly how the different amorphous ice forms and supercooled liquid water are connected with the one second critical point. No "no man's land" region largely prohibits direct experimental access to the low temperature liquid because of the inevitable onset of crystallization (24) in this region. Therefore, computer simulation studies, in which crystallization does not take place, have been used extensively to establish the existence of a liquid-liquid transition. The location of the corresponding second critical point strongly depends on the interaction potential that was used in these simulations (26-28). It may be shifted to negative pressures, which are correlated with the prediction of a van der Waals-like model developed by Poule et al. (19), in which such a shift occurs with decreasing hydrogen bond strength. In such a scenario, the experimentally observed diverging fluctuations in supercooled water at ambient pressure do not develop by approach to the critical point; instead, these fluctuations develop by the approach to the spinodal line that emerges from the critical point at negative pressures. This finding could explain the early observation of Angell (20, 21), which suggested that all temperature-response functions and temperature coefficients diverge at the same temperature in ambient pressure supercooled water. The unavoidable crystallization occurs after passing the spinodal as it encounters a phase transition to the low-density liquid state, which has a local structure that is very similar to crystalline ice (29).

Some indirect experimental evidence exists for the liquid-liquid critical point hypothesis from the changing slope of the melting curves, which was observed for different ice polymorphs (30, 31). A more direct route to the deeply supercooled region, by confining water in nanopores to avoid crystallization, has been used more recently by experimentalists. These researchers applied neutron-scattering, dielectric, and NMR-relaxation measurements (32-35). These studies focus on the dynamic properties and will be discussed later. They indicate a continuous transition from the high to the low-density liquid at ambient pressure. The absence of a discontinuity in this case could be explained by a shift of the second critical point to positive pressures in the confinement. This finding correlated with simulations, which yield such a shift when water is confined in a hydrophilic nanopore (36).

A through the presented scenarios are still under discussion, the existence of a first-order-like transition between metastable high- and low-density supercooled water with a second critical point at negative pressures in bulk water and positive pressures in confinement is strongly suggested (20). Alternatively, singularity-free scenarios are discussed to explain the properties of supercooled water (24, 29).

As indicated above, the study of amorphous solid water in bulk and in confinement is an important source of information for the understanding of the liquid. In fact, water was the first liquid to show "polyamorphism": the mentioned existence of high density and low-density amorphs. A morphous solid water can be produced experimentally along very different routes by vapor deposition, by pressurizing crystalline ice, or by fast temperature quench of tiny droplets. Also, different subsequent annealing procedures have been used. Recently, also a very high-density form (VHDA) of amorphous water has been observed and shown to be distinct from HDA (37). Neutron scattering data revealed that the transformation between HDA and VHDA is related to an increasing population of "interstellar" water molecules (38). Simulation studies indicate that VHDA (not HDA) should be considered as the amorphous solid counterpart to the high-density liquid water phase at ambient conditions (39, 40). The question whether the HDA to VHDA transition is also first-order-like (as LDA to HDA) is not yet resolved (41, 42). The important influence of the preparation method in the first liquid to show "polyamorphism": the mentioned existence of high density and low-density amorphs. A morphous solid water can be produced experimentally along very different routes by vapor deposition, by pressurizing crystalline ice, or by fast temperature quench of tiny droplets. Also, different subsequent annealing procedures have been used. Recently, also a very high-density form (VHDA) of amorphous water has been observed and shown to be distinct from HDA (37). Neutron scattering data revealed that the transformation between HDA and VHDA is related to an increasing population of "interstellar" water molecules (38). Simulation studies indicate that VHDA (not HDA) should be considered as the amorphous solid counterpart to the high-density liquid water phase at ambient conditions (39, 40). The question whether the HDA to VHDA transition is also first-order-like (as LDA to HDA) is not yet resolved (41, 42). The important influence of the preparation method

Hydrogen Bond Network

In the perfect crystalline structure of "ordinary" (hexagonal) ice, each water molecule is H-bonded to four tetrahedrally
arranged neighbors. From the comparison of the enthalpies of sublimation, melting, and evaporation, it can be concluded that about 80% of all H-bonds survive the melting process. Despite such a wide range of possible definitions of intact versus broken H-bonds (46), it is therefore generally accepted that the water molecules in the liquid form at any instant a random, quasi-infinite, space-filling network (48). This network is subject to constant restructuring ("transient gel" (49)), the lifetime of the individual bonds are in the subpicosecond range (46, 50, 53). Computer simulations revealed that this network could be described quantitatively by combinatorial calculations and percolation theory (52).1

The physical mechanisms, which are connected with this primarily topological phenomenon of the existence of a percolating H-bonded network, are still not analyzed in detail. Nonetheless, several observations have been compiled recently that show a correlation between the existence of a spanning network and properties of physical and biological relevance (53–56). These observations concern the occurrence of phase separation in mixtures as well as the conformational transition and function of biomolecules. Computer simulations revealed that the phase separation in a water/tertarypropanol mixture is preceded by the formation of mesoscopic structures, but “sparse” H-bonded clusters in the organic rich phase, which grow to be space filling at phase separation with a fractal dimension $d_f = 2.5$, as expected for a percolation cluster in an infinite three dimensional system (55, 57). Such percolating networks have also been detected by neutron-scattering experiments in completely miscible aqueous solutions (58).

The space-filling network, which is identified in pure water at ambient conditions, even exists in supercritical water; the percolating line of demixing phase transitions is an extension of the boiling line (55). The close relation between demixing phase transition and percolation transition of physical clusters has also been used in simulations to localize the liquid-liquid transition region in supercooled water. The lowest density amorphous water phase (solid or liquid) has been characterized by the presence of a percolating network of well-ordered (ice-like tetrahedral), four-coordinated water molecules, whereas in high-density amorphous water phases, a percolating network of tetrahedrally bonded molecules is missing (54).

The formation of spanning H-bonded water networks on the surface of biomolecules has been connected with the widely accepted view that a certain amount of hydration water is necessary for the dynamics and function of proteins. Its percolative nature has been suggested first by Careri et al. (59) on the basis of proton conductivity measurements on lysozyme; this hypothesis was later supported by extensive computer simulations on the hydration of proteins like lysozyme and SNase, elastine like peptides, and DNA fragments (53). The extremely interesting question of protein hydration is a huge field by its own but beyond the scope of this article.

### Dynamics of Water Molecules

The molecular motion in water has been studied for decades with all available modern spectroscopic and scattering methods, including neutron scattering, nuclear magnetic and dielectric relaxation, infrared spectroscopy, and light scattering. Each applied method probes different aspects of the motional behavior on different length and time scales. A NMR furnishes diffusion coefficients and integrals over orientational correlation functions, quasielastic neutron scattering reveals information on the short-time translational and rotational motion. The results that were obtained for a wide range of temperature and pressure conditions have been interpreted in the frame of translational and rotational diffusion models. The temperature dependence of characteristic parameters like reorientation and residence times has been discussed in detail (12, 60–62). That water is so fluent is an apparent contradiction to the fact that the space-filling network of hydrogen bonds is made up of bonds that have an interaction energy strength well above the thermal energy $k_B T$. This puzzle was resolved by showing the importance of network defects: The presence of an excess (fifth) neighbor in the first-neighbor shell of water molecules allows the intermediate formation of bifurcated H-bonds, which provides a low-energy barrier path for reorientation and coupled translational motion (63–65). Consequently, a decrease of the local water density (which makes the presence of an excess neighbor less probable) decreases the mobility of water molecules. For example, this effect has been observed by NMR experiments in the hydration shell of convex hydrophobic particles, in which the molecular mobility is decreased (66). However, it does not decrease to such an extent that one could speak of “icebergs,” as this is still done occasionally (see the section entitled “Hydrophobic hydration and interaction”). In cold water, the increasing expansion of water reduces the mobility of the water molecules in addition to the pure thermal activation, which leads to a strong non-Arrhenius temperature dependence of reorientation times, diffusivity, and viscosity (20) (see below).

Implications of the existence of a liquid-liquid phase separation for the dynamic behavior of water have been discussed by Angell et al. (67, 68), who postulated a crossover from a so-called fragile to a strong glass-forming liquid behavior because of a transition into the region of the low-density liquid at deep supercooling. Possible mechanisms were discussed that dominate the molecular mobility in the different temperature ranges (69), which lead to different temperature dependences: At high temperatures, as mentioned above, the switching through bifurcated H-bonds is most effective and is connected with a low activation energy. At lower temperatures beyond the density maximum, a strong non-Arrhenius behavior with increasing apparent activation energy is produced by the development of a more perfect local order, which enforces an approach to structural arrest of the water molecules in the cages of their neighbors (70). This arrest is then overcome at even
lower temperatures by jump diffusion (71, 72); in other models by the collective relaxation of the cage of neighbors (73). Finally, in the locally well-ordered, low-density liquid, when approaching the glass transition, the formation of Frenkel-type defect pairs may enable a diffusion behavior that parallels the “strong glass former” Arrhenius line of the Angell plot (69).

The expected crossover could not be studied experimentally in pure water because of the onset of crystallization at strong supercooling. Recently, the possibility to supercool water to a much larger extent than bulk water, when it is confined to small pores, has been exploited (34). From dielectric spectroscopy and quasielastic neutron-scattering experiments on water confined in the nanopores of clays and silica glass, a transition (crossover) from a strongly activated non-Arrhenius motional behavior to a low activation energy Arrhenius line at even lower temperatures has been observed (32, 33). This observation correlates with the expected fragile-to-strong transition when crossing from “normal” to low-density water. Using such experiments in an extended pressure range, the position of the second critical point could be estimated for the confined water. This fragile-to-strong dynamic crossover was also observed for the hydration water of biomolecules (proteins and DNA) (74, 75). Most interestingly, this crossover occurs at the same temperature as the so called “protein glass transition,” which suggests that this transition in the dynamics of the protein is the result of the approach to the above-mentioned extension of the liquid-liquid equilibrium line of the solvent (the so-called Widom line of the second critical point of water). It has to be mentioned here that some controversy still surrounds the origin of this abrupt change in the temperature dependence of the mobility of the water molecules: This behavior has also been attributed to the limitation of the spatial extension of fluctuations in confinements (76).

Hydrophobic Hydration and Interaction

The “hydrophobic effect” is manifested thermodynamically by the low solubility (large positive solvation free energy) that nonpolar molecules or aggregates experience in water (for more extensive reviews, see References 77-79). The hydrophobic effect is of great relevance for a variety of phenomena, which includes protein folding as well as the structural organization of amphiphilic aggregates. The latter are forming micelles of various topology, as well as lyotropic mesophases and lipid membranes.

Surprisingly, the low solubility of small-sized particles does not stem from a weak interaction of particles with their surrounding water environment (77). For example, the heat of solvation of methane in water at ambient temperature is of similar magnitude as the heat of vaporization of pure liquid methane (80). The positive solvation free energy of small apolar particles at low temperatures is the consequence of negative solvation entropy, which overcompensates for the negative solvation enthalpy. It is widely believed that this “entropy penalty” is caused by the orientation order introduced to the hydration shell of water molecules as they try to maintain an intact hydrogen bond network (77). Parallel to the entropy decrease observed for low temperatures, theoretical and experimental studies also indicate a slowing down of the translational and reorientational dynamics of water in the hydration shell of an apolar moiety (66, 82-83). A rather thermodynamic signature of hydrophobic hydration is the large positive solvation heat capacity. The heat capacity increase is attributed to the temperature-induced mutual interactions among the solvent molecules in the hydration shell (84). It is considered to be caused by the progressing disintegration of the hydrogen bond network around the solute with increasing temperature (77, 84). Because the solvation of small apolar molecules is accompanied by an entropy decrease of the solvent, the formation of contact pairs of apolar particles is a way to reduce this “entropy penalty.” The tendency to form apolar contact pairs in solution is termed “hydrophobic interaction” and essentially controlled by the solvent. Because the association of small apolar particles is entropically favorable, a temperature increase leads to more stable apolar contacts. “Hydrophobic interaction” is a classic example of an “entropic force.”

Contrasting the behavior close to small apolar solutes, water behaves differently at an extended (planar) interface. Here, the thermodynamic features are mostly governed by water’s interfacial tension, which is essentially entropic in nature (weakening with increasing temperature). Consequently, at some length-scale a “crossover” has to occur (85, 86) from an entropy to an enthalpy dominated solvation behavior. Recent studies indicate that this transition appears at a length-scale significantly below 1 nm (87, 88).

The thermodynamic signatures of small apolar particle hydration can be modeled by simple two-state models (89-92) that solely focus on water’s hydrogen bonding as supposedly dominating effect. Stronger hydrogen bonds close to an apolar particle are counterbalanced by fewer possible hydrogen bonds. Silverstein et al. (92) consistently related experimental data that described water’s hydrogen bond equilibrium with hydrophobic solvation calorimetric data. Their calculations suggest that at lower temperatures, the hydrogen bonds are more intact than in the bulk, whereas at high temperatures, hydrogen bonds are more broken. The model moderately readsout older theories by Franks and Evans in their so called “iceberg” model (93), in which the hydrophobic particles where thought to be stabilizing structured ice-like entities in water. However, because the entropy change experienced by a water molecule in a hydrophobic hydration shell is about five times smaller than a crystal-like environment (77), the “iceberg” model too strongly exaggerates the degree of ordering that is present in a hydrophobic hydration shell (77). Simple two-state models seem to fail in reliably predicting absolute solvation free energies (77) because altering hydrogen bonding does not provide sufficient information to determine the entropic “free volume contribution” (94, 95).

A conceptually complementary approach to describe hydrophobic effects has been introduced by Pratt and coworkers (78, 96). Their information theory (IT) model is based on an application of Widom’s potential distribution theorem (97) combined with the perception that the solvation free energy of a small hard sphere, which is essentially governed by the probability to find an empty sphere, can be expressed as a limit of the distribution of water molecules in a cavity of the size...
of the hydrophobic particles. Because the distribution functions are essentially determined by density fluctuations of water at the molecular scale, the IT model relates the hydration and interaction of hydrophobic particles with the temperature dependence of water's thermodynamic response functions, such as expansivity and compressibility.

An instructive, simplified computer model for water is the "Mersenne–Benz" (MB) model of Silverstein et al. (98). It has been shown to capture qualitatively the anomalous thermodynamic behavior of water as well as the thermodynamic features of the hydrophobic effect. The MB-model notably captures the effect of increasing particle size. A hydrophobic particle of about twice the size of a water molecule is found to increase the free energy by a different mechanism, namely by increasingly breaking the hydrogen bonds. Similar to the thermodynamic behavior observed for planar interfaces, the mechanism increases the enthalpy but has only little effect on the entropy and heat capacity. The simulations indicate that at a large, extended interfacial surface, water is geometrically unable to form its maximal number of hydrogen bonds to other water molecules. Thus, enthalpically costly “dangling” hydrogen bonds form pointing toward the interface (99, 100).

Realistic three-dimensional computer models for water were proposed already more than 30 years ago (14). However, even relatively simple effective water model potentials based on point charges and Lennard-Jones interactions are still very expensive computationally. Significant progress with respect to the models ability to describe water’s thermodynamic, structural, and dynamic features accurately has been achieved recently (101–103). However, early studies have shown that water models essentially capture the effects of hydrophobic hydration and interaction on a near quantitative level (81, 82, 104). Recent simulations suggest that the exact size of the solvation entropy of hydrophobic particles is related to the ability of the water models to account for water’s thermodynamic anomalous behavior (105–108). Because the “hydrophobic interaction” is inherently a multibody interaction (105), it has been suggested to compute pair- and higher-order contributions from realistic computer simulations. However, currently it is inconclusive whether three-body effects are cooperative or anticooperative (109).

An analysis of computer simulations of water at different pressures by Hummer et al. (110) suggested that hydrophobic contact pairs become increasingly destabilized with increasing pressure. The proposed scenario could explain the pressure denaturation of proteins as a swelling in terms of water molecules that enter the hydrophobic core by creating water-separated hydrophobic contacts. Additional support for the validity of Hummer’s IT-model analysis has been achieved by pressure-dependent computer simulation studies of isolated pairs of hydrophobic particles, as well as rather concentrated solutions of hydrophobic particles (111, 112). Recently, the pressure-induced swelling of a polymer composed of apolar particles at low temperatures can be observed (113).

Ion Hydration

As already suggested by Max Born in 1920 (114), the large negative solvation free energies of ions in aqueous solution can be explained by mostly purely electrostatic effects, which assume water to be represented by a dielectric continuum (115). Small changes of the ion diameter are found to affect the solvation free energies strongly. The measured solvation free energies roughly scale with the third power of the ion diameter, as proposed by the Born theory (115). However, a structuring effect on the first hydration shell water is obvious and has been experimentally determined by X-ray and neutron scattering techniques (116–119). In case of an anion, the first shell water molecules form a hydrogen bond type configuration in which the OH-bond points toward the anion (118), although on average it does not point exactly to the center of the ion (117). For the case of cations, the water molecules are found to be pointing with their oxygen toward the ion. The water dipole axis, however, seems to exhibit an average tilt of about 30 degrees with respect to the ion-water-oxygen connecting vector (117, 119).

Recent first principles simulations of aqueous salt solutions suggest that this might be an artifact caused by averaging a rather broad tilt angle distribution (120). In those simulations, the dipole vector that points directly toward the ion is the most likely configuration of a broad distribution. Earlier classic MD simulations had revealed a more filled “cone-pair”-type of ion-water bonding (121), which was possibly a consequence of the tetrahedral charge distribution of the employed water model (17) and is perhaps an artifact.

Ionic Influence on Hydration Water and Bulk Water

Salts are known to influence several properties of aqueous solutions in a systematic way (122, 123). The effect of different anions and cations seems to be ordered in a sequence; this theory was already proposed by Hofmeister in 1888 (124) from a series of experiments on the salts ability to precipitate “hen-egg white protein.” Numerous other properties of aqueous salt solutions are also found to be systematically salt dependent, such as the surface tension or the surface potential (122). However, the exact reason for the observed specific cation and anion sequences is still not fully understood (125). Model calculations (126), as well as nuclear magnetic relaxation experiments (127), propose a delicate balance between ion adsorption and exclusion at the solute interface. This balance is tuned by the solvent (water) structure modification according to the ion hydration (128, 129) and hence is possibly subject to molecular details.

In principle, two different mechanisms have been proposed on how the ions influence protein stability. Firstly, it has been suggested that a modification of water’s structure is the origin of the Hofmeister sequence (130). It has been hypothesized that some ions “kosmotropes” enhance the structure that surrounds the ions, which leads to a strengthening of the hydrophobic effect and thereby stabilizes the proteins (131). However, the ions that break the structure that surrounds the ions (“chaotropic”)
The evolutionary process. As we have tried to show, many of the properties, many of which have been exploited by nature during liquid water provides a unique wealth of unusual liquid/solvent properties, many of which have been exploited by nature during the evolutionary process. As we have tried to show, many of water’s unusual properties, or “anomalies,” stem from water’s tendency to form a roughly four-coordinated hydrogen bond network. Computer simulations indicate that many effects can be explained in great detail by Scraton-Yates ion molecular models. A pattern reveals that in water, hydrogen bond-based local-order (entropy) and interaction energies have the beneficial tendency to compensate each other, which is important for many solvation processes and for water structuring and phase behavior. The small size of the water molecule and its effective hydrogen-bond formation make it a particularly helpful agent in the process of protein folding; it is deemed essential to enable protein motions.

Conclusion

Liquid water provides a unique wealth of unusual liquid/solvent properties, many of which have been exploited by nature during the evolutionary process. As we have tried to show, many of water’s unusual properties, or “anomalies,” stem from water’s tendency to form a roughly four-coordinated hydrogen bond network. Computer simulations indicate that many effects can be explained in great detail by Scraton-Yates ion molecular models. A pattern reveals that in water, hydrogen bond-based local-order (entropy) and interaction energies have the beneficial tendency to compensate each other, which is important for many solvation processes and for water structuring and phase behavior. The small size of the water molecule and its effective hydrogen-bond formation make it a particularly helpful agent in the process of protein folding; it is deemed essential to enable protein motions.

Several pathways are compartmentalized in the endoplasmic reticulum (ER). These intraluminal activities require the passage of substrates, cofactors, and products through the ER membrane. The arguments for a general permeability of the ER membrane are contradicted by strong biochemical, pharmacological, clinical, and genetic evidence, which indicates that the lipid bilayer has a barrier function and that specific transport activities are needed in the membrane. Consequently, the ER lumen can be regarded as a separate metabolic compartment. This article overviews the best characterized intraluminal processes in which the compartmentation is important either by defining an intraluminal milieu, by limiting the rate of the reaction, by determining the specificity, or by creating a common substrate pool because of the colocalization.

The best known functions of the ER require a high membrane surface and/or a separate, specific microenvironment within the organelle. Although many enzymes hosted by the ER use its membranous structure only as a scaffold, others are compartmentalized within the ER: i.e., their active site is localized in the lumen. The activity of these enzymes usually is dependent on the special composition of the luminal compartment. The enzymes often receive their substrates and cofactors from or release their products to the cytosol, therefore, the transport of these compounds across the ER membrane is indispensable. This article focuses on this latter group of the ER enzymes, the functioning of which makes the ER a separate metabolic compartment of the eukaryotic cell.

Biologic Background

The ER is a continuous network of membranous tubular and lamellar structures in the cytosol (1, 2). The membranes that build up the organelle can constitute more than 95% of the total cellular membranes, and the total volume of the organelle can compose about 10% of cell volume, e.g., in hepatocytes. Although the ER is a single, spatially continuous compartment, it can be divided structurally and functionally into different subdomains. The ER forms contact sites beside the nuclear envelope with practically all the other organelles and the plasma membrane; these functional regions might have specific composition and features, but they are restructured continuously to adapt the actual cellular requirements. The ER network can be divided into rough (RER) and smooth (SER) domains on the basis of the presence or absence of ribosomes on the outer surface of the membrane, respectively. Functional and morphological differences are linked: Whereas the ER is responsible for the synthesis, posttranslational modification, and folding of secretory and membrane proteins, the SER is responsible for lipid biosynthesis, biotransformation, and the production of small molecules to be secreted.

The ER hosts several enzymes: Some of them are facing toward the cytosol and use the ER membrane as a scaffold, e.g., cytochrome P450 isozymes, NADPH:cytochrome P450 reductase, or hydroxymethyl-glutaryl-CoA reductase. Others are compartmentalized in the ER: that is, their active center is localized in the lumen. The reactions catalyzed by these enzymes belong to various pathways of biochemistry and cell biology, such as carbohydrate and lipid metabolism, biotransformation, signaling, steroid metabolism, and protein processing. Table 1 presents a list of some important intraluminal enzymes. Usually, because their substrates derive from the cytosol, the corresponding membrane transport processes are required for their action.
Table 1. Some important activities compartmentalized within the ER lumen

Arguments for and against the general permeability of the ER membrane

It has been questioned whether the ER lumen can be considered as a separate metabolic compartment or whether the lumen is just a specific localization for some enzymatic reactions. The inward and outward traffic of a wide variety of molecules led some scientists to the conclusion that the ER membrane is permeable to any low-molecular-weight compounds and acts only as a molecular sieve to keep the luminal proteins together. Several arguments can support this hypothesis. The composition of the ER membrane is different from that of the plasma membrane; it has a low cholesterol and high protein content. The less-ordered membrane structure might increase leakiness for small molecules (3). The RER is abundant in translocon protein channels, which can allow the passage of ions and small-molecular-weight molecules (4–6). Other transiently open transmembrane channels might also allow nonselective fluxes. Moreover, a high number of structurally unrelated molecules, i.e., xenobiotics or bioisosteres, have been shown to enter the ER lumen. The total enzymatic activity can be revealed on the intact ER membrane, which excludes the substrates from the lumen. The characteristic micro-environment of the ER lumen hardly is just as important a determinant of the ER metabolism as the pattern of the compounds that cannot enter or leave the lumen.

In vivo evidences

Recent in vivo observations support the hypothesis that the ER membrane has a barrier function. The two best studied gradients across the ER membrane are related to the calcium homeostasis and the oxidative protein folding. Compared with the cytosol, the ER lumen is characterized by a magnitude level of free calcium ion (29) that is four orders higher and nearly a hundred times lower than the ratio of glutathione (GSH) and oxidized glutathione disulfide (GSSG) (30). Although the generation of these gradients is dependent on largely the poor permeability of the ER membrane to calcium ion and glutathione, the gradients necessarily are created and maintained by continuous active processes, such as the pumping of calcium (29) and the luminal oxidation of thiols (12), respectively. Therefore, it can be also concluded that high-capacity active processes surpass the velocity of the passive transmembrane fluxes.

The strongest evidence for the separation of the cytosolic and endoplasmic compartments is provided by the genetic analyses of two ER-related human syndromes, namely glycogen storage disease type 1 (GSD 1) and cortisone reductase deficiency (CRD). GSD 1 refers to the congenital deficiency of glucose 6-phosphatase (G6Pase) activity, which causes a complex metabolic disorder, including the abnormal storage of glycogen in the liver (31). In addition to the defects of G6Pase enzyme (GSD 1a), the mutations in a different gene were proven to cause similar metabolic disturbances combined with some additional symptoms (32) — a disease called GSD 1b. The protein encoded by this other gene turned out to be the G6PT, which is needed to access the luminal G6Pase to its substrate (8, 24, 32). GSD 1b pathology was mimicked fully by G6PT knockout mice (33). The existence of GSD 1b proves that glucose 6-phosphate (G6P) cannot enter the ER lumen unless it is mediated by a specific transporter.

CRD is characterized by the insufficient reduction of cortisone to cortol by 11β-hydroxysteroid dehydrogenase type 1 (11βHSD1) in the ER lumen. The analyses of the mutation suggest that the CRD phenotype is caused by the combined defects of 11βHSD1 and hexose 6-phosphate dehydrogenase (H6PDH) (34). This finding indicates that the luminal generation of NADPH by H6PDH (rather than the cytosolic NADPH production) drives cortisone reduction in physiologic conditions. In other words, luminal cortisone reduction is dependent on local NADPH generation because the cytosolic and endoplasmic pyridine nucleotide pools are separated. Although recent investigations revealed that the combined mutations do not necessarily cause CRD (35, 36), the importance of the collaboration between the two enzymes was validated additionally by the results obtained in H6PDH knockout mice (37).

Another proof against the general permeability of the ER membrane and for the necessity of specific transporters is derived from the field of immunology. TAP peptide transporters (TAP1 and TAP2), which were characterized at the molecular level, belong to the ABC transporter superfamily (38). They translocate oligopeptides (approximate length of 8–16 amino acid residues) into the ER lumen and the target compartment is needed for the transport of the presented peptides to the pathway of antigen presentation. A recent study revealed that the particular function of TAP is the presentation of peptides with a high density of MHC class I molecules (39). Thus, the luminal environment of the ER lumen could be maintained if the passive diffusion driven by the gradients equalized effectively the concentrations on both sides of the membrane.
acid residues) produced by the proteasome in the cytosol to the ER lumen, where they bind to the major histocompatibility complex (MHC) Class I molecules. MHC–peptide complexes leave the ER by vesicular transport to the cell surface for recognition by cytotoxic T lymphocytes. The loss of the TAP function leads to the impairment of antigen presentation, as it is observed commonly in tumors and virus-infected cells that escape immune surveillance (39). This condition shows clearly that the basal permeability of the ER membrane does not permit the appearance of these small oligopeptides in the lumen.

Chemistry

In this section, the elucidated role of the ER membrane (as a barrier with selective transport) is summarized in the best studied metabolic systems of the ER.

Glucose 6-phosphatase system

The means of glucose production in liver and kidney is derived either from hydrolysis of G6P glycogen breakdown or gluconeogenesis. The reaction is catalyzed by G6Pase, which is an integral membrane protein of the ER with an intraluminal active center (8). Theoretically, the system composes three transporters (for G6P, glucose, and phosphate) associated with the enzyme activity functionally (8). G6PT has been identified at the molecular level (24, 32), and the protein-mediated glucose transport across the ER membrane has been characterized recently (40). The intact membrane barrier is an important determinant of the physiologic characteristics of G6Pase. Permeabilization of microsomal vesicles or in situ ER membranes (41, 42) only doubles the rate of G6P hydrolysis, and it causes a 1015-fold enhancement of the hydrolysis of mannose 6-phosphate and various other sugar phosphates by the same enzyme (14). It is important that the ER membrane separates the unselective G6Pase from intermediates of glycolysis/gluconeogenesis and amino sugar metabolism. However, the high substrate specificity of G6Pase in physiologic conditions is not an intrinsic property of the enzyme but relies on the selective transport of G6P into the lumen of ER.

GSD 1a (G6Pase deficiency) and GSD 1b (G6PT deficiency) cause the same metabolic derangements based on insufficient G6Pase activity (31, 33). This fact is inconsistent evidence with the theory of an unspecifically permeable ER membrane.

Hexose 6-phosphate dehydrogenase and 11β-hydroxysteroid dehydrogenase type 1

Interconversion of cortisone and cortisol catalyzed by 11βHSD1 is fully reversible in vitro. The physiologic direction in vivo is cortisone reduction, which is driven by a high NADPH/NADP+ ratio in the ER lumen. The high ratio can be maintained only by local NADP+ reduction catalyzed by certain luminal dehydrogenases, such as the H6PDH (15, 16, 24), because the permeability of the ER membrane to pyridine nucleotides is negligible (17, 18).

It has been reported that extravascular NADP+ and NADPH can penetrate the ER membrane in long incubations and that the cytosolic [NADPH]/[NADP+] ratio can affect 11βHSD1 activity (43). Nevertheless, the H6PDH knockout mice lack 11βHSD1-mediated glucocorticoid generation (37), which proves that the enzyme cannot rely on cytosolic NADPH resources and that a separate luminal pyridine nucleotide pool exists. It also shows that clearly the high luminal [NADPH]/[NADP+] ratio is dependent on H6PDH activity.

G6P is transported to H6PDH from the cytosol across the ER membrane. In fact, similarly to G6Pase, the substrate specificity of H6PDH is dependent on largely its localization in the ER. The enzyme has dehydrogenase activity on various hexose 6-phosphates, such as G6P, galactose 6-phosphate, or 2-deoxyglucose 6-phosphate and on simple sugars such as glucose and, it has dual nucleotide specificity for NADP+ and NAD+ (44). Nevertheless, under physiologic conditions in the ER lumen, the native substrates for H6PDH are believed to be G6P and NADP+ (44). These findings indicate that the enzyme has no access to the cytosolic NAD+, sugars, and sugar phosphates, except G6P, which is transported by the specific G6PT (8).

Oxidative protein folding and antioxidant metabolism

Luminal proteins and luminal domains of membrane proteins of the ER contain remarkably more disulfide bridges and less thiol groups than the cytosolic proteins. In accordance with this low [protein thiol]/[protein disulfide] ratio, the ER lumen shows also a characteristically low (about 1:1) [GSH]/[GSSG] ratio, which is nearly 100:1 in the cytosol (30). Such a high potential difference and concentration gradient would be expected if the membrane was permeable to both GSH and GSSG. The finding that indicates that isolated hepatic microsomes still contain GSH and GSSG (22) suggested strongly that the ER membrane represents a barrier for these molecules. Indeed, the membrane is impermeable to GSSG, whereas GSH has a slow protein-mediated transport (23). Therefore, the oxidizing environment in the compartment can be maintained by local oxidation of GSH that yields GSSG, which is entrapped in the lumen.

Luminal thiol oxidation is facilitated by ascorbate (vitamin C) (45) or FAD (12, 13), so the physiologic role of their transport has been proposed. ER membrane is permeable selectively to dehydroascorbate, the oxidized form of ascorbate (10, 11). Luminal reduction of dehydroascorbate to ascorbate is associated with thiol oxidation and leads to ascorbate entrapment (46). FAD uptake and a consequent thiol oxidation have also been found in yeast and in liver microsomes (12, 13). In contrast to FAD, pyridine nucleotides—NADP(H), NAD(H)—of similar size and structure cannot enter the ER lumen at a significant rate, which is indicated by the high latency of intraluminal H6PDH and 11βHSD1 (15) and by direct transport measurements (18).

Glucuronidation

The quantitatively most significant second-phase reaction of hepatic biotransformation is glucuronidation that takes place in the ER. The transfer of glucuronosyl group from glucuronic acid residues produced by the proteasome in the cytosol to the ER lumen, where they bind to the major histocompatibility complex (MHC) Class I molecules. MHC–peptide complexes leave the ER by vesicular transport to the cell surface for recognition by cytotoxic T lymphocytes. The loss of the TAP function leads to the impairment of antigen presentation, as it is observed commonly in tumors and virus-infected cells that escape immune surveillance (39). This condition shows clearly that the basal permeability of the ER membrane does not permit the appearance of these small oligopeptides in the lumen.
UDP-glucuronate (UGA) to appropriate functional groups of the substrates is catalyzed by UDP-glucuronosyltransferases (UGTs). These enzymes are integral membrane proteins of the ER with their active center localized in the lumen (47). UGA is synthesized in the cytosol, and the produced glucuronides are pumped out of the cell by plasma membrane transporters. Thus, conjugation with glucuronate requires UGA import (19) and glucuronide export across the ER membrane. It has been demonstrated, using a photoaffinity-labeling technique, that UGA, but not UDP-glucose, has access to the active center of UGTs in intact microsomal vesicles (48). The high latency (more than 90%) of UGTs observed in both microsomal vesicles and isolated permeabilized hepatocytes indicates that the transport processes (presumably UGA uptake) are rate limiting (20, 21). Activity of the luminal β-glucuronidase, a glucuronide-cleaving enzyme, is also limited by substrate (glucuronide) transport, although it has moderate (approximately 40%) latency (49).

A protein-mediated glucuronide transport across the ER membrane has been demonstrated (50), and a competition for the transport has been found between glucuronides of similar size (28). The pattern of interactions suggested the presence of multiple glucuronide transporters with overlapping specificities in the ER membrane (28).

Translocon and permeability of (R)ER membrane

A bundle of channels may contribute theoretically to a general permeability or leakiness of the ER membrane, which has been demonstrated in case of the ribosome-bound translocon complex, which cotranslationally imports nascent peptides into the ER lumen (51). The average diameter of the translocon tunnel is approximately 20 Å, which is wide enough to allow the transport of Ca²⁺ (52) and small water-soluble molecules (4–6). Therefore, the presence of translocon complexes might be responsible for the higher permeability of the RER membrane versus the SER membrane.

Unspecific permeability is prevented in the translationally active translocon because the tunnel is occupied by the peptide chain being polymerized. Similarly, the pore is blocked by BiP proteins, prominent intraluminal chaperones, after dissociation of the ribosome from the complex (53). In fact, it has been argued that the BiP locks form a smaller barrier for uncharged polar molecules than for charged ones. Furthermore, the dissociation of ribosomes from translocon complexes is delayed after the termination of protein synthesis. When a nontranslating ribosome is associated with the translocon complex, they form a transitional low-selectivity channel between the cytosol and the ER lumen (5).

Chemical Tools and Techniques

**In vivo studies**

Measurement of the concentrations in the cytosolic and luminal compartments in vivo has been achieved in the case of calcium ions but remains a merely theoretical possibility for most organic molecules except glutathione (54). In fact, a remarkable transmembrane gradient has been detected in case of both Ca²⁺ and glutathione, which supports the barrier function of the ER membrane. The maintenance of high concentration differences would require continuously intensive pump activities and lead to unreasonable heat generation if the membrane is highly permeable.

**Studies in cellular systems**

The potential role of transport across the ER membrane was investigated in cells by using selective and general membrane permeabilizing toxins, antibiotics, or detergents. Intact ER can be exposed to the incubation medium in cells whose plasma membrane has been permeabilized selectively. Alternatively, the intraluminal enzymes can be directly exposed by general (including plasma and ER membranes) permeabilization. Experiments using these models revealed that the transport of substrates or cofactors across the ER membrane is rate limiting for glucosidase (42), UGT (20), and β-glucuronidase (49) activities.

The transport of exogenous compounds has been investigated recently by determining the amount of modified intraluminal proteins upon addition of nonphysiologic biotin-derivatives capable of chemical protein modification (7). The ER membrane has been shown to be permeable to three different biotin-derivatives, and it has been concluded that it does not form a barrier to small molecules; that is, either the lipid bilayer or the integral membrane proteins allow their diffusion unspecifically.

**Studies in subcellular systems**

Isolated ER-derived vesicles (microsomes) maintain their original orientation (i.e., their intravesicular surface corresponds to the intraluminal side of the ER membrane (55, 56)) and keep some of their low-molecular-weight luminal components during the long-lasting preparation procedure. For example, both oxidized and reduced forms of glutathione (22) and of pyridine nucleotides (17) are present in liver microsomes, which suggests strongly that the ER membrane acts as a barrier to these molecules.

Microsomes are used widely for the determination of "isotope space" and for in vitro transport assays, such as "rapid filtration" and "light scattering" measurements. Isotope space reveal the distribution of the studied compound between intra- and extravesicular water compartments; hence, the measurements provide information on the permeability but not on the transport kinetics. The total water space and the extravesicular space can be measured using radiolabeled analog of water or a completely impermeable compound, respectively (57). Rapid filtration is based on the quick separation of vesicle-associated molecules from the medium and on the calculation of the intraluminal content after various incubation periods. This method allows the application of physiologic concentrations but offers a limited time resolution (58). On the contrary, the light scattering technique requires high concentrations but provides a real-time monitoring of traffic. This indirect detection takes advantage of the transport-associated osmotic shrinkage and the swelling of the vesicles.
microsomal vesicles (58). The permeability to several molecules of a wide size-range has been compared with these methods, and very slow permeation, or complete impermeability, has been demonstrated in certain cases.

A sophisticated approach using active site-directed photoaffinity substrate analogs has also been applied to study the inward transport in isolated microsomal vesicles. These experiments provided convincing and elegant evidence for the translocation of UDP-glucuronate (48) and of FAD (12) by photo incorporation of the probes into the luminally oriented enzymes in intact microsomes. The drawback of the method is that it is not suitable to determine of the rate or capacity of transport.

Enzyme latency is an experimental manifestation of compartmentation, which means that the activity of certain intraluminal enzymes is increased remarkably when the membrane is permeabilized either by detergents or by channel-forming antibiotics (e.g., amphotericin). It is based on the rate-limiting transport of substrates and/or effectors across the intact ER membrane. Some activities in the ER are more than 90% latent; i.e., they increase more than 10-fold during permeabilization (20, 21).

Conclusion

The ER membrane represents a real barrier between the cytosol and the lumen for water-soluble, charged small molecules. Although this barrier function is compromised at a certain extent by the existence of nonspecific pores (e.g., the translocon protein channel), the ER lumen can be considered still as a separate metabolic compartment. This barrier generates a characteristic microenvironment in the lumen with a higher Ca²⁺ concentration than the cytosol. This barrier function is maintained, which means that the activity of certain intraluminal enzymes is increased remarkably when the membrane is permeabilized either by detergents or by channel-forming antibiotics (e.g., amphotericin). It is based on the rate-limiting transport of substrates and/or effectors across the intact ER membrane. Some activities in the ER are more than 90% latent; i.e., they increase more than 10-fold during permeabilization (20, 21).

doi: 10.1002/9780470048672.wecb321

The field of pathway bioinformatics is concerned with the representation and the manipulation of metabolic information within computers. By organizing genome information into pathways, pathway bioinformatics places genes and their products into a mechanistic framework. This article describes how metabolic pathways are represented in a computer, and it describes the BioCyc (SRI International, Menlo Park, CA) collection of pathway/genome databases for several hundred organisms. Each BioCyc database describes the genome and the metabolic network of a single organism. This article describes computational algorithms for computing with pathway data. Pathway visualization algorithms help scientists comprehend this complex information space and facilitate analysis of large-scale omics datasets. Pathway analysis algorithms predict the metabolic network of an organism from its genome, identify the genes coding for missing enzymes in metabolic pathways, and enable the comparison of metabolic networks from multiple organisms. They also allow the prediction of the metabolic capabilities of an organism and identify potential drug targets within the metabolic network.

Together, Pathway Tools and BioCyc permit extremely fast and accurate modeling of the metabolic network of an organism from its genome sequence. Previously, hundreds of person-years of laboratory work were required to characterize an organism’s metabolic map. Now, given an annotated genome sequence for the organism, its metabolic network can be predicted computationally within a few days. Manual review of that computational prediction will yield a more accurate result within a few weeks. Computational reconstructions of metabolism are not perfectly accurate; thus, for increased model fidelity, we recommend following the computational reconstruction with manual curation of the metabolic network. A manual curation effort surveys the past biochemical literature for an organism, tracks newly emerging literature on an ongoing basis, and updates the metabolic model within a PGDB to reflect those findings.

Introduction

The bioinformatics subfield of pathway bioinformatics is concerned with developing computer representations of the metabolic network of an organism, with developing databases of metabolic information, and with developing algorithms for computing with metabolic information. This article will discuss the approaches for each of these problems in the Pathway Tools and BioCyc (SRI International, Menlo Park, CA) projects. Pathway Tools is a set of algorithms for computational analysis of metabolic data, and it includes computer representations of the metabolic network (1). BioCyc is a collection of Pathway/Genome Databases (PGDBs) for several hundred organisms (2). The BioCyc databases were constructed using Pathway Tools, and they can be queried and analyzed using Pathway Tools.

Representing Metabolic Knowledge in PGDBS

Metabolites, reactions, and pathways

Two alternative ways exist in which one might choose to represent the metabolic network in a computer: by listing of all metabolic reactions that occur in the cell or by partitioning that reaction set into a carefully delineated set of metabolic
Database relationships and attributes

The previous two subsections described the important types of objects in a PGDB. Here, we describe how these objects are linked together by biologically meaningful database relationships. PGDB relationships knit together the objects in a PGDB by defining how these objects are related. For example, queries can follow the relationship from a gene to the protein that it codes for, from a protein to a reaction that it catalyzes, and from a reaction to a metabolic pathway in which it is a component. To answer questions such as “find all metabolic pathways in which the products of a gene play a role.”

Every PGDB object has a stable unique identifier (ID), that is, a symbol that identifies that object uniquely within the PGDB. Example unique IDs include TRP (an identifier for a metabolite), RXN0-2382 (an identifier for a reaction), and PWY0-1280 (an identifier for a pathway). Relationships within a PGDB are implemented using IDs. For example, to state that the TRP (tryptophan) object is a reactant in the reaction RXN0-2382, a field of RXN0-2382 called LEFT (meaning “reactants”) contains the value TRP. Many PGDB relationships exist in both forward and backward directions; for example, the TRP object contains a field called APPEARS-IN-LEFT-SIDE-OF that lists all reactions in which TRP is a reactant. The fields LEFT and APPEARS-IN-LEFT-SIDE-OF are called inverses.

Figure 1 shows the relationships that link together levels 1–3 of the metabolic network representation. Note how inverse fields allow the user to query relationships in any direction within a PGDB; for example, given a metabolite we can query for the pathways in which it is involved, and given a pathway we can query for its metabolites.

Figure 2 shows the relationships that link together the genome and the proteome. For clarity, many related objects are omitted from Figs. 1 and 2, such as the many other Escherichia coli genes that are components of its chromosome, the other reactions that are components of TRYPSYN-PWY, and the reactants and products of RXN0-2382.

The representations in Figs. 1 and 2 must be connected because enzymes in the proteome catalyze reactions in the reactome. Thus, PGDBs contain relationships that link enzymes with the reactions they catalyze. However, these relationships are indirect, passing first through an intermediary object called an enzymatic reaction, as shown in Fig. 3. This arrangement allows us to capture the many-to-many relationship that exists between enzymes and reactions— one reaction can be catalyzed by multiple enzymes, and multifunctional enzymes catalyze multiple reactions. The purpose of the enzymatic reaction is to encode information that is specific to the pairing of the enzyme with the reaction, such as cofactors, activators, and inhibitors. Consider a bifunctional enzyme with two active sites, in which one of the active sites is inhibited by pyruvate, and the second active site is inhibited by lactate. We would represent this situation with two enzymatic reactions that link the enzyme to the two reactions it catalyzes, and each enzymatic reaction would specify a different inhibitor.
Cellular Organization of Metabolism

Figure 1 Relationships that link levels 1–3 of the metabolic network. The metabolite tryptophan (ID TRP) is a reactant of the reaction whose ID is RXN0-2382, which in turn is a member of the pathway whose ID is TRYPSYN-PWY. The field IN-PATHWAY is the inverse of the field REACTION-LIST.

Figure 2 Relationships that link the genome and proteome of a PGDB. The E. coli chromosome contains thousands of genes, one of which is EG11025 (trpB). Its product is the TrpB protein, whose ID is TRYPSYN-BPROTEIN. That monomer forms a homomultimer represented by the object CPLX0-2401.

Metabolic Databases

The preceding conceptual structure underlies all PGDBs created by Pathway Tools. Those PGDBs fall into several categories. The BioCyc collection of PGDBs is a collaboration between the Bioinformatics Research Group at SRI International and the Computational Genomics Group at the European Bioinformatics Institute (2). In addition, many other PGDBs have been created by other users of Pathway Tools. Some are listed in a table on the BioCyc home page (http://BioCyc.org). These PGDBs can be accessed through the web sites operated by their creators, and in some cases they are available through the BioCyc web site. In addition, some PGDBs can be downloaded for local use within Pathway Tools through SRI’s online registry of PGDBs (http://BioCyc.org/registry.html).

The overall framework of BioCyc is to define a single foundational database of experimentally elucidated pathways from many organisms (MetaCyc; SRI International, Menlo Park, CA) that is used to predict the metabolic pathways of other organisms from their sequenced genomes. Each prediction is modeled as a single organism-specific PGDB. Thus, the BioCyc organism-specific PGDBs each model the metabolism of a single organism in detail, whereas MetaCyc captures well-defined pathways from many organisms but does not define a comprehensive model of the pathways of any organism (except for E. coli, because MetaCyc contains all metabolic pathways from the EcoCyc [SRI International, Menlo Park, CA] PGDB).

BioCyc is divided into three tiers that reflect the degree of manual curation of these databases. The Tier 1 PGDBs EcoCyc and MetaCyc have undergone more than two person decades of curation each. By curation, we mean effort on the part of biologists to read the biomedical literature and to enter information from publications into these PGDBs.

Tier 1: EcoCyc

EcoCyc (4) describes the genome, the metabolic pathways, and the transcriptional regulatory network of E. coli K-12. EcoCyc curators enter newly discovered functions of E. coli genes into EcoCyc, as reported in the literature. They also enter E. coli metabolic pathways and information about E. coli operon organization, promoter locations, and control of those promoters by binding of transcription factors to nearby DNA sites. EcoCyc contains a written summary of the function of every E. coli gene for which experimental information is available. The information in EcoCyc was obtained from the more than 14,000 publications cited by EcoCyc.

Tier 1: MetaCyc

MetaCyc (5) is a multiorganism encyclopedia of metabolic pathways and enzymes. Like EcoCyc, it contains literature-derived information on experimentally elucidated metabolic pathways and enzymes. MetaCyc version 10.5 (October 2006) contains all...
197 metabolic pathways from EcoCyc and all EcoCyc metabolic enzymes. MetaCyc includes another 600 metabolic pathways from other organisms. Approximately half of the pathways in MetaCyc are from microorganisms, and approximately one-third of the pathways are from plants, with the remainder that comes largely from animals. The metabolic pathways in MetaCyc were elucidated experimentally in more than 700 organisms, and the information in MetaCyc has been drawn from more than 10,000 publications. MetaCyc contains extensive mini-review summaries and literature citations in its pathways. It also contains enzyme entries to explain the biologic functions of pathways and enzymes as well as to make this information accessible to scientists who are not experts in each pathway and enzyme.

The Tier 2 and Tier 3 PGDBs were derived computationally by applying the following sequence of computational operations to the annotated genomes of each organism, as described in more detail in the next section, and in Reference 2.

1. The annotated genome of each organism was converted to PGDB format.
2. The PathoLogic program predicted the metabolic pathway complement of each organism.
3. The PHFiller program predicted which genes within the organism will code for missing enzymes within the predicted metabolic pathways.
4. An operon predictor was executed for the bacterial genomes.
5. A cellular overview diagram was computed for each organism.
Tier 2

The Tier 2 PGDBs were created computationally by the preceding methodology, and then some amount of manual curation was applied to these PGDBs. For example, after being created computationally, the HumanCyc (SRI) International, Menlo Park, CA) PGDB (6) received extensive curation to assign human metabolic enzymes manually to their associated reactions; to enter 10 metabolic pathways and their enzymes from the literature into HumanCyc; and to enter associated summaries, literature citations, and other information such as enzyme regulators, cofactors, and subunit structure.

Tier 3

The Tier 3 PGDBs were created computationally by the preceding methodology, with no subsequent manual curation. We encourage scientists to adopt Tier 2 and Tier 3 PGDBs for ongoing curation and refinement. No single group can curate all the world’s genomes, so we encourage experts of the biology of an organism to assume responsibility for updating its PGDB to reflect existing and emerging information in the literature, on an ongoing basis.

Computing with the Metabolism of a PGDB

Once the metabolic network of an organism has been encoded using the preceding representation, many types of computational analyses are enabled.

Querying and visualization of metabolism

We are confronted immediately with the need to allow users to access information within metabolic databases. Pathway Tools provides several types of queries for each datatype within a PGDB. Users can query pathways, enzymes, metabolites, and proteins by exact name or by substring search. Additional queries supported include querying reactions by their Enzyme Commission (EC) number; querying metabolites by chemical substructures expressed in the SMILES language; querying pathways and reactions according to their substrates; and querying enzymes by molecular weight, pl, and by the small molecules that activate and inhibit them.

In presenting the answer to a query, the complexity of metabolic information demands the development of visualizations of the data that speed their comprehension by the user. Thus, an important aspect of the bioinformatics of metabolism is the visualization of metabolic information. Pathway Tools contains several visualizations of metabolism, all of which are generated automatically. It can produce drawings of individual metabolic pathways and of clusters of related pathways called superpathways. These drawings can be generated at multiple levels of detail so that the user can choose to show or to hide information such as enzyme and gene names, names of intermediate or side metabolites, and the chemical structures of metabolites. The drawings depict substrate-level regulation of the enzymes within a pathway, and all components of the drawing are clickable by the user. For example, clicking on a metabolite takes the user to a page that shows the metabolite structure and lists all its synonyms, all reactions and pathways in which it is a substrate, and all enzymes whose activities it regulates. Pathway Tools also generates information pages for enzymes and for biochemical reactions.

Pathway Tools can generate a visualization of the entire metabolic network of an organism, which we call the cellular overview diagram (7). This diagram is generated automatically from any PGDB, and it depicts all metabolic pathways in the PGDB as well as reactions not assigned to any pathway and all transporters identified in the PGDB. The overview diagram can be used to visualize omics datasets in a mode of operation called the Omics Viewer (7). The input to the Omics Viewer is a combination of gene expression data, proteomics data, metabolomics data, or other measurements that associate numbers with genes, reactions, or metabolites. The numbers are mapped to colors that are painted onto the elements of the cellular overview to allow the power of the human visual system to be used to interpret large-scale datasets in a pathway context. For example, a dot in the diagram that represents a single metabolite would be assigned a color that indicates the measured concentration of that metabolite in a metabolomics experiment. Finally, Pathway Tools can generate a poster-size version of the cellular overview complete with labels for entities in the diagram.

Prediction of metabolic pathways and pathway hole fillers

Pathway Tools predicts the metabolic pathway complement of an organism by assessing what known pathways from the MetaCyc PGDB are present in the annotated genome of a new organism. This inference is performed in two steps. First, enzymes in the annotated genome are assigned to their corresponding reactions in MetaCyc, which defines the reactome of the organism. The assignment proceeds by matching both the gene-product names (enzyme names) and the EC numbers assigned to genes in the genome. For example, the fabD gene in Bacillus anthracis is annotated with the function “malonyl CoA-acyl carrier protein transacylase.” That name was recognized by Pathway Tools as corresponding to the MetaCyc reaction whose EC number is 2.3.1.39. Therefore, Pathway Tools imported that reaction and its substrate into the B. anthracis PGDB, and it created an enzymatic-reaction object to link that reaction to that B. anthracis protein.

Once the reactome of the organism has been established, Pathway Tools imports into the new PGDB all MetaCyc pathways that contain at least one reaction in the organism’s reactome. Once imported, Pathway Tools attempts to prune out those pathways that are likely to be false-positive predictions. That pruning process considers both the fraction of reaction steps in the pathway that have assigned enzymes and how many of the reactions with assigned enzymes are unique to that pathway (as opposed to being used in additional metabolic pathways in that organism). The remaining pathways are those predicted to occur in the organism under analysis.
A final inference tool provided by Pathway Tools is called the pathway hole filler. A pathway hole is a reaction in a metabolic pathway for which no enzyme has been identified in the genome that catalyzes that reaction. Typical microbial genomes contain 200–300 pathway holes. Although some pathway holes are probably genuine, we believe that most probably result from the failure of the genome annotation process to identify the genes that correspond to those pathway holes. For example, genome annotation systems systematically under-annotate genes with multiple functions, and we believe that the enzyme functions for many pathway holes are unidentified second functions for genes that already have one assigned function.

The method used by the pathway hole filling program PH-Filler (8) is as follows. Given a reaction that is a pathway hole, the program first queries the UniProt database to find all known sequences for enzymes that catalyze that same reaction in other organisms. The program then uses the BLAST tool to compare that set of sequences against the full proteome of the organism in which we are seeking hole fillers. It scores the resulting BLAST hits by considering information such as genome localization, that is, is a potential hole filler in the same operon as another gene in the same metabolic pathway? At a stringent score-cutoff, our method finds potential hole fillers for approximately 45% of the pathway holes in a microbial genome.

Analysis and comparison of metabolic networks

Once the metabolism of an organism is captured in a computable form, we can write programs to characterize the size and structure of the metabolic network of an organism (9). For example, version 10.5 of the EcoCyc PGDB contains 176
pathways of small-molecule metabolism, which contain 702 component reactions. A total of 245 reactions of small-molecule metabolism are not assigned to a specific pathway. The cellular overview diagram can be used for comparative purposes by coloring those metabolic reactions shared between two organisms by using the desktop version of Pathway Tools. The Web version of Pathway Tools provides a suite of comparative analysis tools. For example, Fig. 4 shows comparisons of the overall pathway complements of E. coli and B. anthracis, which is broken down according to the Pathway Tools ontology of pathways. Figure 5 shows a detailed comparison of the pathways of biosynthesis of fatty acids and lipids in these two organisms.

A second form of pathway analysis is computing the potential outputs that the metabolic network might produce when supplied with a set of input metabolites (10). A third computational analysis method predicts choke points in the metabolic network, which are enzymes that if inhibited would be likely to create a major bottleneck in the metabolic network, and they are therefore likely to be good targets for developing antimicrobial drugs (11). In addition, it is possible to compute the equilibrium flux rates through an entire metabolic network (12).

Computational access to PGDBs
In addition to the user-friendly graphical interfaces to PGDBs provided through the Web and desktop versions of Pathway Tools, we provide the following modes of access to PGDBs to facilitate the construction of programs that explore pathway data computationally.

Programmatic access through application program interfaces (APIs)
Programmers can access and update PGDB data directly by writing programs in the Java, Perl, and Common Lisp languages (13).

Downloadable files in multiple formats
Pathway Tools can export PGDBs into several different file formats that are described at http://bioinformatics.ai.sri.com/ptools/flatfile-format.html. These formats include column-delimited tables, SBML (see http://sbml.org/), BioPAX (see http://biopax.org/), Genbank, FASTA, and attribute-value.

Relational database access via biowarehouse
For those who want to query PGDB data through a relational database system, the attribute-value files exported by Pathway Tools can be loaded into SRI’s BioWarehouse system (14). BioWarehouse is an Oracle or MySQL-based system for integration of multiple public bioinformatics databases. PGDB data can be queried through BioWarehouse alone or in combination with other bioinformatics databases such as UniProt, Genbank, NCBI Taxonomy, ENZYME, and KEGG.
Queries using the pathway tools query language, BioVelo

Pathway Tools provides a powerful and easy-to-use query language for querying PGDBs, called BioVelo. See http://biocyc.org/query.html for details.

Cell membranes are two-dimensional fluids that exhibit a wide range of dynamic behaviors. Recent technical advances have enabled unprecedented views of membrane dynamics in living cells. In this technical review, we provide a brief overview of three well-studied examples of membrane dynamics: lateral diffusion of proteins and lipids in the plane of the membrane, vesicular trafficking between intracellular compartments, and exchange of proteins on and off membranes. We then discuss experimental approaches to monitor membrane protein and lipid dynamics, and we place a special emphasis on the use of genetically encoded fluorescent probes and live cell-imaging techniques.

The concept that membranes are fluid, dynamic structures is now over 35 years old (1, 2). In this review, we describe three of the best-studied examples of cell membrane dynamics—lateral diffusion of proteins and lipids within the plane of the bilayer, membrane trafficking between intracellular compartments, and exchange of proteins on and off membranes—along with the recent technical advances that have enabled researchers to visualize these motions directly within living cells. In particular, we describe how the use of green fluorescent protein (GFP) from Aequorea Victoria and other, more recently developed labeling technologies can be used to mark molecules to study inside cells. We also summarize common fluorescence microscopy techniques for live cell imaging, including conventional techniques such as wide-field and confocal microscopy, and more specialized techniques such as total internal reflection fluorescence (TIRF) microscopy. Finally, we cover advanced methods used to study cell membrane dynamics, including single particle tracking (SPT), fluorescence recovery after photobleaching (FRAP), photoactivation, fluorescence correlation spectroscopy (FCS) and image correlation spectroscopy (ICS).

Types of Cell Membrane Dynamics

Lateral diffusion

Membranes are two-dimensional fluids whose protein and lipid components continuously exchange positions because of Brownian motion, a process commonly referred to as lateral diffusion. Lateral diffusion enables proteins and lipids to explore their environment, which encourages interactions between molecules. Thus, the speed of lateral diffusion is one of the limiting factors that regulate intermolecular interactions, and, consequently, cellular function. Diffusional mobility of molecules can be estimated based on their size and the viscosity of the lipid bilayer and surrounding aqueous phase. As a result, deviations from this behavior can provide important insights into the environment that proteins and lipid encounter in biologic membranes.

How rapidly diffusion occurs is characterized by the diffusion coefficient \( D \), a parameter that provides a measure of the mean of the squared displacement \( x \) of a molecule per unit time \( t \). For diffusion in two dimensions such as a membrane, this is given by \( \langle x^2 \rangle = 4Dt \). The Saffman-Delbrück model of Brownian motion in biologic membranes describes the relationship between membrane viscosity, solvent viscosity, the radius \( R \) and height of the diffusing species, and \( D \) for both lateral and rotational diffusion of proteins in membranes (3, 4). This model predicts for example that for lateral diffusion, \( D \) should be relatively insensitive to the radius of the diffusing species, scaling with \( \log (1/R) \).

Interestingly, the diffusional behavior of membrane proteins measured experimentally by FRAP, FCS, or single particle tracking in cells is more complex than predicted by this model. This technique is described best for the case of cell surface proteins, as assessed by FRAP. Such measurements indicate that diffusion is typically much slower than one would expect based on membrane viscosity. In cell membranes, typical values of \( D \) for transmembrane proteins are approximately 0.05 \( \mu \)m^2/s or less, which is much slower than observed in artificial membranes composed of purified lipids. In addition, a significant fraction of proteins is often immobile over the timescale of diffusion experiments (4, 5). Furthermore, diffusional mobilities vary among proteins, and sometimes they differ for the same protein expressed in different cell lines (4, 5). Deviations from pure diffusion are more readily apparent when the trajectories.
of single molecules are analyzed (Fig. 1). Individual molecules exhibit a range of diffusive behaviors, characterized as immobilization, transient confinement, free diffusion, and in some cases directed motion (6).

Features of cell membranes that contribute to this complex diffusional behavior include the presence of membrane domains, interactions of proteins with the cytoskeleton and extracellular matrix, and molecular crowding because of the high protein concentrations found in cellular membranes (4, 5). The diffusional mobility of proteins and lipids can also be modulated actively.

For example, crosslinking of certain cell surface molecules causes dramatic changes in their mobility, which reflects interactions with other cellular components. A well-studied example of such a protein is FcεR1, the high affinity IgE receptor, which undergoes a substantial loss of mobility on the formation of small aggregates of IgE-FcεR1 (7). Using an advanced technique known as FCS cross correlation analysis, it is now possible to detect transient interactions of membrane proteins that occur during cell signaling by virtue of their codiffusion (8).

Until recently, experiments that probe protein diffusion relied on fluorescent antibody-based probes, and thus were limited to plasma membrane proteins with extracellular epitopes. In contrast, the mechanisms that regulate diffusion of intracellular membrane proteins remained unexplored because of their inaccessibility to labeling. With the development of genetically encoded fluorescent probes, such studies have become tractable because proteins targeted to a particular organelle can be fluorescently labeled directly with GFP. In addition, improved technology has now made it possible to monitor the movement of multiple types of proteins or lipids, tagged with different markers simultaneously. Some examples of the types of questions it is now possible to address include:

How is protein diffusional mobility regulated in intracellular compartments?

Some of the first investigations of diffusion in organelle membranes such as the Golgi complex and endoplasmic reticulum suggest that unlike the plasma membrane, protein diffusion in intracellular membranes approaches theoretic limits (9). These findings suggest that intracellular membranes contain considerably fewer barriers to free diffusion than the cell surface. Diffusion studies can also be used to test whether protein immobilization is responsible for retaining proteins within a specific organelle, the effect of unfolding on protein mobility, and how various perturbations influence both the luminal and membrane environment experienced by proteins (10).

Is the mobility of proteins influenced by how they are attached to membranes?

Lateral diffusion is predicted to be relatively insensitive to the size of the transmembrane domain of the diffusing species. This prediction suggests that membrane anchorage should not strongly influence diffusion. However, membrane anchorage would be expected to influence the types of interactions that occur between a given protein and the complex environment of the cell. For example, the diffusion of peripheral membrane proteins localized to the inner leaflet of the plasma membrane by lipid anchors has been shown to be much faster than transmembrane proteins and nearly as fast as that of lipid probes in some instances (11). This finding suggests that because of their lipid anchors, these molecules do not experience the same barriers to diffusion as transmembrane proteins. It also likely reflects the ability of some proteins to undergo rapidly reversible binding to membranes (12, 13).

Do cholesterol-enriched lipid domains organize proteins into functional complexes?

Interest in the role of membrane domains in regulating protein and lipid diffusion has recently been revitalized by the lipid raft model, which proposes that cell membranes are divided into cholesterol and sphingolipid-enriched and-depleted microdomains. As a result, much effort has been made recently to relate lipid and protein diffusion in cells and model membranes (14) and to determine the effect of cholesterol levels on protein and lipid diffusion by both FRAP and FCS (11, 15). The role of cholesterol-dependent domains in regulating events such as T-cell signaling has also been investigated by examining closely the mechanisms of diffusional trapping of proteins at the single molecule level by TIRF microscopy; unexpectedly, protein-protein interactions seem to play a more important role than cholesterol-dependent domains in this process (16).

Membrane trafficking

Although integral membrane proteins and lipids are laterally mobile within the plane of a given cell membrane, they cannot exchange between different membrane compartments unaided because of the high energetic barriers to exposing their hydrophobic portions to water. The movement of transmembrane proteins between cellular compartments is accomplished by the formation of closed bilayer structures known as transport vesicles that bud off from one compartment and fuse with another. The term “membrane trafficking” refers to the movement
structures involved in this process (21, 22).

Membrane trafficking involves many highly regulated events, which include cargo selection, recruitment of coat and accessory proteins, vesicle budding, intra-organellar transport, targeting to and fusion with the target membrane, and recycling of cellular machinery for another cycle of transport (17). Recent work has now begun to focus on the temporal and spatial regulation of these events in living cells (18–20). Such approaches are especially powerful when coupled with cell biological manipulations such as drug treatments, the introduction of mutant proteins into cells, or knockdown of protein expression to probe the cellular mechanisms that underlie membrane trafficking (20). Examples of the types of questions being addressed are listed in the following sections.

What are the kinetics of intracellular transport through the secretory pathway?

The transmembrane protein VSVG is a classic tool used to study protein transport through the secretory pathway. Some early studies of vesicular transport in living cells visualized the movement of a GFP-tagged version of VSVG by time-lapse confocal microscopy (21, 22). From these data, it was possible to derive a kinetic model of the movement of this well-studied protein between intracellular compartments, while at the same time providing information about the nature of the vesicular structures involved in this process (21, 22).

What pathways do pathogens use to enter cells?

Certain viruses and bacterial toxins are endocytosed by a specialized pathway that involves invaginations of the plasma membrane known as caveolae. Recent studies have traced out this caveolar endocytic pathway by jointly tagging the cellular machinery with GFP and labeling viruses or bacterial toxins with fluorescent dyes, which enables their dual visualization in real time (23, 24). Such work has revealed several unanticipated properties of this pathway, such as the ability of viruses to induce formation of actin comets that propel virus-containing vesicles (23) and the stable, immobile nature of the caveolar coat that encases these vesicles (24).

How do cargo molecules and trafficking machinery progress through the endocytic pathway?

Movement of cargo through the endocytic pathway could occur by vesicular transport between stable compartments. Alternatively, it could involve progressive maturation of endosomal membranes. Recent work has tested these models by using fast, live cell imaging in combination with tools to quantify dynamic changes in the levels of the small GTPases Rab5 and Rab7 on endosomal structures during transport of fluorescently labeled cargo (25). These data suggest a model in which conversion in Rab proteins is a mechanism by which cargo progresses between early and late endosomes. Other studies have focused on how specific cargo molecules that enter the cell via identical pathways, such as cholera toxin and SV40, ultimately are sorted to various intracellular destinations. Sorting requires the pH-dependent release of cholera toxin from caveolar domains in endosomes; SV40 remains immobilized under these conditions (24).

Cycling of proteins on and off membranes

Although integral membrane proteins must rely on membrane trafficking as their sole mechanism for traversing the cell, many peripheral membrane proteins can move on and off membranes in a reversible manner by shifting between a membrane-bound and a soluble state. This reversible binding is critical for the function of coat proteins involved in the formation of transport vesicles (clathrin, COP1, and COPII), proteins that play roles in organelle identity and membrane trafficking (Rabs and Arf proteins), and a wide variety of signaling proteins (Ras, Raf, and protein kinase C) (26–28). Biochemically, such exchange can be detected by fractionating cells into membrane and soluble fractions, and quantifying the amount of protein found in each. Using live cell imaging approaches, it is possible to begin to monitor these events in real time to address questions such as the following.

On what cellular membranes does exchange occur?

One major advantage to studying membrane/cytosol exchange of proteins in living cells is that it is possible to compare the recruitment of proteins with different organelles simultaneously. For example, such studies have been instrumental in showing that Ras activation, as reported by the membrane recruitment of the FP-tagged Ras binding domain of Raf from the cytosol, occurs on Golgi membranes as well as the cell surface, and that the kinetics of recruitment are different for the two compartments (29).

How rapidly do proteins cycle on and off membranes?

Compared with membrane trafficking, which occurs with characteristic rates of 3% per minute for the case of VSVG movement from the endoplasmic reticulum to the Golgi complex (22), the cycling of proteins on and off membranes can occur over very rapidly. In our own work (30), we have observed in phatural bleaching of GFP fusion proteins that a mutant form of HRas that lacks both palmitoylation sites is able to constitutively cycle on and off membranes of the Golgi complex with half-times of ~5 s (Fig. 2).

Is exchange constitutive or regulated?

Membrane/cytosol exchange is sometimes constitutive, but more often it occurs in a tightly regulated manner. Many proteins are recruited to membranes in response to the transient generation of protein or lipid binding sites on the membrane, which are recognized by modular protein interacting or lipid interacting domains contained within the recruited protein. Alternatively, membrane binding can be regulated by loss of membrane-binding sites or perturbation of binding motifs within

These vesicular structures between organelles and/or the plasma membrane, and includes the processes of endocytosis and exocytosis.

Membrane trafficking involves many highly regulated events, which include cargo selection, recruitment of coat and accessory proteins, vesicle budding, intra-organellar transport, targeting to and fusion with the target membrane, and recycling of cellular machinery for another cycle of transport (17). Recent work has now begun to focus on the temporal and spatial regulation of these events in living cells (18–20). Such approaches are especially powerful when coupled with cell biological manipulations such as drug treatments, the introduction of mutant proteins into cells, or knockdown of protein expression to probe the cellular mechanisms that underlie membrane trafficking (20). proteins. For example, recent evidence suggests that KRas, which contains a cluster of basic amino acids that facilitates its binding to the plasma membrane, can be released via phospho-
rylation of residues in the polybasic domain. This release in turn allows for the regulated redistribution of KRas to mitochondria, where it promotes apoptosis (31).

Chemical Tools and Techniques to Study Cell Membrane Dynamics

**Probes**

Fluorescent probes of membrane dynamics fall into two general classes: exogenous and genetically encoded. Exogenous probes, which include small organic dyes and quantum dots, usually are targeted to the protein of interest via immunolabel-
ing approaches. They are used commonly to label cell surface proteins, although they can be introduced into cells by microin-
jection or by permeabilizing cells. Genetic approaches make use of intrinsically fluorescent proteins (FP) or genetic tags that generate binding sites for small dyes. Here, molecular biology tools are used to engineer DNA constructs that contain fusions of the protein of interest and the genetic tag. The DNA is then introduced into cells by transfection or transduction (Fig. 3).

**Small organic dyes**

Small organic dyes are available with a wide range of spectral properties encompassing the entire visible range, including the near UV and far red (32). Prior to the advent of FP, small organic dyes were the workhorses for fluorescent labeling of plasma membrane proteins, either by using dye-labeled anti-
bodies (Fig. 3a) or by labeling proteins directly that bind to plasma membrane proteins or lipids such as bacterial toxins or growth factors. Indeed, most early work that defines the diffu-
sional mobility of proteins on the plasma membrane relied on immunodetection of cell surface proteins with antibody frag-
ments labeled covalently with fluorescent dyes (5). The use of small organic dyes to label proteins fluorescently remains a valuable tool to study the endocytic itineraries of ligands, viruses, and bacterial toxins (24). However, dye-labeled proteins have historically been much less useful in studies of intracel-
tular proteins in living cells, because this task requires their introduction by either microinjection or permeabilization of the plasma membrane. The susceptibility of many fluorescent dyes to photobleaching also limits their use in live cell imaging ap-
plications.
Probes of lipid dynamics

Synthetic lipid analogs such as DiI and BODIPY-labeled lipids are classic reporters of lipid dynamics (32, 33). Fluorescent glycolipid analogs have also been used for many years, especially in studies of endocytosis and lipid trafficking (34). However, it is important to note the limitations of these probes. Many make use of short-chain analogs to enable their delivery into cells. In addition, some fluorophores used to label these lipids are used to replace a fatty acid chain. As a result, these lipids may not exhibit behavior similar to that of their native counterparts. To address these limitations, polyene lipids, which have a structure similar to that of natural lipids, have been developed recently as an alternative to classic fluorescent lipid analogs (35). Fluorescent cholera toxin analogs have joined the growing list of fluorescent lipid probes (36). Of these, dihydroergosterol is most likely to be a useful structural analog of cholsterol.

An alternative approach to the use of fluorescent lipid analogs to study lipid dynamics is the use of fluorescent reporter proteins that bind specific lipids. Such experiments are also of interest from the biologic standpoint of protein function. For example, plekstrin homolog (PH)-domain-containing proteins bind phosphoinositide lipids (26, 27), whereas cholera toxin binds ganglioside GM1 (20). It should be noted however that protein reporters that interact with a specific lipid might not be "neutral" from a biologic point of view, as they may compete for binding with endogenous molecules.

GFP and its derivatives

Many recent advances in the study of cell membrane dynamics (and indeed in much of cell biology) have been driven by the discovery of green fluorescent protein from Aequorea victoria (37). GFP is exceptionally large (27 kDa) and thus has the potential to disrupt the structure, function, and/or localization of the protein to which it is linked (Fig. 3b). Second, the expression of fusion proteins typically relies on transfection, which can be problematic in some primary cell lines and can lead to overexpression artifacts. Third, certain fluorescent proteins form obligate dimers. Finally, spectral overlap limits the number of different fluorescent proteins that can be used in the same experiment, although this problem is diminishing as new variants are developed.

Chemical labeling of fusion proteins

Recently, methods have been developed to label proteins site-specifically with small molecules for live cell imaging studies as an alternative to the use of FP fusion proteins (42-44). The strategy of these approaches relies on genetically incorporating a "receptor" domain that can serve as a specific binding site for a small molecule to the protein of interest. After expressing the fusion protein in cells, it can then be labeled using cell-permeant small molecule probes. This general scheme offers several major advantages over FP fusion proteins, which include 1) the potential to label proteins with relatively small, and thus in principle, minimally perturbing tags; 2) the possibility of taking advantage of small molecule probes with a wide range of chemical properties; and 3) the ability to control the time at which the proteins of interest are tagged, which allows for temporal regulation of labeling.

The tetracysteine-biarsenical system is one of the first examples of such technology (45). Here, a 12-residue sequence that includes four cysteines is incorporated into the protein of interest to enable binding of membrane permeant biarsenic dyes (FlAsH and R6GSH) (42). In addition to the small size of the tetracysteine motif, advantages of this approach include the possibility to perform correlative electron microscopy analysis and pulse-chase labeling (42). Furthermore, the fluorescence intensity of the biarsenic dyes increases substantially on binding, which decreases background fluorescence. However, the biarsenic dyes exhibit nonspecific binding to cysteine-rich proteins and require a reducing environment for labeling. Compared with the FP, this and other methods that combine genetic tags with small molecules are still in their infancy, but with additional iterations of refinement, they are likely to become useful in the future.

Quantum dots

Quantum dots are fluorescent semiconductor nanocrystals that have been incorporated recently into the toolbox of fluorescent labeling techniques (42). When coated appropriately, quantum dots can be conjugated with streptavidin or antibodies for protein labeling applications in cells (46). Quantum dots are exceptionally bright and photostable, have a broad absorbance spectrum, and can be tuned to emit at specific wavelengths depending on their size. Because of their brightness and photostability, they can be very useful for detecting low abundance proteins and are attractive probes for long-term single particle tracking studies. However, their applications in live cells are hampered somewhat by their large size (~10 to 30 nm) and "blinking" behavior. For example, the size of quantum dots has limited their use primarily to studies of extracellularly localized plasma membrane proteins because their introduction into cells...
tissue imaging a technique of choice for fluorescence microscopy. The forms of fluorescence microscopy used most commonly for live cell imaging are wide field and confocal microscopy. In wide field microscopy, fluorescence is typically excited with an arc lamp and emission is collected using a CCD camera. Such systems can be configured readily for imaging live cells over time. An advantage of this approach is its relative simplicity compared with other imaging modalities.

However, it collects light emitted from the entire depth of the specimen including out-of-plane fluorescence.

In confocal microscopy, out of plane fluorescence is eliminated by the incorporation of a pinhole in the light path, which enables the collection of three-dimensionally resolved images. This task is accomplished by using a single pinhole for the case of laser scanning confocal microscopy or with a series of rotating pinholes in spinning disk confocal microscopy. Because the intensity and position of the laser used to excite samples can be modulated rapidly in many laser scanning confocal microscopes, it is possible to use them for specialized applications such as photobleaching and photobleaching (see below). Spinning disk confocal microscopes are not well suited for photobleaching or photoactivation applications, but they have a greater image acquisition rate than laser scanning confocals.

In addition to confocal microscopy, a technique known as multiphoton microscopy can also be used to generate three-dimensionally resolved fluorescence images. In this case, excitation is limited to those fluorophores that are present within the small region where the laser is focused and thus are of sufficiently high power to excite a single fluorophore to absorb two or more photons simultaneously (47). Other advantages of multiphoton microscopy include reduced photobleaching outside of the focal plane as well as increased penetration into samples because of the use of longer wavelength excitation, which makes this a technique of choice for tissue imaging in vivo.

In some instances, it is of interest to focus exclusively on events that occur at the plasma membrane. Here, a technique known as TIRF microscopy is particularly valuable (48). TIRF uses an evanescent wave generated by a process referred to as total internal reflection to excite the sample. Total internal reflection occurs when light traveling from a medium of high refractive index arrives at an interface with a medium of lower refractive index above a so-called critical angle. Under these conditions, the light is reflected back into the high refractive index material, and an evanescent field is generated in the lower refractive index medium. The field decays exponentially away from the interface, with a typical depth between 50 to 150 nm. Because experimentally, this interface represents the surface at which cells attach to a coverslip, it is possible to selectively excite and visualize only those fluorescent molecules found at this surface. TIRF can also be combined with the advanced methods described in more detail below, which include single molecule imaging (16), FCS (49), and FRAP (50). Thus, TIRF offers an attractive imaging modality for probing plasma membrane dynamics using a variety of techniques. For a more in-depth discussion of the pros and cons of each of these approaches in live cell imaging studies, we refer the reader to several recent reviews (51, 52).

Advanced techniques used to study membrane dynamics

FRAP
FRAP (also known as fluorescence photobleaching recovery or FPR) has been used for many years to study lateral diffusion of plasma membrane proteins as characterized by their diffusion coefficient and mobile fraction (5, 53). In these experiments, a population of fluorescence molecules is bleached irreversibly by exciting with an intense, focused laser spot. Recovery of fluorescence in the bleached region is then monitored over time to determine to what extent and how rapidly the bleached molecules are replaced by unbleached molecules from other regions within the cell (Fig. 4a). Two fundamental assumptions that underlie these experiments are that the bleaching event does not damage the labeled protein or surrounding region of the cell, and that the bleaching is irreversible. In other words, that recovery occurs because of diffusional exchange and not by recovery of fluorescence of an individual fluorophore. FRAP curves are typically fit by equations for free diffusion plus an immobile fraction (53). A variation on this approach is to measure FRAP as a function of spot size, which is a technique that is sensitive to the cycling of proteins on and off membranes (13).

Until the development of the fluorescent proteins, FRAP measurements were confined to measurements of protein or lipid diffusion in the plasma membrane using fluorescently labeled Fabs or fluorescent lipid analogs that could be added to cells exogenously. For such experiments, little need existed for spatially resolved measurements because the fluorescence signal was localized to the plasma membrane. Thus, most classic FRAP studies made use of a spot photobleaching apparatus that consisted of an epi-fluorescence microscope, computer-controlled shutter, laser used both for bleaching and for low-level excitation of the sample, and detector to collect fluorescence emission coupled with electronics to resolve the measured fluorescence intensity (54). In recent years, commercially available confocal microscopes have incorporated FRAP protocols, which allows for imaging-based FRAP measurements of intracellular fluorescent proteins. These two developments have brought FRAP into the mainstream of cell biological techniques, especially those related to questions of membrane dynamics.

Examples of useful applications of confocal FRAP include selective photobleaching and fluorescence loss in photobleaching (FLIP) (18, 55). In contrast with conventional spot photobleaching FRAP, in confocal FRAP it is possible to visualize both the bleach region and the surrounding area of the cell. In addition, confocal FRAP techniques typically use...
Selective photobleaching. Fluorescent molecules in an individual compartment (as illustrated here for the Golgi complex, circled) are photobleached. The sample is then monitored over time to determine whether fluorescence can recover (d) or not recover (e) from other regions of the cell. (Adapted from Reference 62 with permission from Elsevier.)

Figure 4 Principles of photoactivation and photobleaching experiments. For purposes of illustration, regions of bright fluorescence are shaded gray, and areas that contain little or no fluorescence are shown in white. (a) FRAP. Here, molecules in a region of interest (box) are photobleached, and their exchange with fluorescent molecules from the surrounding region is monitored over time. (b) Photoactivation. Similar to FRAP in principle except here the molecules in the region of interest (box) are converted to a different state. The redistribution of photoactivated molecules can then be monitored selectively. (c) FLIP. Repeated photobleaching of a region of interest (square) is performed, while monitoring the loss of fluorescence from other regions of the cell. (d, e) Selective photobleaching. Fluorescent molecules in an individual compartment (as illustrated here for the Golgi complex, circled) are photobleached. The sample is then monitored over time to determine whether fluorescence can recover (d) or not recover (e) from other regions of the cell. (Adapted from Reference 62 with permission from Elsevier.)

Large and/or complex regions of interest and may incorporate repetitive bleaching protocols instead of a single bleaching event. For example, in selective photobleaching experiments, an entire subcellular compartment such as the Golgi complex is photobleached to examine the mechanism and kinetics of recovery from elsewhere in the cell (Fig. 4d-e). Using this approach, it is possible to monitor the kinetics of coat protein cycling on and off membranes (28) as well as to assess the kinetics of vesicular and nonvesicular transport in the secretory and endocytic pathways (18) (Fig. 2). In FLIP, a single region of interest is bleached repetitively, which allows for recovery of fluorescent material to occur in between each repetition. This technique causes a gradual depletion of fluorescence material in regions of the cell that are in communication with the bleach region (Fig. 4c). Thus, the rate and the extent of loss of fluorescent material from the area outside of the bleach region depends on the degree of connectivity between compartments (18).

Photoactivation

A thorough time-lapse imaging is often sufficient to monitor vesicular trafficking and transient membrane binding events, for other experiments it is advantageous to "mark" a particular group of fluorescent molecules and watch their redistribution over time. The generation of photoactivatable fluorescent proteins (39) has now made it possible to "highlight" a population of molecules for optical tracking experiments (55). As a result, movement of the photoactivated molecules can be visualized directly in a "pulse-chase" experiment (Fig. 4a). Many of the same concepts described above for FRAP experiments can also be applied to photoactivation.

Single particle tracking

Single particle tracking is a technique that visualizes directly the movements of individual molecules, small groups of molecules, or even viruses by either fluorescence microscopy or light microscopy (54, 56). For such experiments, individual proteins can be expressed as GFP fusion proteins, labeled with fluorescent antibodies, or labeled with quantum dots. Alternatively, they can be immunolabeled with probes that can be detected by light microscopy such as 30–60 nm gold particles or latex beads. In the limit of sparse labeling, the trajectory of individual tagged molecules can then be tracked with high temporal and spatial accuracy using highly sensitive cameras (54). Although the resolution of fluorescence microscopy is ∼250 nm, the centroid of a single molecule can be determined with an accuracy of ∼10 nm (54). Typical rates of image acquisition are ∼30 frames/sec, although much faster acquisition rates can be obtained with specialized cameras. The resulting trajectories can be plotted directly to show the movements of each molecule, or can be analyzed even more to determine the mean squared displacement as a function of time (Fig. 1). For example, during free diffusion, the molecule moves randomly, which results in a characteristic linear relationship between mean squared displacement and time. A hallmark of confined diffusion is that the mean squared displacement of the particle is at first linear, then plateaus, which reflects the limited movement of the molecule within a confined region of the membrane. A given molecule may shift between several modes of motion during the observation period. Thus, the percentage of molecules that undergo each type of motion and/or the fraction of time they exhibit a particular behavior is often reported.

An obvious advantage of single molecule tracking is that it allows for highly detailed analyses of the movements of individual molecules that are obscured in population-based measurements such as FRAP and photoactivation experiments. However, SPT
experiments are not trivial to perform and are subject to several potential artifacts. The first challenge is to demonstrate that single molecules are being studied. Crosslinking can occur in studies that use antibody-labeled gold beads or quantum dots as probes, and lead to changes in mobility. In addition, large probes can potentially interact with the extracellular matrix. Photobleaching of organic dyes or FP-fusions can be rapid, which limits visualization times. However, photobleaching can also be used to confirm that single molecules are being visualized, because they will undergo a single-step photobleach. Finally, because of the intrinsic variability in trajectories, careful analysis is required to distinguish between motions that arise from free diffusion and confined diffusion.

FCS and ICS

FCS is not an imaging technique per se, although it is often performed using a microscope-based system. Instead, FCS measures the movement of individual fluorescent molecules through a defined observation volume, recorded as fluctuations in fluorescence over time (57). Such measurements require a sensitive photodetector, a dilute sample (~om) and a sampling volume with femtoliter dimensions. The observation volume can be generated using a laser focused to a diffraction-limited spot with a confocal pinhole placed in front of the detector, multiphoton illumination, or TIRF excitation in conjunctions with a pinhole. A notable strength of FCS is its sensitivity to fluorescence fluctuations over a wide range of timescales, from fast kinetics corresponding to photophysical properties of fluorescent proteins to the diffusion of proteins in cell membranes (58). In addition, FCS measurements can be collected within user-defined regions in an individual cell or artificial membrane vesicle, which allows for comparison of protein or lipid dynamics in distinct membrane environments (15). FCS can also be used to measure kinetic rate constants, for example, the association and dissociation of fluorescently labeled molecules to the plasma membrane (48).

The fluorescence fluctuations measured by FCS can be analyzed in several ways. The most common technique, autocorrelation analysis, involves measuring the time dependence of fluorescence fluctuations over a wide range of timescales and then performing a Fourier transform of the autocorrelation. A notable advantage of using a laser-scanning microscope is that it provides a way to visualize the diffusional properties of individual molecules. In addition, FCS can also be used to estimate the rate constants of, for example, the association and dissociation of fluorescently labeled molecules to the plasma membrane (48).

Whereas FCS measures fluorescence fluctuations over time, a related technique, ICS, measures fluorescence fluctuations over space, in particular from images collected using a laser-scanning microscope. ICS analysis of pixels within a single image provides information about protein clustering and density. A variation of ICS known as imagewise correlation spectroscopy evaluates the interactions of molecules labeled with different fluorescent probes. ICS can also be performed on stacks of images collected as a function of time. This spatial-temporal version of ICS can be used to monitor slow protein dynamics, and even be used to generate vector maps of directed protein movements in living cells (60).

Acknowledgments

I apologize to those whose original research could not be cited because of space limitations. I thank Maria Kiskowski, Lynne Lapierre, Erik Snapp, and Michael Edidin for their comments on the manuscript and Erik Snapp for providing Figure 2. Supported by RO1GM-073846.

Membrane Compartments Related to Signaling and Trafficking in Immune Cells

Stephanie Hammond, David Holowka and Barbara Baird, Cornell University, Ithaca, New York
doi: 10.1002/9780470048672.wecb307

Cells of the immune system detect and respond to the presence of foreign antigens by signaling through an array of receptors, which include the multichain immune recognition receptor (MIRR) family. Stimulated changes in membrane architecture, which includes protein and lipid segregation within membranes as well as membrane trafficking, regulate these cellular responses. We provide a brief overview of MIRR signaling, which focuses on signaling through the IgE receptor in mast cells, and we highlight specific examples in which membrane compartmentalization plays a role in this signaling pathway. We summarize biochemical methods used to isolate and characterize membrane subdomains. Finally, we discuss cross-correlation microscopy methods, application of antigen-patterned surfaces, and fluorescence-based trafficking assays to study dynamics of stimulated proteins interactions and membrane trafficking.

Membrane compartmentalization is required for rapid and efficient signaling responses in immune cells, such as mast cells, T cells, and B cells. Changes in the organization of membrane proteins and lipids are necessary for a spatially regulated response, and trafficking of intracellular compartments contribute to this spatial reorganization. Mast cells that express the high-affinity receptor for IgE, FcεRI, are a well-characterized system for investigating the role of membrane domains known as lipid rafts in the signaling pathway. However, changes in membrane compartmentalization necessary for signaling are not limited to plasma membrane lipid rafts. Subdomains of intracellular organelles, specifically the endoplasmic reticulum and the endosomal system, function to regulate membrane interactions and directional trafficking in this system. In this article, we discuss molecular biology tools that are being applied to the study of protein trafficking and membrane compartmentalization. We outline standard methods to isolate membrane subdomains, which include isolation of detergent-resistant membranes, cholesterol depletion, and subcellular fractionation. We then conclude this article by discussing spectrofluorometric methods used to study protein colocalization and membrane trafficking in living cells.

Signaling Through Antigen-Binding Receptors

Immune cells express a variety of receptors to detect foreign antigens and respond in a selective manner to clear pathogens and infected cells from the body. Both soluble and membrane-bound antigens are recognized by the multichain immune recognition receptor (MIRR) family of antigen-binding receptors. This family includes three well-characterized members: the high-affinity receptor for IgE (FcεRI) expressed on mast cells and basophils, the T cell receptor (TCR), and the B cell receptor (BCR). These receptors consist of transmembrane ligand-binding subunits that are noncovalently associated with signaling subunits that contain immunoreceptor tyrosine-based activation motifs (ITAMs) in their cytoplasmic domains (Fig. 1a). The binding of specific ligands cross-links these receptors and initiates signaling. The FcεRI consists of the IgE-binding α subunit, which associates with the signal-transducing γ-homodimer and the signal-amplifying β subunit, and it serves as an archetype for studying immunoreceptor signaling. The TCR consists of an
antigen-binding \( \alpha \beta \) heterodimer, the signal-transducing CD3 \((\kappa \epsilon \gamma)\) complex, and the \( \epsilon \) chain homodimer. TCRs recognize short peptide sequences bound to major histocompatibility complex (MHC) proteins on the surface of antigen-presenting cells. The BCR consists of an antigen-binding membrane immunoglobulin subunit that associates with the signal-transducing Ig-\( \alpha \)/\( \gamma \) complex. B cell signaling is enhanced through interactions with the B cell coreceptor complex that contributes additional phosphorylation sites.

**Mast cell signaling through FcRI and lipid rafts**

Mast cells are the primary cellular mediators of allergic reactions and also function in innate immunity and defense against helminths (1). These tissue-resident cells reside in strategic locations throughout the body, most prominently in the mucosal membranes of the respiratory and digestive tracts. The rat basophilic leukemia (RBL-2H3) cell line, which is derived from mucosal mast cells, is often used as a model system to study FcRI signal transduction. These cells abundantly express FcRI \((-200,000\) receptors per cell) at the plasma membrane, where they bind allergen-specific IgE with high affinity \((K_D \sim 10^{-10} \text{M})\) (2), sensitizing the cell and priming it to respond rapidly during subsequent exposure. Mast cells contain numerous secretory granules that store preformed allergic mediators, which include histamine, and stimulated release of these contents is responsible for the immediate symptoms of allergic reactions.

Signaling through FcRI is initiated by binding of multivalent antigen by receptor-bound IgE and consequent aggregation of individual receptor complexes. FcRI clustering promotes stable association with specialized regions of the plasma membrane, which are termed lipid rafts (3). Lipid rafts are microdomains of ordered lipids that are enriched in cholesterol and phospholipids with saturated acyl chains, including sphingolipids, and they coexist with regions of more fluid, disordered lipids (4). Several types of measurements indicate that as much as 40% of membrane lipids exist in ordered regions, although most transmembrane proteins prefer disordered regions (3). In unstimulated cells, lipid rafts seem to be small, \( \sim 20-100 \) nm, and highly dynamic structures (5, 6). Coalescence and stabilization of lipid rafts by antigen-mediated cross-linking of IgE-FcRI is believed to initiate this signaling cascade. This step is a ligand-sensing event that depends on antigen valency and receptor affinity for the antigen; receptor oligomerization increases receptor residency time in lipid rafts and allows for signal initiation (4).

**Phosphorylation cascade**

Lipid rafts are one mechanism by which cells can segregate plasma membrane components and compartmentalize signaling events. Lyn, which is a Src family kinase, is dually acylated at its N-terminus by myristoylation and palmitoylation that target Lyn to the plasma membrane and confer its association with lipid rafts. Monomeric receptors are located largely outside of lipid rafts and are effectively segregated from the activating kinase in unstimulated cells. After receptor cross-linking and association with lipid rafts, Lyn phosphorylates Fc RI ITAMs (Fig. 1b). The lipid raft environment enhances signaling by protecting Lyn from inactivation through the exclusion of transmembrane phosphatases (7). Phosphorylation of the \( \gamma \) subunits is the first biochemically detectable step in FcRI signaling. The actin cytoskeleton plays a negative regulatory role in mast cell signaling (8), in part by limiting the functional interactions of FcRI and Lyn through segregation of Lyn from cross-linked FcRI complexes (9). The lipid composition of ordered microdomains in the plasma membrane is also regulated by the actin cytoskeleton (3).

In the primary signaling pathway, Syk kinase is recruited to the phosphorylated y subunit via its tandem Src homology 2 (SH2) domains (10). Once activated through phosphorylation and conformational changes, Syk phosphorylates several downstream targets, which include the linker for the activation of T cells (LAT), an adaptor protein with multiple ITAMs that, when phosphorylated, serve as binding sites for SH2 domain-containing proteins (11). LAT forms complexes with several signaling proteins downstream of Syk including phospholipase C-\( \gamma \) (PLC-\( \gamma \)). Activated PLC-\( \gamma \) hydrolyzes phosphatidylinositol-4,5-bisphosphate (PIP2) to produce soluble inositol-1,4,5-trisphosphate (IP3) and membrane-bound diacylglycerol (DAG) (10). These products lead to calcium mobilization and protein kinase C activation, which are both required for mast cell degranulation. Additionally, scaffolding proteins recruit several guanine nucleotide exchange factors (GEFs), which in turn bind to low-molecular-weight GTPases, leading to activation of the MAPK signaling cascade and cytokine production, as well as cell morphological changes.

A complementary pathway activated during FcRI stimulation is initiated by the Src family kinase Fyn, as revealed in bone-marrow-derived mast cells. Fyn mediates phosphatidylinositol-3-kinase (PI-3-K) activation that phosphorylates PI(4,5)P2 to PI(3,4,5)P3 by recruiting pleckstrin homology (PH) domain-containing proteins, such as the Tec family kinase Btk, PLC-\( \gamma \), and GEFs that regulate changes in the actin cytoskeleton through the Rho family of GTPases, PI-3-K activation is necessary for the maintenance, but not the initiation, of calcium signaling required for degranulation and may influence cytokine production because of its ability to affect intracellular calcium concentrations (10). Studies in RBL mast cells with trivalent ligands of defined lengths are consistent with a PI-3-K pathway that operates in parallel to the Lyn-Syk pathway (12).

**Elevation of intracellular calcium levels**

Cytoplasmic calcium concentrations in unstimulated cells are \( \sim 100 \) nM but can rapidly increase to \( \geq 1 \mu \text{M} \) during stimulation. In lymphocytes, this increase is a biphasic process. The initial increase is caused by IP3 binding to the IP3 receptor (IP3R) in the endoplasmic reticulum (ER) and rapid release from intracellular stores. The second, sustained phase results from extracellular calcium influx through calcium-release activated calcium (CRAC) channels in a process termed store-operated calcium entry (SOCE) and also through other calcium channels including the transient receptor potential channels and plasma membrane.
Membrane Compartments Related to Signaling and Trafficking in Immune Cells

Figure 1  Signal transduction pathways from antigen receptors. (a) The MIRR family of receptors consists of the ligand-binding units associated with signal transducing units that contain ITAM sequences on transmembrane receptor subunits. (b) In unstimulated mast cells, monomeric IgE receptors largely reside outside of lipid rafts. After cross-linking by a multivalent antigen, IgE receptors cluster and stably associate with lipid rafts where Lyn phosphorylates the receptors and initiates a signaling cascade that culminates in the release of allergic mediators. Molecules are not shown to scale.

membrane $p_{70,75}$ (13). SOCE is the main mechanism by which cytoplasmic calcium levels are increased in lymphocytes (14). Rapid increases in intracellular calcium are necessary to trigger secretory vesicle fusion and extracellular secretion, whereas sustained calcium elevation is required to activate gene transcription and cytokine production.

ER heterogeneity and organization of ER subdomains in relation to calcium signaling received increased attention recently after several groups independently identified an ER calcium sensor protein, STIM1, and a component of the CRAC channel, Orai1/CRACM1, using genetic approaches (15). After depletion of ER calcium, STIM1 oligomerizes and accumulates in ER subregions near the plasma membrane. Orai1 in the plasma membrane co-clusters with STIM1 in the ER, and the simultaneous accumulation of both proteins allows for activation of CRAC channels (16). Calcium levels are returned to basal levels after stimulation through the actions of sarcoendoplasmic reticulum $\text{Ca}^{2+}$-ATPase channels in the ER, which refill the calcium store, and plasma membrane calcium pumps and exchangers, which export calcium into the extracellular environment.

Degranulation and stimulated membrane trafficking

Mast cell stimulation results in spatially regulated trafficking of several intracellular compartments that include secretory lysosomes, which release allergic mediators during degranulation, and recycling endosomes, a heterogeneous perinuclear compartment of mildly acidic membranes (17). Stimulation increases the outward trafficking of a lipid-raft component of recycling endosomes, as monitored by cholera toxin subunit B (CTxB) binding to GM$_1$ (18), which are targeted toward sites of cross-linked IgE receptors (19), whereas secretory lysosomal fusion occurs at sites distinct from receptor-signaling complexes (19). Furthermore, secretory lysosomal fusion is differentially regulated from cytokine trafficking; the latter may occur through recycling endosomal trafficking (20) as recently demonstrated in macrophages (21).
Members of the Rab and Araf GTase families organize membrane compartmentalization within the endosomal system that is important for regulating transport through these organelles. Several Rab proteins localize to distinct subdomains on early and recycling endosomes and contribute to the sorting and trafficking functions of these compartments (22). These proteins also regulate the outward trafficking of lipid rafts from recycling endosomes (23).

**T cell signaling through the TCR**

T cell stimulation begins with binding of the antigenic peptide-MHC complex on antigen-presenting cells to the TCR, and the Src family kinase Lck initiates a phosphorylation cascade (24). The Syk family kinase Zap-70 is recruited to phosphorylated TCR ITAMs, where it is phosphorylated by Lck. Activated Zap-70 then phosphorylates the adaptor protein LAT, which coordinates the recruitment and activation several downstream targets including PLCγ, PI-3-K, and GEFs that activate low molecular weight GTases. These proteins couple receptor activation to calcium mobilization and changes in the actin cytoskeleton. Sustained calcium signaling is required for the formation of the immunological synapse at the interface between the T cell and the antigen-presenting-cell (14). In this structure, the TCR is localized to a central supramolecular activation cluster and is surrounded by a peripheral ring of adhesion molecules (25). The immunological synapse may facilitate sustained signaling necessary to induce cytokine production and T cell proliferation (14).

Initial signaling begins in small microclusters that form quickly after T cell stimulation and precedes formation of the immunological synapse (26). Coalescence of small structures into a larger signaling complex is dependent on stimulated actin polymerization and requires signaling through additional costimulatory molecules, which lead to actin cytoskeleton-regulated reorganization of lipid rafts (26). TCR signaling induces a transient dephosphorylation of the ezrin, radixin, and moesin (ERM) protein family, which temporarily uncouples lipid rafts from the actin cytoskeleton and allows for their coalescence into larger signaling structures (27). Trafficking of raft-enriched intracellular compartments increases the raft content of the plasma membrane and may contribute to targeting of rafts to the immunological synapse (26).

Concurrent with polarization of actin polymerization, the microtubule organizing center and secretory granules, which contain cytoplasmic agents in cytotoxic T cells and cytokines in helper T cells, are also polarized toward the antigen-presenting-cell (27). Helper T cells also spatially regulate cytokine secretion, releasing IL-2 and IFN-γ into the immunological synapse but repressing TNF multi-directionality (28). Targeting granule release to the target cell produces locally high concentrations while minimizing unwanted effects on surrounding cells, whereas multi-directional release promotes recruitment of additional immune cells.

**B cell signaling through the BCR**

The BCR mediates antigen uptake for processing and presentation of the antigenic peptide-MHC class II complex to T cells, which promotes B cell differentiation into antibody-producing plasma cells and memory cells. A ligand binding to the BCR initiates a signaling cascade that involves Src, Syk, and Tec kinases that results in phosphorylation of the adaptor protein BLNK (B cell linker protein), which couples BCR signaling to calcium mobilization similarly to LAT (29). The role lipid rafts play in BCR signaling is still under investigation as some BCR signaling can occur outside of rafts (30), and the outcome of BCR raft association changes during B cell development (31). BCR signaling also results in transient dephosphorylation of ERM proteins and rapid depolymerization of the actin cytoskeleton, which facilitates coalescence of lipid rafts into stable signaling domains (32). In this system, the actin cytoskeleton may segregate lipid rafts in unstimulated cells and, after a strong stimulus, extensive actin depolymerization leads to stable lipid raft clusters together with dense signaling sites at the synapse (32). BCR signaling coordinates receptor internalization and reorganization of the endomembrane system essential for B cell antigen presentation. Lipid raft association triggers endocytosis of the antigen-BCR complex and delivery to MHC class II-containing intracellular compartments for peptide loading onto MHC class II molecules (30), which is necessary for antigen presentation to helper T cells. Consequent interactions with helper T cells sustain B cell activation, which promotes immunoglobulin class switching and antibody production. The strength of the activation signaling (32) and the B cell microenvironment determines the ultimate outcome of B cell activation.

**Techniques to Study Membrane Compartmentalization**

Changes in protein and membrane interactions are most effectively studied with integrated biological and physical techniques. Recent advances in molecular biology enable mutation, overexpression, or depletion of a specific protein to assess its function within the signaling pathways. These tools to isolate functional membrane domains are used to assess stimulated changes in protein and lipid content. Fluorescence techniques are used to visualize and quantify protein interactions and directional membrane trafficking in live cells under physiological conditions.

**Molecular biology methods**

A protein’s role in a signaling pathway can be assessed by introducing mutations that disrupt interactions, localization, or activity or by silencing gene expression. The dynamics of engineered proteins can be monitored via selective placement of fluorescent tags within the protein sequence.

**Site-directed mutagenesis**

DNA engineering has become a standard laboratory procedure by which engineered proteins are used to study the role of protein localization and function within signaling pathways. Site-directed mutagenesis, in which only one or a few specific amino acids are altered in a protein, is a valuable tool for elucidating the structural properties of proteins that mediate
protein dynamics. This approach was used, for example, to examine the role of MIRR transmembrane domains in mediating lipid raft association in mast cells (33) and B cells (34). The addition or deletion of a lipid modification site within the target protein can also be used as a tool to either enhance or decrease membrane or lipid raft association. A membrane targeted form of the C-terminal Src kinase (Csk), mCsk, was generated via the addition of a myristoylation site and was found to suppress basal Lyn activity in mast cells by phosphorylating the C-terminus of Lyn (35). Site-directed mutation of the myristoylation and palmitoylation sites in Lyn demonstrated that both modifications are required for membrane targeting and that palmitoylation enhances lipid raft association (36).

Differential epitope tagging

One way to distinguish the genetically engineered protein from the cellular endogenous protein is to tag the engineered protein with either a fluorescent label or a nonfluorescent epitope tag. Fusion proteins tagged with green fluorescent protein (GFP) or any flavor of the many spectral variants of fluorescent proteins (FPs) (37) can be used to visualize the spatio-temporal distribution of several different proteins simultaneously within a single cell. Protein dynamics and interactions can be monitored using real-time fluorescence microscopy and quantitative microscopy techniques described below. Protein localization is often mediated by modular protein domains, such as PH domain binding to lipid species within the target membrane or SH2 and SH3 domains that bind to specific protein sequences of the target protein, which results in protein redistribution. The fusion of FPs to these modular domains generates fluorescent probes that can be used to monitor changes in lipid composition (38) and protein phosphorylation (39).

Alternatively, epitope tagging of proteins, in which a small epitope is inserted into the target protein sequence, is used to visualize protein localization by immunofluorescence microscopy of fixed and permeabilized cells. A variety of well-characterized epitope tags are available (40), and commercially available antibodies are used to detect the epitope tagged protein. These antibodies are used to determine the level of endogenous protein by either transient or stable knock down provides an environment for directly assessing the tagged-protein function without the endogenous protein (41). Stable knock down can be achieved with short hairpin RNAs (shRNA), which are processed inside the cell to generate active siRNA structures (42). Viral-mediated RNAi can reduce endogenous mRNA levels by ~75–90%, and co-transfection with multiple siRNA sequences can be used to produce double knockdowns (43). These double knockdowns can be used to generate cell lines or transgenic animals with stably silenced gene expression (43). A further approach to produce stably silenced cell lines is to use antisense cDNA within a plasmid vector, and this method can reduce the levels of endogenous protein by ~90% (46). Either transient or stable knock down provides an environment for directly assessing the tagged-protein function without the endogenous protein background.

Biophysical and biochemical methods

Two common methods to study the role of lipid rafts in signaling pathways are detergent insolubility followed by isolation on a density gradient and cholesterol depletion. Other methodologies exist for isolating plasma membrane samples and intracellular organelles for additional characterization (47).

Detergent-resistant membranes

Detergent-resistant membranes (DRMs) were initially defined in terms of their resistance to solubilization by nonionic detergents, such as Triton X-100 (Pierce, Rockland, IL), at low temperatures, followed by flotation at low densities in equilibrium sucrose gradients (Fig. 2a) (1, 48). Lipids that are tightly packed in ordered regions of membrane are less susceptible to solubilization by small amounts of nonionic detergents than more disordered lipid regions (49). DRMs are also sensitive to the level of cholesterol, which is an abundant lipid in mammalian plasma membranes that comprises ~30–40 molar percent of total plasma membrane lipids (49). Cyclodextrins, which rapidly remove cholesterol from cellular membranes, are used to extract cholesterol and perturb raft association and, thereby, MIRR signaling (50). DRMs do not correspond directly to pre-existing lipid rafts in cell membranes. Because detergents can cause reorganization of membrane lipids, isolated DRMs do not strictly measure
Membrane Compartments Related to Signaling and Trafficking in Immune Cells

(lipid and protein associations that occur prior to detergent treatment (5)). However, protein association with DRMs provides a correlative indication of association with lipid rafts in cell membranes (48, 51). Cholesterol plays multiple roles in cells, and cholesterol depletion can alter the lateral mobility of both raft and non-raft proteins as well as affecting association of the actin cytoskeleton with the plasma membrane (3, 6, 24).

Centrifugation in a dense medium is a common method for separating organelles and membranes from the postnuclear supernatant. Differential centrifugation separates organelles based on size and weight; larger, heavier membranes pellet at slower speeds than smaller, lighter membranes. Successive centrifugation at faster speeds fractionates the sample into cellular components. Equilibrium, or isopycnic, centrifugation separates organelles based on their buoyant density independent of their size and shape. Cellular components are separated on a discontinuous gradient, and fractions float in the medium density that matches their own buoyant density. Sucrose is often used to create discontinuous gradients, but the relative separation of organelles and their distribution within the gradient will vary depending on the gradient medium and the method of sample loading.

Subcellular fractionation

Subcellular fractionation separates organelles based on their biophysical and biochemical properties. Several methods exist for cellular disruption, which include homogenization, sonication, and nitrogen cavitation (47). Homogenization shears a sample by forcing suspended cells through a narrow space and can result in membrane fragments of various size caused by variability in shear forces. When smaller cells, such as lymphocytes, are homogenized, the nuclei may be fragmented along with the plasma membrane. Sonication shears samples by using high-frequency sound waves to disrupt membranes, which nonselectively disrupts intracellular membranes as well as the plasma membrane and can damage membranes because of production of local heating. Nitrogen cavitation ruptures suspended cells, which are first equilibrated with high pressures of an inert gas, during rapid return to atmospheric pressure. This method fragments the ER and plasma membrane into uniform vesicles under inert conditions, which minimizes sample damage. After disruption, the nuclei and large cellular debris (nuclear pellet) are separated from the other organelles and cytosolic components (postnuclear supernatant) by a low-speed centrifugation step. Each of these components can be purified for analysis.

Fluorescence spectroscopic methods

Temporal and spatial changes of fluorescently tagged proteins can be monitored in live cells under physiological conditions using a variety of spectroscopic methods that allow for the quantification of dynamic protein and membrane trafficking responses. Increasing capabilities to monitor protein translocation, protein–protein interactions, lipid turnover, and membrane trafficking will provide a more complete picture of the large-scale reorganization in cells that occurs during antigen receptor stimulation.

Fluorescence microscopy

Direct visualization of fluorescently tagged proteins continues to be a powerful method for examining subcellular localization and dynamics within a single cell. Confocal microscopy, in which only a thin, optical section (~0.3 μm) of the sample is imaged, is
commonly used to study protein localization in both fixed and living samples. The development of advanced imaging tech-
niques at the micron- and submicron-scale resolution have been essential to monitoring small domains of the plasma membrane and intracellular organelles. A more-detailed discussion of ad-
vanced imaging techniques such as fluorescence recovery after photobleaching, single particle tracking, and fluorescence corre-
lution spectroscopy used to study protein dynamics is provided elsewhere (52). A additionally, ultra high-resolution techniques, such as photoactivated localization microscopy and stimulated emission depletion microscopy are being developed to investi-
gate plasma membrane dynamics (53, 54, 55).

Protein colocalization is qualitatively assessed by overlaying individual confocal images and looking for overlapping protein distributions, which is an approximate measurement of protein colocalization on the scale of optical resolution (~300 nm). Alternatively, a structure can be manually identified, and the fluorescence intensity profiles of two proteins along the trace can be correlated. This approach has been used to quantify receptor-protein interactions in mast cells (39, 56).

Correlation methods

Several image correlation techniques, termed image correlation microscopy or image correlation spectroscopy (ICS), have been developed to analyze the density, diffusion, velocity, and inter-
actions of fluorescently labeled membrane proteins. Spatial ICS measures the number and density of protein aggregates as well as changes in aggregation state, whereas temporal ICS measures diffusion coefficients and flow rates (57, 58). A recent exten-
sion of these techniques, which is termed spatio-temporal image correlation spectroscopy, can be used to monitor interactions be-
tween two fluorescently labeled proteins and also enables vector mapping of directed protein movement (58) even when a large percentage of the protein population is immobile (59). Raster image correlation spectroscopy can provide diffusion rates for both fast moving cytosolic species and slow moving membrane species (60).

Another recently developed cross-correlation microscopy methodology analyzes protein redistribution that occurs at the plasma membrane by imaging equatorial sections of the cell (61). This automated methodology allows for rapid analysis of a time-lapse image series in which a plasma membrane trace, defined with a fluorescent probe, is generated for each time point and, therefore, it can accommodate small changes in cell morphology (Fig. 3a). The stimulated recruitment of cyto-
lolic proteins to the membrane (Fig. 3b), and their interactions with aggregated receptors (Fig. 3c) are quantified as a function of time. This methodology was used to analyze early signal-
ing events in FcεRI signaling (61). Because events that occur at the plasma membrane are selectively analyzed, stimulated membrane trafficking events to and from the plasma membrane can also be studied with this approach.

Antigen-patterned surfaces

Mast cells, in addition to responding to soluble antigen, can also polarize responses to the cell-pathogen interface when stimulated by helminths or large pathogens. Patterned silicon surfaces, in which the antigen is deposited on a silicon chip in micron-sized features (Fig. 4a), are used to study protein traf-
ficking and membrane reorganization events that occur at the cell-stimulus interface (Fig. 4b). These surfaces have been used to investigate protein recruitment to aggregated FcεRI com-
plexes in mast cells and demonstrate differential redistribution of inner-leaflet and outer-leaflet markers (62). The differential trafficking of recycling endosomal membranes, which are traf-
ficked to sites of aggregated receptors, and histamine-containing secretory granules, polarized to the interface but not toward ag-
ggregated receptors, was examined using antigen-patterned sur-
faces (19).

A antigen-patterned surfaces have also been used to study the formation and regulation of the immunological synapse
in T cells (63). Patterned surfaces with micron-sized corrals have been used to investigate the dynamics of immunological synapse formation by preventing central clustering of TCR ligands (64). Patterns that prevented TCR microclusters from reaching the central synapse enhanced T cell signaling, which suggests that spatial translocation of TCR microclusters to the central synapse is a method to downregulate TCR signaling (64). The role of peripheral TCR microclusters in T cell signaling can be further investigated with new technologies to produce sub-micron scaled patterns (63).

Spectroscopic methods to study membrane trafficking

The organelles of the endocytic pathway are characterized by progressively more acidic structures as endocytosed material moves through early endosomes, late endosomes, and sent to either acidic lysosomes for degradation or to recycling endo-
somes for return to the plasma membrane. Fluorescent labels that are sensitive to pH, such as pH-sensitive GFP derivatives (pHluorins) or fluorescein isothiocyanate (FITC), can be used to monitor changes in the trafficking along the endocytic and exocytic pathways (65). A "targeted fluorescence" strategy to characterize pH gradients along the endocytic pathway takes advantage of pH-sensitive changes in FITC fluorescence (66). Fluorophore pH-sensitivity can be used to quantify the traf-
ficking of internal membranes to and fusion with the plasma membrane. FITC fluorescence is quenched in endocytic or-
ganelles, but fluorescence increases after exposure of the FITC-tagged protein to more pH-neutral environments. A traf-
ficking assay has been developed to characterize the stimulated outward trafficking of recycling endosomes labeled with either FITC-CTxB or FITC-anti-transferrin receptor in mast cells (18). This assay can be used to screen for inhibitors of recycling endo-
somal trafficking and to elucidate the mechanisms that regulate trafficking of raft, CTxB-labeled endosomes, versus trafficking of nonraft, transferrin receptor-containing endosomes.

Summary

The redistribution of plasma membrane lipid rafts from small, dynamic entities to stable signaling complexes represents one example of stimulated membrane reorganization central to MIRK signaling. However, changes in membrane compartmen-
talization necessary for sustained immune cell signaling are not

MIRR signaling. However, changes in membrane compartmentalization necessary for sustained immune cell signaling are not.
restricted to the plasma membrane; the membrane organization of intracellular organelles such as the ER and vesicles along the endocytic and exocytic pathways contribute to the functionality of these organelles and also to changes that occur at the plasma membrane. Biochemical methods to characterize membrane subdomains, such as detergent resistance, cholesterol depletion, and subcellular fractionation, used in combination with imaging techniques to study protein and membrane dynamics in living cells, are essential to understanding the role and regulation of membrane compartmentalization in immune cell signaling and trafficking.

In the popular fluid mosaic model for biomembranes, membrane proteins and other membrane-embedded molecules are in a two-dimensional fluid formed by the phospholipids. Such a fluid state allows free motion of constituents within the membrane bilayer and is extremely important for membrane function. The term “membrane fluidity” is a general concept, which refers to the ease of motion for molecules in the highly anisotropic membrane environment. We give a brief description of physical parameters associated with membrane fluidity, such as rotational and translational diffusion rates, order parameters etc., and review physical methods used for their determination. We also show limitations of the fluid mosaic model and discuss recent developments in membrane science that pertain to fluidity, such as evidence for compartmentalization of the biomembrane by the cell cytoskeleton.

Introduction

In 1972, Singer and Nicolson (1) suggested the so-called fluid mosaic model of the biological membrane (Fig. 1) (2). This useful hypothesis explained many phenomena that occur in model and biological membranes. According to this model, membrane proteins and other membrane-embedded compounds are suspended in a two-dimensional (2-D) fluid formed by phospholipids. The phospholipids are assumed to be in a liquid state, so they are capable of rapid diffusion within their layer and are in constant motion. This fluid state of membrane lipids is critical for membrane function. It allows, for example, free diffusion and equal distribution of new cell-synthesized lipids and proteins, lateral diffusion of proteins and other molecules in signaling events and other membrane reactions, membrane fusion (i.e., fusion of vesicles with organelles), separation of membranes during cell division, and so on.

Generally speaking, two principal mechanisms operate in the biology of membrane processes, such as membrane transport and permeation. One involves a network of active sites and operates by metabolic energy, and it is referred to as active; another is directed by passive diffusion, and it is called passive. This passive mechanism is determined by various aspects of lipid dynamics and lipid-protein interactions, and it can be described in quantitative terms of chemical and phase equilibrium and molecular physics. However, in the highly anisotropic membrane environment, some aspects must be generalized and redefined compared with the simple isotropic case. One term, which received a new interpretation in the context of membrane science, is “fluidity.” Membrane fluidity, which describes the ease of movement for molecules in the membrane environment, is a general concept that lacks a precise definition. It is much broader than the strict physical definition of fluidity as the reciprocal of viscosity in the case of isotropic liquids. In general, “membrane fluidity” implies various anisotropic motions, which contribute to the mobility of components of a membrane. It includes lateral diffusion of molecules in the plane of the membrane, flexibility of acyl chains, “flip-flop” diffusion of molecules from one monolayer to the other, and so on. The most important parameters to quantify the notion of membrane fluidity are translational and rotational diffusion constants, order parameters (or tensors), packing, and permeability. In general, greater membrane fluidity is associated with higher diffusion rates, high permeability, lower ordering, and looser packing. The relation between the parameters, however, is purely empirical, and in most cases speculative. Many membranes have large diffusion constants and large order parameters and vice versa.

The lipid membrane, as a whole, shows a unique combination of fluidity and rigidity. In terms of the solubility and the diffusion of small nonpolar molecules, the membrane behaves very much like an oil drop. In contrast, the translational diffusion...
constants of lipids and proteins in membranes are characteristic of media with the viscosity over two orders of magnitude greater than that of oil, such as hexadecane. Also, in most cases the membrane represents an impermeable barrier for ions and other hydrophilic compounds.

### Physical Parameters Associated with Membrane Fluidity

#### Diffusion constants

Diffusion is the random movement of a particle because of an exchange of thermal energy with its environment. Membrane lipids and proteins participate in highly anisotropic translational and rotational diffusion motion. Translational diffusion in the plane of the membrane is described by the mean square lateral displacement after a time $\Delta t$: \( \langle r^2 \rangle = 4 D_{ll} \Delta t \). Lateral diffusion coefficients in fluid phase bilayers are typically in the range $D_{ll} \sim 10^{-8}$ to $10^{-7}$ cm$^2$/s.

Rotational diffusion is characterized by the mean square angular deviation during the time interval $\Delta t$: \( \langle \theta^2 \rangle = 60_s \Delta t \). Highly anisotropic motion, which is typical for lipid molecules in the membrane, is usually described by two rotational diffusion coefficients $D_{\parallel}$ and $D_{\perp}$, which correspond to diffusion about the long diffusion axis and perpendicular to it, respectively. The diffusion coefficients are related to corresponding rotational correlation times measured by nuclear magnetic resonance (NMR), electron spin resonance (ESR), fluorescent depolarization, and so on, as:

\[
\tau_{\parallel} = \frac{1}{6} D_{\parallel}, \quad \tau_{\perp} = \frac{1}{6} D_{\perp}.
\]

For fluid phase bilayers, the typical rotational diffusion coefficients are of the order of $D_{\parallel} \sim (1-4) \times 10^{-8}$ s$^{-1}$ and $D_{\perp} \sim (1-4) \times 10^{-7}$ s$^{-1}$.

#### Flip-flop diffusion

Lipid molecules, in principle, can exchange between the two monolayers of the bilayer. For polar lipids, it is an extremely slow process with characteristic times of hours or even days. For membrane proteins, no appreciable flip-flop mobility has yet been observed, which is in good accord with the fact that inner and outer leaflets of natural membranes are usually asymmetric with respect to their protein and lipid composition. On the other hand, cholesterol has a relatively high rate of spontaneous flipping between two membrane leaflets ($t_{\text{flip}} \sim 1$ s).

#### Order parameters

The membrane lipid layer is a lamellar phase with the preferred orientation of the lipid molecules perpendicular to the membrane plane. By definition, if $\hat{n}$ is the angle of the long molecular axis with respect to the bilayer normal, then the order parameter $S$, which is a measure of the orientation distribution, is given as the average of $P_2(\cos \theta)$, the second Legendre polynomial: $S = \frac{1}{2} (3 \cos^2 \theta - 1)$.

One can see that $S$ varies between $-1/2$ and 1. These limiting cases have the following meaning: when $S = 1$, all molecules are exactly perpendicular to the membrane plane. When $S = -1/2$, $\theta = 90^\circ$, and all molecules have their long axis parallel to the membrane surface. The case of $S = 0$ usually corresponds to a random distribution of molecular axes relative to the membrane normal. In energy terms, the rotation of the molecular long axis
in the liquid crystal is restricted within an orienting potential that is simply approximated as: $U(\theta) = \lambda \cos^2 \theta$, where $\lambda$ is the strength of the potential. The ordering of the lipid chain relative to the bilayer normal can then be expressed \((7)\) as:

$$S_\theta = \frac{1}{2} \left[ 3 \cos^2 \theta - 1 \right] \exp \left[ \frac{U(\theta)}{kT} \right] \sin \theta d\theta$$

Permeability

The passive permeability of lipid membranes is another fluidity related parameter. In general, two mechanisms of membrane permeability can operate in the membrane (8). For many nonpolar molecules, the predominant permeation pathway is solubility-diffusion, which is a combination of partitioning and diffusion across the bilayer, both of which depend on lipid fluidity. In a few cases, such as permeation of positively charged ions through thin bilayers, an alternative pathway prevails (9, 10). It is permeation through transient pores produced in the bilayer by thermal fluctuations. This mechanism, in general, correlates with membrane fluidity. However, for model membranes undergoing the main phase transition, permeation caused by this mechanism exhibits a clear maximum near the phase transition point (11).

---

**Phase State and Membrane Fluidity**

A remarkable property of lipid bilayers is their structural phase transitions (thermotropic polymorphism). For example, fully hydrated pure diacyl-phosphatidyl cholines exist in one fluid phase, $L_\alpha$, and three crystalline phases: P$_{α}′$, L$_{α}′$, and L$_β′$ (12). Because of the high degree of disorder caused by defects, the P$_{α}$ and L$_{α}$ phases usually are called gel phases. The P$_{α}$ phase is sometimes called a "ripple phase," because the surface of the bilayer is rippled (13) and presents a wave-like appearance in electron micrographs (Fig. 2). Depending on the nature of the lipid and the presence of additional components (cholesterol etc.), the P$_{α}$ phase may be present or absent in the phase diagram, and a tilted gel $L_{α′}$ could be replaced by the L$_{α}$ phase, which has similar physical properties but no tilt of the hydrocarbon chains.

In the gel phase, lipid chains are usually well aligned with little rotation around the C-C bonds that are predominantly in the trans position. The lipid chains are tightly packed, the chain ordering is high, the bilayer thickness is maximal, and the surface area per lipid headgroup is relatively small. Lipids in the gel phase in most cases can be handled as solids. For example, aligned thick multibilayers in the gel phase can be sliced in thin pieces in an arbitrary direction so that each piece retains macroscopic alignment (14). The physiological importance of gel-like phases is limited.

At the "main transition" temperature, $T_{m}$, the gel phase undergoes a transition to the $L_{β′}$ (liquid crystal) phase. At the transition point, the surface area increases (15), and the bilayer thickness and chain order decrease (16). In the fluid phase, hydrocarbon chains tend to contain more gauche isomers (17). At this transition, the DSC (differential scanning calorimetry) shows a sharp peak in the heat capacity that occurs over a very narrow temperature range. The transition between $L_{α}$ and P$_{α}$ phases also can be detected by DSC and is called the pretransition (18). The transition between $L_{α}$ and L$_{α′}$ phases is in most cases hard to observe because of typical supercooling of the L$_{α}$ phase. Depending on the membrane composition, hydration, and temperature, several 2-D and three-dimensional nonlamellar lipid phases are possible, including the well-studied hexagonal (H$_{β}$ and H$_{α}$) and cubic phases (19).

Natural biomembranes contain a complex mixture of various phospholipids with cholesterol and sphingomyelins. In general, they exist in the fluid phase. Maintaining membrane fluidity seems to be extremely important for the survival of the cell and the whole organism. It is well known for model membranes that a decrease in the chain length or the introduction of unsaturation into the hydrocarbon chain causes a decrease in the main transition temperature. Consistent with this observation, microorganisms, plants, and animals (pikoklothers or hibernating mammals) are acclimated to low temperatures by altering their membrane lipid composition, increasing the degree of lipid unsaturation, or decreasing the average chain length (20–23).

In an attempt to relate natural and model membranes, many lipid mixtures have been examined experimentally. It has been shown that additional components broaden the main phase transition, with a wider temperature range of coexisting gel and liquid phases (24). Another important feature of lipid mixtures is the formation of nonideal solutions with nonzero enthalpy.
Membranes, fluidity of and/or entropy of mixing. It often makes the components completely or partially immiscible in one or both phases and manifests itself in complex phase diagrams (25).

Cholesterol, which is an important constituent of cell membranes, plays an important role in maintaining membrane fluidity. It effectively inhibits the transition to the gel phase (26, 27). Even though some plasma membranes, such as nerve myelin membranes, contain a high concentration of lipids that form gel phase bilayers, the presence of cholesterol keeps these membranes in a fluid phase. However, interaction with the rigid cholesterol ring affects hydrocarbon chains of lipids in the liquid crystal phase (Lα) and leads to formation of a new phase, the liquid ordered (Lo) phase (27). This phase is well characterized by a variety of physical methods and does not exist in pure lipids or their mixtures. In the liquid ordered phase, the long axis rotation and lateral diffusion rates are similar to the Lα phase, but the acyl chains are predominantly in an all-trans conformation and, hence, the order parameters are similar to the Lα phase (see Table 1). Recently, the cholesterol-rich Lo phase has been strongly associated with microdomains in live cells—the so-called "lipid rafts."

### Physical Methods for Measuring Fluidity Parameters

In the membrane environment, a wide range of motions has been observed and studied by a variety of physical methods. The characteristic times of the motions span 20 orders of magnitude, from about $10^{-14}$ s for molecular vibration to days for transbilayer flip-flops. Figure 3 shows characteristic frequencies (reciprocal of characteristic times) of different kinds of molecular motions in the membrane in comparison to frequency ranges in which various spectroscopic techniques are sensitive to molecular motion (28).

A spectroscopic technique that probes membrane fluidity can either directly measure mobility and order parameters for membrane constituents (NMR) or use probes (ESR, fluorescence). Some fluorescent and ESR probes are shown in Fig. 4. The connection between the rotational correlation time of a membrane embedded probe and the membrane fluidity can be illustrated using the example of a simple isotropic liquid, in which fluidity is merely a reciprocal viscosity $\eta$ and the rotational correlation time $\tau$ for a molecule with a hydrodynamic volume $V$ is given by the well-known Debye–Stokes–Einstein relation:

$$\tau = \frac{V}{6\pi \eta} \frac{1}{kT},$$

where $k$ is the Boltzmann constant and $T$ is the temperature.

absolute temperature, the rotational diffusion coefficient \( D_\theta \) is given by \( D_\theta = \frac{1}{6} \nu_\theta \).

In the highly anisotropic membrane environment, one can expect several different correlation times that correspond to the anisotropic membrane environment and/or the nonspherical molecular probe as well as variations that exist along the membrane normal within the bilayer. Furthermore, the molecular motion is often limited by constraints imposed by the ordered surroundings of the probe. Properly designed spectroscopic experiments can, in many cases, extract both mobility and order parameters and can give a comprehensive picture of membrane fluidity.

**Fluorescent experiments for measuring molecular mobility and ordering**

A absorption of a photon instantaneously brings the probe molecule to the first excited singlet state \( S_1 \). Usually it takes \( 10^{-8} \) seconds to return to the ground state. It can occur via collision with neighbors and loss of the energy as heat or through the emission of a photon (fluorescence). The fluorescence lifetime \( \tau_\parallel \) is the characteristic time for the population of excited molecules to return to the ground state after a flash of excitation light.

The fluorescence depolarization technique for mobility and ordering is based on the fact that the probability of absorption and emission is directional. Light polarized along a certain axis will preferably excite molecules oriented with their transition dipole moment in the same direction. The probability varies with \( \cos^2 \theta \), where \( \theta \) is the angle between the transition dipole moment and the electric field vector of the light. Emission of a photon obeys the same \( \cos^2 \theta \) \((28)\) rule. That means that a molecule oriented with its transition dipole moment along the \( Z \)-axis will be likely to emit a photon with the same polarization. In the depolarization technique, polarizers are used to quantify the intensity of the parallel (\( I_\parallel \)) and perpendicular (\( I_\perp \)) components to the original direction of polarization.

The values of \( I_\parallel \) and \( I_\perp \) are obtained after exciting the anisotropy with light of parallel polarization in a random direction, \( I_\parallel > I_\perp \), and \( \tau \) has a maximal value equal \( 0.4 \). In the opposite limit \( \tau \gg \tau_\parallel \), and isotropic rotation) the molecules will emit in a random direction, \( I_\parallel = I_\perp \), and \( r \) has a minimal value equal \( 0.0 \). In the intermediate range, for \( \tau_\parallel < \tau < \tau \), the value of \( r \) is sensitive to molecular motions.

An important advantage of the depolarization technique is that it allows one to measure the molecular ordering, as well as the motional parameters. For this purpose, it is necessary to detect the time dependence of the anisotropy. In the presence of ordering constraints, the value does not decay to zero, but to some limiting value \( r_{lim} = r_{lim} = \frac{1 - 10^{-4} \nu_\parallel}{1 - 10^{-4} \nu_\perp} \). The rate of decay defines a rotational correlation time, and \( r_{lim} \) is a direct measure of the order parameter through the following relation: \( r^2 = r_{lim} \tau_\parallel \). The fluorescence depolarization method works well as long as fluorescence lifetimes, which are typically \( 10^{-8} \) s, are not too different from the rotation relaxation times to be measured. When the rotational correlation time is slower than about \( 10^{-8} \) s, however, the method fails because the fluorescent emission decays before any detectable rotation can occur. For studying rotational diffusion of membrane proteins, it is almost always the case that correlation times are in the microsecond time range or longer, because membranes are at least 100 times more viscous than water. Several phosphorescent probes (e.g., derivatives of eosin) were developed to measure such slow rotation correlation times. In such molecules, after initial excitation, transition into the lowest triplet state \( T_1 \) (intersystem crossing) effectively competes with \( S_1 \rightarrow S_0 \) transition. Because the \( T_1 \rightarrow S_0 \) transition is spin forbidden, the lifetime of the lowest triplet state (typically \( 10^{-3} \) s) is much longer than that of the \( S_1 \) (typically \( 10^{-5} \) to \( 10^{-6} \) s).

**Solid state NMR**

Solid state NMR is characterized by relatively broad lines. It can be described as magnetic resonance on molecules frozen in solids or with very slow rotational correlation times. It is appropriate not only for solids, but also for viscous solvents, lipids in membranes, or large macromolecules in solution. High resolution (solution) NMR deals with relatively small molecules with molecular weight less than about 50,000 Da in aqueous solution. The rotation of such molecules is so fast on the NMR time scale that it effectively averages out all orientational anisotropy yielding an isotropic spin Hamiltonian including the Zeeman term and the \( J \)-\( J \) coupling with another spin \( S \): \( H = \gamma B_0 \hat{I}_0 \). Here, \( I \) and \( S \) are spin operators for two nuclear spins. \( B_0 \) is the external magnetic field strength, \( \gamma \) is the magnetogyric ratio for the studied nucleus, \( \sigma \) is the chemical shielding constant, which is directly related to the chemical shift \( \delta \); \( J \) is the spin-spin coupling constant for spins \( I \) and \( S \). For no or very slow rotational reorientation the spin Hamiltonian requires a tensorial expression: \( H = \gamma I \cdot B_0 + (1/2) \sum_{s=1}^{3} J_{s} S_{s} \) where

\[
\delta = \begin{pmatrix}
\sigma_{XX} & \sigma_{XY} & \sigma_{XZ} \\
\sigma_{YX} & \sigma_{YY} & \sigma_{YZ} \\
\sigma_{ZX} & \sigma_{ZY} & \sigma_{ZZ}
\end{pmatrix}
\]

and \( J = \begin{pmatrix}
J_{11} & J_{12} & J_{13} \\
J_{21} & J_{22} & J_{23} \\
J_{31} & J_{32} & J_{33}
\end{pmatrix} \)

are chemical shielding and spin-spin coupling tensors.

Tensor values should also be assigned to quadrupole splittings (see below).

The tensor \( \delta \) is usually symmetrical, and in the appropriate molecular frame it is represented in a diagonal form:

\[
\delta = \begin{pmatrix}
\sigma_{XX} & 0 & 0 \\
0 & \sigma_{YY} & 0 \\
0 & 0 & \sigma_{ZZ}
\end{pmatrix}
\]

The components \( \sigma_{XX}, \sigma_{YY}, \) and \( \sigma_{ZZ} \) give chemical shifts along main molecular axis in \( X-, Y-, \) and \( Z- \) direction, respectively. When the molecule is oriented along the main axis, for example the \( Z \)-direction, the chemical shift is just \( \sigma_{ZZ} \). Other orientations give intermediate values. In the limiting case of absence of molecular motion (rigid limit) and a statistical distribution of molecular orientations, for example polycrystalline or glass, the spectrum shows a superposition of spectra for all orientations.
Membranes, Fluidity of

Phosphorus 31 has spin $I = \frac{1}{2}$. The chemical shift tensor is substantially anisotropic. For static, statistically disordered molecules, the spectrum is a superposition of spectra that correspond to different orientations. If the molecule undergoes fast rotation about one axis, then the motion averages the components perpendicular to that axis. In the case of fast isotropic rotation (limiting case of high resolution NMR), a single sharp line is observed in the spectrum (Fig. 5). For example, the rotation of the vesicle depends on its size and the viscosity of the environment. The smaller the vesicle, the faster is the rotation. Very fast isotropic tumbling of the vesicle gives a single isotropic peak. For large vesicles, however, the spectrum corresponds to anisotropic rotation of the lipid molecule itself about the main axis.

Diffusion along the membrane surface affects the averaging of tensor components, especially if the surface is curved. Lipids can form other aggregates than bilayer membranes. For instance, a common form is the inverse hexagonal phase (HII--phase). It consists of cylindrical lipid tubes with the lipid hydrocarbon chains on the outside and directed radially and the water phase in the center. Diffusion of lipids leads to a different type of anisotropic averaging of the tensor components than in the case of large vesicles. Figure 6 (33) shows $^{31}$P-NMR spectra from lipids in the bilayer membrane, the HII phase and the isotropic case. If a lipid system undergoes the L$_\alpha$–HII transition, then the $^{31}$P-NMR lineshape abruptly changes at the transition temperature as shown in Fig. 6.

Use of $^2$H-NMR for membrane studies is based on the fact that deuterium nuclei, with spin $I = 1$, have an electric quadrupole moment. It originates from the asymmetrical charge distribution in the nucleus. In the presence of an external field gradient, which is always almost the case for (deuterium) atoms in molecules, the different orientations of the nuclear spin experience different interaction energies with the quadrupolar field of the environment.

For a system with spin 1 and the absence of any quadrupolar interaction, one has three spin energy levels in the external magnetic field for $m = -1, 0, +1$. They have the same energy splitting between adjacent levels, which yield only one resonance line. Through the quadrupole interaction, the energy levels are no longer equidistant, and one observes two resonance lines. If the quadrupolar splitting is much less than the Zeeman splitting, then the approximate expression for a fixed orientation of the molecule is (34):

$$
\Delta \nu = \frac{3}{8} \left( \frac{\epsilon^2 Q}{h} \right) (3 \cos^2 \phi - 1),
$$

Where $\epsilon$ is the quadrupole coupling constant, $Q$ is the quadrupole moment of the nucleus, and $h$ is Planck’s constant.

**Figure 5** $^{31}$P-NMR spectra of phospholipids with different modes of molecular motion. a: rigid limit; b: fast axial rotation about X-axis averages Y- and Z-components of the chemical shift tensor. In the spectrum one can observe two principal values of $\sigma_\perp = 1/2(\sigma_{yy} + \sigma_{zz})$ and $\sigma_\parallel = \sigma_{xx}$; c: atypical case of fluid membrane. Along with fast X-axial rotation molecular motion also partially averages $\sigma_\parallel$ and $\sigma_\perp$. In the spectrum one observes effective values $\sigma'_\parallel < \sigma_\parallel$ and $\sigma'_\perp < \sigma_\perp$. d: Isotropic case (high resolution NMR): $\sigma_{iso} = 1/3(\sigma_{xx} + \sigma_{yy} + \sigma_{zz})$.
Membrane fluidity of

\[ \text{Figure 7} \] 2H-NMR spectra at 23.3 MHz of 1-[16,16,16-2H] palmitol,2-palmitoleoyl-PC at different temperatures. (From Reference 30.)

where \( q \) is the quadrupole moment, \( e_q \) is the magnitude of the principal component of the gradient of the electric field, and \( \phi \) is the angle between the direction of that component and the external magnetic field. The two resonance lines are split by a frequency of \( \Delta \nu \). For the special case of \( \phi = 54.7^\circ \) (magic angle), \( \Delta \nu = 0 \) and no quadrupole splitting occurs. A superposition of all orientations gives a sum of two broad spectra that are symmetrical about the central resonant frequency, which is a lineshape similar to a Packe doublet for two interacting protons in a single water molecule.

For fast rotation (the case of high resolution NMR), the quadrupolar splitting is averaged out yielding a single resonance line. For intermediate cases, the splitting and the line shape of the quadrupolar NMR signal is indicative of the rotational correlation time and/or ordering effects (Fig. 7) (30).

ESR spectroscopy

Although theoretically NMR can obtain both molecular dynamics and ordering, a close look at the literature shows that in membranes, NMR is used mostly for extracting order parameters. Much information on rotational mobility of membrane constituents is traditionally obtained using another magnetic resonance technique, ESR. ESR is extremely useful in the study of membrane fluidity, because of its unique time scale, which spans almost all motional range in membranes.

For studies of membrane fluidity, lipids or membrane proteins are usually spin-labeled with cyclic nitroxide radicals. The theoretical analysis of the spin Hamiltonian of ESR is analogous to that for NMR, although the interaction terms are much larger. The position of ESR lines for nitroxides is determined by the \( g \)-factor and the hyperfine splitting, which roughly correspond to the chemical shift and \( J \)-coupling in NMR, and the sensitivity of ESR spectroscopy to molecular motion emerges from the dependence of these parameters on the orientation of the nitroxide moiety in the magnetic field.

The ESR-Hamiltonian is given as

\[ H = \beta S \cdot gB_0 + \gamma I \cdot A, \]

where \( S \) and \( I \) are spin operators for electrons and nuclei, \( \beta \) and \( \gamma \) are principal values of the \( g \)-tensors and the hyperfine splitting tensors \( A \), respectively. At the fast motion limit, one can observe a narrow triplet centered around the average \( g \) value \( (g_{xx} + g_{yy} + g_{zz})/3 \) with a distance between lines of \( \alpha_{iso} = (A_{xx} + A_{yy} + A_{zz})/3 \), where \( g_{ii} \) and \( A_{ii} \) are principal values of the \( g \)-tensor and the hyperfine splitting tensor \( A \), respectively. At the slow motion limit, which is also referred to as the rigid limit, the spectrum (shown in Fig. 8) is a simple superposition of spectra for all possible spatial orientations of the nitroxide with no evidence of any motional effects. Between these limits, the analysis of the ESR lineshape and spectral simulations, which are based on the Stochastic Liouville Equation, provide ample information on lipid/protein dynamics and ordering in the membrane (36).

\[ \text{Figure 8} \] ESR spectra of TEMPO nitroxide radical in glycerol at different temperatures. (From Reference 35.)
For the most common ESR frequency of 9 GHz, the limits are approximately from $10^{-7} < \tau_c < 10^{-11}$ seconds. However, using a range of ESR frequencies and pulse and continuous wave (CW) ESR techniques (such as ELDOR or saturation transfer ESR) expands the range from $10^{-8}$ to $\sim 10^{-12}$ seconds, which covers virtually all modes of molecular motion in the membrane that can be associated with membrane fluidity (37). In the past, to study the range of $10^{-7} - 10^{-4}$ seconds, an empirical technique known as saturation transfer ESR was used. It is based on detection of an out-of-phase ESR signal with large modulation amplitude (typically 5G) of the external magnetic field (38). The most direct way to observe the “saturation transfer” is ELDOR or electron-electron double resonance, when two different microwave frequencies are applied to the sample. One is called the “pump” frequency and used to modify the populations by saturating certain portions of the ESR spectrum. Another one (the “probe” frequency) is used to observe the effect of the “pump” frequency on other parts of the spectrum. The response to an intense (saturating) microwave field is affected by diffusion of saturation (“saturation transfer”) between different portions of the resonance spectrum. In the case of nitroxide labels, this diffusion is dominated by rotational modulation of the anisotropic magnetic interactions. The method is most sensitive when the rotational correlation time is comparable with or greater than the spin lattice relaxation time, which for nitroxides near the rigid limit is $\sim 10^{-5}$ seconds. In the CW mode, usually the intensity of the ESR signal at the “probe” frequency is recorded as a function of the “pump” frequency. A huge improvement has been achieved by using the Pulsed Two-Dimensional Fourier Transform technique, which is known as 2-D ELDOR. This experiment very efficiently provides all combinations of pump and probe frequencies in a single 2-D experiment, and in addition it dramatically improves the spectral resolution, which enables accurate assessment of mobility and ordering parameters. As observed in Fig. 9 (39), 2-D ELDOR spectra show dramatic changes as membrane properties are varied.

Membranes, Fluidity of
Membranes, Fluidity of

Lateral Diffusion in Membranes

As we will see later, studying lateral diffusion in biomembranes gives important insights into their structure and function. Methods for measuring diffusion coefficients for lipids in membranes can be classified into two distinct categories. In the first category, which corresponds to short-range diffusion measurements, \( D \) is obtained from determination of frequencies of bimolecular collisions within the membrane, through fluorescence, ESR, and so on. In the second category, which corresponds to long-range diffusion measurements, \( D \) is usually determined from the time required to fill a defined region of the membrane.

Short-range lateral diffusion

ESR is very useful in the study of dynamic properties of membrane components because of its high sensitivity and favorable time scale. Early ESR studies of short-range lateral diffusion in membranes were based on Heisenberg exchange (HE) effects of nitroxide spin-label linewidth. The HE contribution to the ESR linewidth is given for \(^{14}\text{N} \) nitroxides by

\[
\tau^{-1} = 8\pi^2 d^6 N_A C f
\]

where \( d \) is the encounter distance for two spin-bearing molecules, \( D \) is the microscopic self-diffusion coefficient, \( N_A \) is the Avogadro number, and \( C \) is the molar concentration of spins (41). The factor \( f \) can be deduced from the assumed model of intermolecular potential energy for the interaction between two spins. For a simple, hard-sphere potential \( f \equiv 1 \). The technique based on direct determination of changes in the ESR linewidth because of HE (42) was later improved by using ELDOR and/or saturation recovery. These techniques are based on the effects of the HE on saturation transfer between hyperfine lines of the spin labels, and they allow one to detect substantially lower HE rates. Additional improvement of this technique based on use of \(^{14}\text{N}-^{15}\text{N} \) spin-label pairs gave \( \sim 20 \)-fold in the sensitivity and allowed experiments on cells (43).

For the measurements of short-range diffusion, the collision rate can also be obtained by optical spectroscopy from fluorescence quenching. In the isotropic case of diffusion-controlled dynamic quenching, the change in fluorescence intensity obeys the equation:

\[
\frac{\Phi_1}{\Phi_0} = 1 + K_{SV}(Q)
\]

where \( \Phi_0 \) and \( \Phi \) are the quantum yield in the absence and presence of quencher, respectively; \( Q \) is the concentration of quencher, and \( K_{SV} \) is referred as the Stern-Volmer constant, which is related to the diffusion coefficient by the Smoluchowski equation. However, the isotropic and three-dimensional theory of fluorescence quenching does not apply in the membrane, and a Stern-Volmer modified treatment has been developed for this case (44).

Long-range diffusion measurements

For studying long-range diffusion, many studies have been conducted using the technique of fluorescence recovery after photo-bleaching (FRAP) (45). The translational diffusion coefficients that can be measured using this technique range from about \( 10^{-7} \) to \( 10^{-12} \) cm/s. For a small area of the membrane, that contains fluorescent-labeled molecules of interest, the initial level of fluorescence is determined. Then, a flash of intense laser beam is applied irreversibly to bleach a substantial (100% in the ideal case) fraction of fluorophores in this area, so it appears black after the flash. The intensity of the laser light for the bleaching is typically \( \sim 10^3 \) times greater than the light used to monitor the fluorescence. For the bleached area, the fluorescence intensity is recorded as a function of time. The brightness will gradually increase as fluorescent molecules diffuse into this area. Two parameters are determined from a FRAP experiment (Fig. 10): 1. The lateral mobility, which gives the diffusion coefficient directly and is determined by the slope of the fluorescent recovery curve. The steeper the curve, the more mobile the molecules.

![Figure 10 FRAP experiment. (From Reference 28.)](image-url)
2. The percent recovery, which is determined as $(Y/X) \times 100 = \%$ recovery. It gives the mobile fraction of the probe. If the radius of the illuminated area is small compared with the diffusion area (cell, vesicle, etc.) and the molecules are free to diffuse, then the percent recovery must be 100. On the other hand, if the fluorescence fails to recover to the same intensity observed before the bleaching pulse, then it indicates that a fraction of fluorophores exist, which are immobile on the time scale of the experiment ($D < 10^{-11}$ cm$^2$/s).

In recent years, FRAP for diffusion measurements in membranes has been superseded by fluorescence correlation spectroscopy (FCS). FCS is very similar to FRAP in both theoretical and experimental approaches to the observation of diffusion. The difference between these two closely related techniques is that FRAP measures relaxation from an initial nonequilibrium state after photobleaching, whereas FCS detects stochastic fluctuations that occur even in a system remaining in equilibrium (46).

ESR techniques for studying long-range diffusion usually observe the spreading of a small region of concentrated spins over time. For diffusion rates typical of a membrane environment, the most appropriate method is dynamic imaging of diffusion by ESR (DID-ESR) (47), which has been used to measure $D > 10^{11}$ cm$^2$/s. The measurement of the diffusion coefficient, $D$, by DID-ESR involves two stages. After preparing the sample with an inhomogeneous distribution of spin probes along a given direction, the investigator uses the ESR imaging method to obtain the (one-dimensional) concentration profiles at several different times. Spatial resolution results from a magnetic field gradient, because spin probes at each spatial point experience a different resonance frequency. With time, the inhomogeneous distribution will evolve toward a homogeneous distribution via translational diffusion. The second stage is to fit the time-dependent concentration profiles to the diffusion equation to obtain $D$. The ESR spectrum recorded in the presence of a magnetic field gradient $B$ ($G/cm$) is a convolution of the usual ESR spectra (gradient-off spectrum), $I_0(\xi)$, with the concentration of spins $C(x, t)$, which initially varies along the direction $x$. $I(\xi, t) = \int_{-\infty}^{\infty} C(t) I_0(\xi x - \xi x') dx'$

Here, $\xi = (B - B_0)$ measures the spectral position as the deviation of the magnetic field $B$ from the field $B_0$ at the center of the spectrum, which corresponds to the position $x = 0$, because the field gradient $B'$ maps $x$ onto $\xi$, as given by $\xi = B' x$. The determination of $C(x, t)$ from the two spectra $I_0(\xi, t)$ and $I(\xi, t)$ is a straightforward calculation through Fourier transformation. Fitting the $I(\xi, t)$ profile to the diffusion equation gives the diffusion rate.

Pulse field gradient (PFG) NMR spectroscopy is now generally regarded as the method of choice for measuring the translational diffusion coefficients of molecules of virtually any type under many conditions (48). $^1$H, $^13$C, $^19$F, and $^{31}$P variants of this method have been used successfully to study lateral diffusion of cholesterol, phospholipids, and water in model membranes (49, 50). This technique introduces two identical gradient pulses of the external magnetic field into the standard spin-echo NMR rf pulse sequence, one is between the $n/2$ and $n$ pulses and another is after the $n$ pulse. If spins do not undergo any translational diffusion, then the effect of the two applied gradient pulses cancels out and after the rf $n$-pulse the echo refocuses to the same value as in the absence of the gradient. However, the diffusion movement of spins between the gradient pulses causes additional dephasing, which cannot be refocused by the $n$-pulse and manifests itself in a decrease in the resulting echo intensity. The degree of dephasing is proportional to the displacement of spins in the direction of the gradient and, hence, the translational diffusion rate.

In the last decade, motion of lipid and protein single molecules in biomembranes was studied extensively by either single-particle tracking or by ultra-sensitive single-molecule fluorescent microscopy or fluorescence correlation spectroscopy. In single-particle tracking, a particle of typical diameter of 30–50 nm is attached to the lipid or protein molecule as a label. Colloidal gold and fluorescent particles have been used as labels. The particle motion is then followed by computer-enhanced video microscopy. Single-molecule fluorescence measurements are based on the repetitive excitation of a single fluorophore, which generates repeated cycles of absorption and fluorescence and count rates of up to tens of thousands of counts per second. The fluorescence is detected by single-photon counting modules.

Lipids diffuse freely in fluid model membranes. FRAP measurements show full recovery and diffusion coefficients on the order of magnitude of $10^{-4}$ cm$^2$/s. Free diffusion with a similar rate is often observed for lipids in the biomembrane. However, many cell membrane proteins show lower diffusion rates and incomplete recovery after photobleaching. For membrane proteins, dramatically different behavior in model and biological membranes is a common case. In model membranes, membrane proteins also diffuse freely and their diffusion coefficients are often similar to the diffusion coefficients of lipids. On the contrary, in biomembranes, the diffusion of proteins is 2–3 orders of magnitude slower and the fluorescence recovery is often incomplete. This observation points to limitations of the fluid mosaic model as will be discussed below.

Fluidity Versus Mosaicity—New Concepts in Membrane Science

The Singer-Nicolson model of the membrane played a very important role in understanding membrane structure and function. However, many properties of biomembranes are not consistent with this model. In recent years, a growing consensus points to limitations of the fluid mosaic model as will be discussed below.
membranes and biomembranes deprived of their cytoskeleton (blebs). A notable observation is the oligomerization-induced slowing of diffusion (51). It manifests itself in much greater effect of diffusant size on the translational diffusion rate than predicted by the theory of Saffman-DeBrück based on the Singer-Nicolson model (52). If a transmembrane protein is approximated as a rigid cylinder of radius $r$ and height $h$, floating in a two-dimensional liquid of viscosity $\eta_1$ with matching thickness $h$, then the theory gives the following expression for its translational diffusion coefficient $D$:

$$D_T = \frac{k_B T}{4 \pi \eta_1 h} \left( \ln \frac{h}{r} - \frac{1}{2} \right)$$

where $\gamma$ is the Euler constant ($\approx 0.577216$). This formula predicts very weak dependence of translational diffusion on the size of diffusant. For example, for a 10-fold increase in the protein radius, from 5 to 50 Å, the theory predicts for a 50-Å thick bilayer a decrease in the diffusion rate by a factor of 1.57. A rather factor of 10-increase in the radius, which corresponds to a 75-fold increase in the aggregation number, slows the diffusion rate by a factor of 2.6. Although this insensitivity looks somehow counterintuitive, the Saffman-Debrück formula gives good results for proteins incorporated into model membranes.

On the contrary, for the plasma membrane, the effect of oligomerization on the diffusion rate is much stronger than predicted by the formula. For example, for linked couples of green fluorescent protein-E-cadherin oligomerization with an aggregation number between 2 and 10 slows down the diffusion up to 40 times (53). Also, spectacular single-particle tracking experiments carried out by Kusumi et al. (51) showed that in natural biomembranes, the diffusion does not follow usual Brownian patterns but consists of a series of random Brownian walks within confined areas (compartments) followed by longer-distance hops between compartment. (see trajectory in Fig 11) (54). The compartment size varies depending on the cell nature but is relatively insensitive to the diffusant, which shows simple Brownian diffusion with a single diffusion coefficient (55).

Because the assumption of simple Brownian diffusion breaks down, the diffusion in biomembranes cannot be described by a single diffusion coefficient. For instance, FRAP experiments in the plasma membrane showed that the observed translational diffusion rates depend on the size of the initial photobleached spot, which is also inconsistent with a simple Singer-Nicolson model.

A cumulating evidence clearly points at involvement of the cell cytoskeleton in the compartmentalization of the membrane, in particular, the fine cytoskeleton filaments formed by actin in most eukaryotic cells or spectrin in mammalian red blood cells. However, single-particle tracking experiments show the same patterns of hop-diffusion for lipid molecules located in the extracellular leaflet of the plasma membrane. How can the membrane skeleton, which is located only on the cytoplasmic surface of the membrane, suppress the motion of lipids on the extracellular side?

To reconcile this apparent contradiction the membrane skeleton fence and anchored transmembrane picket model was proposed (54). According to this model, transmembrane proteins anchored to and lined up along the membrane skeleton (fence) effectively act as a row of posts for the fence against the free diffusion of lipids (Fig. 31). This model is consistent with the observation that the hop rate of transmembrane proteins increases after the partial removal of the cytoplasmic domain of transmembrane proteins, but it is not affected by the removal of the major fraction of the extracellular domains of transmembrane proteins or extracellular matrix. Within the compartment borders, membrane molecules undergo simple Brownian diffusion. In a sense, the Singer-Nicolson model is adequate for dimensions of about 10 × 10 nm, the special scale of the original cartoon depicted by the authors in 1972. However, at these distances simple extensions of the fluid mosaic model fail and a substantial paradigm shift is required from a two-dimensional continuum fluid to the compartmentalized fluid.

Microtubule Dynamics
Manu Lopus, Mythili Yenjerla and Leslie Wilson, Department of Molecular, Cellular, and Developmental Biology and The Neuroscience Research Institute, University of California, Santa Barbara, California
doi: 10.1002/9780470048672.wecb338

Microtubules are cylindrical, cytoskeletal protein polymers found in all eukaryotic cells. They perform a plethora of functions associated with cellular structure, organization, and movement. They polymerize and depolymerize by the reversible addition and loss of \( \alpha: \beta \) tubulin heterodimers, which are their building block subunits, at the microtubule ends. Importantly, microtubules are not simple equilibrium polymers. The hydrolysis of GTP that occurs when tubulin dimers add to the ends of microtubules creates two distinct and often coexisting dynamic behaviors: dynamic instability and treadmilling. These dynamic properties are crucial in guaranteeing the faithful segregation of chromosomes during cell division, in many kinds of intracellular transport, in cell signaling, and even during programmed cell death. Microtubule dynamics play critical roles in terminally differentiated cells as well. In neurons, microtubule dynamics regulate neuronal plasticity, growth-cone motility, and maintenance of mature neurons. Suppression of mitotic spindle microtubule dynamics by small drug molecules is an important therapeutic strategy for treatment of many types of cancer. In addition, agents that stabilize microtubule dynamics offer potential for treating neurodegenerative diseases in which the dynamics are misregulated. Agents that modulate microtubule dynamics can be used as experimental tools or could be used therapeutically to perturb the functions of any cellular disease processes dependent on the dynamics.

This review focuses on the dynamic behaviors of microtubules. Because of space limitations, we concentrate on the molecular, mechanistic, and kinetic aspects of microtubule dynamics, their significance and regulation in dividing cells, and how microtubule-targeted drugs that modulate microtubule dynamics act to inhibit mitosis and kill tumor cells. It is an extensive and rich area of research; thus we must direct the reader to the cited literature including the Further Reading list for a more thorough coverage of the field.

General Features of Microtubule Structure and Polymerization

Microtubules are physically robust, dynamic, cylindrical, cytoskeletal polymers (Fig. 1) composed of the protein tubulin, which is a heterodimer that consists of one alpha and one beta subunit. The structural, mechanical, and polymerization properties of microtubules are essential for normal cell division, for development and maintenance of cell structure, for many kinds of intracellular transport, for positioning of intracellular organelles, and for programmed cell death (reviewed in References 1 and 2). Microtubules polymerize and depolymerize by the reversible noncovalent addition and loss of \( \alpha: \beta \) tubulin dimers at their ends. The orientation of \( \alpha: \beta \) tubulin dimers in the microtubule provides the polymer with structural and kinetic polarity, with the end designated as the plus end, where \( \beta - \)tubulin is exposed, being relatively more dynamic than the opposite or minus end, where \( \alpha - \)tubulin is exposed. The opposite ends of microtubules exhibit remarkably different behaviors. For example, during assembly of microtubules, tubulin polymerizes more rapidly at plus ends than at minus ends. Also, as described in more detail below, the plus ends alternate between phases of growth and shortening more frequently and fluctuate in length to a greater extent than the minus ends (3).

The self-assembly of tubulin to form microtubules was described initially in a classic polymerization model of nucleated helical polymerization by Masayama and Osawa (4). A assembly involves two phases: a nucleation phase followed by an elongation phase. With purified systems in vitro, nucleation can...
be achieved in several ways, such as by inclusion in polymerization reactions of various stabilizing microtubule-associated proteins (MAPs), by using preformed microtubule seeds prepared either by shearing preformed microtubules through a 25 gauge needle or by using sea urchin axonemes (5). The nucleation of tubulin assembly in vitro also can be achieved with microtubule-stabilizing chemical substances such as glutamate, dimethyl sulfoxide, and glycerol (6).

Microtubule assembly in cells differs in some ways from assembly in vitro. In cells, nucleation of microtubules requires a third type of tubulin, which is called γ-tubulin, that functions in concert with other proteins in the form of a γ-tubulin ring complex. In most animal cells, the γ–tubulin ring complex is located at the pericentriolar region of the microtubule organizing center (or centrosome) where it nucleates microtubule assembly at the minus ends (7). The γ–tubulin does not become incorporated into the microtubule, but rather it only localizes to the minus ends. Assembly of tubulin to form microtubules during the early stages of polymerization in vitro can be considered a pseudo first-order reaction. A steady state is eventually attained in which both the soluble tubulin concentration and the microtubule polymer mass attain stable plateaus (8). The critical concentration at apparent equilibrium (actually a steady state, see below) is the concentration of soluble tubulin in apparent equilibrium with the microtubule polymers.

The assembly of tubulin to form functional microtubules is a complex process (see References 2, 8, and 9). Two GTP binding sites are on the tubulin dimer: One is on β-tubulin, which is readily exchangeable when the tubulin is in solution, and the other on α-tubulin, which is not exchangeable, located at the interface between α- and β-tubulin (1). The GTP bound to the exchangeable site (the E site) undergoes hydrolysis when soluble tubulin adds to the microtubule ends, which creates the nonequilibrium dynamic properties of the microtubules. In its simplest form the assembly may be written as:

$$P = (1 - f)T - Sc$$

where the concentration of polymers, $P$, depends on the critical concentration of the tubulin subunits for assembly ($Sc$), the fraction of the proteins that are not participating in the process ($f$) (for example, because of sequestration by regulatory proteins or denaturation of the tubulin), and the total protein concentration ($T$) (9). $Sc$ can be determined from the total protein concentration by measuring the polymer content as a function of the total protein concentration at apparent equilibrium. Extrapolation of the total protein concentration to zero polymer content allows determination of the critical concentration. Studies that involve video-enhanced differential interference contrast microscopy and cryo-electron microscopy have provided considerable insight into the nature of growth and shortening of microtubules (10). Accordingly, microtubules, when growing rapidly, display sheet-like extensions at the growing ends, with the eventual closure of the sheets to form the cylindrical microtubule structure. These growing tips are thought to be stabilized by a so-called stabilizing GTP cap (see below). The protofilaments at the ends of rapidly shortening microtubules form tightly curled oligomeric rings, which indicates that GTP hydrolysis creates a strain in the microtubule lattice, and when the cap is lost, the strained and destabilized protofilaments can dissociate rapidly from the microtubule end because of their intrinsic curvature.

**Microtubule Dynamics—Mechanistic Aspects**

Although the classic model of nucleated helical polymerization accurately describes many aspects of microtubule polymerization, it is now well established that microtubules are not simple equilibrium polymers. Rather, the hydrolysis of GTP to GDP that occurs as tubulin adds to growing microtubule ends creates two unusual nonequilibrium dynamic behaviors, which are known as treadmilling (11, 12) and dynamic instability (13). Treadmilling is the phenomenon of net growth of individual microtubules by the addition of tubulin at one end and net shortening by the loss of tubulin at the other end. Dynamic instability is the stochastic switching between growth and shortening (often called shrinking) phases at the microtubule ends. Although both behaviors are intrinsic properties of microtubules composed solely of tubulin, microtubule dynamics in cells are modulated by a wide variety of microtubule-associated proteins (MAPs) and in an enormous variety of ways (e.g., see Reference 2).
Treadmilling

Treadmilling, which is the unidirectional flow or flux of tubulin from plus ends to minus ends (Fig. 2a), was discovered in vitro using single- and double-radiolabeled GTP (3H–GTP and 14C–GTP) incorporation and loss experiments at the microtubule ends by Margolis and Wilson in 1978, while investigating the mechanism of substoichiometric poisoning of microtubule assembly by colchicine (11, 12). Use of double-label and pulse-chase strategies demonstrated that the net uptake and loss of tubulin occurred at opposite ends of the microtubules, whereas the total polymer mass and the lengths of the microtubules remained constant as determined by electron microscopy. These first treadmilling studies were conducted with MAP-rich brain microtubules. Because of the high MAP contact (see below), the treadmilling rates were slow (∼0.7 μm/h) and dynamic instability was almost completely suppressed. Later, Hotani and Horio provided the first visual proof for treadmilling (14). They decorated the center block of a three-block microtubule with Tetrahymena dynein and found that the length of microtubules at one end of the decorated block decreased and that at the other end increased, which left the length of the center block unchanged. The authors also discovered that in the presence of neural MAPs, dynamic instability was strongly suppressed, which left treadmilling the prevailing dynamic behavior (see Reference 14). Most recently, experiments with microtubules made in the absence of MAPs, but stabilized sufficiently with low concentrations of glycerol to inhibit dynamic instability, demonstrated that the treadmilling rate of MAP-free microtubules in vitro is quite rapid and can approach the rates observed in living cells (15) (see below). This work indicated even more that the treadmilling rate can be increased greatly by increasing the dissociation rate constant for tubulin loss at the minus ends, which is an action that can be accomplished readily by certain MAPs. Treadmilling is believed to be caused by the differences in the individual critical concentrations for tubulin addition at the opposite microtubule ends (15). The idea is that
the critical concentration for tubulin assembly at the growing end is lower than at the shortening end, and that at steady state, the overall critical subunit concentration is maintained between the two. For treadmilling to occur, both microtubule ends must be free for tubulin exchange (that is, neither end can be blocked such as occurs at minus ends of microtubules attached to centrosomes), and the microtubules must be at or near steady state so that the soluble tubulin level is not so high or so low that both ends grow or shorten. Because treadmilling can occur in the absence of the rapid shortening typical of that observed during dynamic instability, it is reasonable to think that both ends of a treadmilling microtubule retain their stabilizing cap (15).

Dynamic instability

In 1984, Mitchison and Kirschner (13) discovered dynamic instability in vitro when they observed the coexistence of growing and shrinking populations of microtubules that interconverted infrequently. The coexistence of the two populations of microtubules in a dynamically unstable manner was substantiated by Horio and Hotani by analyzing individual microtubules using dark-field microscopy (3). Dynamic instability thus came to be defined as the stochastic switching between the growing and shortening phases at microtubule ends (Fig. 2A (16, 17)). Dynamic instability in vitro occurs at both microtubule ends, with the dynamics at the plus ends considerably more robust than those at the minus ends (18). In cells, however, dynamic instability has only been observed at plus ends. Minus ends in cells have not been observed to grow; they either remain the same length or they shorten (19).

A minimum of four parameters are now used to define the various features of dynamic instability. These parameters are the growth rate, the shortening rate, and the switching frequencies from growth to shortening and from shortening to growth. The abrupt switching of an end from growth to shortening is referred to as a “catastrophe,” and the switching from shortening to growth is referred to as a “rescue” (18). Additional parameters are used to describe dynamic instability behavior. Specifically, microtubules both in cells and in vitro often do not change length for periods of time. This parameter is called “pause” in cells and “attenuation” in vitro. In both situations, tubulin may be exchanging at the microtubule ends, but the extent of addition or loss may be too low to be detected by video microscopy.

An especially useful parameter is termed the “dynamics” (see Reference 16), which is a measure of the total tubulin exchange per unit time for a microtubule, including periods of attenuation or pause. As examples of the various parameters, Table 1 shows the major dynamic instability parameters for a set of control microtubules in vitro and for microtubules in the presence of the microtubule-targeted drug tasidotin (20).

Hydrolysis of E-site GTP during or shortly after addition of tubulin to the microtubule ends and the gain and loss of a short region of GTP-(or GDP–Pi)-liganded tubulin at the extreme ends of the microtubules that stabilize the microtubule tips are believed responsible for dynamic instability. The tubulin dimer has intrinsic GTPase activity, with a rate that is relatively slow when tubulin is in solution (21). However, hydrolysis is triggered when the $\beta$-subunit of an incoming tubulin dimer with bound GTP docks at the end of an exposed $\alpha$-subunit at the end of the microtubule (22). Evidence in support of the existence of a very short stabilizing GTP cap, perhaps no larger than a single layer of tubulin-GTP (or GDP–Pi), has been obtained in many studies (too numerous to be described here). Studies show that tubulin addition to the microtubule ends and GTP hydrolysis are very closely coupled events (23, 24), and in experiments that use the slowly hydrolysable GTP analog guanylyl-(a, b)-methylene-diphosphonate (GMPCPP), a stable cap is formed from tubulin-GMPCPP subunits (25). The current thinking is that only the tip of the microtubule contains GTP-tubulin (or GDP–Pi) and that the “GTP cap” is required for continued growth to occur. Most of the microtubule core consists of GDP-tubulin, which is believed to be in a strained conformation (1, 10, 26). Thus, when the cap is lost (a catastrophe), the strained GDP-tubulin core is exposed at the ends, which rapidly depolymerize in the form of curved protofilaments (26). The re-establishment of the cap (a rescue) would result in regrowth. The interconversion between these two phases with microtubules composed of pure tubulin (no accessory MAPs) is explained by stochastic loss or by reacquisition of a stabilizing cap by this two-state model, but it is speculated that a closed-tube state, which presumably exists as a structural intermediate between polymerizing ends with sheets and depolymerizing ends with peeling GDP–tubulin oligomers, may represent a structural correlate of a kinetic intermediate in a three-state model (2). A similar model with a growing open state, shrinking state, and a third intermediate closed state has been proposed by Tran et al. (27).

Microtubule Dynamics and its Modulation by Microtubule-Targeted Drugs and Regulatory Proteins

Both dynamic instability and treadmilling occur extensively in all eukaryotic cells. Except for extremely stable microtubules such as those found in organelles such as cilia and flagella, most microtubules are dynamic and display dynamic behaviors that vary enormously in their robustness and type from one cell type to another and even within the cytoplasm of individual cells (2, 18, 28). Dynamic instability and treadmilling (or flux) are extremely rapid during mitosis, and the rapid dynamics are critically important because they are required for distribution of the duplicated chromosomes to the daughter cells in an exquisitely time-sensitive and accurate fashion (29). At the onset of mitosis in animal cells, the dynamics of the microtubules increase many fold and change qualitatively from the dynamics of interphase microtubules. For example, the minus ends of the microtubules tethered at the centrosome during interphase do not seem to grow or shorten. But when the centrosome develops into a mitotic spindle pole, the minus ends become unblocked and dynamically active (29). Also, dynamic instability at the plus ends of the microtubules that grow out from the spindle poles, characterized by frequent switching between growth and shortening states, facilitates microtubule attachment to the
kinetochores of the chromosomes (called chromosome capture) and facilitates chromosome alignment at the metaphase plate and their accurate segregation to the daughter cells (29). Reduced tubulin flux of kinetochore microtubules from their attachment point at the kinetochore toward their attachment region at the poles, which seems to be treadmilling facilitated by various associated motors and other regulators, creates necessary tension in the spindle and facilitates the accurate and timely segregation of the chromosomes to the daughter cells at anaphase (29). Clearly, whereas spindle microtubules remain tethered at both their plus and minus ends, their ends remain free for rapid flux (see Reference 2). Thus, they must be transiently anchored to other structures near their ends in a fashion that leaves the ends free for substrate loss or gain.

Dynamic microtubules are important not only in dividing cells but also in terminally differentiated cells. For example, they play crucial roles both in the post mitotic development of neurons and in mature neurons such as in the formation of functional neuronal networks and the correct arborization (branching) of dendrites (30). Misregulation of microtubule dynamics, as for example caused by mutations in the neuronal MAP-lau, can lead to microtubules whose dynamics fall outside the normally permissible range thus possibly contributing to neurodegeneration in tauopathies such as Alzheimer’s disease and FTDP-17 (Fronto-Temporal Dementia with Parkinsonism associated with Chromosome 17) (see Reference 31) (see below).

Modulation of microtubule dynamics by microtubule-targeted drugs

Here we will focus on how the functions of dynamic microtubules can be modulated powerfully by chemical agents. The fact that microtubule dynamics are indispensable for normal cell function and survival leads naturally to the idea that targeting their dynamics with small molecules is a highly attractive strategy for drug development and chemical biology. This has been especially fruitful in cancer chemotherapy. Several classes of microtubule-targeted drugs are vitally important in the treatment of cancer, which includes the vinca alkaloids and the taxanes. Although high concentrations of these drugs can increase or decrease the mass of assembled microtubules in vitro and in cells, the most sensitive actions of these drugs on microtubules, which occurs at low drug concentrations in the absence of changes in polymer mass, is to suppress their dynamics (16). Despite their opposite effects on microtubule polymerization and their different specific mechanisms of action, most successful chemotherapeutic drugs that act on microtubules share the common property of suppressing spindle microtubule dynamics, which leads to inhibition or slowing of cell cycle progression at prometaphase of mitosis and at the transition from metaphase to anaphase (32). In sensitive tumor cells, mitotic arrest is followed by apoptosis. The mechanism that underlies the relationship between disruption of spindle dynamics and induction of apoptosis is yet to be fully explored, although evidence that diffusible factors maybe released as the result of changes in microtubule polymerization is consistent with the hypothesized role of microtubules in sequestering signals (33). In fact, several successful microtubule-targeting drugs are known to promote apoptosis in tumor cells (34).

Microtubule interfering drugs act by binding to various sites on the tubulin dimer and at different positions within the microtubule. Although other categories clearly exist, currently most drugs are classified into three major categories based on their respective tubulin binding domains: which include the Vinca alkaloid domain, the colchicine domain, and the paclitaxel domain. These may be some of the same regions of microtubule surfaces used by natural regulators of dynamics in cells and, thus, the drugs can be thought of as possible mimics of microtubule regulatory proteins (35). Vincristine and vinblastine have long been used for the treatment of hematological cancers. Vinca alkaloids currently used for treatment of cancer include two natural products: vincristine, and vinblastine, and several novel semi-synthetic drugs, vindesine, vinorelbine and vinflunine. At low concentrations, vinca alkaloids suppress both dynamic instability and treadmilling, apparently by binding to microtubule ends. The superior anti-tumor efficacy and reduced toxicity of vinflunine (36) over vinblastine may be attributed to its less powerful inhibitory effects on microtubule dynamics. Defective checkpoints in certain cancer cells may make them more susceptible to the less powerful inhibitory effects of vinflunine than normal cells (36). Drugs such as vinflunine, various derivatives of the dolastatins including tasidotin (20) (Table 1), cryptophycin analogs (37), and halichondrin B analogs such as eribulin (E7389) (38) comprise a series of chemically distinct compounds that bind in the vicinity of the Vinca binding domain and are under various stages of development for cancer treatment. The microtubule seems to be exquisitely sensitive to the action of these drugs as the binding of only a few drug molecules along the microtubule surface or at its ends is sufficient to suppress microtubule dynamics (see Reference 16). Colchicine and compounds that bind in the vicinity of the colchicine-binding domain of tubulin comprise another class of drugs with potential for treatment of cancer. Colchicine binds to tubulin at αβ dimer interface, and acts by being incorporated with low stoichiometry at the ends of the microtubules as a tubulin-colchicine complex (39). Although colchicine has...
antitumor properties, its therapeutic use is hampered by its high toxicity. Drugs that bind to tubulin at or near the colchicine site that are in clinical trials include 2-methoxyestradiol and combretastatin A-4 phosphate. 2-methoxyestradiol induces mitotic arrest by suppression of microtubule dynamics (40), whereas the vascular targeting agent combretastatin A-4 phosphate acts by destabilizing microtubules at plus ends (41).

Pacilaxel and docetaxel are among the most successful microtubule-targeted drugs currently used to treat solid tumors, which include ovarian, breast, head and neck, lung, and prostate (42). The binding site for the taxanes is on the β-tubulin and is located on the inside surface of the microtubule (43). Binding of only a few molecules of paclitaxel to tubulin in microtubules strongly suppresses dynamic instability at microtubule plus ends with only a marginal increase in microtubule polymer mass (44). Other promising anticancer compounds believed to act at the taxane binding sites include the epothilones (45), discomelaid (46), eleutherobin, and several novel taxanes (47). Pacilaxel may find a role in the treatment of neurodegenerative diseases. Specifically, it improved axonal function and ameliorated neurological problems in mice that carry a defective human tau gene (48). Interestingly, some evidence indicates that pacilaxel and tau may share the same binding site on the microtubule surface (49), and the effects of tau on microtubule dynamics are rather similar to those of pacilaxel (31).

Regulation of microtubule dynamics by cellular MAPs

A plethora of proteins regulate microtubule dynamics in cells. All these regulators are potential targets for chemical biology. As indicated on the left, presence indicates that the drug molecules may mimic the effects of natural regulators of dynamics, perhaps by binding to the microtubules at similar sites or regions of tubulin (50). Identifying proteins that regulate microtubule dynamics have traditionally been classified into two groups: microtubule-stabilizing proteins and microtubule-destabilizing proteins. A third recently described group of proteins known as +TIPs, which track the plus ends of growing microtubules in cells, also are thought to regulate microtubule dynamics (28).

Regulation by stabilizing proteins

Several MAPs have been known to promote tubulin assembly and to stabilize microtubules. Members of this family include the neuronal proteins tau and MAP2, which are present in axons and dendrites, respectively, and MAP4, which is found in all non-neuronal vertebrate cells (50). This group of structural MAPs also includes MAP1A and MAP1B, which are found mainly in axons and dendrites (51, 52). Regulation by these MAPs is complex because their ability to regulate polymerization and dynamics is in turn regulated by phosphorylation (53). Currently, tau is attracting considerable attention because of its involvement in various neurodegenerative diseases and because it may be a target possible treatment of Alzheimer’s disease (31,54–56). Tau is a complex family of MAPs found specifically in neurons that strongly promotes microtubule polymerization and stabilizes microtubules. Although only a single tau gene exists, six developmentally regulated tau isoforms are produced in human brain because of alternative splicing of the single tau gene. Tau is also the target of multiple kinases that can phosphorylate it at a great many sites, which produces many more isoforms. The various tau isoforms differentially modulate dynamic instability (reviewed in Reference 31). For example, an adult form of tau with 4 microtubule binding repeats (called 4R tau) strongly suppresses the shortening rate at plus ends, whereas a fetal form of tau with only 3 repeats (3R tau) does not (55). In the neurodegenerative disease FTDP-17, mutations that result in altered mRNA splicing change the crucial expression ratio of the 3R and 4R tau isoforms (56). Altered expression of normal tau isoforms could result in misregulation of microtubule dynamic in axons and thus contribute to neurodegenerative disease.

Regulation by destabilizing proteins

Stathmin/Osp1B (oncoprotein1B) and certain members of the kinesin-related motor proteins are among the major classes of proteins that cause microtubule destabilization. Stathmin is a ubiquitous microtubule-destabilizing protein that is believed to play an important role in linking cell signaling to the regulation of microtubule dynamics. It is known to sequester free tubulin and therefore to impede microtubule formation (57). Clearly, such an action can affect microtubule dynamics. But like the action on microtubules of many drugs, the effects of stathmin on tubulin and microtubules are complex. Specifically, relatively low concentrations of stathmin increase the steady-state catastrophe frequency by a direct action on microtubules, with the catastrophe-promoting activity being considerably stronger at minus ends than at the plus ends (58). Stathmin also greatly increases the microtubule treadmilling rate. These data indicate that stathmin may be an important regulator of minus-end dynamics, as for example, by increasing depolymerization at microtubule minus ends at spindle poles during mitosis thereby increasing the plus to minus end flux rate (58). Other destabilizing proteins include microtubule severing proteins such as katanin (59) and the kinesin-related motor protein, XKC M1 (60).

Plus end tracking proteins

Finally, we want to mention briefly a group of proteins known as +TIPs or plus-end tracking proteins (28). This group of proteins is composed of microtubule motor complex components, signal transduction molecules, and molecular adaptors. These proteins can recognize and associate with growing microtubule plus ends and include CLIP-170 (cytoplasmic linker protein), which is an endosome-microtubule linker protein that was the first +TIP identified; members of the family EB1, EB2, and EB3 (end-binding proteins) that bind to APC (adenomatous polyposis coli, a tumor suppressor protein); the dynactin/dynactin microtubule motor complex, in particular the 150kDa subunit of dynactin; and several other proteins such as CLASP1 (CLIP-associated protein) and LIS1 (28, 61). EB1 enhances microtubule polymerization by increasing rescues and preventing catastrophes (62). Using dominant negative constructs, it was shown that in the absence of CLIPs, the microtubule rescue frequency was reduced, which suggests a mechanism that
involve CLIPs by which microtubule plus ends may be concentrated near the cell margin (63). Although many functions of the +TIPs are not yet understood, targeting their association with the growing tips of microtubules could be an area for future development through chemical biology.

Conclusion

Treadmilling and dynamic instability—two intrinsic dynamic properties of microtubules—are critical for mitosis and many other cellular functions that involve dynamic microtubules. Because the dynamics of microtubules and their tight regulation by a host of MAPs play crucial roles in so many cell functions, it is reasonable to think that modulating their dynamics in specific cell functions by targeting the microtubules themselves or by targeting the regulatory proteins through chemical biology will remain an attractive area of research for many years to come.

Specific receptors on the surface of mammalian cells actively internalize cell-impermeable ligands by the mechanism of receptor-mediated endocytosis (RME). This process is critical for the acquisition of nutrients, signal transduction, development, neurotransmission, and cellular homeostasis. Binding of ligands to internalizing receptors on the plasma membrane results in clustering of the complex in clathrin-coated pits or other dynamic membrane regions. Invagination of these regions yields intracellular vesicles that fuse to form membrane-sealed endosomes. Receptors typically dissociate from ligands in these acidic compartments, which allows the free receptor to cycle back to the cell surface, whereas ligands are often degraded on delivery to lysosomes, which liberates amino acids and other nutrients. By mimicking endogenous ligands, certain protein toxins, viruses, and other pathogens exploit RME to enter the cytoplasm or reach other intracellular destinations. Similarly, artificial delivery systems that mimic ligands or receptors can enhance efficiently the cellular uptake of impermeable molecules, including drugs, proteins, and nucleic acids. Advances in small-molecule probes, structural biology, and genetic methods are beginning to illuminate the complex mechanisms of this process at the molecular level.

The plasma membrane of eukaryotic cells encapsulates the inner cellular machinery, thereby protecting fragile biologic structures from potentially toxic or opportunistic extracellular materials. Only small hydrophobic molecules can penetrate rapidly this lipid bilayer through passive diffusion. More polar essential amino acids, sugars, and ions access the cell interior by interacting with membrane proteins that function as selective pumps or channels. For many other cell-impermeable small molecules, macromolecules, and particles to access the cell interior, cells must facilitate uptake actively, with regions of the plasma membrane functioning to capture solutes by invagination and pinching off to form intracellular vesicles. This process is termed endocytosis, which represents multiple related mechanisms for the internalization of extracellular molecules (1). Endocytosis is divided into two primary categories: phagocytosis (cell eating) and pinocytosis (cell drinking). Phagocytosis enables the uptake of large particles, including intact bacteria and yeast, through an actin-mediated mechanism that is generally restricted to specific cell types, such as macrophages, monocytes, and neutrophils. Pinocytosis, by contrast, occurs in all nucleated mammalian cells and involves the active invagination of small regions of cellular plasma membrane to capture solutes within vesicles of less than 200 nm in diameter. These vesicles fuse in the cytoplasm to form membrane-sealed compartments termed endosomes, and their contents are sorted to allow trafficking to specific destinations. Pinocytosis can involve the nonspecific uptake of extracellular fluid, as well as the uptake of specific molecules in the extracellular environment, mediated by receptors on the plasma membrane. Some mechanisms of endocytosis operate rapidly and continuously. In cultured fibroblasts, under physiologic conditions, membrane equivalent to the entire cell surface is perpetually internalized with a half-life of 15 to 30 minutes (2). Most pinocytic pathways involve specific interactions of receptors with ligands. In receptor-mediated endocytosis (RME), internalizing receptors on the cell surface bind cell-impermeable ligands to concentrate ligands in the cell. This mechanism is thousands of times more efficient than nonspecific pinocytosis for the cellular acquisition of nutrients and other impermeable molecules. The receptors involved in RME comprise a structurally diverse group of biomolecules that project ligand-binding motifs into the extracellular environment. Cell-impermeable small molecules, lipids, peptides, proteins, nucleic acids, and carbohydrates are internalized by RME, which enables the consumption of nutrients, elimination of pathogens, and termination of signals initiated by extracellular stimuli. RME followed by subsequent exocytosis...
of the ligand from one side of the cell to another is termed transcytosis, and this mechanism allows the delivery of nutrients across membrane barriers, such as the blood-brain barrier (3). Receptors involved in RME are listed in the following sections. Other representative examples of the interactions with the receptor include the structure of LDL determined by cryoelectron microscopy (shown reduced in scale compared to our model above or as a complex with receptor extracellular fragments) (15). Transferrin, human growth hormone, the bovine rhodopsin (12), and the FcγRIIB (CD16) (13) are shown as part of a composite image that illustrates the nature of attachment of the receptor to the plasma membrane. The small glycolipid receptor ganglioside GM1 is shown to the right, rendered as a molecular model (14). Structures of cognate ligands are positioned above or as a complex with receptor extracellular fragments. These ligands include the structure of LDL determined by cryoelectron microscopy (shown reduced in scale compared to the receptor) (15), transferrin, human growth hormone, the bovine rhodopsin (12), and the bovine rhodopsin (16). Brief descriptions of these and related receptors and ligands are provided in the following sections. Other representative examples of receptors and ligands involved in RME are listed in Table 1.

### The LDL receptor: a macromolecular membrane-spanning protein critical for cellular uptake of cholesterol

Uptake of cholesterol-laden LDL particles by the LDL receptor (LDLR, Fig. 1) is one of the best-characterized examples of RME (9, 17–18–19). The mature LDL receptor is a single-pass transmembrane glycoprotein of 839 amino acids (∼115 KDa, Fig. 1). LDL ligands are characterized as particles of ∼22 nm in diameter (∼2500 KDa) that comprise a core of ∼1500 molecules of cholesterol esters, esterified primarily by linoleic acid, encapsulated by a monolayer of free cholesterol, phospholipids, triglycerides, and a single large protein termed apolipoprotein B-100 (apo-B, ∼550 KDa). By recognizing the protein component of LDL, the LDLR enables cells in all tissues of vertebrate animals to internalize exogenous cholesterol, which is a key building block required for the biosynthesis of steroid hormones, bile acids, and cellular membranes. By interacting with the protein apolipoprotein B, which forms coated pits on the cytosolic face of the plasma membrane, the LDLR constitutively delivers LDL into endosomes, followed by cycling of the receptor back to the cell surface. Inherited mutations in the LDLR that disrupt endocytosis, and thereby increase serum LDL, have been shown to accelerate atherosclerosis in patients with familial hypercholesterolemia (17). Rapidly proliferating cells have a particularly high demand for cholesterol because mammalian plasma membranes are composed of one-third protein and two-thirds lipid plus ∼30% of the cellular plasma membrane lipids are cholesterol (20). For this reason, the LDL receptor is often overexpressed on cancer cells, and LDL receptors provide a target for the selective delivery of anticancer and tumor imaging agents (21, 22). The LDLR is also a portal exploited by Hepatitis C virus and other Flaviviridae viruses to penetrate into cells (23).

The transferrin receptor: a homodimeric transmembrane protein that enables cellular uptake of iron

Iron is an essential nutrient that functions as an enzyme cofactor in redox reactions and plays a structural role through ligand coordination. Under physiologic conditions, iron can be converted readily between the ferrous (Fe$^{2+}$) and the ferric (Fe$^{3+}$) oxidation states. However, ferrous iron is dangerous to living cells because it can generate hydroxyl radicals that oxidatively damage proteins, nucleic acids, and lipids. Additionally, iron in the ferric (Fe$^{3+}$) oxidation state forms a highly insoluble hydroxide complex that is not readily available to cells. In vertebrate animals, ferric iron is transported in serum bound to the protein transferrin (TF), which is a bilobed glycoprotein of 85 KDa in humans (Fig. 1; 10). This protein binds Fe$^{3+}$ using a synergistic anion, typically carbonate, two Tyr, one His, and one Asp residue. Cellular uptake of TF is mediated by the transferrin receptor (TFR, Fig. 1), which is a homodimeric transmembrane protein of BKDa in humans that binds two dfferent transferrin ligands. Internalization of TF by RME results in the release of Fe$^{3+}$ in acidic endosomal compartments. However, the apo-TF remains bound to TFR, the receptor-ligand complex cycles back to the plasma membrane, and apo-TF is released from the TFR at neutral pH. Ferric iron is reduced to the ferrous state within endosomes, and the iron transporter DMT1 delivers the Fe$^{2+}$ ion into the cytoplasm. Like the LDLR, the TFR is upregulated on certain cancer cell lines, and drugs conjugated to transferrin have been used as targeted delivery systems (5). In mice, the mouse mammary tumor virus exploits the TFR to enter cells (24).

### Receptors for Growth Factors and Hormones

Human growth hormone (GH1, Fig. 1), epidermal growth factor (EGF), insulin (INS), platelet-derived growth factor (PDGF), and many cytokines bind receptors that activate intracellular tyrosine kinase activity. The major isoform of GH1 is a protein of 191 amino acids (22 KDa) that functions in part to stimulate the growth of bone and internal organs in children. As shown in Fig. 1, the human growth hormone receptor (GHR), which is a member of the cytokine-hematopoietin receptor superfamily,
Receptor-Mediated Endocytosis

From left to right, X-ray crystal structures of the extracellular domains of the human LDL receptor, the human transferrin receptor, the human growth hormone receptor, bovine rhodopsin, and FcγRIIIB are shown illustrating the nature of attachment to the plasma membrane. A molecular model of the glycolipid ganglioside GM1 is on the far right. A structure of LDL determined by electron cryomicroscopy (27 Å resolution) is shown on the upper left (not drawn to scale; image courtesy of Dr. Wah Chiu, Baylor College of Medicine). Other ligands shown from left to right include receptor-bound transferrin, receptor-bound human growth hormone, receptor-bound Fc region of human IgG, and the B-subunit of cholera toxin.

comprises a transmembrane glycoprotein of 620 amino acids (130 KDa) (25). Binding of GH1 results in dimerization and conformational changes in the GHR that initiate cellular signaling via recruitment and activation of tyrosine kinases. The GHR is internalized constitutively via clathrin-coated pits, and both this receptor and its ligand are degraded by proteolysis in lysosomes, which provides a mechanism to terminate the extracellular signal. The receptors for EGF and insulin are receptor tyrosine kinases (RTKs) that become internalized only upon binding of ligands. The EGF family of RTKs includes EGFR (HER1, erbB-1), HER2 (erbB-2), HER3 (erbB-3), and HER4 (erbB-4). Upregulation of expression or the production of activating mutants of this family is known to cause several cancers (26). By binding its extracellular domain, the FDA-approved monoclonal antibody drug Herceptin downmodulates HER2, thereby inhibiting the proliferation of the subset of breast cancers that overexpress this receptor.

G-protein-coupled receptors

G-protein-coupled receptors (GPCRs), also known as seven transmembrane receptors (7TMs), are the largest known superfamily of proteins. They are involved in all types of responses to stimuli, from intercellular communication to the senses of vision, taste, and smell. They respond to diverse ligands ranging from photons (e.g., rhodopsin, Fig. 3) to small molecules (e.g., binding of epinephrine to the β-adrenergic receptor) and proteins (e.g., chemokine receptors). Binding of ligands to the extracellular or transmembrane domains of these proteins causes conformational changes that relay a signal to intracellular G proteins that trigger additional cellular responses. Many GPCRs undergo RME by binding to intracellular arrestin proteins that associate with clathrin. The importance of GPCRs in normal biologic processes and disease has made this family of proteins the target of up to 50% of all modern drugs.

Receptors anchored to the plasma membrane by lipids: Glycosylphosphatidylinositol (GPI)-anchored proteins and glycolipids

Some cell-surface receptors are attached to the plasma membrane by lipids that penetrate only into the outer leaflet of the bilayer. Posttranslational modification of proteins with GPI-lipids allows proteins such as folate receptor-2 (FOLR2) to attach to the cell surface and promote RME of the vitamin 5-methyltetrahydrofolate. Folate receptors are upregulated in certain cancers, and folate derivatives have been linked to drugs and molecular probes to treat and image certain tumors. The related GPI-linked receptor FcγRIIB (CD16, 26.2 KDa, Fig. 3) is involved in the immune response. This receptor binds the invariant Fc region of immunoglobulin-G to promote RME of this

Examples of receptors and ligands involved in RME. Specific gene symbols of representative human receptor and ligand proteins are listed in parentheses. TM: transmembrane protein; GPI: glycosylphosphatidylinositol anchored protein; 7TM: Seven-transmembrane protein.

ligands. Much smaller glycolipids also participate in RME. Ganglioside GM1 (Fig. 1), a 1.6 KDa glycolipid, enables the protein cholera toxin (16) and the nonenveloped virus SV40 to penetrate into cells upon binding to its pentasaccharide headgroup (27).

Because of the lack of a direct connection to clathrin via a cytoplasmic region, the endocytosis of GPI-linked proteins and other lipid-linked receptors is slower than the uptake of most transmembrane proteins. Instead of clathrin-mediated endocytosis, the internalization of many lipid-linked receptors has been proposed to involve distinct membrane subdomains termed lipid rafts (28). These domains are enriched in cholesterol and sphingolipids and in some cell types include flask-shaped invaginations termed caveolae (29, 30). Many proteins covalently or noncovalently associated with cholesterol, sphingolipids, and in some cell types include lipid rafts with segregation and concentration membrane proteins, regulate signal transduction pathways (31), and control the endocytosis of specific receptors (32). Protein toxins and viruses often exploit receptor-mediated endocytosis involving lipid rafts or clathrin to penetrate into the cell interior (4).

Receptor-Mediated Endocytosis Visualized by Confocal Laser Scanning Microscopy

Microscopy has been used extensively to investigate mechanisms of RME. Electron microscopy was instrumental in the identification of clathrin-coated pits, endosomes, and other cellular features involved in this process (33). More recently, confocal laser scanning microscopy of living cells has been employed to investigate the uptake of fluorescent ligands, the influence of molecular probes, and the localization of fluorescent receptors and other proteins during endocytosis. An example of RME as imaged by confocal microscopy is shown in Fig. 2. In this figure, Jurkat lymphocytes, a human helper-T cell line, were treated with a mixture of transferrin conjugated to the bright green fluorescent Alexa Fluor 488 and cholera toxin B-subunit conjugated to the red fluorescent Alexa Fluor 594. After treatment for 5 minutes, transferrin is internalized by its receptor substantially more rapidly than cholera toxin, which remains partially localized at the cellular plasma membrane. Uptake of these proteins results in delivery in part into distinct early endosomal compartments, which is consistent with significant differences in the mechanisms of endocytic uptake.
Receptor-Mediated Endocytosis

After 1 hour of treatment, fluorescent transferrin can be localized in early endosomes and the endosomal-recycling compartment, whereas the cholera toxin B-subunit distinctly traffics to the trans-golgi network of living cells. In cells treated with holo-cholera toxin comprising the B-subunit and the catalytic A-subunit, the toxin would traffic further to the endoplasmic reticulum, which would enable the release of the toxic A-subunit into the cytoplasm.

Mechanisms of Receptor-Mediated Endocytosis

Cell-surface receptors are involved in both phagocytosis and pinocytosis. At least four distinct mechanisms of pinocytosis have been characterized: macropinocytosis, clathrin-mediated endocytosis, raft/caveola-mediated endocytosis, and clathrin- and caveola-independent endocytosis (1). Selected receptor-mediated aspects of these mechanisms are outlined below.

Phagocytosis

Phagocytosis is an actin-mediated mechanism of RME predominantly employed by specialized cells such as macrophages, neutrophils, and monocytes (34). This process allows these cells to clear large pathogens, such as bacteria and yeast, or debris, such as the remnants of dead cells, or deposits of cholesterol and other lipids in arteries. Binding of specific cell-surface receptors to their ligands triggers phagocytosis. For example, Fc receptors on macrophages bind the Fc region of antibodies that coat surface antigens on pathogens or particles. These recognition events activate signaling cascades involving Rho-family GTPases, which triggers the actin-driven formation of membrane protrusions. The formation and collapse of these plasma membrane ruffles generate large endocytic vesicles, termed macropinosomes, with diameters of 0.5 to 2.5 \( \mu \)m. Constitutive macropinocytosis by dendritic cells allows the efficient capture of exogenous antigens; presentation on the cell surface bound to MHC molecules provides a mechanism for stimulation of immune responses (36). Macropinocytosis also may be involved in the downregulation of activated signaling molecules.

Clathrin-mediated endocytosis

Clathrin-mediated endocytosis (CME) is responsible for the uptake of about 50% of all ligands internalized by cell-surface receptors. This process is critical for the continuous uptake of nutrients, intercellular communication during development, and regulation of signal transduction throughout life. CME modulates cellular signaling by controlling the levels of cell-surface receptors and downregulating activated signaling receptors. CME affects cell and serum homeostasis by controlling the internalization of membrane pumps involved in the transport of ions and small molecules across the plasma membrane. In...
Receptor-Mediated Endocytosis

Figure 3  Pathways of endocytic trafficking of receptors and ligands. The model illustrates uptake of LDL mediated by the LDLR, diferric transferrin (TF-Fe3+) internalized by the transferrin receptor (TFR), and entry of cholera toxin (CTX) and simian virus-40 (SV40) after binding to ganglioside GM1. Related trafficking of glycosylphosphatidylinositol-anchored proteins (GPI-AP) is also shown. The LDLR and TFR concentrate in clathrin-coated pits and initially deliver ligands into endocytic vesicles that fuse with sorting endosomes. The acidic environment of sorting endosomes dissociates most receptor–ligand complexes, and membrane proteins typically exit these compartments rapidly and return directly to the plasma membrane or are shuttled to the endocytic recycling compartment (ERC or recycling endosome). LDLRs and TFs are recycled from the ERC back to the cell surface. LDL is sorted to late endosomes and lysosomes, where it is degraded and releases cholesterol and amino acids into the cell. TF-Fe3+ releases iron in the acidic sorting endosome, but under acidic conditions, iron-free TF remains bound to the TFR. Upon return to the cell surface, at neutral pH, iron-free TF dissociates from the receptor. Binding of CTX and SV40 to GM1 primarily results in endocytic uptake via uncoated pits and caveolae, respectively. Internalized GPI-APs, CTX, and SV40 traffic through either the GPI-anchored protein-enriched early endosomal compartment (GEEC) or a related compartment termed the caveosome. SV40 moves from the caveosome directly into the endoplasmic reticulum (ER). In contrast, CTX exits the GEEC and passes through the trans-Golgi network to the ER. From the ER, CTX and SV40 penetrate into the cytosol, resulting in toxicity or infection, respectively. The t1/2 values shown are approximate and are cell-type dependent.

neurons, CME promotes the uptake of voltage-gated ion channels, which affects the strength of synaptic transmission, and it is involved in the recycling of membrane proteins of synaptic vesicles after neurotransmission. The protein clathrin comprises 190-KDa and 25-KDa subunits that form a basket-like structure on the cytoplasmic face of the plasma membrane. These subunits assemble as complexes with adapter proteins into highly ordered polygonal arrays that define pits on the cell surface. When clathrin-coated pits invaginate and pinch off, they form clathrin-coated vesicles (CCVs) with a diameter of ~120 nm. Assembly of a CCV in cultured cells takes ~1 minute, and hundreds to a thousand or more can form every minute. Clathrin-mediated endocytosis is the best-characterized mechanism of ligand uptake, and interactions of clathrin with receptors such as LDLR and TFR result in clustering of receptor–ligand complexes in clathrin-coated pits (Fig. 3). The LDLR and TFR interact with clathrin via adapter proteins such as the autosomal recessive hypercholesterolemia (ARH) protein and AP-2, respectively, but the LDLR also interacts directly with clathrin (37). GPI-APs are linked to clathrin via an adapter-like protein, β-arrestin, which interacts with AP-2. Specific peptide sequences bind adapter proteins and couple receptors to the clathrin-controlled endocytic machinery. The best-defined coated pit internalization signals are the tyrosine-based FxNPxY (F = phenylalanine, x = any amino acid, N = asparagine, P = proline, and Y = tyrosine) motif found in the LDLR, the YxΨ1ø motif of the TFR, and a dileucine motif of the insulin and β2-adrenergic receptors (1). Internalization of LDL and transferrin is a constitutive and rapid clathrin-mediated process. However, binding of other ligands, such as EGF to EGFR or epinephrine to the β2-adrenergic receptor, induces internalization via clathrin (32). Expression of dominant negative mutants of dynamin, the AP-2 binding partner Eps15, and its binding partner epsin have been used to inhibit CME and to identify mechanisms controlling receptor-mediated endocytosis.

Receptor–ligand complexes clustered in clathrin-coated pits are internalized when the plasma membrane invaginates, GTP-driven conformational changes of dynamin trigger membrane...
EGFR and GPCRs, ubiquitination of receptor lysine residues is for use by the cell (18, 38). For some receptors, such as the other components of LDL in lysosomes liberates these nutrients drolytic enzymes. Hydrolysis of cholesteryl esters, protein, and lysosomes, more acidic organelles (pH the cell surface, they can become internalized on binding of Although caveolae are considered relatively static structures on caveolins and lack these morphological membrane features. the pit. Lymphocytes and many neuronal cells do not express proteins of the caveolin family on the cytoplasmic face of cell types, including adipocytes, endothelia, and muscle cells. These lipid rafts can be observed by electron microscopy as distinctive flask-shaped pits of ~60 nm in diameter and include proteins of the caveolin family on the cytoplasmic face of the pit. Lymphocytes and many neuronal cells do not express caveolins and lack these morphological membrane features. Although caveolae are considered relatively static structures on the cell surface, they can become internalized on binding of ligands to receptors that associate with these raft subdomains. After activation, caveolae are internalized with relatively slow kinetics (half-life ~ 20 min) compared with CME (1).

In cells bearing caveolae, binding of simian virus-40 (SV40) to ganglioside GM1 in these subdomains triggers internaliza-
tion into compartments termed caveosomes. This DNA virus subsequently undergoes trafficking to the endoplasmic reticu-
lim, which is a destination that allows escape into the cytoplasm through an unknown mechanism, before the virus enters the nu-
cleus. In line cells lacking caveolae, other lipid raft domains are thought to promote delivery into distinct compartments termed GPI-anchored protein early endosomal compartments (GEECs) (37). For example, binding of chlorella toxin to ganglioside GM1 results, at least in part, in uptake through uncoated pits and in trafficking to the GEEC through the trans-golg network even-
tually to the ER, where a catalytically active fragment can escape into the cytosol and exert toxic effects. Chlorella toxin, however, is not a specific marker for raft-mediated endocyto-
sis; this protein is known to be internalized by three distinct mechanisms: clathrin coated pits, caveolae, and a clathrin- and caveolin-independent pathway (40). The mechanism that cou-
ples recognition of the glycolipid on the outer leaflet of the membrane to the clathrin machinery on the inner leaflet is un-
known. The relationship between lipid rafts and clathrin is also not yet well defined. For example, the EGFR is internalized through a mechanism that seems to simultaneously involve both lipid rafts and clathrin (41). Mechanisms of endocytosis that are independent of both clathrin and caveolin are not well under-
stood.

Receptor-mediated endocytosis via caveolae and other mechanisms

Lipid raft microdomains of mammalian plasma membranes are thought to regulate the endocytosis of specific ligands (32, 39). These domains are envisaged to comprise islands of or-
dered cholesterol, sphingolipids, and saturated lipids that move within the plane of disordered unsaturated lipids. The forma-
tion of lipid rafts depends on the availability of cholesterol in the membrane, and agents that sequester cholesterol, such as niacinamide, can selectively disrupt these microdomains. Dominant negative mutants of dynamin also block endocy-
tosis via this mechanism. GPI-anchored receptors, such as FcγRIIIB and folate receptors, and glycolipids, such as gan-
glioside GM1, are thought to reside in lipid rafts and become internalized at least partially by caveole mediated and clathrin-
independent/caveolin-dependent endocytic pathways. Caveolae represent a subset of lipid rafts found on specific cell types, including adipocytes, endothelia, and muscle cells. These lipid rafts can be observed by electron microscopy as distinctive flask-shaped pits of ~60 nm in diameter and include proteins of the caveolin family on the cytoplasmic face of the pit. Lymphocytes and many neuronal cells do not express caveolins and lack these morphological membrane features. Although caveolae are considered relatively static structures on the cell surface, they can become internalized on binding of molecular and cellular probes of receptor-mediated endocytosis

Molecular and Cellular Probes of Receptor-Mediated Endocytosis

Small molecules, proteins, and genetic constructs that activate, block, or label specific endocytic components or pathways represent key tools for studies of RME. Representative examples of probes of RME and related cellular processes are provided in Table 2. An overview of these approaches is provided in the following subsections.

Small-molecule regulators of phagocytosis and macrophagy

Many compounds that perturb the cellular cytoskeleton affect phagocytosis and macrophagy. Binding to actin filaments by the natural product cytochalasin D blocks both of these up-
take mechanisms. Disruption of microtubules by the antimitotic agent colchicine and nocodazole inhibits macrophagy and affects some mechanisms of phagocytosis. The diuretic drug amiloride, which is an inhibitor of Na+/H+ antiporters, selec-
tively blocks macrophagy. By activating protein kinase C, phorbolesters represent a class of small molecules that promote macrophagy.

Examples of small molecules, altered cell culture conditions, proteins, and genetic constructs used to probe RME. CID: chemical inducer of dimerization.

Small molecules and modified cell culture conditions that block CME

Clathrin-mediated endocytosis can be blocked by several pharmacologic inhibitors, including the antipsychotic drug chlorpromazine (Thorazine), the natural product ikarugamycin, and the antiviral drug amantadine. The metabolic poisons phenylarsine oxide and sodium azide also block CME but additionally inhibit protein synthesis. Culture of cells under conditions that deplete potassium or calcium, treatment of cells with hypertonic sucrose, or acidification of the cytoplasm by addition of acetic acid to media, have also been used to block this mechanism of cellular uptake. However, many of these treatments tend to be relatively nonspecific and inhibit multiple cellular uptake processes. To block selectively dynamin-dependent endocytic mechanisms, a small molecule termed dynasore has been identified as a specific inhibitor of dynamin (42). Another strategy for inhibiting CME with high specificity uses a chemical inducer of dimerization (CID) combined with a genetic approach to promote aberrant oligomerization of clathrin in cells transfected with a clathrin fusion protein. This system can rapidly and reversibly inhibit 70% of the endocytosis of TFR (43).
Inhibitors of raft/caveolin-mediated endocytosis

Lipid raft domains of plasma membranes are enriched in cholesterol and sphingolipids. As a consequence, compounds that extract or sequester cholesterol, such as β-cyclodextrins, nystatin, and filipin, can block selectively endocytosis of cholera toxin, GPI-linked proteins, and other receptors that associate with lipid rafts and caveolae. However, cholesterol is also critical for CME, secretion of proteins, and the actin network. Therefore, conditions designed to affect selectively raft-mediated endocytosis by perturbing cholesterol levels must be carefully controlled to avoid disrupting other mechanisms of endocytosis (40).

Small-molecule probes of other endocytic trafficking pathways

Phosphatidylinositol-3-0H kinase [PI(3)k] plays an important role in the fusion of endosomes. Phosphatidylinositol-3-phosphate [PI(3)P], a product of this enzyme, is enriched in early endosomes, and blocking PI(3)k activity with the small molecule wortmannin prevents endosome fusion. This fungal natural product has been shown to inhibit the endocytosis of transferrin, horseradish peroxidase, and albumin (44, 45).

Fluorescent probes of endocytosis

Fluorescent small molecules and proteins represent powerful tools for labeling ligands, receptors, and other targets involved in endocytosis. By conjugating ligands of receptors to fluorophores, the uptake of these molecules can be analyzed by fluorescence microscopy, flow cytometry, and other methods. Small-molecule fluorophores have been installed through site-specific protein labeling on modified cell-surface receptors, such as TFR (46), NK1 (47), and EGFR (48), which are expressed in transfected cell lines. Studies of trafficking of the TFR/TFR complex that combine site-specific protein labeling with analysis by fluorescence resonance energy transfer (FRET) have demonstrated that this method is a powerful tool for studying endocytosis and exocytosis (46).

Green fluorescent protein (GFP) and related fluorescent proteins can be used to label practically any protein or subcellular compartment of living cells (49). Transfection of cells with plasmids that encode appropriately targeted fluorescent fusion proteins has been used to define the plasma membrane, early endosomes, late endosomes, caveolae, the golgi complex, the ER, and other subcellular locations. Several fluorescent small molecules are also available for labeling specific cellular organelles, including endosomes and lysosomes, for analysis by fluorescence microscopy.

Antibody probes and regulators of endocytosis

Immunofluorescence techniques are often used to identify specific cellular targets, including proteins, involved in endocytosis. However, because antibody reagents are not cell permeable, cells typically must be fixed or microinjected to allow binding to intracellular proteins. For example, microinjection of antibodies against clathrin (50) and dynamin (51) has been used to block CME. However, because of their cell impermeability, antibody reagents are limited in studies of dynamic cellular processes (52).

Genetic approaches for targeting specific components of endocytic pathways

Genetic methods, such as the expression of dominant negative proteins and RNA interference (RNAi), represent some of the most highly specific approaches for studies of endocytosis. Dominant negative mutants of clathrin, dynamin, Eps15, and other components of the endocytic machinery have been used widely to probe endocytic pathways. More recently RNAi has emerged as an important new tool for downregulating specific targets, including clathrin, AP-2, and epsin (53). Although these genetic methods have the potential to inactivate proteins in cells with a high degree of specificity, they also have associated limitations. For example, RNAi against clathrin heavy chain and AP-2 can suffer from cross-reactivity with other endocytic pathways (54). Another disadvantage of RNAi is that it can require several days to eliminate the targeted protein, which allows the activation of alternative compensatory mechanisms. The identification of temperature-sensitive alleles that result in inactivation of a specific protein at a defined temperature can also provide powerful tools for studies of dynamic cellular processes such as RME. However, these systems can be difficult to implement in mammalian cells.

Synthetic Mimics of Ligands and Receptors

Mimics of ligands and receptors have been used to promote the endocytic uptake of drugs, proteins, DNA, and other cell-impermeable molecules. Ligands linked to cargo of interest can often access efficiently the cell interior via binding to internalizing cell-surface receptors. Modified natural cell-surface receptors and small synthetic mimics of receptors have been shown to promote the uptake of specific ligands via RME. Examples of mimics of ligands and receptors are shown in Fig. A.

Cellular uptake of cargo conjugated to ligands of internalizing receptors

Numerous ligands of cell-surface receptors have been linked to cell-impermeable macromolecules, drugs, and other cargo for delivery into mammalian cells. Macromolecular ligands modified in this way include transferrin (5), LDL (22), growth factors, and antibodies that bind the extracellular domains of cell-surface receptors. An example of an FDA-approved drug that functions in this way is mylotarg, which is a monoclonal antibody drug that comprises the anticancer agent calicheamicin linked to a humanized antibody that binds the CD33 antigen on myeloid leukemia cells (55). Binding of mylotarg to CD33 results in endocytosis of the antibody drug conjugate, release
Receptor-Mediated Endocytosis

Figure 4 Examples of mimics of ligands and receptors used to deliver cargo into cells. (a, b) Ligands such as folate can be linked to macromolecules (e.g., nucleic acids and proteins) and small molecules (e.g., drugs, radiochemicals, and fluorophores) to promote cellular uptake. (c) Peptides and small molecules linked to $N$-alkyl derivatives of $3\beta$-cholesterylamine or $3\beta$-dihydrocholesterylamine mimic cell-surface receptors by cycling rapidly between the plasma membrane and the intracellular endosomes. The synthetic Fc receptor shown in (c) enables treated mammalian cells to internalize human IgG.

of calicheamicin in endosomes, escape of the drug into the cell nucleus, and antiproliferative effects against targeted cells.

The vitamins folate (vitamin B9) (56, 57) and cobalmin (vitamin B12) (58) have been investigated as vehicles for delivery of impermeable molecules into cells. By binding with high affinity ($K_d \sim 10^{-10} M$) to folate receptors, folate-linked drugs, radio-pharmaceuticals, nucleic acids, and nanoparticles can become internalized by RME. Similarly, transcobalamin receptors bind and promote the endocytosis of cobalamin and cobalamin conjugates complexed to soluble transcobalamin (59). This approach has been used to target selectively tumor cells that overexpress these receptors.

Artificial cell-surface receptors

Synthetic mimics of cell-surface receptors have been constructed using plasma membrane anchors derived from $N$-alkyl-3$\beta$-cholesterylamine and related compounds (14). Synthetic receptors comprising protein and other binding motifs linked to this membrane anchor become incorporated rapidly into plasma membranes of mammalian cells. By constitutively cycling between the plasma membrane and the endosomes, cells treated with these compounds gain the capacity to endocytose cell-impermeable ligands. For example, the synthetic Fc receptor shown in Fig. 4 enables human cells that lack Fc receptors to internalize human IgG (60). This strategy, termed synthetic receptor targeting, seems to mimic the initial steps of uptake of cholera toxin mediated by ganglioside GM1. This approach may have applications as a method for drug delivery (61).

A related strategy, termed cellular painting, has been used to incorporate proteins linked to GPI lipid anchors into cellular plasma membranes (62, 63). This approach has been used to study cellular signaling, plasma membrane organization, and immunologic responses to modified cell surfaces. Because GPI-linked proteins undergo raft-mediated endocytosis, Jurkat lymphocytes treated with a GPI-linked variant of the immunoglobulin Fc receptor FcγRIII will endocytose ligands that bind this receptor (64). Single-chain antibodies covalently linked to lipids have also been used to construct related cell-surface receptors (65).

Metabolic cell-surface engineering to promote the endocytic uptake of ligands

Metabolic cell-surface engineering has been used to modify carbohydrate components of cell-surface receptors and to enable endocytic uptake of impermeable ligands (66). By feeding cells unnatural sugars, cellular metabolism can be harnessed to display bioorthogonal functional groups, such as ketones and azides from glycoproteins and glycolipids, on cell surfaces. The reaction of these ketones with hydrazine derivatives to yield
Future Research Directions

Molecular and cellular probes of RME

The molecular mechanisms controlling CME are beginning to be characterized. However, other mechanisms of RME, particularly those involving lipid rafts, caveolae, and other pathways, are less well understood. Although genetic methods such as RNAi and expression of dominant negative proteins represent important tools for inactivating key players in endocytic pathways, the delayed cellular response associated with many of these approaches can allow compensatory gene expression or other mechanisms that can complicate the analysis. Because small molecules can inactivate rapidly defined protein targets, the identification of highly specific inhibitors of proteins involved in RME may provide the best tools for studying the molecular mechanisms of this process. Screens based on “composite synthetic lethality” are particularly promising for the identification of small molecules that target specific membrane trafficking pathways (69).

Mimicry and modifications of ligands

Mimics of ligands that bind cell-surface receptors and undergo RME are becoming an increasingly important class of targeted therapeutics. For example, folic acid derivatives show substantial advantages of green fluorescent and related fusion proteins, including their high molecular weight and relatively low intrinsic brightness as well as the reaction of azides with modified phosphines in the Staudinger ligation (68), can immobilize molecules on the cell surface and promote delivery of proteins such as the toxin ricin (67).

Several inorganic chemical elements play fundamental roles in biological processes. The contribution of inorganic chemistry to the understanding of biological processes is presented here from a historical perspective: from the first discoveries of metal ions in living organisms to the modern approaches of inorganic structural biology and bioinformatics, through the characterization of metal binding sites in proteins and in biomimetic model compounds. Definitions are provided for the fundamental concepts of metal cofactor, metalloprotein, and metalloenzyme.

The importance of inorganic chemistry for chemical biology is based on the distribution of the elements of the periodic table in living organisms, which is summarized in Fig. 1. Amino acids, nucleic acids, carbohydrates, lipids, organic cofactors (e.g., ATP, ADP, and NADH), and metabolites are composed of the six bulk biological elements: carbon, hydrogen, nitrogen, oxygen, phosphorus, and sulfur. The chemistry of these elements in living systems is the subject of classic biological chemistry. However, it has been established that at least 20 elements other than C, H, N, O, P, and S are essential for life, even though they are considered generally “inorganic” (Fig. 1). The first metal-containing species identified in living systems were pigments such as chlorophylls and hemoglobin, whose discovery dates back to the nineteenth century. To complement the work aimed at the chemical characterization of these molecules, several studies showed that some metal ions, such as zinc and iron, are essential for life. Hemoglobin, myoglobin, and cytochromes were among the first biological macromolecules to be investigated at the molecular level because of their abundance in living organisms and their intense color, which eased their detection. Nevertheless, it was only in the second half of the twentieth century that the contribution of inorganic chemistry to the characterization of biological systems translated into a well-defined discipline, named bioinorganic chemistry (and later also called biological inorganic chemistry). The establishment of this new branch of science paralleled advancements in spectroscopic tools, in structural methods, and in the development of inorganic chemistry as the chemistry of coordination compounds. This ensemble of approaches has provided momentum and has given great impetus to the characterization of the binding mode of metal ions in biological macromolecules and to the understanding of their reactivity. Two primary approaches have guided the study of metal binding sites in proteins: 1) the synthesis and characterization of model compounds and 2) the direct characterization of metalloenzymes and metalloproteins.

Metal Cofactors

Typically, metal ions are cofactors that function as catalytic centers in several fundamental biological reactions, play a role in electron transfer reactions, or impart structural stabilization to the macromolecular fold. Proteins offer such a large variety of metal binding sites associated with widely disparate functions that biological inorganic chemistry focuses primarily on the study of metal ions in proteins. Other areas of research in the field include the metal–RNA and metal–DNA interactions. However, these aspects are not addressed here, as the chemistry largely electrostatic in nature. On the contrary, the ability of proteins to bind metal ions is related essentially to the presence of amino acid side chains that can act as metal ligands. Figure 2 represents the possible binding modes of these side chains. In some cases, the coordination geometry of the metal ion is completed by exogenous ligands such as H₂O or OH⁻, or by protein backbone amides or carbonyls.

Traditionally, when the association between the metal ion and the protein is relatively strong (i.e., binding constant higher than 10⁸ M⁻¹) the complex is called a metalloprotein. When the protein is performing catalytic activity at the metal center, it is called a metalloenzyme.

Although the different sequences and folds of proteins provide the most disparate metal binding sites (some examples of which are provided in Fig. 3), Nature has evolved to select other organic or inorganic ligands for metal ions in proteins, which we call "special metal cofactors." These cofactors can be grouped into two broad classes: tetrapyroles and metalloclusters.

Tetrapyroles are macrocyclic ligands that provide a common skeleton to hemes (that contains iron), chlorophylls (that contains magnesium), corrinoids (that contains cobalt), siroheme (that contains iron), and methanogenes factor F430 (that contains nickel).
Iron-porphyrins are a widespread group of tetrapyrroles present in heme proteins (1). They are all derived from protoporphyrin IX, but they have different substituents (Fig. 4). The so-called heme b coincides with protoporphyrin IX. Heme o differs from heme b by the presence of a farnesylhydroxyethyl group at position 2, and it differs from heme a by the presence of a farnesylhydroxyethyl group at position 2 and a formyl group at position 8. In heme c, the two vinyl groups are substituted with thioether bridges that involve sulfhydryl groups of protein cysteine residues, which results in two covalent linkages between the porphyrin and the protein matrix. Heme P460 can be viewed as a c-type heme with an additional covalent bond between the \(\alpha\)-meso position and a \(C_\varepsilon\) of a nearby tyrosine ring. Heme d, heme d1, and siroheme have unconjugated pyrrole rings. The common oxidation states for iron in heme proteins are +2 and +3, although the iron(IV) = 0 moiety
Metalloclusters consist of at least two metal ions associated with inorganic and/or otherwise nonprotein ligands. Binuclear centers in which the metal ion ligands are composed of H₂O/OH⁻ ligands in addition to amino acid side chains are excluded from the definition of a metallocluster. Several metalloclusters have been characterized structurally in metalloproteins. Among the most abundant metalloclusters are those of the iron-sulfur family (2, 3). Iron-sulfur clusters are characterized by iron ions that exhibit almost exclusively tetrahedral coordination to donor sulfur atoms, provided by either Sγ of cysteines or by bridging sulfides (sometimes called inorganic sulfurs). Metalloproteins contain basic cluster types with two, three, or four iron ions, as depicted in Fig. 5. In this figure, the mononuclear iron center of rubredoxin is shown: This iron center is not a cluster but can be considered as the “prototype” of the tetrahedral iron units that constitute the Fe₅S₅ clusters. The simplest type of iron-sulfur cluster is represented by the diamond structure of the Fe₂S₂ center, in which the two iron ions are coordinated to two bridging sulfides. Each iron is then bound to two Cys or two His ligands (the latter in the case of Rieske proteins, Fig. 5). The Fe₅S₅ unit is constituted by four iron ions and four sulfide ions arranged in a cubane structure. A gain, the tetra-coordination of each iron ion is accomplished on binding of the sulfur of a Cys protein residue. The Fe₅S₅ cluster seems to be derived from the Fe₅S₅ cluster by the removal of one iron. Rubredoxins are electron transfer proteins in which the iron oxidation state cycles between +3 and +2. In the clusters, the number of potential oxidation states increases with the number of metal ions. Assuming that each iron can exist formally in the ferric and ferrous states, an iron-sulfur cluster with n iron can exhibit a maximum number of n + 1 oxidation states. Nevertheless, only a few oxidation states have been observed in proteins. For instance, in Fe₂S₂ systems, only two of the possible three oxidation states are found: the one that contains two ferric ions [i.e., the (Fe₂S₂)⁺ state] and the one that contains one ferric and one ferrous ion [(Fe₂S₂)⁺]. This type of cluster is typical of electron transfer proteins or of electron transfer centers in multidomain redox metalloenzymes. The Fe₅S₅ cluster in which the iron coordination is completed by two Cys per iron is present in ferredoxins.

In recent years, X-ray crystallography has led to the discovery of several novel metalloclusters of complex architecture that contain at least four metal ions (4, 5). They represent the active site of several redox enzymes that contain molybdenum, nickel, and manganese, as well as the most commonly encountered iron and copper (Fig. 6). These enzymes are extremely specialized in the oxidation or reduction reactions of the smallest molecules and anions (which include N₂, CO, and H₂). A common feature of such clusters is that they are present in enzymes as part of a more extensive electron transfer chain that involves a series of
metallocenters (often heme and iron-sulfur centers) that serve to carry electrons into and out the active site. For several of them, extensive spectroscopic and functional studies are required to unravel oxidation states, substrate binding sites, and reaction mechanisms at these sites.

The first and second coordination sphere modulates the reactivity of metal ions so that the functional roles of a given ion may be largely different, as summarized in Table I. A good example of the effects of the first and second coordination sphere on modulating the reactivity of metal cofactors in proteins is provided by heme proteins (1). Heme-iron in heme proteins can be five-coordinate or six-coordinate. Axial ligation seems to be related strongly to protein function. Six-coordination (His/His or His/Met) is typical of cytochromes and electron transfer proteins in which the heme iron has to cycle between the iron(III) and the iron(II) oxidation states for its function. Usually, penta-coordination is found in globins that bind oxygen and in redox heme-enzymes. In globins, the imidazole ring of the “proximal” His residue provides the fifth heme iron ligand; the other axial heme iron position remains essentially free for O₂ coordination. In heme-enzymes, the His has a sixth coordination position is available for substrate binding. The basicity of the fifth (or proximal) His ligand modulates the redox potential of the heme iron. In peroxidases, the His has a strong imidazolate character because of a strong H-bond between the Nδ₁ of the imidazole ring and a nearby Asp residue; this bond facilitates the higher oxidation states for the heme iron (6). The resting state of these enzymes contains iron(III), and higher oxidation states are reached during the catalytic cycle. In globins the His is essentially neutral, with a weak H-bond between the imidazole and a backbone carbonyl, and these proteins are commonly in the iron(II) state.

Model Compounds

The discovery of metal centers in metalloproteins has stimulated inorganic chemists to synthesize compounds capable of mimicking the spectroscopic and functional properties of the protein metal cofactors. Biomimetic model compound chemistry has flourished since the 1970s, when several advantages existed in the study of the model compound instead of the protein itself. The much smaller size of the model compound made it more suitable for biophysical studies, and advancements in chemical synthesis offered opportunities to play with ligands and metal geometries. Some notable examples of the synthetic analog approach deal with iron-porphyrin model compounds (and metalloporphyrins in general) (7), iron-sulfur clusters (3), and model compounds aimed at reproducing the unusual spectroscopic and electrochemical properties of blue copper proteins (8). In more recent times, synthetic models have been developed to reproduce the characteristic features of the binuclear Cu₄ electron-transfer center of cytochrome c oxidase (9) (Fig. 3e), of high-nuclearity MoFe₅S₇ clusters of the cofactors of nitrogenases (10) (Fig. 6a), and of the Cu₄ center of nitrous oxide reductase (11) (Fig. 6b).

Today, the advancements in spectroscopic, structural, and biological tools make it easier than ever before to study metal centers in their biological context. As a consequence, the impact of model compounds has been reduced; although from an inorganic point of view, biological metal centers may represent a synthetic challenge and are relevant for science beyond their importance as model compounds.

The synthetic approach is also suffering from the intrinsic difficulties encountered in the design of ligands capable of mimicking the secondary coordination sphere effects and...
Inorganic Chemistry in Biology

Figure 6. (a) The FeMo-cofactor of nitrogenases: The overall stoichiometry is MoFe$_7$S$_9$, and it can be viewed as a MoFe$_3$S$_3$ cluster and a Fe$_4$S$_3$ cluster, bridged by three sulfides. The molybdenum is also bound to a homocitrate molecule. (b) The C-cluster of carbon monoxide dehydrogenase: This can be viewed as a Fe$_4$S$_4$ cluster bridged to a binuclear Ni-Fe center. (c) The oxygen-evolving center of photosystem II: A cubane-like Mn$_3$CaO$_4$ cluster is linked to a fourth Mn ion (Mdh) by a µ-oxo bridge. (d) The tetranuclear Cu$_Z$ center of nitrous oxide reductase: Three of four copper ions bind two His, the fourth binds a single-His, and it has been suggested that it represents the substrate coordination site.

Biogeochemical Cycles

The second half of the twentieth century has observed the illustration of many of the central reaction steps and enzymatic catalysts of biogeochemical cycles, which led to the discovery of key complex cofactors that contain transition metal ions. Indeed, the key catalysts in the global cycles of oxygen (13, 14), nitrogen (15–18), carbon (19–24), sulfur (25–32), and hydrogen (33, 34) are redox metalloenzymes that contain unique metal cofactors. The cycles are represented in Figure 7 and describe the natural transformations of several "inorganic" molecules and ions. The biogeochemical cycles of C, O, N, S, and N are interlinked intimately. The O$_2$ produced in the oxygen cycle serves as an oxidant for the reduced compounds of C, N, and S by both biological and human activities. H$_2$ is a key carrier to reduce equivalents in the anaerobic world. The full understanding of these enzymatic mechanisms represents a challenge for biological inorganic chemistry at present.

The occurrence of metalloproteins

Between 1995, when the first genome (H. influenzae) was sequenced and, when the first draft of the human genome was published, a revolution in the approach to the study of gene products (i.e., proteins) occurred. This revolution has led to so-called post-genomic research. Genome sequencing projects provide researchers with lists of all the proteins that an investigated organism can produce and their amino acid sequences. From a bioinorganic point of view, however, the question is which proteins need a metal ion to perform their physiologic function. This question is fundamental, and the answer cannot be derived from genomic information alone. Bioinformatic tools have been developed to identify metalloproteins in genome databanks (35–37). This method relies on the exploitation of known metal binding-patterns (MBPs), which are available experimentally from the three-dimensional structures deposited in the protein data bank. MBPs are strings of the type A$.X$.B$.X$.C...$, where A, B, C... are the amino acids that act as metal ligands, and n, m... are the number of amino acid residues in between two subsequent ligands. Gene banks are then browsed to search for MBPs and primary structure.
Inorganic Chemistry in Biology

Figure 7  Simplified global biogeochemical cycles. (a) Combined C and O cycles. The biomass formed by photosynthesis can be transformed anaerobically by bacteria and fungi to produce small C-containing molecules such as CO, CO\textsubscript{2}, formate, and acetate. These products can be transformed (anaerobically) into methane by archaea. CH\textsubscript{4} can then be converted aerobically into CO\textsubscript{2}. (b) The hydrogen cycle, with the indication of the nature of the metal centers at the catalytic site of the involved enzymes. (c) The sulfur cycle. The top part of the external cycle (thick arrows) summarizes the key steps of aerobic sulfide oxidation; the bottom part summarizes the steps of sulfate respiration. Thiosulfate, trithionate, and tetrathionate may also represent possible intermediates for this cycle. The inner cycle describes the cycling between HS\textsuperscript{-} and S\textsuperscript{0} performed by different organisms with respect to those involved in the outer cycle. The thin arrows that connect SO\textsubscript{2}\textsuperscript{2-}, H\textsubscript{2}SO\textsubscript{3}\textsuperscript{-}, and H\textsubscript{2}S represent the essential steps of an assimilatory pathway. (d) The nitrogen cycle. Denitrification is the anaerobic use by certain bacteria of nitrogen oxide species (NO\textsubscript{3}\textsuperscript{-}, NO\textsubscript{2}\textsuperscript{-}, NO, and N\textsubscript{2}O) as terminal electron acceptors instead of O\textsubscript{2}. The final product N\textsubscript{2} is released into the atmosphere; therefore, the process is referred to as dissimilatory. The nitrogen fixation reaction is carried out by the enzyme nitrogenase. The lower part of the cycle represents the assimilatory nitrate reduction that leads to the incorporation of reduced nitrogen species into biomass. The upper part of the cycle describes the nitrification process (i.e., the oxidation of reduced nitrogen compounds in the presence of oxygen).

Such an approach has been used successfully to identify all zinc, nonheme iron, and copper proteins. The human genome encodes approximately 2800 zinc-proteins, 250 nonheme-iron proteins, and 100 copper-proteins. These figures correspond to 10%, 0.8% and 0.3% of the human proteome, respectively. Corresponding averages for five eukaryotes of known genome sequence are 8.8%, 1.1%, and 0.3%, respectively and for 40 selected bacterial organisms are 3.9%, 4.9%, and 0.3%, respectively.

Metal homeostasis

It is well established that for each metal ion a dose-dependent effect exists (Fig. 8). Still, the optimal concentration for healthy organisms should not be considered as the concentration of the free metal ions, which is generally extremely low, but rather as the concentration of the metal ions bound to proteins and other metal ligands. The way in which organisms uptake and control the trafficking of metal ions has attracted the attention of researchers in recent times (38–40). This research has led to the identification of several metallochaperones. No established molecules that serve this function were known before 1997, but today metal trafficking pathways have been identified for metal ions such as copper, manganese, and zinc, although at different degrees of understanding. The comprehension of such processes requires the identification of the proteins involved in metal uptake; transfer and incorporation into the final metallo-enzymes; and identification at the molecular level of the factors that control the specificity, selectivity and efficiency of the mechanisms. Even essential elements, at high concentrations, can become toxic. Organisms have developed mechanisms to detoxify from nonessential metal ions or from excess of essential metal ions.
(40): The study of these pathways is another aspect of the quest to understand metal homeostasis.

**Metal-based drugs**

A special application of inorganic chemistry to biological problems concerns the use of metal-containing compounds as therapeutic or diagnostic agents. The greatest success of metallotherapeutics dates back to 1978, when cisplatin was first approved to treat clinical testicular and urinary tumors after the discovery in 1965 that cisplatin inhibits cell division (41). The biological target of cisplatin is DNA, where its primary binding site is the major groove N7 of guanine. The bending and local unwinding of the DNA double helix induced by cisplatin binding causes the loss of important structural motifs to recognize and to process damaged DNA. The need for a new anticancer drug that can overcome the limitations of cisplatin (high toxicity, activity against a wider range of cancer types, resistance to cisplatin after repeated treatment) has prompted chemists to develop new generation platinum drugs or compounds that contain different metal ions (e.g., palladium, ruthenium, gallium). Metal complexes are also employed to treat other diseases, for example gold(I) compounds are used as antiarthritic drugs.

Metal complexes are used largely in imaging and diagnostics. Several radiolysis products of metal ions (e.g., Ga, In, Tl, Tc) are suitable as radiodiagnostic and radiomaging agents. Finally, gadolinium (III) compounds are largely used as contrast agents for magnetic resonance imaging because of the effectiveness of this metal ion to relax H2O protons.

**Perspectives**

It is clear from the discussion of metal homeostasis that the full characterization of a protein requires not only its study in the isolated form but also the investigation of its relevant interactions. Therefore, the interactions of metal-binding proteins with small molecules and other proteins are an obvious perspective in biological inorganic research. This implies the importance of the identification and structure characterization of weak protein–protein complexes that represent the key steps of the biochemical processes discussed here. Moreover, metal-mediated protein–protein interactions are just beginning to be identified and will become an important field of research.

Nature: A Model System for Chemists

Ronald Breslow, Department of Chemistry, Columbia University, New York, New York
doi: 10.1002/9780470048672.wecb378

Chemists have learned to imitate the principles of biologic chemistry in the quest to produce artificial enzymes, artificial receptors, and, ultimately, artificial living cells. The field of natural products chemistry is concerned chiefly with discovering the structures of the molecules produced in living systems as well as the paths by which they are produced. Biomimetic chemistry takes nature as a model and extends what exists in biology into what is possible. This process includes using hydrophobic effects in water to achieve selective reactions and making new amino acids and new nucleotides to generalize the properties of proteins and nucleic acids. Potent new catalysts are based on the chemistry performed by coenzymes using bifunctional acid–base catalysis and the water exclusion achieved by natural enzymes. Exciting new areas include molecular machines, mimics of the chemical senses, and work on the origin on earth of the homochirality observed in biomolecules. The studies using nature as a model have enriched chemistry greatly and furnished interesting insights into biochemistry.

Since the beginning of time, people have learned about the world by observing nature and by imitating aspects of what we have learned. This observation is true particularly of what we see in living creatures. For example, people observed birds and insects in flight and dreamed of being able to fly. Our most important clue was wings. We adopted this idea in the successful invention of airplanes. However, birds and insects power their flight by flapping the wings; this concept proved less useful. Nature has limitations, and one of them is that a powered propeller—and even more so a jet engine—were not practical for living creatures. Thus, we did not mimic birds slavishly; we adopted the central idea of their ability to fly and added ways to power the flight that nature could not achieve. As Philip Ball said (1): “A jumbo jet is not just a scaled up pigeon.”

Chemists have also taken many lessons and inspirations from natural chemistry; but, again, they have adapted their ideas so as not to be limited by the special requirements of natural chemistry. For example, nature designs proteins in three dimensions by folding linear polypeptide chains. This design indicates that genetic information is one dimensional, as is the sequence of nucleotides in genes. Although it might be interesting to use such a scheme in a mimic of an enzyme, chemists generally plan and then synthesize their three-dimensional structures, an option not open to nature.

Natural Products

In this brief article, I will focus on the ways we have learned from the chemistry of the life process itself. However, I must first call attention to another part of natural chemistry that has an effect on chemical thinking: the field called the Chemistry of Natural Products. Chemists have explored nature and have discovered several special types of chemicals: sugars, fats, terpenes, alkaloids, acetogenins, amino acids, heterocyclic coloring matters, macrocyclic lactones, steroid hormones, and so on. These compounds have been produced by living organisms and they are secreted by or isolated from them. This field is concerned with the substances of nature and the biochemical processes by which they are formed.

Chemists have devoted much effort to exploring this natural world of chemistry as well as to determining structures; the natural world has stimulated the extension of the chemical world into models and analogs of the natural chemicals. The field of organic chemistry was influenced heavily by the types of chemical structures found in natural products; many medicinal compounds are still invented by using natural products as models for analogs. Chemists have also invented important polymers once nature showed us the natural polymeric carbohydrates, polypeptides, nucleic acids, and the polymers such as rubber that are produced from natural materials.
Biomimetic chemistry

The field concerned directly with imitating the chemistry of life processes has been called biomimetic chemistry or bio-inspired chemistry. The two terms differ in how close the mimic is to the natural process. As the author of this article, I will favor biomimetic, a word I coined (3).

Chemistry in water

A most important difference between human-made chemistry and living chemistry is that the latter occurs in water. Most chemical processes use organic solvents, which dissolve the components better; but water has special properties that are appreciated increasingly. Most significantly, the hydrophobic effect in water is the force that causes membranes, micelles, and liposomes to form, which pushes hydrocarbon chains together to diminish the high-energy hydrocarbon/water interface. The hydrophobic effect is also a major reason that hormones bind to receptors and substrates bind to enzymes, and it causes the folding of polypeptide chains into the three-dimensional structure of proteins by promoting the clustering of hydrocarbon side chains in the protein interior away from water.

Chemists now use water as a solvent for synthetic reactions, which takes advantage of the selectivities that the hydrophobic effect can induce (4). Many enzyme mimics (vide infra) also use water as the medium to promote substrate binding into the catalyst. Of course, water as a solvent also has important environmental advantages over volatile organic solvents. It remains to be seen how much impact the special properties of water as a solvent will have within chemical synthesis and manufacturing.

Molecular recognition and self-assembly

Small molecules such as hormones and allosteric effectors can bind to proteins selectively — including enzymes — and can modify their properties. Indeed, such binding is a common mechanism for the regulation of biologic effects; living cells do not simply run all processes as rapidly as possible. These natural processes have engendered a biomimetic field of molecular recognition and self-assembly, in which chemists develop such selective binding systems for analysis and as part of molecular devices. As mentioned above, medicinal chemists invent new molecules to bind to important receptors and enzymes, which imitate the natural ligands.

Proteins are assembled in living cells from amino acids, guided by the information in DNA that is passed on through RNA. Generally, chemists are inspired to generalize and extend such natural processes. A particularly interesting example is the synthesis of unnatural amino acids and the development of ways in which they can be incorporated into new kinds of proteins by modifying the biologic protein synthesis machinery (5). Some of these novel protein types promise to have new useful properties.

Nature appreciation

Another kind of generalization of natural chemistry involves viewing the natural chemistry in context by observing how well other related structures could perform the function of their natural models. In other words, why were these particular biologic molecules selected? A good example is the study of generalized forms of DNA.

In one example, some of the heterocyclic bases were modified drastically and were replaced by substituted benzene rings, and yet the base-pairing process of DNA was still observed (6). In other studies, the deoxyribose of DNA was replaced by other sugars, in some cases with an improvement in binding properties (7). As such, the 2-deoxyribose in DNA was replaced by the isomeric 3-deoxyribose to observe how the binding properties were affected (8). Interestingly, the resulting isoDNAs did not pair well with their isoDNA partners, or with the normal DNA partner that had the appropriate base sequences. This result clarified why 2-deoxyribose was selected for DNA even though the 3-deoxy isomer could be formed more easily under prebiotic conditions. However, the isoDNA base did pair well with its conjugate RNA, which furnishes insight into the difference between DNA–DNA pairing and DNA–RNA pairing (9).

The coenzyme thiamine pyrophosphate (1) plays a central role in many parts of metabolism (Fig. 1). Its mechanism of action involves the formation of a thiazolium zwitterion 2 that was stabilized by a carbene resonance form 3 (10). This discovery opened up studies of the chemistry that such “stabilized carbene” could catalyze, as chemists realized that the otherwise impossible chemistry that thiamine pyrophosphate catalyzes in nature could be generalized and adapted for useful synthetic processes.

However, another study was an example of nature appreciation—the structure of thiamine was varied to learn what was special about the particular thiazolium derivative that was natural thiamine (11). As a chemical catalyst—ignoring the question of what effect changes would have on the ability of the coenzyme to bind to the proteins that have evolved to use it—thiamine proved to be the optimal relative to other related structures because of a balance of catalytic ability and chemical stability. The anion 4 derived from an imidazolium ring instead of a thiazolium ring was a weaker catalyst but was more stable in water (10). The imidazolium anion and its dihydro derivative have proven to be very useful metal ion ligands, including...
Enzymatic selectivity involves geometric control

Enzymes operate by different rules than we normally use in synthetic chemistry. In nonenzymatic reactions, the intrinsic reactivity of the substrate dominates the chemistry. If we want to reduce a ketone, an aldehyde group in the same molecule will be more reactive. To obtain selectivity for the ketone group, we would need to block the aldehyde somehow. Moreover, if we want to oxidize a saturated carbon to form an alcohol, usually we would find the product alcohol oxidizes more readily, so the final product would be a ketone or aldehyde. Also, if we want to oxidize an isolated saturated carbon, a carbon–carbon double bond better not exist in the molecule or it would oxidize more readily. Generally, our synthetic procedures involve blocking such side reactions in some way. Enzymatic reactions have no such problems.

In the enzyme that oxidizes lanosterol to convert it ultimately to cholesterol (Fig. 2, three unactivated methyl groups are oxidized, whereas two double bonds and a secondary carbonyl are left untouched initially. This selectivity reflects geometric control in the enzyme, and it is perhaps one of the strongest lessons that chemists have learned from nature. The enzyme binds the substrate in such a position that the oxidizing group of the enzyme, an iron oxo species, can reach the hydrogens on the inactivated methyl groups but cannot reach the more reactive double bonds or secondary carbonyl (it is oxidized at some point later to permit decarboxylations, but then reduced again).

This general principle has inspired chemists to create enzyme mimics that perform biomimetic reactions that are also directed by geometric control (13). Selective attack on particular carbons of steroid substrates occurs as a function of the geometry imposed by binding, as in the enzyme. In one example, a carbon–carbon double bond was left untouched whereas a saturated inactivated carbon was oxidized, as in natural enzymes (14).

Of course, enzymes use geometry to control not only positions of reaction in a substrate but also selectivity in the formation of chiral centers and selectivity among substrates. It is fair to say that chemists were inspired to develop ways to produce optically active compounds as single enantiomers by observations of reaction in a substrate but also selectivity in the formation of chiral centers and selectivity among substrates. If we want to oxidize a saturated carbon to form an alcohol, usually we would find the product alcohol oxidizes more readily, so the final product would be a ketone or aldehyde. Also, if we want to oxidize an isolated saturated carbon, a carbon–carbon double bond better not exist in the molecule or it would oxidize more readily. Generally, our synthetic procedures involve blocking such side reactions in some way. Enzymatic reactions have no such problems.

In the enzyme that oxidizes lanosterol to convert it ultimately to cholesterol (Fig. 2, three unactivated methyl groups are oxidized, whereas two double bonds and a secondary carbonyl are left untouched initially. This selectivity reflects geometric control in the enzyme, and it is perhaps one of the strongest lessons that chemists have learned from nature. The enzyme binds the substrate in such a position that the oxidizing group of the enzyme, an iron oxo species, can reach the hydrogens on the inactivated methyl groups but cannot reach the more reactive double bonds or secondary carbonyl (it is oxidized at some point later to permit decarboxylations, but then reduced again).

This general principle has inspired chemists to create enzyme mimics that perform biomimetic reactions that are also directed by geometric control (13). Selective attack on particular carbons of steroid substrates occurs as a function of the geometry imposed by binding, as in the enzyme. In one example, a carbon–carbon double bond was left untouched whereas a saturated inactivated carbon was oxidized, as in natural enzymes (14).

Of course, enzymes use geometry to control not only positions of reaction in a substrate but also selectivity in the formation of chiral centers and selectivity among substrates. It is fair to say that chemists were inspired to develop ways to produce optically active compounds as single enantiomers by observing how nature produces single enantiomers of amino acids and sugars, and essentially every natural compound that can exist as two enantiomers. Again, the secret in enzymatic reactions is geometric control of the processes where the chiral centers are produced because of the geometry of the enzyme-substrate complex. Such enantiomeric selectivity is the target of much modern synthesis.

A particular example from our laboratory is observed in compound 5, in which a basic amino group held rigidly on a mimic of the coenzyme pyridoxamine phosphate is able to convert ketoacids to amino acids with high enantioselectivity (15). This reaction is modeled closely to the way in which transaminase enzymes achieve the same goal.

Enzymes can perform bifunctional acid–base catalysts

Any enzymes use coenzymes to achieve the detailed transformations they catalyze, but the enzyme proteins themselves also supply important elements of the catalysis. Enzyme proteins are the source of the entire catalytic effect when coenzymes are not involved. As a common process, acid and base groups in enzymes perform proton transfers that are critical to the catalytic mechanism. A particularly informative example is observed in the enzyme ribonuclease A, which catalyzes the cleavage of RNA (16). The catalytic process (Fig. 4) involves the imidazole ring of the amino acid histidine that removes the proton from the 2-hydroxyl of the ribose. A different protonated histidine transfers a proton to the RNA to promote the cleavage process. Studies with D2O–H2O mixtures established that the two proton transfers occur at the same time (17).

This reaction taught chemists the importance of simultaneous bifunctional catalysis, if it can be achieved. To avoid entropy problems, such bifunctional catalysts should have both catalytic groups in the same molecule, which are held in the correct position to participate in the simultaneous process. In ribonuclease A, the curling up of the peptide chain brings histidine-12 and histidine-119 close enough to let them participate in this way, even though they are separated by over 100 residues in the peptide chain. In a second step of the biologic process, the cyclic phosphate produced in the first step is hydrolyzed by the enzyme, again using the same two histidine side-chain imidazole groups.

We created a mimic of the cleavage of the cyclic phosphate by this enzyme by attaching two imidazole groups to a cyclodextrin molecule in well-defined positions (18). In water, the cyclodextrin bound a cyclic phosphate substrate—net, however, one derived from RNA—and performed the cleavage of the cyclic phosphate by using the two imidazoles as the enzyme does. That is, one functioned as a base, which delivered water...
to the phosphorus, and the other one, protonated, which functioned as a proton donor group in the hydrolysis reaction. The best catalyst in this process was one in which the proton was delivered to the phosphate anion group, which formed a five-coordinate phosphorane intermediate. In a subsequent fast step, this went to the final hydrolysis product, with the proton ending up on the OH group that is formed in the hydrolysis.

We also examined the reaction rate in different mixtures of D$_2$O and H$_2$O, and we saw that the proton transfers were simultaneous, not sequential (19). Remarkably, the detailed data were almost identical with those observed in the enzyme process, which raised the question of whether the enzyme also used a mechanism proceeding through a five-coordinate phosphorane intermediate, rather than going to the ring-opened product directly. We examined another biomimetic system to explore this question.

We studied the reaction of a tiny fragment of RNA, uridyldine 6, catalyzed by high concentrations of imidazole buffer (20) (Fig. 5). This buffer imitated the imidazole and imidazolium groups of the enzyme. In the enzyme, the effective concentration of these groups is high because of substrate binding right next to them. The products of the buffer-catalyzed reaction were uridine 7 and uridine cyclic phosphate 8, just as in an enzymatic cleavage process. However, we also saw that the buffer catalyzed an isomerization of the phosphate diester 6—originally attached to the 3-oxygen of uridine—to an isomer 9 in which it had migrated to the 2-oxygen.

The chemistry of phosphate reactions, and in particular the nonequivalence of the five groups in a phosphorane, requires that such a migration proceed through a phosphorane intermediate that undergoes pseudo-rotation to permit the migration (21). Our other kinetic studies made it clear that the cyclization process went through the same phosphorane intermediate.

We have proposed that the normal enzymatic hydrolysis process also proceeds through such a phosphorane intermediate, but isomerization does not occur because pseudo-rotation is not permitted in the enzyme (22). Complete agreement does not exist with our proposal (23). In this case, the biomimetic model system was not based only on nature’s enzyme; it pointed to possible aspects of the natural enzyme that had not been considered previously. Thus we had learned something from nature, and we returned the favor by learning something that could give insight into nature itself.

**Water exclusion by enzymes**

Natural enzymes are large molecules, which raised the question of what particular advantages such large catalytic systems could have. This question stimulated Klotz and Suh to study large synthetic polynucleotides as enzyme mimics (24). The compounds, derived by polymerizing aziridine, are available commercially in various sizes and with different degrees of polydispersity. Klotz and Suh used a large polyaziridine with extensive cross-links, and in some cases they added alkyl chains to form a hydrophobic region. In his independent research, Suh pursued this area, examining other polymers as well such as polystyrene (25). Also, Hollfelder et al. examined this system quantitatively and concluded that there was a medium effect in the polynucleotides with added hydrocarbon chains (26).
Generally, their studies involved hydrolytic and fragmentation reactions. We took up the study of such systems as mimics for transaminase enzymes and showed with the polyaziridines that we achieve very large accelerations of the conversion of ketocids to amino acids (27). This result reflected several ways in which these polyamines mimic enzymes.

First of all, transaminations involve many steps in which protons are added and subtracted from the reacting species and the reaction intermediates. In enzymes such as ribonuclease, normally imidazoles are used to perform such proton transfers. Their pKas are close to the operating pH for the enzyme, which makes them both the strongest base and the strongest acid that can exist in free form. A stronger base would be protonated by the medium and a stronger acid would be deprotonated. It can be shown that the catalytic result of increased acid or base strength does not make up for the loss of concentration of the free acid and base species.

The polyaziridines have their nitrogens so close to each other that they titrate over the range of pH 13 to pH 3, so they are half-protonated at pH 8 and have the strongest base and acid groups possible, just as in enzymes that use imidazole with a pK near neutrality. Of course the polyaziridines achieve this not with special basic groups, just with the effect of neighboring charges that make it harder to add more positive charge.

We also saw that the potency of the polyaziridines as enzyme mimics was increased strongly when hydrophobic chains were added to some of the nitrogens (described in Refs. 24–27 and 28–30), which was evident in two ways. First of all, with the hydrophobic core that these chains produced, we achieved strong binding in water solution of ketocids that carried hydrophobic components. The binding was much better, as reflected in a Michaelis K_m for indolepyruvic acid— that produced tryptophan on transamination— than for pyruvic acid that produced alanine, which is not surprising. Perhaps more interestingly, the hydrophobic chains increased the rate constants significantly for reaction of the complex (28), which reflects a medium effect that is invoked often for natural enzymes. Water is to some extent an enemy of rate because acids, bases, and substrates often need to lose their bound waters to react. In nature, this problem is solved by performing the reactions in the hydrophobic interior of the enzymes away from the external water. The hydrophobic chains in our enzyme mimic performed the same function, which excluded water from the reaction site.

The transformations themselves involved reactions of ketocids with a pyridoxamine unit, either covalently attached to the polymer or reversibly bound to the hydrophobic core (29), which converted the ketocids to amino acids, and the pyridoxamine was converted to a pyridoxal unit either covalently attached to the polymer or reversibly dissociated from the polymer. This reaction was modeled directly on the transamination process observed in natural enzymes. However, the second part of a full transamination in nature is the reaction of the pyridoxal with a different amino acid, which runs the transamination backward to form the pyridoxamine again while converting the new amino acid into its corresponding ketocid. We found that such a process was too slow in our biomimetic system and could not compete with the rapid aldol condensation of the ketocids with the pyridoxal.

To solve this problem, we used a mimic of a different enzyme, dialkylglycine decarboxylase (30). In this enzyme, pyridoxal phosphate reacts with an alpha-disubstituted glycine to perform an irreversible decarboxylation (Fig. 6) while converting the pyridoxal species to a pyridoxamine. We imitated this with our model transaminations using pyridoxal species that carried hydrophobic chains, and we were able to achieve as many as 100 catalytic turnovers. Thus, we could imitate one enzyme—the ordinary transaminases—by also imitating another enzyme that solved the turnover problem.

As we read more about disubstituted glycines, we learned that some such species are delivered by carbonaceous chondritic meteorites, and with partial enantioexcesses. This information offered a clue as to how biologic homochirality could have originated on earth (see below).

The mechanism used in the oxidative decarboxylation of alpha disubstituted glycines by an enzyme, which, in mimics, solved the problem of converting pyridoxal species to pyridoxamine species in biomimetic transaminase systems.
Cells as organized chemical systems

A living organism is more than just a collection of enzymes and other important species—it is an organized collection. The components of the cell are compartmentalized into organelles such as the nucleus, and the cell is structured additionally by internal and external membranes. This powerful type of system still waits to be fully mimicked.

Molecular machines

Living systems can convert chemical energy into mechanical motion. The most obvious examples are the motion in muscle contraction and the motion exhibited by flagella in bacteria and in sperm cells. These models from nature have stimulated a few chemists to try to mimic such properties with promising results (31, 32). We do not yet know what practical benefits such mimics will bring, but the creation of molecular machines by imitating those in nature is an exciting adventure. It is part of the fundamental change that chemistry itself is undergoing. Instead of being concerned only with the properties of pure chemical substances, the chemistry of the future will be concerned with the properties of organized multimolecular systems. It is an exciting prospect, which is stimulated by our observation of the wonderful properties of nature’s organized multimolecular system: the living cell.

Energy from sunlight

Nature performs a process, called photosynthesis, that is of great interest to chemists and that has stimulated several attempts to model it. Many ideas about the future sources of energy on earth involve the large amount of energy that sunlight delivers. Fossil fuels—petroleum and coal—are derived from plants that stored chemical energy derived from sunlight and the animals that ate those plants. Although producing artificial photosynthesis is a more practical way to obtain energy than “letting nature do it” with growing plants, however the details of photosynthesis still wait to be fully mimicked.

During photosynthesis, an electron of chlorophyll is pumped to a higher energy orbital by light absorption while a hole is created in the orbital that contained the electron previously. In photosynthesis itself, the excited electron produces the biological reducing agent required for the chemistry of photosynthesis, while also generating phosphate anhydrides such as ATP. Meanwhile, the hole from a second chlorophyll—whose photoreacted electron fills the hole in the electron-deficient first chlorophyll—picks up an electron from the oxidation of water, which generates molecular oxygen. However, biologic photosynthesis requires water and carbon dioxide; water in particular is in demand for many other uses. Thus, it is more appealing for human energy generation from sunlight to use the combination of an excited electron and a hole to produce an electrical current, to use the photovoltaic effect. This process does not consume water, so it can be carried out in deserts without competing with agriculture. Many scientists are now trying to produce practical photovoltaic devices. Perhaps not always consciously modeled in nature, the processes do involve the same step as in photosynthesis—the photoassication of an electron.

The chemical senses

Among biologic organisms, the ability to detect specific chemicals in the environment is universal—to find food, to avoid danger, and to find receptive mates. In higher animals, this ability is lodged to some extent in the sense of taste, but it chiefly occurs in the sense of smell. One of the most baffling aspects of such chemical senses is the ability of animals to detect, selectively, substances that were created newly by chemists. How could the genetic code produce a specific receptor for every possible compound, with compounds numbering in the millions and with more continually being created? The solution to this puzzle by nature, brilliantly discovered by Axel (33) and Buck (34) in their Nobel Prize-winning work, was multiplexing. In principle, a finite group of receptors could react to a compound, but not all with the same strength of reaction. Thus a fingerprint was created, which reflects the different strengths of reaction of each receptor to the chemical. Every chemical, old or new, could elicit a different pattern of such signals and thus be perceived differently.

Eric Arndt (35) has mimicked and adapted this principle for the detection and analysis of chemicals in a nonbiologic application. This principle promises the same ability to detect a great range of chemicals by using a multiplexed group of chemical detectors; but the different strengths of signals this group are transmitted to a computer, not to a brain.

The origin of life on earth

Nature has inspired chemists to mimic not just the details we understand, but also some important details about which we can only speculate. Chemists are making major efforts to understand how life could have begun on earth. Nature has presented us with the puzzle, in the form of biology as it now exists.

The L amino acids in proteins, the D carbohydrates, the nucleic acids, all are found to be homochiral, as observed as a single enantiomer. When the opposite enantiomers are found in biology, they are used for different functions, such as the D amino acids in some bacterial cell walls. Ordinary chemical reactions that create a new chiral center from optically inactive precursors normally produce a racemic mixture unless some chiral catalyst is present to direct the process. How did it get started before chiral catalysts such as enzymes were present?

Various theories exist, but one with considerable support takes note of the fact that some meteorites have brought to earth amino acids that are partially enantiomeric, with 3–15% enantiomeric excess of the L-amino acids (36). They are not normal amino acids, but they have a methyl group on the alpha carbon in place of the usual hydrogen so they cannot racemize. It is believed that they are formed as racemates in interstellar space, but then are deacetylated partially by circularly polarized light emitted by synchrotron processes at neutron stars.

Chemists have been inspired to study how these partially enantiomeric “seeds” could induce the formation of normal biologic molecules—amino acids and carbohydrates—under credible prebiotic conditions (36, 37), and unpublished work). Furthermore, chemists have been inspired to research how low levels of enantiopurity can be amplified into high levels—such
as a 95 to 5 ratio of L-phenylalanine starting with only a 50.5 to 49.5 ratio—under credible prebiotic conditions (38, 39).

Such studies—and others attempting to understand how spontaneous chemistry in the primitive earth could have formed living cells—are not directed indirectly by information about how life originated, but they are inspired by nature as we see it, which is populated as it is by life forms. The work does not aim to show how life originated, which is an historical question. However, it tries to develop the scientific evidence that can support a reasonable hypothesis of how it may have started.

**Artificial life**

A rather important goal of modern chemistry is directly inspired by nature: the hope to produce artificial life, or at least some systems that share many of the attributes of life. The ultimate goal of biomimetic chemistry is to mimic life itself, not in the form that it now has but in alternate forms. Chemists have generalized so many types of substances—novel polymers, novel carbohydrates and amino acids, novel hormones and enzyme inhibitors—that to generalize natural chemistry is one of their most characteristic activities. Can they generalize life itself? Time will tell.

**Other authors**

A good fraction of modern chemistry, which includes medicinal chemistry, derives some of its inspiration from a consideration of nature as a model. It is impossible, in this brief article, to describe more than a fraction of the efforts. For additional work in the spirit of biomimetic chemistry, the following is a list of some authors not yet mentioned whose independent work should be consulted. Even here, this list is certainly not complete: Jacqueline Barton, Steven Benkovic, Albrecht Bickle, Stephen Buchwald, Donald Cram, Peter Dervan, Francois Diederich, Berkessel, Thomas Bruice, Jik Chin, Jean Chmielewski, E. Matta, VC, Grubbs RH. Ruthenium(II) methathesis catalysts bearing an N-fluorophenyl-N-methyl-substituted unsymmetrical N-heterocyclic carbene. Organometallics 2007;26:2469-2472.

Physical Chemistry in Biology

Alan Cooper, WestChem Department of Chemistry, Glasgow University, Glasgow, Scotland, United Kingdom

doi: 10.1002/9780470048672.wecb451

Physical chemistry is that area of science that attempts to describe the properties and processes of matter in terms of underlying physical laws. Biology is no exception to these laws. This introductory article briefly sketches the role played by traditional physical chemistry in analyzing and understanding the behavior and control of biologic processes, focusing mostly on the molecular level. Thermodynamics and kinetics place restrictions on the kinds of reactions and processes that can take place as well as on how fast they occur. Electrochemistry, a branch of thermodynamics that deals with charge transfer processes, underpins much of redox biochemistry and membrane phenomena. Spectroscopy gives rise to a wealth of experimental techniques for structural and functional analysis, while quantum chemistry lurks in the background.

Thermochemistry and Thermodynamics

Thermodynamics is the area of science that relates to the interplay of heat and other forms of energy. At the molecular level, this science describes the balance between two generally opposing thermodynamic forces: the natural tendency for mechanical systems to move toward lower energies and the equally natural tendency for thermal Brownian motion to perturb this mechanical order. For open systems at constant pressure, this balance is expressed by the classic Gibbs free energy change (∆G):

\[ \Delta G = \Delta H - T \Delta S \]

Physical chemistry is the area of science that attempts to describe the chemical properties and processes of matter in terms of the underlying physical laws that govern the molecular world. It is a subject of enormous breadth that underpins most areas of science and technology, that lies at the very diffuse interface between physics and chemistry, and that consequently has important ramifications in biology. Throughout history, investigations of physical and biologic phenomena have been closely associated. Scientists, the "natural philosophers" of previous generations, were rightly curious about all aspects of the natural world, with none of the restrictive demarcation issues between "physical" and "biologic" sciences that came later.

Physical chemistry is that area of science that attempts to describe the chemical properties and processes of matter in terms of the underlying physical laws that govern the molecular world. It is a subject of enormous breadth that underpins most areas of science and technology, that lies at the very diffuse interface between physics and chemistry, and that consequently has important ramifications in biology. Throughout history, investigations of physical and biologic phenomena have been closely associated. Scientists, the "natural philosophers" of previous generations, were rightly curious about all aspects of the natural world, with none of the restrictive demarcation issues between "physical" and "biologic" sciences that came later.

Thermodynamics is the area of science that relates to the interplay of heat and other forms of energy. At the molecular level, this science describes the balance between two generally opposing thermodynamic forces: the natural tendency for mechanical systems to move toward lower energies and the equally natural tendency for thermal Brownian motion to perturb this mechanical order. For open systems at constant pressure, this balance is expressed by the classic Gibbs free energy change (∆G):

\[ \Delta G = \Delta H - T \Delta S \]

The objective here is to describe how the traditional field of physical chemistry applies to the study of biology, specifically to provide a broad and relatively nontechnical introduction for nonspecialists. However, a comprehensive description of the role of physical chemistry in biology is a mammoth task that cannot possibly be tackled adequately in a short article such as this. Consequently, I shall simply attempt to give a broad overview from the point of view of a former physicist, now physical chemist, working toward the physical understanding of biomolecular processes. I shall follow the traditional headings, such as might be found in conventional physical chemistry texts (some are listed below in Further Reading, but almost any standard text in any edition will do—like London buses, another one always comes along soon!) and shall note particular relevance to biologic systems, with a few specific examples and associated remarks as we proceed. This approach will be entirely unsatisfactory for most readers who require more detail, but it should act as an aide-memoir stimulating interest in additional details that may be found elsewhere in this volume.

Thermodynamics is the area of science that relates to the interplay of heat and other forms of energy. At the molecular level, this science describes the balance between two generally opposing thermodynamic forces: the natural tendency for mechanical systems to move toward lower energies and the equally natural tendency for thermal Brownian motion to perturb this mechanical order. For open systems at constant pressure, this balance is expressed by the classic Gibbs free energy change (∆G):

\[ \Delta G = \Delta H - T \Delta S \]
where $\Delta H$ is the change in “enthalpy” or heat content that describes changes in internal kinetic and potential energies of all molecules in the system, corrected for any pressure-volume work done on or by the surroundings during the process; $T$ is the absolute temperature (K or eV); and $\Delta S$ is the change in entropy of the system.

It is convenient (although sometimes confusing) to express the equilibrium constant ($K$) of a chemical process in terms of the “standard Gibbs free energy change”, $\Delta G^\circ = RT \ln K$, where $R$ is the universal gas constant. The standard Gibbs free energy change is the hypothetical free energy change for the process in which the reactants and products are imagined to be present in (arbitrarily) “standard states.” In solution, for example, the convention in (most of) chemistry is to adopt a standard-state concentration of 1 M (1 mole per liter) for all reacting species. This convention is clearly a long way from reality for biochemical systems, especially for reactions involving hydrogen ($\text{H}^+$) ions, so an alternative convention is frequently adopted here with $[\text{H}^+] = 10^{-7}$ M to reflect more closely the near-neutral pH of most biologic processes.

Under any conditions, the actual free energy change depends on concentrations of reactants and products:

$$\Delta G = \Delta G^\circ + RT \ln Q$$

where the reaction quotient, $Q$, is a quantity rather like the equilibrium constant, $K$, but involves the actual concentrations pertaining to the system rather than concentrations when it has reached equilibrium.

For example, for a hypothetical reaction $A + B \rightarrow C + D$ with $K = [C][D]/[A][B]$ compared with

$$Q = \frac{[C][D]}{[A][B]}$$

where $[A]$, $[B]$, $[C]$, and $[D]$ are the actual concentrations, compared with what they would be ($[A]^\circ$ $[B]^\circ$ $[C]^\circ$ and $[D]^\circ$) if the system was at thermodynamic equilibrium, in which case $\Delta G = 0$. (Note that in more rigorous treatments, one should replace concentrations with activities. The activity is related to concentration, but corrected for the nonideality that occurs from interactions not accounted for elsewhere in the analysis. This distinction can be significant for macromolecules in crowded environments inside living cells.)

Such basic thermodynamic considerations are essential to understanding biomolecular energetics. The $\Delta G$ places fundamental constraints on the amount of work (mechanical, chemical, electrical, etc.) that may be done by or on a system under ideal conditions. It follows from the above that any chemical reaction or process away from equilibrium can act as a source of free energy. The prime example here is the way that biology makes use of adenosine triphosphate (ATP) and its hydrolysis to ADP, as a ubiquitous free energy currency. ATP is produced during by a wide range of catabolic (energy-producing) reactions such as glycolysis, and its hydrolysis is coupled to free energy transcription in most molecular machines that drive living processes—muscle contraction, flagellated motion, cell division, membrane pumps, nerve signals, and so forth. Yet perhaps surprisingly, and in contrast to much ill-informed speculation about “high energy phosphate bonds,” the hydrolysis of ATP is not particularly energetic: The standard free energy of hydrolysis ($\Delta G^\circ$) of ATP to ADP and inorganic phosphate (about -35 kJ mol$^{-1}$) at physiologic pH is relatively small compared with many chemical reactions, and actual free energy values will, in any case, depend on the relative concentrations of all reactants and products and the extent to which they are away from equilibrium. Rather, it would seem that it is the relative ease with which ATP synthesis and hydrolysis can be coupled to the biomolecular energy transduction machinery that has led to its ubiquity. Despite considerable advances in determining the molecular structures of many enzymes and other proteins involved in this machinery, no consensus view yet exists as to how ATP hydrolysis and work are linked at the molecular level. Thermodynamics is a harsh taskmaster here, and proposed mechanisms need to satisfy these fundamental constraints. As the fictional Homer Simpson once said: “In this house we obey the laws of thermodynamics.”

In statistical thermodynamics, the Gibbs free energy ($G$) is related to the statistical probability (p) of finding the system in a particular state: $G = -k_B T \ln p$, where $k_B$ is the universal Boltzmann constant. Consequently, changes in Gibbs free energy ($\Delta G$) tell us about the relative probabilities that processes will occur in the absence of other interventions: Reactions with a positive $\Delta G$ involve transition to a less likely (smaller p) state and, therefore, are unlikely to occur of their own accord; however, reactions with a negative $\Delta G$ involve transition to a more probable state (larger p) and may proceed. Technically, the latter are said to be thermodynamically “spontaneous” processes—a term that can lead to confusion because many such processes, although thermodynamically feasible or spontaneous, will be limited by kinetic barriers and may not take place on a reasonable timescale.

The Boltzmann statistical definition of entropy, $S = k_B \ln W$, shows how this quantity, often expressed as a measure of “disorder” in a system, is more rigorously defined in terms of the number of ways ($W$) in which a system might adopt a particular energy. It follows that in a molecule system, the higher the energy, the greater the number of ways to partition that energy among the various forms of kinetic (translation, rotation, vibration, etc.) and potential energies. As a consequence, systems with high entropy (larger W) tend to be more likely, overall. For closed systems, such as the entire universe for which the total energy is constant, therefore, the total entropy must always be increasing ($\Delta S > 0$). However, for regions within such a system that can exchange energy with their surroundings, this mandatory increase is not necessarily the case, and it is the Gibbs free energy described above that determines the way things proceed. Obviously, this occurrence is relevant to living systems that, at first sight, seem to violate the rule of increasing W (or S). However, in the wider context, the flux of energy through such systems contributes to the whole, and thermodynamics remains ineluctable. Such concepts of nonequilibrium thermodynamics and dissipative structures have been
a major development in twentieth-century physical chemistry (1, 2).

One consequence of this statistical view of thermodynamics must play a significant role in our understanding of processes that involve biologic macromolecules (3–4–5–6–7). Although normally insignificant for macroscopic objects, thermally induced fluctuations in structural and thermodynamic properties of mesoscopic systems—systems between microscopic and macroscopic, typically relating to objects a few nanometers in size—such as individual proteins or other macromolecules, will be crucial to their function. (Mesoscopic: intermediate between micro- and macroscopic, typically relating to objects a few nanometers in size.) A dramatic illustration of this importance, first highlighted by Max Perutz (8), comes from the structures of the oxygen carrier proteins myoglobin and hemoglobin. Structures for these molecules were among the first to be determined by the emerging techniques of protein crystallography, and they were a major breakthrough in structural biology. Yet these high resolution structures immediately revealed a puzzle. In the (static) X-ray pictures, the oxygen-binding centers are buried deep inside the globular protein structure, with no apparent pathways within the protein structure through which individual oxygens may flow. Incidentally, this discovery also resolves another paradox, because burial of the oxygen-binding iron (heme group) within the fluctuating structure allows binding of O2 to take place with exclusion of water, which would otherwise facilitate irreversible oxidation (“rusting”) of the iron.

At a more basic level, measurements of the energetics of biochemical processes and their couplings to metabolic processes, following the rules of thermodynamics, underpin our understanding of how organisms can function. This understanding operates at all levels, from the “calorific value” of foodstuffs in nutritional biochemistry and food science to the coupling of ATP synthesis/hydrolysis to hydrogen ion gradients (the “proton-motive force” or “chemiosmotic” principle (9)) at one extreme, to entire ecosystems at the other (10). Experimental physical chemistry has played a role here from the very beginning by supplying the calorimetric tools to measure heat and related thermodynamic quantities in biologic systems and organisms. Indeed, one of the first quantitative applications of calorimetry was the use by Lavoisier of his ice calorimeter in the late eighteenth century to measure metabolic heat from a guinea pig, which established the crucial link between respiration and combustion. More recently, advances in instrumentation have led to the widespread use of microcalorimeters for the determination of biomolecular thermodynamics and, much more generally, as a generic analytic technique. It is now possible to measure directly the heat effects associated with noncovalent processes in quite dilute biomolecular systems (11).

Kinetics

Thermodynamics describes what could possibly happen at equilibrium. Kinetics tells us how fast we are getting there. The world around us, including the subset that we call biology, is never at thermodynamic equilibrium. Living organisms succeed because of the very careful way in which the rates of biochemical processes are controlled. Consequently, the study of kinetics has had a major impact on biologic science.

Catalysis and control is crucial here. For a chemical reaction to take place, it is generally necessary that the molecules collide in the correct orientation and with sufficient energy to overcome the activation energy barrier \(E_A\), which leads to reaction products. This reaction is encapsulated in the classic empirical Arrhenius rate law:

\[
R = A \cdot \exp(-E_A/(RT))
\]

where \(R\) is the gas constant and where the pre-exponential factor, \(A\), can be related to the apparent collision frequency and the exponential term reflects the Boltzmann probability that the colliding species will have sufficient energy.

A more rigorous description is given by transition state theory (12, 13):

\[
R = (k_B T/h) \cdot \exp(-\Delta G^*/RT)
\]

where \(h\) is the Planck constant and \(\Delta G^*\) is the (notional) Gibbs free energy of activation to the transition state. This equation strictly derives from a quantum statistical mechanical treatment of two-body collisions, so its application to more complex systems (especially those that involve biologic macromolecules in water) needs to be interpreted with due caution.

It follows from this equation that the rates of chemical reactions can, in general, be affected by manipulation of either collision factors or activation parameters or both. And, of course, reaction rates will be very sensitive to temperature change—a key consideration in the evolution of complex pathways of interdependent chemical processes that are necessary for maintenance of biologic organisms.

A biologic reaction rates can be affected by molecular diffusion processes that dictate the rates at which collisional encounter complexes occur before reaction. This affect usually shows up in the way reaction rates depend on the physical form of the reactants (gas, liquid, solid, solution, etc.), particularly on concentrations for reactants in gas or liquid phases. A disortion of reactants onto surfaces can enhance the effective concentra- tions of reactive species and/or reduce the dimensionality of the diffusion process. Classic work by Eigen and Richter (14) showed how restricting diffusion to one or two dimensions can dramatically increase potential reaction rates, and this principle has been applied to the kinetics of protein translocation along DNA chains, for example. See References 15 and 16 for more information.

Enzyme catalysis completely exploits all these aspects of the physical chemistry of reaction kinetics. Despite the great enhancement in reaction rates and specificities that can be achieved by biologic catalysts, it is now generally accepted that no new underlying physical principles are involved, just that enzymes are much better at using and optimizing the various factors required for any chemical reaction—particularly...
Spectroscopy and Photochemistry

The interaction of electromagnetic waves (photons) with matter is crucial to many biologic processes. This interaction is also the basis for a wide range of spectroscopic techniques in physical chemistry that probe the structure and function of molecules, many with applications and implications for biology. Absorption and emission of electromagnetic radiation invariably involves changes in electric or magnetic dipoles, such as relative displacements of electrical charges in atoms or molecules, or reorientation of nuclear magnetic moments, and the frequencies (energies) with which these transitions take place dictates the region of the electromagnetic spectrum involved and the sorts of processes that may occur.

Electromagnetic radiation in the ultraviolet (approximately 180–340 nm) or visible (approximately 340–800 nm) region generally interacts with matter through excitation of electronic transitions in atoms or molecules. This interaction gives rise to the characteristic colors of molecules and materials and is the basis for a multitude of analytical techniques in biochemistry and elsewhere. Life, itself, is dependent on the electronic transitions that exploit fundamental effects in electronic energy transfer and transduction (20). Changes in electronic absorbance properties give rise to color changes that underpin many analytical techniques in biochemistry and medicine, and differences in absorbance of left- or right-circular polarized light by chiral structures that exploit fundamental effects in electronic energy transfer and transduction (20). Changes in electronic absorbance properties give rise to color changes that underpin many analytical techniques in biochemistry and medicine, and differences in absorbance of left- or right-circular polarized light by chiral structures that exploit fundamental effects in electronic energy transfer and transduction (20).

The electronic excited state is inherently unstable and can decay back to the ground state in various ways; some of which involve (re)emission of a photon, which leads to luminescence phenomena (fluorescence, phosphorescence, and chemiluminescence) (22). Some biologic molecules are naturally fluorescent, and phosphorescence is a common property of many marine and other organisms. Fluorescence is photon emission caused by an electronic transition to ground state from an excited singlet state and is usually quite rapid. Phosphorescence is a much longer-lived process that involves formally forbidden transitions from electronic triplet states of a molecule. Fluorescence measurement techniques can be extremely sensitive, and the use of fluorescent probes or dyes is now widespread in biomolecular analysis. For example, the large increase in fluorescence of a dye molecule (e.g., ethidium bromide) when bound to double-helical DNA is widely used in molecular biology to detect and locate DNA fragments. Chemiluminescence occurs when the electronically excited state develops as a result of chemical reaction. Chemiluminescence is the basis for many biologic light shows, including the flashing lights of firefly tails (using enzyme luciferase-catalyzed hydrolysis of ATP) and many marine organisms.

Vibrational motions of chemical bonds that involve changes in electric dipole moment or polarizability can be detected by IR absorbance or Raman scattering techniques. The strong infrared (IR) absorbance by water makes conventional IR spectroscopy less generally useful in biology, although this disadvantage is overcome by Raman spectroscopy, which relies on the inelastic scattering of high intensity visible (laser) light. Resonance Raman spectroscopy has been particularly useful in picking out the vibrational spectra of biologic chromophores in otherwise complex mixtures, and the differential scattering of circularly polarized light (Raman optical activity) has been developed as a high resolution probe of chiral features, particularly in biologic macromolecules (23).

Phenomena associated with the reorientation of nuclear or molecular magnetic dipoles in applied magnetic fields have led to dramatic advances in molecular spectroscopy and imaging techniques. Nuclear magnetic resonance spectroscopy (NMR) is now routinely applicable to the study of the structure and dynamics of biomolecules, large and small (24), and NMR imaging techniques are used for whole-body diagnostics and related investigations. Electron paramagnetic resonance (EPR) techniques that rely on the reorientation of electronic spins are less generally applicable because of the relative scarcity of appropriate paramagnetic species in biology. However, specific “spin probes” are used in some instances, for example, in the investigation of biologically significant free radical chemistry, and new probes and improved technologies are being developed.

Most spectroscopic processes mentioned so far involve relatively low energy transitions that do not (usually) affect the covalent structure of the sample. However, absorption of higher energy photons (UV, and others) can lead to higher energy-excited electronic states in which chemical transformations can occur. Such photochemistry can be harmful to biologic organisms, particularly at the DNA level (melanomas, etc.), but can also form the basis for useful techniques and therapies. Photochemistry is also, of course, central to biologic processes such as photosynthesis (20) and visual transduction (25). And the speed with which photoprocesses can be initiated is exploited in many biophysical techniques for studying structure and dynamics, for example, flash photolysis and fluorescence recovery after photobleach (FRAP).

Mass spectrometry is one physical technique that does not (at least directly) involve electromagnetic radiation. However, some sample desorption and ionization processes do use high intensity pulses of laser light in techniques such as MALDI (Matrix-Assisted Laser Desorption Ionization) that have proved very useful in mass analysis of proteins and other biologic macromolecules. High resolution mass spectrometry derives from atomic/molecular beam studies in which the trajectories of ionized particles in a vacuum can be manipulated by static
Quantum Theory and Bonding

Quantum mechanics is probably the most successful theory of the twentieth century, if not ever. It explains the structure and spectroscopic properties of atoms and molecules with remarkable precision and is the foundation for our understanding of chemical bonding. It is therefore surprising, perhaps, that it has not yet had any great impact on our understanding of biologic processes. This occurrence is mainly a matter of scale. Quantum theory is remarkably good at describing the electronic structures of atoms and molecules. And, to the extent that biologic (macromolecules are held together by the same covalent bonds as any other kinds of molecules, the quantum mechanical nature of chemical bonding is inherent to their structure and properties. However, knowing the wave function for the human genome, even if we could calculate it, would be of little use to a molecular biologist. Solving the Schrödinger equation for a polypeptide would not likely tell us how it folds or what its function might be; these problems, for the time being at least, do not need the degree of precision at the atomic and electronic level afforded by quantum theory.

This principle can be illustrated by the wave–particle duality aspects of quantum theory. The de Broglie wavelength (\(\hbar/mv\)) for a typical macromolecule (10 kDa) traveling at thermal velocities (>50 m s\(^{-1}\)) is around 0.01 Å or less. Consequently, quantum effects deriving from the wave-like behavior of matter and the Heisenberg Uncertainty Principle are unlikely to be of significance at the level of resolution (typically 1 Å) currently available for biologic molecules, and classic mechanics is adequate in most cases, which is not to say that quantum effects are entirely absent, however. Quantum mechanical tunneling has been observed in some instances and may be of importance in some enzyme-catalyzed reactions. Tunneling or barrier penetration is a uniquely quantum phenomenon whereby the wave-like nature of particles at the atomic and subatomic level allows them to pass through, rather than over, energy barriers. In some enzyme reactions, this phenomenon is manifested by the deviations from classic Arrhenius kinetic behavior at very low temperatures. Classical, at absolute zero (0 K) all molecular motion stops and chemical reactions should cease, because the molecules no longer have sufficient thermal energy to overcome activation barriers. However, for some reactions, especially those that involve hydrogen transfer, for example, finite reaction rates have been observed at liquid helium temperatures (27, 28). Room temperature tunneling effects are also significant in electron transfer processes within or between proteins (29, 30). The possible importance of significant quantum effects in wave-like energy transfer processes in the early stages of photosynthesis has recently been reported (31).

More generally, electronic and vibrational spectroscopic properties of biologic molecules will, of course, be subject to the underlying rules of quantum mechanics. However, except in special circumstances, the spectra of biologic molecules in solution rarely show the discrete quantized energy-level structure seen in simpler atomic or small-molecule systems in vacuum. This rare display is because the significant conformational flexibility and dynamic solvent environment gives rise to heterogeneous and homogeneous spectral broadening effects that mask the underlying energy-level structures.

At the theoretical level, full quantum mechanical calculations on biologic macromolecules are not computationally feasible, nor would they be particularly helpful in understanding macromolecular properties without proper inclusion of the solvent water or other biologic matrix on which these properties so intimately depend. However, ab initio quantum mechanical calculations on smaller systems that represent crucial steps in an enzymic reaction, for example, can be helpful in understanding specific processes within macromolecules or in estimating intermolecular forces and stereochemical effects in molecular mechanics simulations that are not experimentally accessible.

Symmetry and Group Theory

Group theory is a very powerful mathematical technique for analyzing molecular structures in terms of their symmetry properties. These properties can be characterized in terms of the various symmetry operations, symmetry elements, and space groups or point groups into which they fall. A symmetry operation is any action (translation, rotation, reflection, etc.) that leaves the object looking the same. A symmetry element is the point, line, or plane about which the symmetry operation is performed. A point group is the list of all possible symmetry operations that leave at least one point in the object unchanged (i.e., without spatial translation). In contrast, a space group is the set of all operations that move a molecule (or object) to another position in space. Symmetry considerations can be very useful in determining, for example, spectral characteristics of small molecules or functional groups; for instance, the different selection rules regarding IR absorbance or Raman scattering bands in vibrational spectroscopy of small molecules are equally applicable to such group vibrations in larger systems. But most biologic macromolecules and larger complexes lack sufficient symmetry for the full rigor of group theory to be applicable in any generally useful way. Two significant exceptions exist. The classic work of Caspar and Klug on the structures of icosahedral viruses was based on symmetry considerations, many of which derived from the architectural symmetries in the building designs of Buckminster-Fuller (32). And space groups are, of course, central to the analysis of protein crystals, where determination of the space group is the first essential step in crystallographic resolution of protein (and other structures) by X-ray diffraction techniques.

Electrochemistry

Processes that involve the transfer of charge can be manipulated by electrical potential or, conversely, can generate voltages that...
can drive other reactions or can be used for analytical purposes. Electron transfer between molecules or chemical groups (i.e., oxidation/reduction or "redox" processes) can be configured as electrochemical cells for numerous purposes, and the thermodynamics of such systems is key to understanding biologic redox processes such as in various intermediate stages of photosynthesis and respiration. Ion transport across membranes or against chemical potential gradients is involved in all aspects of electrolyte balance in biologic systems, both at the microscopic level of individual cells or organelles and at the macroscopic level of whole organisms. It is the basis for the transmission of nerve signals and for the use of membrane potentials for ATP synthesis (9).

The key expression here is the Nernst equation that, under ideal conditions, relates the electrical potential (E) of a system participating species:

\[ E = E^\circ - \frac{RT}{nF} \ln \frac{Q}{Q^\circ} \]

where \( E^\circ \) is the standard electrochemical potential of the process, \( n \) is the number of moles of charge transferred per mole of reaction, \( F \) is the Faraday (96,500 coulomb/mole), and \( Q \) is the "reaction quotient" that involves the relative concentrations (activities) of reactants and products.

This process is the basis for several analytical devices, electrochemical cells, pH- and ion-specific electrodes, and other sensors in which concentrations and electrochemical properties can be determined in terms of the voltage (electrochemical potential) developed across membranes or other partitions separating the two halves of a redox reaction. Various microelectrode technologies employ this approach to study electrochemical potential gradients in single cells, in tissues, and across biologic membranes. Chemical potential gradients across membranes can also drive chemical reactions. This approach is the thermodynamic rationale for chemiosmotic and protonmotive force effects in which \( H^+ \) or other ion gradients across membranes can provide the driving free energy for synthesis of ATP for example (9).

The molecular machinery that involves membrane-associated proton pumps and ATP-synthesizing enzymes must still be worked out in detail, but the basic principles of electrochemistry must apply.

The mobility of ions in an electric field, especially in water, formed the basis of early work in the physical chemistry of solutions. It has now blossomed into the wide range of multi-purpose electrochemistry techniques that are the mainstay of most biochemistry and molecular biology laboratories today. Protein gel electrophoresis, in which protein mixtures may be separated on the basis of their size and charge, is a standard analytical and quality assurance methodology. The same is true for DNA and RNA biochemistry. Sequencing the human genome, for example, would not have been possible (or at least greatly hindered) without the development of the high-resolution electrophoresis methods capable of separating strands of DNA that differ in length by just one nucleotide.

### Experimental Techniques

Perhaps the greatest contribution of physical chemistry to biology lies not in the theoretical fundamentals, although important, but in the experimental techniques that have developed from physical chemistry. Textbooks are written with the benefit of hindsight, and can give the impression that theory comes first, with experiments playing a subsidiary supporting role. Reality is somewhat different. Most scientific development comes from curiosity-driven observation and experimentation, and experimental techniques developed to study the physics and chemistry of matter are applicable equally to biologic systems. Indeed, the need to study biomolecular processes has acted as a spur to the development and applications of physico-chemical methods, which benefits both sides. Here is a list of just some techniques derived from physical chemistry that have applications in biology:

1. In no particular order: UV/visible spectroscopy; fluorescence spectroscopy; circular dichroism; Raman spectroscopy; rapid reaction kinetics; stopped-flow and flash photolysis methods; isothermal and scanning (micro)calorimetry; specific electrode technologies; electrophoresis; chromatography; light scattering and diffusion methods; viscosity and rheology; analytical ultracentrifugation; NMR spectroscopy and imaging; X-ray and neutron diffraction; Langmuir–Blodgett films and other surface technologies; mass spectrometry; and EPR spectroscopy . . .

### And the Rest . . .

A short introductory article such as this cannot possibly cover completely such a wide-ranging subject, and much has been left out. Flick through any physical chemistry textbook and you will find many other topics that we have missed, all of which possess one or more important roles in biology. Here are just a few (with a hint of some biologic significance in parentheses):

- Properties of gases (physiology of oxygen uptake); acid-base equilibrium, buffering in aqueous solution (pH control in cells and organisms); colloid, detergents, and micelles (biologic membranes); surface chemistry (bioadhesion and biocatalysis); polymer structure and dynamics (polypeptides, polynucleotides, polysaccharides); crystallography and diffraction techniques (structural biology); noncovalent interactions (hydrogen bonding); and so on.

The list could continue, but it illustrates the key role that physical chemistry has played, and continues to play, in our understanding of biology.

### References

Normal regulation of the cell cycle ensures the passage of genetic material without mutations and aberrations. Proper completion of each phase is critical to the initiation of the following phase, and the pathways that cell division occur in an ordered, sequential, and irreversible procession. The two major cell-cycle events that are regulated tightly are DNA replication and cell division. Progression through each phase transition is regulated by extracellular signaling, transcription factors, cyclin-dependent kinases (CDKs), and checkpoints, which prevent uncontrolled cell division.

Cyclin/CDK complexes are the primary factors responsible for the timely order of cell-cycle progression, which include entry into S phase, initiation of DNA replication, and mitotic entry. Each phase of the cell cycle and the different cyclin/CDK complexes, as well as other important factors that regulate cell-cycle progression and checkpoints, will be discussed.

The cell cycle is the sequence of events by which growing cells duplicate and divide into two daughter cells. In mammalian cells and other eukaryotes, cell division represents a process of highly ordered and tightly regulated molecular events. The cell cycle is composed of five phases in mammals, including G0, G1, S, G2, and M phases. Replication of DNA occurs during S phase and division occurs during M phase. During the two gap phases, G1 and G2, cells produce RNA and proteins required for the subsequent S and M phases, respectively. Cells in a resting, quiescent state are in G0 phase. Stimulation by external growth factors or mitogens triggers quiescent cells to reenter the cell cycle in G1 by activating numerous signaling cascades, and it leads to the sequential activation of cyclin-dependent kinases (CDKs). Activation of CDKs requires interaction with a cyclin partner, T-loop phosphorylation at T160 (CDK2) or T161 (CDK1) catalyzed by CDK activating kinase (CAK), and dephosphorylation at T14 and Y15 by CDC25 dual phosphatases. The inhibitory phosphorylations at T14 and Y15 are catalyzed by the serine/threonine kinase Wee1 and threonine/tyrosine kinase Myt1, and these cause misalignment of the glycine-rich loop and the ATP phosphate moiety. CDKs phosphorylate multiple substrates. The proper regulation of CDKs is necessary for orderly cell-cycle phase transitions. A general representation of the key players and events during the cell cycle can be observed in Fig. 1.

Numerous checkpoints also exist to ensure normal cell-cycle progression and transmission of an unaltered genome. These checkpoints are conserved signaling pathways that monitor cell growth conditions, cell-cycle progression, and structural and functional DNA defects; they are critical for cell survival or death. Checkpoint responses induce and sustain a delay in cell-cycle progression, and activate machinery to respond to changes in cell growth conditions, repair DNA, and stall replication. When cellular damage cannot be repaired, these checkpoints can induce apoptosis. The mammalian checkpoints include the quiescent checkpoint, G1/S checkpoint, replicative checkpoint, G2 checkpoint, mitotic checkpoint, and the DNA damage checkpoints. Improper checkpoint control promotes tumorigenesis through increased mutation rates, aneuploidy, and chromosome instability. The following sections will give an overview of the regulation of the various phases of the mammalian cell cycle, activation of specific checkpoints, and the molecules involved in the mechanisms that regulate these processes.
Cell Cycle, Regulation of

Figure 1  Regulation of the mammalian cell cycle by cyclin/CDKs. Activation of growth factor receptors in G0 leads to activation of many signaling cascades that lead to the expression of cyclin D. Progression into S phase is mediated by Rb and E2Fs that lead to the initiation and progression of DNA synthesis through cyclin E/CDK2 activity. On completion of DNA replication, cyclin B/CDK1 activity promotes phosphorylation of substrates required for entry into mitosis and eventual cytokinesis, which produces two identical daughter cells.

From Quiescence to the Point of No Return

G0-G1 transition

After cell division, the daughter cell enters into G0 phase where it becomes ready to divide again before entering into G1. In most cases, the newly formed cell increases in size and mass for division to occur again, by enhancing ribosome biosynthesis (1). This task is accomplished by phosphorylation of the S6 ribosomal subunit by S6 kinase (2). This kinase is regulated by members of the PI3K family, including TOR, PDK1, and PI3K, which are activated by insulin receptor signaling (3, 4). These family members phosphorylate the translational inhibitor 4E-BP1, leading to dissociation of the initiation factor eIF4E, which promotes cyclin D and Myc translation (5). In the absence of growth factors, these kinases are inactive and cannot signal progression from quiescence to G1. Acetylation and phosphorylation of the tumor suppressor p53 also seem to be involved in maintaining cellular quiescence (6, 7).

G1 phase

In the presence of growth factors during the G0 and G1 phases, ras and mitogen-activated protein kinase (MAPK) cascades are activated and subsequently regulate cell cycle progression (8). MAPK regulates cyclin D expression directly by controlling the activation protein-1 and ETS transcription factors, which transactivate the cyclin D promoter (9, 10). Consequently, the MAPK cascade activates cyclin D-dependent kinases (CDK4 and CDK6) and regulates cell proliferation. Additionally, the MAPK cascade regulates directly the synthesis of the CIP/KIP family of CDK inhibitors (CKIs), specifically p21(CIP) and p27(KIP), which regulate CDK activity negatively and influence cyclin D/CDK4/6 complex formation in G1 (11, 12).
The growth factor-dependent synthesis of D-type cyclins occurs during the G1/S transition and peak in concentration in late G1 phase (13). These proteins have a very short half-life and are degraded rapidly after removal of mitogenic stimulation. The INK family of CKIs primarily inhibits cyclin D/CDK4/6 complexes. Only when the concentration of cyclin D exceeds that of the INK proteins can these cyclin D/CDK4/6 complexes overcome their inhibition (14, 15).

In early to mid G1 phase, active cyclin D/CDK4/6 complexes phosphorylate the three Rb pocket proteins (pRb, p130, and p107), which results in their partial repression (16–18). E2F proteins (E2F1-6) and cyclin E/CDK2 form heterodimers with a related family of DP proteins (DP1-3), and can act as both activators and repressors of transcriptional activity. In G0, and early G1, Rb is in an active, hypophosphorylated form. Active Rb represses the activity of the E2F transcription factor family by binding directly to the transactivation domain of E2F proteins and recruiting histone deacetylases, methyltransferases, and chromatin remodeling complexes to E2F-regulated promoters (19, 20). This activity results in the modification of histones, compaction of chromatin structure, and prevention of promoter access by transcription machinery (20). Phosphorylation of Rb by cyclin D/CDK4/6 complexes during G1 releases histone deacetylase, which alleviates transcriptional repression partially (13, 19, 20). As a result, the E2F/DP transcription factors activate the transcription of cyclin E and many genes responsible for the G1/S transition and DNA synthesis including CDK2, cyclin A, cyclin E, RPA1, MAT1, PCNA, DHFR, c-Myc, DNA polymerase-ε, p20(MMT), and CDC25A (21).

G1/S transition

Cyclin E expression in mid to late G1 results in the formation of cyclin E/CDK2 complexes, which are required for S-phase entry and the initiation of DNA replication. Cyclin E/CDK2 also phosphorylates Rb, except on different residues than those catalyzed by cyclin D/CDK4/6 complexes (22). Cyclin E/CDK2 phosphorylation of Rb promotes the dissociation of E2F transcription factors from Rb, which results in complete relief of transcriptional repression (23). Thus, Rb inactivation occurs through the sequential phosphorylation by CDK4/6 and CDK2. Additional E2F and cyclin E/CDK2 activity increases through a positive feedback mechanism because cyclin E is one of the many genes activated by E2F (24). Cyclin E/CDK2 activity enhances this positive feedback even more by promoting the degradation of its own inhibitor, p27kip1. These complexes have been shown to phosphorylate p27kip1 at Thr187, which promotes its association with the Skp-Cullin-F-boxp1 (SCFp1) complex to target p27kip1 for ubiquitination and proteasomal degradation (25). Cyclin D/CDK4/6 complexes have been hypothesized to sequester the bound CDK inhibitor p27kip1 away from cyclin E/CDK2 complexes to facilitate their activation (26). However, recently p27kip1 was shown to be phosphorylated by Src-family tyrosine kinases at Y88, which reduces its steady-state binding to cyclin E/CDK2. This action facilitates p27kip1 phosphorylation at Thr187 by cyclin E/CDK2 to promote its degradation (27, 28). Thus, rather than cyclin D/CDK4/6 sequestering of p27kip1, these tyrosine kinases may be responsible for activation of p27kip1-bound cyclin E/CDK2 complexes at the G1/S transition.

The c-myc proto-oncogene encodes another transcription factor involved in many processes, which include E2F regulation (29). Its expression is induced by mitogenic stimulation, promotes S-phase entry in quiescent cells, and increases total cell mass. Myc activates the transcription of cyclin E, CDC25A, and several other genes (30). The Myc-induced proliferation mechanism activates cyclin E/CDK2 activity directly through increased cyclin E levels and CDC25A activity, which removes Thr14 and Tyr15 inhibitory CDK2 phosphorylation catalyzed by Wee1/Myt1 (31). Additionally, this activity is enhanced indirectly through Myc by mediating the sequestration of p27kip1 from cyclin E/CDK2 into cyclin D/CDK4/6 complexes, which in turn promotes the cyclin E/CDK2 catalyzed phosphorylation and degradation of p27kip1 (32). Cul-1, a component of the SCFp1 complex, was shown to be a transcriptional target of Myc, which may explain the link between p27kip1 degradation and Myc activation (33).

Cyclin E/CDK2 also phosphorylates p20(MMT), which is a protein involved in the regulation of histone gene expression. This phosphorylation is a major event that occurs as cells begin to enter S phase (34). The phosphorylation of p20(MMT) by cyclin E/CDK2 is required for histone gene expression activation at the onset of S phase (35). Once cells have passed through the restriction point, they are committed to initiate DNA synthesis and complete mitosis. Cell-cycle progression continues independently of the presence of growth factor stimulation after passage through the restriction point.

Regulation of DNA Synthesis and Mitotic Entry

S phase

At the G1/S transition, the cell enters S phase in which DNA synthesis occurs and each chromosome duplicates into two sister chromatids. During S-phase entry, the initiation of replication occurs at sites on chromosomes termed origins of replication. Replication origins are found in two states within cells: a pre-replicative complex (pre-RC) that is present in G1 before DNA replication initiation, and the post-replicative complex (post-RC) that exists from the onset of S phase until the end of M phase (36). At the onset of S phase, an increase in cyclin A expression and cyclin A/CDK2 activity occurs (37, 38), and the protein kinase GSK-3β phosphorylates cyclin D and signals its relocalization to the cytoplasm where it is degraded by the proteasome (39, 40). Cyclin A/CDK2 activity controls each round of DNA replication, and this dictates the state of the replicative complexes. Low CDK activity permits the assembly of the pre-RC to form a licensed origin at the end of M phase, whereas the increase in CDK activity during the G1/S transition triggers initiation of DNA replication and converts origins to the post-RC form (41). Replication of the pre-RC is prevented...
Cell Cycle, Regulation of

by high CDK activity, which acts to inhibit re-replication events that would result in numerous copies of chromosomes.

The initiation of DNA replication requires both the assembly of the pre-RC complex at origins of replication and the activation of these complexes by CDKs and other kinases to initiate DNA synthesis (42–44). Numerous proteins are required for pre-RC formation of the DNA replication initiation complex, which include the Origin Recognition Complex (ORC), cdc6/18, cdt1, the GINS complex, and mini chromosome maintenance (MCm) proteins (43). ORC proteins (ORC-1-6) bind directly to replication origins as a hexamer and facilitate the loading of other components of the pre-RC (45, 46). The cdc6/18 and cdt1 proteins play a central role in coordinating chromatin licensing. They bind directly to the ORC complex independently of each other (47). Here, they facilitate cooperatively the loading of the Mcm proteins (MCm2-7), which form a hexameric ring-complex that possesses ATP-dependent helicase activity (48, 49). Cyclin E/CDK2 is recruited to replication origins through its interaction with cdc6, and this event regulates cdt1, cdc6/18, and MCm loading, which makes chromatin replication competent. A fiber binding of the Mcm proteins, the affinity of both cdc6/18 and cdt1 for the ORC is reduced, and they dissociate (48, 49). Then, cyclin A/CDK2 phosphorylates cdc6 to promote its export from the nucleus and cdt1 to target its ubiquitination (48, 49). Then, cyclin A/CDK2 phosphorylates cdc6 to promote its export from the nucleus and cdt1 to target its ubiquitination by the SCF^CMCc complex (50, 51). In this way, after initiation and release of these factors from the ORC, cyclin A/CDK2 activity acts to prevent re-replication by inhibiting reformation of the pre-RC. However, cyclin E/CDK2 activity acts primarily to promote the initiation of DNA synthesis (52).

Dbf4-dependent kinase (DDK) contains the kinase subunit cdc7, and it is required for DNA replication initiation (53). DDK targets Mcms for phosphorylation, thereby increasing the affinity of these proteins for cdc6, which is a factor required for the initiation and completion of DNA replication (54). The GINS complex, which consists of the four subunits Sld5, Psf1, Psf2, and Psf3, is required for the initiation and progression of eukaryotic DNA replication (55). The GINS complex associates with Cdc45 and the Mcm proteins to activate their helicase activity. As a result of GINS and cdc45 binding to the Mcm complex, the DNA is unwound, which results in single stranded DNA (ssDNA) (49, 57). Replication protein A (RPA) is recruited to single stranded DNA, and it is required for the subsequent binding and activation of DNA polymerase-α (58–60). The GINS complex also interacts with, and stimulates the polymerase activity of the DNA polymerase-α-prime complex (61).

G2 phase

After completion of DNA duplication, the cell enters the second restriction point of the cell cycle, referred to as the G2 phase. Similar to what happens during G1, in this second gap phase the cell halts to synthesize factors required for initiation and completion of mitosis and to check for any aberrations that result from DNA synthesis (62, 63).

Cyclin B/CDK1 is the primary regulator of the G2/M transition, and its activity is required for entry into mitosis. It was termed the mitosis-promoting factor (MPF) because it was originally shown to be essential for Xenopus oocytes maturation after hormonal stimulation, and it was found subsequently to be equivalent to a mitosis-promoting activity (64). CDK1 activity is regulated primarily by localization of cyclin B, CDC25C activity, and p21^CIP levels, which are controlled by checkpoint machinery (65). Cyclin B/CDK1 complexes remain inactive until their activity is required for mitosis entry in late G2. Toward the end of S phase, cyclin B expression is increased. However, during the onset of G2, cyclin B is retained in the cytoplasm by its cytoplasmic retention signal (CRS), and the CK1 p2A^T inhibits CAP-mediated activation of cyclin/CDKs (66). Additionally, Wee1 and Myt1 phosphorylate T14 and Y15 on cyclin B/CDK1 in the cytoplasm to keep these complexes inactive even when CDK1 is phosphorylated by CAK (67). The transcription factor F53 also mediates the inhibition of cyclin B/CDK1 activity by promoting p21 expression, and it down-regulates expression of CDK1 (63, 68). Furthermore, cyclin A/CDK2 phosphorylates and inactivates members of the E2F transcription family in G2 to suppress cell growth during this gap (69–71).

G2/M transition

During the G2/M transition, the localization of cyclin B changes dramatically and regulates CDK1 activity (72). The CRS is phosphorylated by MAPK and polo-like kinase 1 (Plk1), which promotes its nuclear translocation (73, 74). Concomitant with nuclear import, cyclin B is phosphorylated to a greater extent to prevent association with CEN1, which promotes its nuclear retention (75, 76). This relocalization occurs at the onset of mitosis toward the end of the G2/M transition when the cell is ready to begin the mitotic process (77). Activation of cyclin B/CDK1 in late G2 is achieved by preventing the access of cytoplasmic Wee1/M1 and to the complex and by promoting shuttling of the CDC25 phosphatases to the nucleus, where they dephosphorylate and activate CDK1 (78–80). Cyclin B/CDK1 complexes phosphorylate CDC25A to promote its stability and CDC25C to promote its activity (81, 82). Both CDC25A and CDC25C activate CDK1 even more, which results in a positive feedback loop that sustains cyclin B/CDK1 activity in the nucleus to signal mitotic entry (82, 83). ERK-MAP kinases also regulate cyclin B/CDK1 activity by phosphorylating CDC25C at T48 (84). ERK2/2 activation of CDC25C leads to removal of inhibitory phosphorylations of cyclin B/CDK1 complexes and is required for efficient mitotic induction. Thus, MAPKs are involved in the positive feedback loop that leads to cyclin B/CDK1 activation.

The increase in nuclear cyclin B/CDK1 activity promotes phosphorylation of nuclear substrates that are necessary for mitosis, such as nuclear envelope breakdown, spindle formation, chromatin condensation, and restructuring of the Golgi and endoplasmic reticulum (55, 85, 86). Numerous cyclin B/CDK1 substrates have been defined, which include nuclear lamins, nucleolar proteins, centrosomal proteins, components of the nuclear pore complex, and microtubule-associated proteins (87–89). Cyclin B/CDK1 complexes also phosphorylate Mcm4 to block replication of DNA, the TFIIH subunit of RNA polymerase II to inhibit transcription, and the ribosomal 56 protein kinase to prevent translation during mitosis (90–92).
Regulation of Cell Division

The centrosome

Normally, the centrosome is composed of two centrioles and the pericentriolar material. It functions not only as a microtubule nucleation center, but also as an integrated regulator of cell-cycle checkpoints. Recent data indicates it is required for cell-cycle progression (93). The centrosome duplication process begins in late G2 and is regulated primarily by CDK2 activity (94). Cyclin A/E/CDK2 phosphorylates the Mps1p kinase and nucleoplasmin, which are two centrosome associated proteins. CDK2 activity is required for Mps1p stability and Mps1p-dependent centrosome duplication (95). Cyclin E/CDK2 phosphorylates nucleoplasmin at T199, releasing it from unduplicated centrosomes, which are a requirement for centrosome duplication (96). Completion of centrosome duplication and initiation of their separation occur in G2 and are dependent on cyclinA/E/CDK2 activity. These processes are necessary for proper spindle formation and for balanced chromosome separation during mitosis.

The Aurora kinase family members play a role in centrosome function, spindle assembly, and chromosome alignment, and they are essential for mitosis. Specifically, Aurora-A activity is maximal during G2/M; it regulates mitotic spindle assembly, centrosome separation, and it facilitates the G2/M transition by phosphorylating CDC25B at the centrosome, which is an important event for cyclin B localization to the nucleus (97). Aurora-B activity is maximal from metaphase to the end of mitosis and regulates chromatin protein modification, chromatid separation, and cytokinesis (98). During mitosis, a complex process of degradation and phosphorylation regulates Aurora kinase activity to ensure proper mitotic advancement. Aurora-A is activated mainly by autophosphorylation (99), Ajuba (100), TPX2 (101), and HEF1 (102), whereas INCENP is thought to inhibit Aurora-A/B (103). Both Aurora-A and B are degraded rapidly at the end of mitosis.

M phase

The mitotic phase is divided into five phases, which include prophase, prometaphase, metaphase, anaphase, and telophase. During prophase, nucleoli disappear, chromatin condensation takes place, and the mitotic spindle is formed at centrosomes that contain centrioles. In prometaphase, fragmentation of the nuclear envelope occurs and mitotic spindles extend from the poles toward the center of the cell. At metaphase, centrioles pair at opposite poles, and the chromosomes align in the cell center along the metaphase plate. Then, microtubules bind to the kinetochores located at the centromeres of each chromatid of the chromosomes. The transition from metaphase to anaphase is triggered by MPF inactivation through the degradation of cyclin B by the E3 ubiquitin ligase anaphase-promoting complex (APC/C) (104). APC/C is required for activation of the ubiquitin ligase activity of APC/C, which promotes degradation of securin. Subsequently, a release mechanism activates the protease known as separase, which cleaves cohesion and promotes sister chromatid separation and anaphase entry (105, 106). This mechanism induces the separation of chromatids in anaphase as microtubules from each pole pull them apart through their kinetochore. Because of cyclin-B/CDK1 inactivation in late anaphase, the major ubiquitin ligase activity is switched from APC/C-Cdc20 to APC/C-Cdh1. The latter continues to regulate many proteins whose degradation is required for cell-cycle progression, including Cdc20, which becomes one of its targets and a substrate of the Aurora kinase. (107–111).

In telophase, nuclei for each daughter cell form at the two poles, and the mitotic spindle apparatus disappears. Furthermore, nuclear membranes, nuclear lamina, nuclear pores, and nucleoli are reformed. The cell is now ready for cytokinesis, which is physical division of the cytoplasm. The cytokyme divides as actin/myosin filaments contract and pinch off the plasma membrane, which results in two daughter cells that enter into G0 or G1 for another round of division. The main checkpoint that exists during M phase in mammalian cells is the spindle checkpoint; it is in place to ensure proper mitotubule assembly, proper cell division, and that each daughter cell receives one copy of DNA.

Spindle checkpoint

The spindle checkpoint is activated when microtubules fail to attach to the kinetochores of each sister chromatid and/or when misalignment of chromosomes occurs along the metaphase plate (112–114). This mechanism blocks entry into anaphase and ensures proper segregation of the chromatids to opposite spindle poles. Misregulation of this checkpoint results in aneuploidy daughter cells after division (115, 116). Checkpoint proteins associated with kinetochores monitor microtubule-kinetochore attachment and tension; these proteins regulate this checkpoint by preventing cdc20 binding to the APC/C (117–119).

The main spindle checkpoint proteins include Mad1, Mad2, BubR1, Bub3, Mps1p, and CENP-E. These proteins act both independently and dependently of their interaction with kinetochores. Association of Mad2 with kinetochores and cdc20 requires the presence of Mad1 (120). At the kinetochores, Mdm2 is converted to a form that can bind and sequester cdc20 away from the APC/C, which results in its inhibition (121). Additionally, formation of the mitotic checkpoint complex BubR1/Bub3/Mad2/Cdc20 occurs independently of interaction with unattached kinetochores, and signals anaphase to wait by binding and inhibiting the APC/C (122, 123). An unattached kinetochore activates a kinase cascade that involves the dual-specificity kinase Mps1p and the serine/threonine kinase BubR1 and Bub3 that amplifies this wait signal (124, 125). Furthermore, Bub1 interacts directly with the kinesin-like protein CENP-E to regulate microtubule tension at kinetochores, which is also involved in regulation of the spindle checkpoint (126, 127). Thus, this checkpoint serves to inhibit the APC/C indirectly through cdc20 sequestration and directly through association with the mitotic checkpoint complex, and to regulate the tension at kinetochores required for anaphase entry (128).

DNA Damage Checkpoints

In addition to checkpoints that ensure normal cell-cycle progression, numerous DNA damage checkpoints exist in mammalian
cells. These checkpoints exist to regulate the highly conserved mechanisms that control DNA replication and mitosis to ensure mutations within the genome are not passed on to the daughter cells. Misregulation of these pathways is associated with genomic instability and cancer development. The key players involved in the DNA damage checkpoint cascade (Fig 2) include the DNA damage sensors ATM (Ataxia Telangiectasia M mutant), ATR (ATM and Rad3 Related), Rad1, Rad9, Hus1, and ATRIP, and the effectors Chk1/2 (Checkpoint Kinase 1/2), and CDC25.

**G1/S-phase checkpoint**
The primary DNA damage checkpoint is the G1/S checkpoint, which acts to prevent the replication initiation of damaged DNA. During G1 and even after passage through the restriction point (but prior to initiation of DNA synthesis), DNA damage activates two checkpoint-signaling pathways sequentially, and both pathways function to inhibit CDK2 activity. The first pathway initiated is p53-independent and is rapid and short-lived (129). This pathway results in phosphorylation and degradation of CDC25A (130, 131). DNA damage leads to the activation of ATM and ATR, which phosphorylate and activate Chk1 and Chk2 (132, 133). CDC25A is phosphorylated by these kinases, which target its ubiquitination and proteasomal degradation (134). As a result, the inhibitory phosphorylations of CDK2 are increased, which diminishes CDK2 activity. Ultimately, this lack of CDK2 activity inhibits the cdc45 leading to pre-RCs and the subsequent initiation of DNA replication to halt the cell cycle and to allow time to repair damaged DNA (133).

The second pathway activated in the presence of DNA damage prior to initiation of DNA synthesis acts in a p53-dependent manner. As stated above, the tumor suppressor p53 is a transcription factor, which acts primarily to increase expression of the CK1/p21^{*WAF1} during DNA damage. Like CDC25A, the activation of ATM/ATR promotes the phosphorylation of p53, which enhances the stability of p53 by preventing efficient interaction with the E3 ubiquitin ligase MDM2, which is a protein responsible for targeting p53 degradation (135). This mechanism leads to the transcription and accumulation of p21, which silences CDK2 activity to prevent cell-cycle progression and to allow for DNA repair (136). MDM2 is also a target of p53 transcription, which creates a negative feedback loop with p53 (137). After repair of damaged DNA has been completed, the checkpoint is turned off and progression into S phase resumes.

**S-phase checkpoints**
Cells that have passed the G1/S checkpoint are ready to begin S phase and DNA replication. The S-phase checkpoints are a group of three mechanistically distinguishable checkpoints (138) of which two respond directly to DNA damage. One is independent of ongoing replication and is activated in response to DNA double-stranded breaks (DSBs), which is known as the intra-S-phase checkpoint. The second checkpoint, the replication checkpoint, responds to replication fork stalling caused by the collision of replication machinery with DNA damage, direct inhibition of polymerases, or depletion of dNTPs. Although these two checkpoints respond to different forms of stress, both checkpoints prevent cell-cycle advance, inhibit ongoing replication, prevent origin firing, and stabilize the replication fork so that repair and replication resumption can occur. The third type of S-phase checkpoint is the SIM checkpoint. Currently, this checkpoint is not understood as well as the previous two, but it is known to prevent entry into mitosis when replication is stalled or incomplete. It acts to preserve genomic stability by preventing premature chromatin condensation and breaks at common fragile sites.

**The replication checkpoint**
The replication checkpoint is activated when the replication machinery encounters DNA damage or when the replicative polymerase is inhibited and stalled (139, 140). This checkpoint stabilizes stalled replication forks and signals for DNA damage repair while preventing exit from S phase. Stalling causes uncoupling of the helicase from the polymerase, which leads to DNA unwinding without subsequent new strand polymerization. This action leads to accumulation of ssDNA, which is a trigger for checkpoint activation (141–143). ssDNA is also believed to activate other checkpoints which include those initiated by DNA repair mechanisms such as nucleotide excision repair (144, 145) or resection of DSBs generated during homologous recombination (146, 147). The ssDNA is coated by RPA proteins (148, 149), which set up a scaffold for the recruitment and localization of DNA damage sensors in S phase. ATR is central to the replication checkpoint and is recruited to RPA-coated Figure 2 Brief model of DNA damage checkpoint signaling. DNA damage elicits a conserved response headed by the ATM and ATR kinases. Phosphorylation cascades and localization of mediators to sites of damage allows for signaling to the effector kinases Chk1 and Chk2. Chk1/2 elicit cell-cycle arrest through phosphorylation-dependent degradation of the Cdk2 family of phosphatases. Parallel activation of p53 by both ATM/ATR and Chk1/Chk2 leads to upregulation of the CDK inhibitor p21, which enforces cell-cycle arrest to a greater extent. See text for in-depth discussion of the checkpoint pathways.
ssDNA through its interaction with its binding partner, ATM-P (150–152). In addition, other sensors of DNA damage, including Rad17, which is an RIF-like clamp loader, and the 9-1-1 complex, which is a heterotrimeric clamp composed of Rad9, Rad1, and Hus1, are recruited to RPA coated ssDNA and serve to activate ATR and to help recruit and activate downstream mediators of the checkpoint (153–155). After ATR activation and recruitment/activation of other sensors, numerous proteins are recruited to the site of damage and act as mediators of the DNA damage-signaling cascade. Most mediators are involved in the activation of the effector kinase Chk1 (156). One mediator, Claspin, is recruited to sites of damage, is phosphorylated by ATR, and recruits Chk1 subsequently. Direct interaction between Claspin and Chk1 is required for phosphorylation and activation by ATR (157–160). Other mediators include BRCA1 and BRCA1C-terminal motif (BRCT)-containing proteins. These mediators form large multimeric complexes and are often visualized as nuclear foci by immunofluorescence microscopy (156, 161). MDC1 (a mediator of DNA damage-checkpoint protein 1) recruits mediators of the checkpoint, such as S3BP1 and NBS1 (162-164). These proteins function to maintain foci oligomerization and to promote ATR mediated phosphorylation of its substrates, which include all of these mediators and SMC1 (Structural maintenance of chromosomes 1). SMC1 is part of the cohesin complex and is required for sister chromatin cohesion in S phase (165, 166). Finally, Chk1 is recruited to the nuclear foci that contain the large scaffold of BRCT-containing proteins and is activated in an ATM,Rad179-1BRCA1C/Claspin dependent fashion (157–159). Then, Chk1 facilitates the checkpoint by phosphorylating family members (167) and p53 (see above for more detail on these events); this results in cell-cycle arrest, DNA repair, and survival choices.

The intra-S-phase checkpoint

Unlike the replication checkpoint, the intra-S-phase checkpoint does not require replication to be activated (138, 168). At the head of this checkpoint is the ATM protein kinase, which is a member of the PI3K family of protein kinases (including ATR and DNA-PK), ATM and the intra-S-phase checkpoint are activated by the detection of DSBs, which can be achieved without direct interaction of the replication machinery with sites of damage. Another interesting difference between the replication checkpoint and the intra-S-phase checkpoint is that activation of the latter does not alter the progression of active replication units, only the inhibition of late origin firing (169). Thus, the intra-S-phase checkpoint causes delays in, but not complete arrest of, S-phase progression (138).

Although the sensors of DSBs are not definitively known, two protein complexes serve as excellent candidates because of their ability to enhance ATM activity. These complexes are the MRN (Mre11-Nbs1-Rad50) complex and the Rad179-1-1 complex (discussed above). The MRN complex has nuclelease activity that localizes to DSBs independently of ATM. At sites of damage, it plays a role in activation of ATM, efficient phosphorylation of ATM substrates, and recession of DSBs (170-172). Although much of the checkpoint from here out involves the same mediators including S3BP1, BRCA1, MDC1, and SMC1, it has two more distinct features compared with the replication checkpoint.

The first feature involves the recession of DSBs, which activates a parallel ATR/ssDNA signaling cascade similar to that discussed above (146, 173, 174). The second feature involves the activation of Chk2. Unlike Chk1, which is only present in S and G2 phases, Chk2 is present throughout the entire cell cycle (175, 176). Chk2 also differs from Chk1 in that it must dimerize to be fully active (177–179), and in response to DNA damage, it becomes soluble in the nucleus and dissipates from damage sites as a mechanism to enhance signaling (180, 181). When phosphorylated by ATM, Chk2 plays similar roles as Chk1 in the degradation of CDC25 family members and phosphorylation of p53.

Although the replication and intra-S-phase checkpoints have distinct mechanisms of activation and signaling, the final goal is the same: to delay or to inhibit S-phase progression providing time and signaling events that lead to DNA repair, so that mutations are not transmitted to daughter cells in the ensuing mitotic division.

S/M checkpoint

The S/M checkpoint can be activated by replication inhibition or when DNA replication is not completed (182-186). This checkpoint signals through the ATR/Chk1 pathways and prevents premature chromatin condensation (PCC) and entry into mitosis (183, 185, 187). Depletion of ATR in Xenopus egg extracts or Chk1 in embryonic stem cells results in premature entry into mitosis prior to completion of replication (183, 185).

In addition, different regions of the genome replicate at different rates, and common fragile sites are known to be late replicating regions. These common fragile sites are often left unreplicated during mitotic entry (188–191). PCC causes breaks when fragile sites are not fully replicated (189). Therefore, mitotic delay is required to ensure the proper replication of the entire genome to prevent breaks that might occur because of PCC. Both ATR (187) and Chk1 (188) are involved in the stability of common fragile sites, which indicates that the S/M checkpoint is required to maintain genomic stability by ensuring proper replication prior to mitotic entry.

G2/M-phase checkpoint

The G2/M checkpoint acts to ensure that cells that experience DNA damage in G2 or that contain unresolved damage from the previous G1, or S phase do not initiate mitosis. Much like the G2 checkpoint and in contrast to the S checkpoints, cell-cycle arrest or delay that results from the G2 checkpoint involves a combination of acute/transient and delayed/sustained mechanisms. The acute/transient mechanisms involve the rapid posttranslational modification of effector proteins, whereas the delayed/sustained mechanism involves the alteration of transcriptional programs (192).

Of all molecules targeted in the G2/M checkpoint, cyclin B/CDK1 seems to be the most important as its activity stimulates mitotic entry directly. DNA damage in the G2 phase activates ATM/ATR pathways (as described above), which results in
mitotic entry to allow for repair of DNA lesions (68). The more delayed and prolonged mechanisms by which the checkpoint silences Cdk1 activity is through the activation of the p53 pathway. Activation of p53 is achieved by phosphorylation by ATM/ATR or Chk1/Chk2 and results in nuclear localization, tetramerization, and stimulation of p53 transcriptional activity toward p21CIP1, p27KIP1, and p16INK4a. BRCA1 can cooperate to achieve maximal inhibition of Cdk1 and to prevent mitotic entry to allow for repair of DNA lesions (68).

The centrosome also regulates the G2/M DNA damage response, and numerous checkpoint proteins are associated with the centrosome (194). Centrosome separation is regulated by the kinases Nek2 and Plk1, and this process is inhibited by DNA damage in an ATP-dependent manner. ATM activation leads to Plk1 and Nek2 inhibition, which results in deregulation of the centrosome (195). By this mechanism, centrosome separation is inhibited, and it contributes to maintaining the G2/M checkpoint (196). Plk1 is also known to phosphorylate and activate CDC25C (197). Thus, Plk1 inhibition also results in CDC25C inhibition, inactivation of cyclin B/CDK1, and a halt in cell-cycle progression. Normally, cell-cycle progression resumes when DNA damage repair is completed; otherwise, apoptosis prevents genomic instability and allows cell-cycle arrest and apoptosis. However, data from Saccharomyces cerevisiae, Xenopus, and human cells, suggests that pathways to re-enter cell-cycle progression exist even when unrepaired DNA damage is present. This process of “checkpoint adaptation” has been shown to allow mitotic entry in response to ionizing radiation in human cells in a Plk1-dependent manner, and it may promote carcinogenesis and genomic instability (198, 199). It has been speculated that activation of centrosomal cyclin B/CDK1 plays a central role in this process, and it may occur through Plk1-mediated degradation of Wee1 and/or inhibition of Chk1 activity that leads to stabilization of CDC25 (200). Although its function is not well understood, checkpoint adaptation has been proposed to move cells into a phase where they can die, allow progression into other phases where difficult DNA damage can be repaired, and even exist to allow natural evolution (201).

**Conclusions**

The mammalian cell cycle is controlled by numerous factors involved in regulation of CDKs and checkpoint responses. Although many proteins involved in the pathways that lead to activation or inactivation of these have been elucidated over the years, much remains to be explored. Although most CDKs control the cell division cycle, regulation of the cell cycle is clearly more than progression from growth to DNA synthesis to division and transmission of genetic material. Growing evidence exists for the role of CDKs in controlling the balance between senescence, cell growth, checkpoint activation, and apoptotic signaling. Clearly, the inability to respond properly to DNA damage and cellular stress through checkpoint activation and apoptosis has a role in oncogenic potential and therapeutic considerations. The identification of novel factors and signal cascades that mediate the regulation of the cell cycle will lead to new drug targets in the fight against cancer and numerous other diseases.

DNA Damage: An Overview
DNA Damage, Sensing of
DNA Replication, an Overview
The process of regulated or programmed cell death (PCD) executed through genetically encoded intrinsic cellular machinery is widely accepted to represent one of the key cellular responses to extrinsic and intrinsic stimulation. Extensive analysis of PCD carried out during the last decade clearly established that proper execution of PCD is important for normal mammalian development and also for homeostasis of the adult organism. Deregulation of PCD has been linked to development of many severe human diseases like cancer, autoimmunity, stroke, and some neurodegenerative diseases. Although apoptosis, which is the first discovered form of PCD, has been and remains the mainstay of PCD research, better understanding of the process of apoptosis led to the surprising discovery that other forms of PCD also exist and play multiple important roles in health and disease. Small-molecule inhibitors of apoptotic and nonapoptotic cell death have been successfully developed and proved very useful in defining the mechanisms and functional role of various PCD processes. Furthermore, some molecules have been developed extensively and represent emerging new therapies for human pathologies. In this article, we will discuss the major PCD-related protein targets of chemical inhibitors and describe the major classes of small molecule inhibitors developed to this point.

Introduction

The paradigm of programmed cell death (PCD) has emerged in the last decade as the critical mechanism of normal development and homeostasis of multicellular organisms. Apoptosis, which was the first discovered form of PCD (1), remains the central topic in the field of PCD research. Alterations to apoptotic signaling either through genetic or small-molecule means can cause significant developmental abnormalities, including mortality, and they can also lead to the development of serious pathologies in adult animals, such as cancer and autoimmunity.

Apoptosis is associated with several highly uniform and characteristic morphological changes, such as cell shrinkage, cell membrane blebbing, condensation of nuclear chromatin, micronuclei formation, extensive vacuolization of cytoplasm, and disintegration of the cell into small fragments (apoptotic bodies) (2), which are reflective of the highly conserved nature of the apoptotic execution machinery. In general, two different general pathways of apoptotic cell death initiation exist: extrinsic and intrinsic (Fig. 1). The extrinsic pathway is activated by external stimuli, such as engagement of death domain receptors (DRs) with their cognate ligands. The intrinsic pathway is stimulated by intracellular stress, such as DNA damage. The pathway of DR-induced apoptosis has been studied and characterized extensively. It involves recruitment of the proforms of cysteine proteases, caspase-8 and caspase-10, into the receptor-induced death inducing signaling complex (DISC), which results in their autocatalytic cleavage and activation. Apical caspases can trigger execution of apoptosis directly by processing and activation of the “effector” caspases (caspase-3, caspase-6, and caspase-7) (3). Effector caspases execute apoptosis by cleaving various cellular substrates, which leads to the orderly cell demise. In some types of cells, DR signaling relies on a mitochondrial amplification step, which is carried out through caspase-8 and caspase-10 mediated cleavage of the BH3 domain-only Bcl-2 family member Bid (4–6). Processed Bid translocates to the mitochondria, where it causes release of cytochrome c from the intermembrane space through induction.
Cell Death, Biological Mechanisms and Small Molecule Inhibitors of Caspases

Death-receptor signaling may involve direct caspase-8-mediated caspase-3 activation (type 1 cells) or a Bid-cleavage-dependent mitochondrial amplification step (type 2 cells).

Death-receptor signaling may involve direct caspase-8-mediated caspase-3 activation (type 1 cells) or a Bid-cleavage-dependent mitochondrial amplification step (type 2 cells). The intrinsic pathway of apoptotic death also proceeds through release of cytochrome c from mitochondria, and different forms of stress use different BH3-only factors for signaling.

Although apoptosis remains the mainstay of PCD research, rapidly accumulating evidence indicates that programmed or intrinsically regulated cell death can occur through additional pathways independent of caspase activation and other proapoptotic factors. Multiple alternative processes of regulated cell death have been described, including autophagic cell death, mitotic catastrophe, necroptosis, oncosis, and so on. In most cases, mechanisms of these processes are much less understood than that of apoptosis. Here, we will discuss some emerging small-molecule regulators of these pathways, which have proven helpful in understanding the processes of nonapoptotic cell death. We have omitted several important protein factors from our discussion, such as PI3-kinase, Akt, and p53, and the process of autophagy. Although corresponding cellular pathways make important contributions to the regulation of cell death, they play much broader role in cellular regulation and deserve separate discussion.

Caspases

The family of cysteine proteases, which are called caspases, plays a major role in the execution of apoptotic cell death. Many studies suggest that increased apoptosis and caspase activity contribute to tissue damage in both acute (e.g., myocardial infarction, stroke, sepsis, spinal cord injury) and chronic (e.g., Alzheimer’s, Parkinson’s, Huntington’s disease) human diseases. Caspase family members are also prominently

Figure 1 Schematic representation of the receptor-mediated (extrinsic) and the intracellular stress-mediated (intrinsic) pathways of caspase activation.
involved in inflammatory responses and are required for processing and secretion of proinflammatory cytokines (15). For example, deficiency in caspase-1 or caspase-11 leads to significant protection from septic shock (16, 17). Thus, inhibition of caspase activity has emerged as a promising direction for cytoprotective therapies. All caspases, with the exception of caspase-9, are expressed in the form of catalytically inactive single-chain zymogens that contain a large and a small subunit (18). Activation of the proform occurs by proteolytic cleavage that releases N-terminal pro-domain and separates large and small subunits. An active enzyme is a heterotetramer composed of two large and two small subunits with two identical active sites, which are formed with the contribution from both large and small subunits (19). A small molecule activator of pro-caspase-3, PAC-1 (Fig. 2c), has been identified recently in an in vitro screen of 20,500 compounds (20). This molecule displayed an EC\textsubscript{50} = 220 nM in an in vitro assay and EC\textsubscript{50} < 1 \mu M in cancer cell lines. Furthermore, this molecule was significantly more toxic to primary colon cancer cells compared with matched normal cells (at least 10-fold difference), which suggests that activation of procaspase-3 may represent a new approach for selective killing of cancer cells. Indeed, administration of PAC-1 was found to attenuate growth of three different types of cancer in vivo. However, the precise mechanism of caspase activation by PAC-1 has not yet been described. Unlike many other proteases, caspases possess a high degree of substrate specificity, that is, they display an almost absolute requirement for an aspartic acid residue in the P1 position of a substrate. This requirement stems from several hydrogen bonds that Asp forms within the caspase substrate-binding pocket (21). Furthermore, three preceding amino acid residues (P2–P4) of the substrate contribute to substrate recognition by specific caspase family members, although substrate selectivity of caspases is typically not absolute (22). Based on their substrate preferences, caspases can be divided into three groups (23). Group 1, including caspase-1, -4, and -5, prefers a hydrophobic amino acid in the P2 position.
acid in the P4 position. Group 2 displays strong preferences for Asp in the P4 position and includes caspase-2, -3, and -7. Activity of group 3 caspases, which consists of caspase-6, -8, -9, and -10, is less dependent on the identity of a P4 residue.

Most caspase-inhibitor design strategies target their active sites and are based on caspase substrate preferences. Tetrapeptide inhibitors, which are based on identified sequences of the four amino acid recognition motifs, were shown to inhibit caspase family members selectively (24) (Fig. 2a). Overall, a typical peptide-based caspase inhibitor consists of three major structural components:

1. the “warhead” moiety that interacts with an active site Cys of the caspase
2. Aasp in P1 position (invariable for all peptide-based inhibitors); and
3. P2-P4 sequence, which provides some selectivity toward individual caspase sub-classes (21) (Fig. 2b).

Selectivity of peptide substrates is mainly defined by P4 and to a lesser extent by P2 and P3 residues (Fig. 2b) (12, 22).

The warhead is an electrophilic group that reacts with the nucleophilic Cys of the active site to form reversible or irreversible adducts. Use of aldehyde, semicarbazone, or thiomethylketone groups leads to reversible caspase inhibitors, whereas fluoroacetamidinoketones, chloromethylketones and acyloxymethylketones are used to generate irreversible inhibitors (21). Although peptide inhibitors can be very useful in defining the functional role of apoptosis and caspases in particular cell death paradigm in vitro and even, in some cases, in vivo (25), peptide inhibitors possess several general disadvantages, including toxicity of the leaving group, limited half-life in cells and in vivo, modest selectivity toward individual caspases, and lack of oral bioavailability. These disadvantages limit their use mostly to cell-based studies. Specificity of these molecules toward caspases is somewhat limited, as for example, an irreversible pan-caspase inhibitor DAV-Dmk found to inhibit unrelated cysteine proteinases, such as cathespin B and H (26).

Several promising nonpeptide inhibitors of caspases have also been developed, which may overcome many limitations of tetrapeptide molecules. Lee et al. (27, 28) used high-throughput screening to identify 5-nitrosoin as a caspase inhibitor, which was optimized significantly to obtain selective, low-nanomolar inhibitors of caspase-3 and -7 (Compound 1, Fig. 2d) and caspases -2, -7 and -9 (Compound 2, Fig. 2d). In contrast to peptide inhibitors, these compounds displayed high activity despite the lack of interaction with 51 residue of caspase substrate pocket, and X-ray crystallography suggested that they primarily interacted with the S2 subsite. These compounds inhibited apoptosis in several different cell types, which include camptothecin-treated Jurkat T cells and chondrocytes and cyclophosphamide-treated neutrophils (27, 28).

Okamoto et al. (29) pursued development of peptidomimetic caspase-1 inhibitors based on the crystal structure of caspase-1/A-C-Tyr-Val-Ala-Asp-H complex, which resulted in an inhibitor displaying potent activity in an in vitro caspase assay (EC\textsubscript{50} = 38 nM) and blocking IL-1\textbeta processing in the cells with EC\textsubscript{50} = 230 nM. Furthermore, this molecule blocked IL-1\textbeta release in mice in a dose-dependent fashion. X-ray analysis revealed that naphthoyl- and methyl groups of the methanesulfonamidecarboxyl group, limited half-life in cells and in vivo, even, in some cases, with IL-1\textbeta. VX-740 was found to reduce inflammation and disease symptoms significantly in patients during Phase 2 clinical trials (33, 34). However, clinical trials also demonstrated significant liver toxicity associated with long-term dosing of this molecule, which is likely associated with activity of the warhead group. This finding led to premature termination of clinical trials. Synthesis of improved and highly selective caspase-1 inhibitor, VX-765, which is a prodruk resulting in 4-hydroxybutyrolactone “warhead” moiety, has also been reported recently (35, 36). This molecule efficiently blocked release of inflammatory cytokines in the cells and in vivo; however, no data from clinical trials has been reported thus far.

IDUN Pharmaceuticals (San Diego, CA) also reported development of a potent peptidomimetic irreversible oxamylpeptide inhibitor IDN-6556 that uses 2,3,5,6-tetrafluoroxyphenoxyacetylketone warhead (Fig. 2b) (37, 38). This molecule preferentially accumulates in the liver, which results in pronounced liver protection in animal models (for example, after Fas-induced liver injury (39)), and showed significant promise in clinical trials of acute alcoholic hepatitis, human liver preservation injury, and chronic hepatitis C (38, 40, 41).

To overcome limitations of peptidomimetic inhibitors, such as limited central bioavailability caused by accumulation in the liver, a novel strategy for rapid identification of nonpeptidomimetic caspase inhibitors, tethering has been recently proposed (42, 43). Tethering is based on covalent capture of sulfhydryl-containing small molecules that interact within the active site of caspase-3. For this assay, caspase is modified to contain a free thiol-bearing “extender” attached covalently to the active site cysteine, which is used for small molecule capture. Using this approach, a caspase-3 extender complex was screened against a library of fragments modified to contain a free sulfhydryl group. Selected fragments were subsequently combined with a reversibly binding form of extender, which resulted in rapid selection of potent and reversible caspase-3-specific inhibitor with K\textsubscript{i} of 2.8 nM. Additional chemical modifications enhanced its potency into low nM range (Fig. 2g) (42).

**BCL-2 Family**

Members of the Bcl-2 protein family are key regulators of the mitochondrial step in apoptotic pathway (44). Upregulation of antiapoptotic Bcl-2 family members is commonly observed in many types of cancers and is well established to play a major role in substrate recognition by caspases.

Vertex Pharmaceuticals (Cambridge, MA) reported development of several additional caspase-1 peptidomimetic inhibitors, such as VX-740 (Pranalacasan, Fig. 2e), for the treatment of rheumatoid arthritis (30–32). VX-740 is a pro-drug, which is converted in vivo into an aldehyde active form with K\textsubscript{i} of 1 nM against caspase-1. VX-740 was found to reduce inflammation and disease symptoms significantly in patients during Phase 2 clinical trials (33, 34). However, clinical trials also demonstrated significant liver toxicity associated with long-term dosing of this molecule, which is likely associated with activity of the warhead group. This finding led to premature termination of clinical trials. Synthesis of improved and highly selective caspase-1 inhibitor, VX-765, which is a prodruk resulting in 4-hydroxybutyrolactone “warhead” moiety, has also been reported recently (35, 36). This molecule efficiently blocked release of inflammatory cytokines in the cells and in vivo; however, no data from clinical trials has been reported thus far.

IDUN Pharmaceuticals (San Diego, CA) also reported development of a potent peptidomimetic irreversible oxamylpeptide inhibitor IDN-6556 that uses 2,3,5,6-tetrafluoroxyphenoxyacetylketone warhead (Fig. 2b) (37, 38). This molecule preferentially accumulates in the liver, which results in pronounced liver protection in animal models (for example, after Fas-induced liver injury (39)), and showed significant promise in clinical trials of acute alcoholic hepatitis, human liver preservation injury, and chronic hepatitis C (38, 40, 41).
role in apoptosis evasion of cancer cells under chemotherapeutic treatment conditions (45). The Bcl-2 family can be further subdivided into three classes of proteins. The proapoptotic members Bax and Bak activate apoptosis through formation of a pore in the outer mitochondrial membrane, which results in cytochrome c release and activation of the apoptosis (46). The primary function of antiapoptotic proteins Bcl-2, Bcl-xL, Bcl-w, Mcl-1, and Bfl-1 is to inhibit the functions of Bak and Bax by preventing their oligomerization (47). The members of the third “BH3-only” group have homology with the other family members only in the BH3 domain and serve as upstream sensors of apoptotic signaling. Once activated by an apoptotic signal, BH3-only proteins are proposed to act through two different mechanisms. Some BH3-only factors, which are termed “sensitizers” (Bad, Bik), may act primarily by inhibiting antiapoptotic Bcl-2 family members through BH3-mediated binding to the hydrophobic cleft formed by BH1, BH2, and BH3 domains of antiapoptotic factors. A other subgroup of BH3-only factors, termed “activators,” including BID and Bim, were proposed to activate Bax and Bak directly, which induces their oligomerization (48).

Initial studies of BH3-dependent heterodimerization found that an isolated 16 a.a. BH3 peptides derived from several Bcl-2 family proteins can bind antiapoptotic Bcl-2 family members with submicromolar affinity (49) and agonize Bcl-xL heterodimerization with proapoptotic proteins Bax and Bad (50, 51). The ability of synthetic BH3 peptides to trigger apoptosis was first demonstrated in a cell-free system based on extracts of Xenopus eggs (52). In these studies, BH3 peptides derived from Bak, Bax, and Bad were all found to induce apoptosis through rapid activation of caspases. Because BH3 peptides cannot permeate the cell readily, several strategies were used to generate cell-permeable BH3 peptide-based proapoptotic agents. Wang et al. (53) demonstrated that attachment of decanoic acid allows generation of cell-permeable BH3 peptides. One such peptide, termed CPM-1285 and containing the BH3 domain of mouse Bad, was shown to compete with a fluorescein-labeled Bax BH3 peptide for binding to Bcl-2 (IC50 of 130 nM) in vitro and to trigger apoptosis in human myeloid leukemia HL-60 cells. In another approach, Bcl-2 BH3 peptide was fused to an internal “crosslinks” into Bcl-xL peptides, which led to stabilization of a helical structure, increased cell permeability, and bioavailability. Subsequently, a “stapled” Bcl-xL BH3 peptide efficiently induced apoptosis in leukemia cells in vitro and in vivo, and this activity was increased even more by membrane targeting of the peptide (57). The first proapoptotic inhibitor of Bcl-2 family proteins was identified by Wang et al. (58) in 2000 using a virtual-screening strategy. This method relies on the high-resolution three-dimensional structure of a targeted receptor protein and computer-aided techniques to screen a large number of organic compounds for a potential ligand. Virtual screening of more than 190,000 organic molecules resulted in identification HA14-1 (Fig. 3b) and subsequent in vitro binding assay demonstrated the interaction of HA14-1 with the surface pocket of Bcl-2 with an IC50 value of 9 µM. Subsequently, multiple research groups reported activation of apoptosis by HA14-1 in a variety of cell types through mechanisms related to regulation of the Bcl-2 family as well as retardation of glioblastoma tumor growth in vivo when this molecule was combined with etoposide (59). The group of Dr. Shaomeng Wang (University of Michigan) also successfully used computational strategies to identify a number of different submicromolar small molecule antagonists of antiapoptotic Bcl-2 family members (TW-37, Fig. 3c, IC50 = 290 nM (60)); pyrogallol-based inhibitors, Fig. 3d, IC50 = 110 nM (Bcl-2) (61); flavanoid compound B1-33, Fig. 3e, IC50 = 17 nM (Bcl-2) (62)). These molecules were all found to trigger apoptosis in tissue culture, with some molecules displaying very potent effect (IC50 for Bcl-2 in MDA-MB-231 breast cancer cells = 110 nM). Furthermore, one of these molecules, TW-37, was found to enhance the antitumor effect of standard chemotherapy (cyclophosphamide-doxorubicin-vincristine-prednisone, CHOP) in mouse lymphoma model (63). Overall, these data suggest that computational approaches can be very powerful in designing proapoptotic inhibitors of the Bcl-2 family.

Using a competitive binding assay based on fluorescence polarization (FP), Depterev et al. (64) screened a chemical library of 16,320 compounds to identify two classes of small molecule inhibitors of Bcl-xL, which are termed BH3I-1 and BH3I-2 (Fig. 3a). These compounds were shown to inhibit BH3 peptide binding to Bcl-xL and Bcl-2 with Ki values in the low micromolar range (Ki of 2.4-15.6 µM) as determined by NMR titration assays (64, 65). The NMR titration experiments suggested that BH3I molecules directly interact with the BH3 binding pocket in disrupting Bcl-xL heterodimerization. These compounds were found to induce apoptosis in Jurkat cells through disruption of Bcl-2/Bcl-xL heterodimerization measured in intact cells (64). In addition to affecting Bcl-2-dependent regulation of outer mitochondrial membrane permeability, BH3I-2 was also found to induce damage to inner mitochondrial membrane, likely also through interaction with Bcl-2 (63). In another report, small scale FP-based screening of polyphenols identified gossypol (Fig. 3f) as a novel Bcl-2 and Bcl-xL inhibitor (66). This molecule was found to possess significant activity as a sensitizer when combined with CHOP in a mouse lymphoma model (67) and ionizing radiation in prostate cancer xenograft (68). Using a similar FP screen, PKC inhibitor cheterythrine (Fig. 3g) was identified as a low micromolar Bcl-xL/BH3 inhibitor (69). Curiously, NMR analysis and molecular docking suggested that unlike BH3I-1, this and related sauraphagine molecules may bind to the hydrophobic cleft of Bcl-xL, but rather to the BH groove and BH1 domain, respectively. This analysis suggests a distinct mechanism of Bcl-xL domain displacement, which was proposed to explain increased cytotoxicity of these molecules compared with BH3I-1 (70). Researchers at Abbott Laboratories used a different approach for discovering high-affinity protein ligands, the “structure-activity relationships by nuclear magnetic resonance” (“SAR by NMR”) (71). In this method, the relatively large site is divided into two smaller half-sites that are targeted individually by small molecules. The BH3 binding region of Bcl-xL was first divided into two smaller half-sites that are targeted individually by small molecules.
molecules. The two lead molecules are then chemically linked to improve affinity. In this approach, although the two molecules that target each half displayed $K_i$ values of only 0.3 and 4.3 mM, the combined molecule displayed a $K_i$ of 36 nM against Bcl-2. Subsequent chemical modifications to improve affinity and decrease nonspecific binding to human serum albumin yielded ABT-737 molecule with a $K_i < 1$ nM for Bcl-xL, Bcl-2, and Bcl-w (Fig. 3i) (72). ABT-737 was found to kill the cells efficiently through Bcl-2 or Bcl-xL-dependent mechanism. Furthermore, ABT-737 induced cytochrome c release from isolated mitochondria, which was dependent on inhibition of Bax and Bak by Bcl-2 (72). In other words, ABT-737 was found to antagonize prosurvival activity of Bcl-2 aimed at inhibition of Bax and Bak. Furthermore, Oltersdorf et al. (72) demonstrated that ABT-737 can act as a selective cancer therapeutic drug that displays potent single-agent efficacy against small cell lung cancer (SCLC) cells and cells from lymphoid malignancies, which are known to express high levels of Bcl-2, with EC50 as low as 10 nM. In mouse xenograft models, ABT-737 treatment provided significantly improved survival in mice injected with either lymphoma or SCLC cell lines (73). Curiously, very high specificity of ABT-737 binding to Bcl-2 may actually limit efficacy of this molecule as it has been found not to inhibit activity of the antiapoptotic Bcl-2 family member, Mcl-1, which results in reduced activity in multiple cancer cell lines (74, 75).

Another small-molecule pan-Bcl-2 inhibitor that mimicks BH3-only proteins, GX15-070 (developed by GeminX, Montreal, Canada) (Fig. 3k), was shown to be a potent apoptosis inducer in breast cancer, chronic lymphocytic leukemia, multiple myeloma, and mantle cell lymphoma cell lines (76-79).
GeminiX is currently conducting several clinical trials of GX-15-070 in multiple cancer types as a single agent and in combination with other agents.

The laboratory of Dr. David Hackenberry discovered that increased sensitivity of Bcl-2 and Bcl-xL-expressing cells to mitochondrial respiratory chain inhibitor, antimycin A, is caused by its direct interaction with Bcl-2 family members (80). Furthermore, this effect is retained by 2-methoxy antimycin A (2MAA) (Fig. 3j), an analog lacking ability to inhibit complex 3 of the respiratory chain. Curiously, activity of 2MAA seems very different from that of all of the abovementioned Bcl-2/Bcl-xL inhibitors, as 2MAA displays preferential toxicity toward Bcl-2/Bcl-xL-overexpressing cells. This activity may be caused by the unique ability of 2MAA to antagonize Bcl-xL-dependent changes in cell metabolism, namely reduction in oxidative phosphorylation and activation of glycolysis (88). Such "gain-of-function" Bcl-xL antagonists may be very beneficial for preferentially inducing cell death in Bcl-2-overexpressing cancers.

The Iap, Xiap, and Smac Mimetic Peptides

The inhibitor of apoptosis proteins (IAPs), which are characterized by the presence of one or more baculovirus IAP repeat (BIR) domains, are a family of endogenous apoptosis inhibitors that possess multiple antiparotic activities, including binding and inhibition of active caspases 3, 7, and 9. By inhibiting the downstream caspases 3 and 7, IAPs block the convergence point of multiple caspase activation pathways and thus inhibit apoptosis induced by various stimuli (81). At least eight human IAP members have been identified, of which XIAP (X-linked IAP) and survivin have received the most attention as therapeutic targets (82).

Survivin is a bifunctional protein that acts as a suppressor of apoptosis and plays a central role in the regulation of cell division. Survivin is preferentially expressed in malignant cells, and its expression is frequently responsible for radioresistance of malignancies (83, 84). However, this effect may not be linked to the direct regulation of apoptosis, but rather to the regulation of cell division. Cell-cycle-dependent transcriptional regulation of the survivin gene (85) as well as posttranslational modifications, including phosphorylation by the p38MAPK (86), were found to be essential for the cell-cycle control. Based on the finding that pharmacologic inhibition of mitotic phosphorylation of survivin accelerated the protein destruction and counteracted its function (87), CDK inhibitors such as flavopiridol (Fig. 4a) and purvalanol A (Fig. 4b), which is a more specific p34cdc2 inhibitor, were tested in tumors induced by arsanilic acid with taxol, which induces hyperphosphorylation of survivin (88). Administration of CDK inhibitors resulted in escape from the mitotic block imposed by taxol, activation of mitochondria-dependent apoptosis, and anticancer activity in vivo (87). The stability and function of survivin depends on physical interaction between its BIR domain and ATPase domain of the molecular chaperone heat shock protein 90 (HSP90). Targeted antibody-mediated disruption of the survivin-Hsp90 complex in cancer cells resulted in professional degradation of survivin, mitotic arrest, and mitochondria-dependent apoptosis (89). A structure-based rational screening for antagonists of the survivin-HSP90 complex identified a cell-permeable peptidomimetic derived from the Lys98-Leu99 sequence of the survivin called sheepdin (90). Sheepdin inhibited HSP90 chaperone function by competing with ATP binding and destabilized several HSP90 client proteins, including A1I, CDK6, and telomerase, to induce cell death via apoptotic and nonapoptotic mechanisms in various tumor cell lines. Sheepdin (79–83), which is a cell-permeable five-residue peptide that contains the Lys98-Gly99 sequence of sheepdin essential for HSP90 binding (91), induced rapid killing of different types of human acute myeloid leukemia (AML) cell lines, but not of normal mononuclear cells. Moreover, sheepdin (79–83) efficiently inhibited the growth of AML xenograft tumors without systemic or organ toxicity (91). More recently, a combined structure- and dynamics-based computational design strategy using sheepdin as a scaffold identified the nonpeptidic small molecule that targeted the HSP90 function, 5-aminomimidazole-4-carboxamide-1-β-D-riboside monophosphoramide (AICAR, also a known activator of AMP kinase (AMPK)) (Fig. 4c) (92). AICAR was shown to destabilize several HSP90 client proteins in vivo, including survivin, and to exhibit antiproliferative and proapoptotic activity in multiple tumor cell lines, but not in normal human fibroblasts. Finally, a small molecule that selectively inhibits survivin gene transcription and protein expression has been identified, YM155 (Fig. 4d), and is currently being evaluated in a Phase 2 study for patients with stage 3 and stage 4 melanoma. It showed marked antiproliferative activity in the nanomolar range in a broad spectrum of human tumor cell lines and induced tumor regression in lymphoma, prostate cancer, and non-small cell lung cancer xenografts (93).

XIAP is the best characterized human IAP and is the only member of this family shown to inhibit both the initiator (caspase-9) and executor (caspases-3 and -7) caspases directly. Structural and functional studies of XIAP have demonstrated that a groove in its BIR3 domain is required for binding and inhibition of caspase-9, whereas two surfaces of the BIR2 domain and the juxtaposed linker region bind and inhibit active caspases-3 and -7 (94, 95). The natural inhibitor of XIAP, cIAP1, and cIAP2, the proapoptotic protein SMAC/DIABLO, is released into the cytosol from the mitochondrial intermembrane space during apoptosis activation (96, 97). XIAP dimers cooperatively bind and inhibit both BIR3 and BIR2 domains of IAPs and thus relieve their caspase inhibitory function (98). Peptides that correspond to the four N-terminal amino acids of SMAC (AVP1) were shown to be sufficient for binding to XIAP and preventing XIAP-mediated inhibition of caspase-9 (99, 100). On the other hand, the SMAC peptides cannot relieve the inhibition of caspase-3 by XIAP, because they do not change the XIAP conformation around the linker region (101). When delivered into the cells either by conjugation with the TAT protein-transduction domain (102) or to polyarginine tail (103), SMAC peptides sensitized the SHEP neuroblastoma
Cell Death: Biological Mechanisms and Small Molecule Inhibitors of XIAP and Omi/HtrA2

(102) and non-small cell lung carcinoma H460 (103) cell lines to apoptotic cell death induced by chemotherapeutic drug treatment. In addition, cell-permeable SMAC peptide delayed tumor growth of lung cancer and glioma xenografts (102, 103). These studies provided the proof-of-concept that small-molecule SMAC-mimics can be effective as the anticancer agents (82).

Nonpeptidic small molecule inhibitors of BIR3 domain of XIAP with micromolar binding affinities were synthesized at Abbott Laboratories (Abbott Park, IL) using structure-based design (104). Having conserved the first amino acid residue of SMAC peptide alanine, the substituted five-membered heterocycles such as thiazoles and imidazoles were identified to serve as a replacement for peptide fragments of the lead (Fig. 4e). Several research groups have also reported the discovery of nonpeptidic XIAP inhibitors active in the cell. Using a high-throughput fluorescent polarization assay, pentapeptides competing with the binding of SMAC-like protein H10 to BIR3 domain of XIAP with affinities in 40–60-nM range were identified (105). Tripeptide peptidomimetics (Fig. 4f) based on these leads were shown to inhibit the interactions between the BIR3 domain of XIAP and SMAC, caspase-9, and SMAC derived peptide (105). When the cytotoxicity of selected peptidomimetics was assessed in various cancer cell lines (105), compounds revealed a wide range of potencies from low nanomolar activity in some cell lines to no activity at 50 µM in most others. The toxicity exhibited by peptidomimetic BIR3 ligands in the xenograft cell lines (breast cancer cell lines BT-549 and MDA-MB-231, melanoma cell line SK-MEL-5, and human myeloid leukemia HL-60 cell line) was observed in the absence of additional apoptotic stimulation (105). Furthermore, the selected peptidomimetics were found to slow the growth of tumors in a MDA-MB-231 breast cancer xenograft model (105). Another research group reported synthesis of a SMAC-mimetic, which was approximately 23 times more potent than SMAC peptide in binding the BIR3 domain of XIAP (Fig. 4g) (106). This compound efficiently inhibited the growth of etoposide-treated Jurkat leukemia T cells, which protects the cells from etoposide-induced apoptosis.

The broad-spectrum peptidomimetic IAP family inhibitors were also recently developed (107). Designed based on (7, 5)-bicyclic scaffold, these SMAC-mimetics were found to antagonize the protein interactions that involve XIAP, melanoma...
IAP (ML-IAP), cIAP1, and cIAP2. The most potent SMAC mimetic was more specific for cIAP1-BIR3 and ML-IAP-BIR with \( K_i \approx 50 \text{ nM} \) (Fig. 4h). The compounds were demonstrated to activate caspase-3 and -7, to reduce cell viability in assays using MDA-MB-231 breast cancer cells and A2058 melanoma cells and to enhance docosahexaenoic acid-induced apoptosis in MDA-MB-231 cells.

Computer-based rational drug design was successfully used to synthesize a tetrazoyl thioether (Fig. 4j), a dimeric SMAC mimetic that binds both the BIR3 and BIR2 domains of XIAP with nanomolar affinity (108). Furthermore, this molecule also cross-reacted with cIAP1 and cIAP2. The potency of this dimeric inhibitor is consistent with the recently reported synergistic BIR2/BIR3 inhibition by dimeric SMAC peptide, which is explained by close proximity (4-5 angstrom) between BIR2 and BIR3 binding sites (109). The tetrazoyl thioether sensitized cells to the death induced by death receptor ligands (tumor necrosis factor alpha (TNFα) and TNF-related apoptosis-inducing ligand (TRAIL)) and promoted the activation of caspase-8. This result was unexpected because XIAP is not known to inhibit caspase-8 directly. Rather, recent analyses suggested that killing by this molecule is primarily mediated by targeting cIAP1 and cIAP2, which promotes their autoubiquitination and degradation (110). This, in turn, leads to stabilization of NIK kinase, NF-kB activation, and TNFα production, triggering apoptosis in an autocrine mode. Furthermore, cIAP degradation promotes TRAF2-dependent RIP1 recruitment to TNFR1, which promotes formation of RIP1-dependent caspase-8-activating complex. These unexpected findings suggest that cIAPs may be more important targets for SMAC mimetic compounds than XIAP, for which this class of molecules was originally developed.

Virtual screening was also used to identify the BIR3 domain inhibitors (111). In this case, a library of Chinese herbal remedies was docked into the BIR3 domain main inhibitors (111). In this case, a library of Chinese herbal remedies was demonstrated to reduce cell viability in assays using MDA-MB-231 breast cancer cells and A2058 melanoma cells and to enhance docosahexaenoic acid-induced apoptosis in MDA-MB-231 cells.

Computer-based rational drug design was successfully used to synthesize a tetrazoyl thioether (Fig. 4j), a dimeric SMAC mimetic that binds both the BIR3 and BIR2 domains of XIAP with nanomolar affinity (108). Furthermore, this molecule also cross-reacted with cIAP1 and cIAP2. The potency of this dimeric inhibitor is consistent with the recently reported synergistic BIR2/BIR3 inhibition by dimeric SMAC peptide, which is explained by close proximity (4-5 angstrom) between BIR2 and BIR3 binding sites (109). The tetrazoyl thioether sensitized cells to the death induced by death receptor ligands (tumor necrosis factor alpha (TNFα) and TNF-related apoptosis-inducing ligand (TRAIL)) and promoted the activation of caspase-8. This result was unexpected because XIAP is not known to inhibit caspase-8 directly. Rather, recent analyses suggested that killing by this molecule is primarily mediated by targeting cIAP1 and cIAP2, which promotes their autoubiquitination and degradation (110). This, in turn, leads to stabilization of NIK kinase, NF-kB activation, and TNFα production, triggering apoptosis in an autocrine mode. Furthermore, cIAP degradation promotes TRAF2-dependent RIP1 recruitment to TNFR1, which promotes formation of RIP1-dependent caspase-8-activating complex. These unexpected findings suggest that cIAPs may be more important targets for SMAC mimetic compounds than XIAP, for which this class of molecules was originally developed.

Virtual screening was also used to identify the BIR3 domain inhibitors (111). In this case, a library of Chinese herbal remedies was docked into the BIR3 domain in silico, which resulted in selection of natural compound benzoxazinone emebilin (Fig. 4i). Subsequent studies confirmed that emebilin binds to the XIAP BIR3 domain, which resulted in the inhibition of its interaction with caspase-9, and induced apoptosis in the prostate cancer cells expressing high levels of XIAP. In stably XIAP-transfected Jurkat cells, emebilin was shown to overcome the protective effect of XIAP effectively, which enhanced etoposide-induced apoptosis. At the same time, this molecule had a minimal effect in Jurkat cells transfected with vector control.

The BIR2 domain of XIAP has also been specifically targeted for inhibition. The linker region immediately to the N-terminus of the BIR 2 domain binds the catalytic domain of caspase-3 and blocks the active site of the enzyme through steric hindrance (94, 112, 113). This interaction is relatively weak and is stabilized by a stronger interaction between the binding groove of BIR 2 and a site on a small subunit of caspase 3 (94, 112). Using a high-throughput enzymatic de-repression assay based on caspase-3 proteolytic activity, Wu et al. (114) identified a series of aryl sulphonamide inhibitors of XIAP (Fig. 4k).

These molecules bind the BIR2-linker region and were found to sensitize resistant cell lines to death triggered by the acti-
Poly(Adp-Ribose) Polymerase (Parp)

The polyADP-ribosilation reactions play important roles in many cellular processes, which include regulation of DNA repair, transcriptional control, cellular transformation, and cell death (123). PARP is an enzyme-sensing single and double strand DNA nicks, which catalyzes addition of ADP-ribose units to DNA, histones, and various DNA repair enzymes (using NAD$^+$ as a substrate) to promote DNA repair. Mouse knockout studies showed that combined deletion of just 2 of the 17 PARP family members (PARP-1 and PARP-2) is sufficient to block DNA repair (124, 125). Curiously, multiple studies suggested that combining inhibition of DNA repair with the use of DNA-damaging agents hypersensitizes cancer cells to cell death, which prompted development of PARP inhibitors as the general sensitizing anticancer agents (126). In addition, tumors deficient in DNA repair-associated factors BRCA1, BRCA2, and ATM, were all shown to be hypersensitive to PARP inhibitors, which suggests that PARP inhibitors can be useful in killing these types of cancer cells (127, 128).

At the same time, overactivation of PARP, which is frequently observed in various pathologies, including cardiovascular, neurological, and inflammatory diseases, was shown to result in the depletion of NAD$^+$, leading to the loss of ATP and necrotic cell death. Cell-based studies showed that overactivated PARP-1 mediates both mitochondrial-dependent apoptosis and necrosis (129, 130). Consistent with this notion, genetic deletion of PARP rendered mice resistant to experimental stroke (131), providing rationale for developing PARP inhibitors as the cytoprotective agents.

Several PARP-1 inhibitors were designed based on 3-amino-benzamide (132) (Fig. 5a), but these molecules lacked specificity and potency (133). A newer early inhibitor, benadrostin, showed high activity in vitro for PARP-1, but still required high concentrations (10-100 uM) for chemopotentiation (137, 138). Subsequently, significant effort has been spent on structure-based drug design utilizing information generated using known inhibitors, which ultimately led to the identification of a number of potent PARP inhibitors. Five of these molecules are currently in clinical trials for oncologic indications, that is, AG014699 (139) (Fig. 5d), KU59436 (140–142), and BSI-201 (BiPar, Brisbane, CA), INO-1001 (140–142), and GPI 21016 (MGI Pharma, Bloomington, MN). ABT-888 (143, 144) (Fig. 5e) is expected to enter clinical trials shortly (145). All of these molecules are low-nanomolar PARP inhibitors, which sensitize cancer cells effectively to chemotherapy or radiotherapy at nanomolar concentrations. In animal studies, all of these molecules are well tolerated and effectively synergize with multiple DNA-damaging anticancer agents.

Conversely, PARP inhibitors showed significant promise as cytoprotective agents in animal models of inflammation, stroke, Parkinson’s disease, spinal cord injury, and myocardial infarction (146–148). In addition, PARP inhibitors showed activity in inhibiting various types of injury associated with type 1 and 2 diabetes, including neuropathy, retinopathy, and nephropathy, as well as beta cell death in a streptozotocin-injection model of type 1 diabetes (149). Overall, PARP has emerged as a very promising therapeutic target, especially in treating cancer, whereas a general lack of success in developing cytoprotective treatments has made this direction of PARP inhibitor development more challenging.

Necroptosis

Necroptosis or programmed necrosis is a novel type of regulated nonapoptotic cell death that was recently described by several research groups (150–153). It was found that in some cell types, stimulation of DR with their cognate ligands (TNFα, FasL, or TRAIL) under specific conditions where apoptosis is inhibited leads to the cellular demise with necrotic morphological features. Similar observations were also reported for cell death induced by some oncogenes (Ras, cMyc) (154, 155), chemoattractive agents (etoposide, camptothecin, and staurosporine) (156–158), and viral and bacterial agents (159, 160).

This unique type of cell demise shares the characteristics of both apoptosis (as a regulated form of cell death) and unregulated pathologic necrosis (by the cellular morphology) (161). Thus, discovery of necroptosis may offer an opportunity for therapeutic targeting the pathologic necrosis, because, in contrary to previously accepted views, it may represent a regulated and, therefore, specifically, inhibitable form of cell death. A clivation of necrosis-like death under apoptosis-suppressive conditions has been observed in various mouse models of acute pathologic death, including experimental pancreatitis (162) and multiple organ failure (163).

The signaling pathway of necroptosis is just beginning to emerge with Holier et al. (150) establishing that Ser/Thr kinase activity of DR-associated adaptor molecule, RIP1, is a key specific upstream activator of necroptosis. RIP1 kinase is a client protein of the molecular chaperone heat shock protein 90 (Hsp90), and inhibition of Hsp90 in the cells by the small molecule geldanamycin was found to result in efficient proteasome-mediated degradation of the RIP1 (164). As a result, geldanamycin (Fig. 5f) has been found to inhibit the activation of necroptosis in human Jurkat T cells (150). However, this effect is not specific to necroptosis as geldanamycin also was shown to block the RIP1-dependent NF-kB activation efficiency (164), which is independent of the RIP1 kinase activity, unlike necroptosis (165). In another study, Temkin et al. (166) have suggested that RIP1 may translocate to the mitochondria and lead to disruption of the VDAC/AntiCyclophilin D complex through an unidentified intermediate mechanism.

Although the mechanisms of necrotic cell death downstream of RIP1 are mostly unclear, inhibition of certain cell-signaling pathways has been found to attenuate necrotic cell death. Overproduction of reactive oxygen species (ROS) is a hallmark of necrotic cell death and is a prominent part of necroptosis in some systems (161). ROS production in conditions of

© 2008, John Wiley & Sons, Inc.
necrotic cell death is mediated by the mitochondrial respiratory chain complexes 1 and 2 (167) and/or through formation of RIP1/Rac1/nicotinamide adenine dinucleotide phosphate (NADPH) oxidase complex resulting in an oxidative burst (168).

The antioxidant 3-tert-butyl-4-hydroxyanisol (BHA) (Fig. 5g) has been found to be effective in blocking necroptosis in mouse fibrosarcoma L929 cells and in mouse embryonic fibroblasts (169), but not in human Jurkat T cells (161). Based on the data that closely related antioxidant butylhydroxytoluene (BHT) (Fig. 5h) was not as effective in inhibiting necrotic cell death as BHA, it was proposed that additional inhibitory activities of BHA, like inhibition of mitochondrial Complex 1 and/or of lipid peroxidation, may be critical for its inhibition of necroptosis (169). Consistent with the role of the respiratory chain in ROS generation during necroptosis, inhibitors of complexes 1 (rotenone, amyntal, Fig. 5j, 5i) and 2 (thenoyltrifluoroacetone, Fig. 5k), but not of complex 4 (cytochrome c oxidase) of the mitochondrial respiratory chain, have provided marked attenuation of cell death (167).

Autophagy is an important large-scale cellular catabolic process (see Reference 170 for review), and it is prominently activated as a part of necroptosis in many systems (161, 171-173). However, inhibition of autophagy with 3-methyladenine has been found to inhibit necroptosis in some cell lines, such as mouse fibrosarcoma L929 cells, but not in the other cell lines (human Jurkat T cells or mouse embryonic fibroblasts), which suggests cell type-specific contribution of autophagy to necrotic cell demise (161).

Activation of acid sphingomyelinase (A-SMase) and ceramide production were also shown to contribute to DR-induced necrosis (174). Inhibition of A-SMase activation by small-molecule inhibitors D609 (Fig. 5l) and desipramine (Fig. 5m) has been reported to attenuate necroptosis (174). D609 inhibits A-SMase activation by small-molecule inhibitors D609 (Fig. 5l) and desipramine (Fig. 5m) has been reported to attenuate necroptosis (174). D609 inhibits A-SMase induction indirectly by inhibiting the upstream-acting phosphatidylcholine-specific phospholipase C, whereas desipramine causes rapid and irreversible degradation of A-SMase. Finally, inhibition of NADPH oxidase C-Jun N-terminal kinase (JNK) axis of the pathway using siRNA tools has been shown to
attenuate necroptosis (168). Although it has not yet been tested directly, it is likely that small-molecule inhibitors of NADPH oxidase, such as diphenyleneiodonium chloride (DPI) (Fig. 5n), and of H/K ATPases, such as SK&F60025 (Fig. 5o), may interfere with necrosis activation. It is important to note that none of the above-mentioned inhibitors is specific for necroptosis, because their target proteins are involved in a wide range of cellular regulatory networks. An additional analysis of the mechanisms of specific activation of the downstream pathways of necroptosis by RIP1 kinase will be important for developing more specific strategies for necrosis inhibition.

The first specific inhibitor of necroptosis, necrostatin-1 (Nec-1), was identified by Degterev et al. (161) in a cell-based screen of ~15,000 compounds. Nec-1 (Fig. 5p) efficiently blocked necrotic death of human monocyctic U937 cells stimulated with TNFα in the presence of broad-spectrum caspase inhibitors zVAD-fmk and other instances of necrotic death (161). Although Nec-1 did not inhibit either activation of apoptosis or NF-κB by TNFα, it completely eliminated all the manifestations of cellular necrosis. Furthermore, optimized derivatives of this molecule were reported with EC50 in the cells of 50 nM (Fig. 5q) (175). A different screening resulted in identification of the other potent inhibitors of necroptosis, termed Nec-3 and Nec-5 (Fig. 5r, s) (175, 176), which created a unique panel of nanomolar inhibitors of this process. Based on implication that necroptosis is responsible, at least partially, for the pathologic necrosis, the necrosatins were tested for the cytoprotective effects in vivo rodent models of acute organ injury, which included cerebral (161) and cardiac (177) ischemia and brain trauma (178). Necrostatins were found to provide significant cytoprotective effect and functional improvement in multiple paradigms of acute injury. In the case of brain ischemia, Nec-1 displayed protection when administered up to 6 hours after 2-hour middle cerebral artery occlusion, which suggested that necroptosis may represent a delayed and, hence, therapeutically targetable injury component. Furthermore, recent data showed that Nec-1 also inhibits necrotic cell death provoked in response to other pathologic stimuli in cellular assays, which includes high doses of glutamate (179), plant sterols (180), and the chemotherapeutic agent shikonin (180). These results suggest that importance of necroptosis likely extends beyond DR signaling, and it may represent a major novel component of acute pathologic injuries.

Mitochondrial PTP

The mitochondrial permeability transition (MPT) is the loss of the inner mitochondrial membrane impermeability to solutes caused by opening of the MPT pore (MPTP). In turn, this action results in a loss of mitochondrial function and provides a common mechanism implicated in activation of mitophagy/autophagy, apoptosis, and necrosis in different cell systems. Although the composition of MPTP is not fully settled, multiple studies suggest involvement of adenine nucleotide translocase (ANT) in the inner mitochondrial membrane, voltage-dependent anion channel (VDAC or porin) in the outer membrane, and cyclophilin D (CypD) in the matrix.

Involvement of other proteins such as benzodiazepine receptor, hexokinase, creatine kinase, and Bax has also been proposed (181–183). The first identified potent inhibitor of MPT is the cyclosporine A (CsA) (184) (Fig. 5t), which inhibits the interaction between CypD and ANT (180). Using isolated mitochondria, CsA was shown to inhibit MPT at submicromolar concentrations (185, 186). CsA is also a potent inhibitor of necrotic death in the cells, for example, induced by oxidative stress and in vivo, notably in models of ischemia/reperfusion injury of liver (187), brain and central nervous system (188, 189), and myocardium (190). This finding suggests that inhibition of MPT may be a promising general direction for treating ischemia/reperfusion injury. This notion is supported by the resistance of observed in CypD-deficient mice to this form of injury (191, 192). The major drawbacks of therapeutic use of CsA are its transient and incomplete PTP inhibition as well as immunosuppressive side effects (193). In addition to CsA, other cytoprotective agents were also found to act as PTP inhibitors. These agents include cyclosporin A, rapamycin, and promethazine (Fig. 5u, v), with both of the latter exerting neuroprotective effects in vivo (194, 195). However, in the case of these agents, the exact mechanism of the cytoprotective effects in vivo is yet to be established.

Conclusion

After the groundbreaking discoveries establishing that the cell death can result from intrinsic cellular regulation, rather than excessive external stress, significant focus has been placed on characterization of the molecular mechanism of this process. Several interesting targets, some of which are described in our review, have been identified, and multiple classes of small molecules have been developed and optimized successfully for use as the research tools and, in particular cases, even as the drug development candidates for various disorders, for which efficient treatments are currently unavailable. Compounds that target the enzymatic activities of cell death regulators, such as caspases, PARP, and HtrA2 inhibitors, as well as compounds that modulate the protein–protein interactions and protein conformational changes were developed successfully. Inhibitors have been identified using a variety of different screening approaches from tethering and SAR-by-NMR to rational drug design and high-throughput screening using enzymatic assays or whole-cell phenotypic readouts. Therefore, chemical inhibitors of cell death represent a very extensive and diverse small-molecule development effort, which attests to the importance of cell death regulatory pathways. In some instances, for example, of necroptosis inhibitors, small molecules provided very useful means for uncovering functional significance of the regulation of novel modes of cell death, even in the absence of the specific protein target information. In the other cases, for example, of the PARP inhibitors, small molecules proved very useful in showcasing the importance of the activity of their targets in the cells and in vivo, prompting additional analysis of the biological regulation associated with these protein factors. Finally, in the case of well-validated targets, such as caspases or Bcl-2 family, specific
small-molecule inhibitors confirmed validity of targeting these regulators and the apoptotic pathway in general for the treatment of human disease. They provide exciting new lead compounds for therapeutic development. Overall, these findings emphasize that the availability of tools and methods for fast and efficient identification of small molecule modulators of important biological processes, stemming from rapid development of synthetic chemistry and small molecule screening technologies, provide a very valuable compliment to biologic research.

Cell division is the process by which a cell creates two genetically identical daughter cells. To maintain genomic integrity, a complex and highly regulated sequence of events ensures that the replicated chromosomes are partitioned equally between the daughter cells. For more than 50 years, strategies designed around small-molecule inhibitors have played a critical role in advancing our understanding of this essential process. Here we introduce a series of questions in the biology of cell division and illustrate how small molecules have been used to design experiments to address these questions. Because of the highly dynamic nature of cell division, the temporal control over protein function that is possible with small molecules has been valuable particularly in dissecting biologic mechanisms.

Biology of Cell Division

Cell division is the process by which a cell creates two genetically identical daughter cells. Each chromosome is replicated before mitosis begins, and after the division, the daughter cells inherit exactly one copy of each chromosome. A complex series of events have been divided broadly into two processes: mitosis, in which the identical sister chromosomes are separated and transported to opposite ends of the cell, and cytokinesis, in which the cell physically divides to create two daughter cells (Fig. 1). Preservation of genome integrity requires that the cell divide only after accurate segregation of sister chromosomes in mitosis. Failure in either chromosome segregation or in the timing of critical events in cell division leads to the loss or gain of whole chromosomes in the daughter cells, which is a condition known as aneuploidy that is strongly associated with developmental defects and human diseases such as cancer (reviewed in Reference 1). For over a century, cell division research has focused on mechanisms that physically segregate the chromosomes in mitosis and that divide the cell in cytokinesis, as well as those that control both processes in space and time. Some fundamental questions are how forces are generated to move chromosomes and to cleave the cell, how chromosome movements and cell cleavage are coordinated in space to ensure that each daughter cell inherits exactly one copy of each chromosome, and how events are coordinated in time so that chromosome segregation is complete before cell cleavage. Progress toward addressing these questions has integrated a structural picture of the machinery of cell division with an understanding of the molecular mechanisms that regulate that machinery.

Examining Cell Division with Small-Molecule Inhibitors

Our understanding of biologic processes such as cell division often develops from discovering or designing ways to perturb the process and observe the effects of the perturbation. Although genetic approaches have been used widely for this purpose, small-molecule inhibitors offer some distinct advantages. Small molecules provide a high degree of temporal control over protein function, generally acting within minutes or even seconds, and often are reversible, allowing both rapid inhibition and activation. The ability to design perturbations on short time scales has proven valuable particularly in examining dynamic biologic processes. All cell division takes place in approximately 1 hour, with many events on second-to-minute time scales, and several small-molecule inhibitors (Table 1) have played an integral role in dissecting the mechanisms of mitosis and cytokinesis.

The nature of spindle fibers

Progress through mitosis is linked closely to chromosome movements (Fig. 3a). Replicated chromosome pairs first move to the center of the cell. After all chromosomes are positioned correctly at metaphase (Fig. 3a III), the sister chromosomes split...
Figure 1 Overview of mitosis. (a) (i) Chromosomes are replicated before mitosis, and sister chromosomes are held together. (ii) The spindle forms and chromosomes attach to spindle fibers. (iii) Chromosomes move to the center of the spindle at metaphase. (iv) Sister chromosomes separate at anaphase and move in opposite directions. (v) The cell divides as the cleavage furrow forms between the separated chromosomes. (vi) Two daughter cells form, each with exactly one copy of each chromosome. apart at anaphase (Fig. 1a iv) and move to opposite sides of the cell before the cell divides into two daughter cells (Fig. 1a v, vi). Because of these coordinated movements, each daughter cell receives exactly one copy of each replicated chromosome. Correlated with chromosome movements is the appearance of a fibrous structure known as the mitotic spindle, initially observed in fixed samples, which forms at mitosis and disappears after the chromosomes have separated. One great challenge in the study of cell division has been to understand the organization and function of the mitotic spindle, particularly in relation to chromosomes movements. The physical properties of the spindle fibers and how they might drive chromosome movements, as well as their molecular components, have been understood in part through use of the small molecule colchicine (Fig. 1b). Exploiting the fact that the spindle fibers are optically anisotropic, or birefringent, with different indices of refraction in different directions (i.e., parallel or perpendicular to the fiber axis), Inoue (2) developed a sensitive polarized light microscope
to visualize directly the fibers in a living cell (2). He used this method to examine the behavior of the fibers after exposure to colchicines, a small molecule that was known to disrupt spindle function. Colchicine eliminated the birefringence over a time course that ranged from a few minutes to an hour depending on the concentration, which indicates a loss of the fibers (3). After the removal of colchicine, the fibers recovered to their original state. The inhibition of protein synthesis during the recovery demonstrated that the fibers were assembled from an available pool of material rather than by synthesis of new proteins (4). These findings, together with similar results obtained by chilling cells to eliminate the fibers (5), suggested that the spindle fibers consist of oriented polymers (hence the birefringence) in equilibrium with free molecules in solution. Treatment with colchicine or chilling pushes the equilibrium toward the depolymerized state, whereas the removal of colchicine or rewarming allows the system to return to its original state.

The same experimental paradigm, which combines the observation of spindle fibers with the perturbation of their function in living cells, was used to demonstrate the potential functional significance of the spindle fiber dynamics. When spindles were treated with low concentrations of colchicine, which did not eliminate the birefringence immediately, the fibers slowly contracted and pulled the chromosomes toward one side of the spindle, which was anchored at the cell surface. After the removal of colchicine, the fibers elongated as chromosomes moved away from the pole (3, 6). This finding demonstrated that polymerization and depolymerization of the fibers could generate force by coupling to chromosome movement. These experiments exploited both the reversibility of colchicine and the ability to manipulate the behavior of the fibers by controlling the compound concentration, both properties of many small molecules.

In the Inoue studies, colchicine was used as an experimental tool to probe spindle function, but its target and mechanism of action were unknown. As 100 nM colchicine was sufficient to arrest cultured cells in mitosis, the implied tight binding suggested that the inhibitor might be used to isolate a colchicine–protein complex. A breakthrough came when colchicine was labeled with ^3H with high specific activity to demonstrate reversible binding to cellular sites (7). When the labeled colchicine was tested with a variety of cells, tissues, and organelles, high-binding activity was observed with the mitotic spindle, cilia, sperm tails, and brain tissue (8, 9). A common feature of these preparations is that all are enriched in intracellular fibers called microtubules, the same fibers observed by Inoue, which suggested that the target of colchicine was a subunit of microtubules. The colchicine-binding activity was extracted by dissolving isolated sea urchin sperm tails, purified by gel filtration and sedimented over a sucrose gradient to identify a single component 10. The same component was isolated from mammalian brain, shown to bind GTP, and biochemically characterized as a GTP-binding protein (11). The protein was named tubulin because it was believed to be the primary constituent of microtubules (12).

It has been known for over 100 years that treatment with colchicine arrests cells in mitosis (reviewed in Reference 13). Other small molecules since then have been identified that also block mitosis by targeting microtubules. The potential of these compounds as cancer therapeutics was demonstrated by the vinca alkaloids, such as vincristine and vinblastine, which have been used in the clinic for 40 years. At high concentrations (10–100 nM), these compounds depolymerize microtubules, which eliminates the mitotic spindle. At lower concentrations that are used clinically, microtubules remain stable but microtubule dynamics are suppressed. A number of small molecules that inhibit microtubule dynamics, taxol, also arrests cells in mitosis and is used widely to treat a variety of cancers (reviewed in Reference 14). The mitotic arrest induced by these drugs eventually leads to cell death (15) through mechanisms that are only beginning to be understood (16–18).

**Progression Through Mitosis**

It is clear from observing chromosome movements that cell division occurs in an ordered sequence of events (Fig. 2a). First chromosomes attach to spindle microtubule fibers and move to the spindle equator. Only after completion of this step do sister chromosomes separate at anaphase and move to opposite sides of the cell, followed by division into two daughter cells. Events must occur in this order for successful chromosome segregation. If the cell enters anaphase prematurely, before chromosomes have attached properly to the spindle, the sister chromosomes will not segregate equally, which leads to aneuploid daughter cells. Therefore, mechanisms that determine the timing of anaphase onset are critical for the success of mitosis.

One hypothesis for how anaphase onset might be regulated is that it could either be washed out, as the effect is reversible, or used at a low dose, so that cells would survive the treatment. With high benomyl (70 μg/ml), which prevents spindle formation, cells arrested in mitosis (Fig. 2a). After the removal of benomyl, cells recovered, proceeded normally through mitosis, and continued to grow (Fig. 2b) (21). Alternatively, with low benomyl (15 μg/ml), spindle assembly was slowed and mitotic progression through the cell cycle was blocked as cells arrested in mitosis (Fig. 2c). However, mitotic arrest was only transient at these drug concentrations, and cells eventually continued through mitosis. This finding demonstrated that feedback control mechanisms make essential contributions to the regulation of mitosis.

Benomyl

Genes identified in the benomyl screens, which generally are well conserved from yeast to mammals. The importance of several of these genes for faithful chromosome segregation has been confirmed in transgenic mice, in which reduced expression increases both aneuploidy and cancer susceptibility, and human tumor cells have been reported to carry mutations in Mad1, Mad2, Bub1, and BubR1, a related vertebrate protein (reviewed in Reference 1). Additionally, human germ-line mutations in BubR1 have been linked to mosaic variegated aneuploidy, a condition associated with a high risk of cancer (23).

Benomyl was used in the mad and bub screens not because of its specific protein target but because of the perturbation of spindle assembly. In principle, the same experiments could have been done without knowing the protein target or by targeting a different component of the spindle. The generality of the spindle checkpoint has been demonstrated through the use of monastrol, a small-molecule inhibitor of the mitotic kinesin Eg5, which was identified in a screen for small molecules that arrest cells in mitosis without targeting tubulin (24). Monastrol treatment arrests cells in mitosis with monopolar spindles because Eg5 is required to separate the spindle poles. The inhibition of
Mad2 by the microinjection of inhibitory antibodies overrides the checkpoint so that cells enter anaphase in the presence of monastrol with monopolar spindles (25). This finding indicates that the principle of feedback control generally applies to spindle perturbations through highly conserved mechanisms. Inhibitors of Eg5 currently are in development as anti-cancer drugs because, like taxol and the vinca alkaloids, they arrest cells in mitosis by activating the spindle checkpoint. Recent studies have demonstrated that the efficacy of drugs targeting either Eg5 or microtubules requires a prolonged, checkpoint-dependent mitotic arrest (17, 26). A compromised spindle checkpoint, for example through reduced expression of Mad2, confers resistance to these drugs.

Primary signals for checkpoint activation: attachment or tension?

Whereas the benomyl screens established the existence of the spindle checkpoint and identified some of the key components in checkpoint signaling, a fundamental question that remained unanswered was what exactly is monitored by the checkpoint. Two general models have been proposed. One is that the checkpoint monitors the attachment of spindle microtubules at the kinetochore, a structure that forms on each chromosome to mediate microtubule binding. Unattached kinetochores keep the checkpoint active and delay anaphase (27). A second model is that the checkpoint monitors force across the centromere, the region of the chromosome where kinetochores assemble (28). When both sister kinetochores are attached correctly, they are pulled in opposite directions by the microtubule fibers and the centromere is under tension (Fig. 3a). In this model, the absence of centromere tension would keep the checkpoint active. Small molecules that target tubulin have provided a way to test these models experimentally. Nocodazole depolymerizes microtubules, which creates unattached kinetochores (Fig. 3c), whereas taxol stabilizes microtubules but inhibits their dynamics, which decreases the centromere tension (Fig. 3b) (29).

To determine the effects of these microtubule perturbations on spindle checkpoint signaling, intracellular localization of Mad2 was examined. At early stages of mitosis (Fig. 3a i, ii), Mad2 localizes to kinetochores. As cells progress through mitosis, however, Mad2 disappears from kinetochores, and at anaphase onset (Fig. 3a iv) none of the kinetochores have detectable Mad2. These findings suggest that the presence of Mad2 on kinetochores serves as a signal to delay anaphase (29-31).

When microtubules are depolymerized with nocodazole (Fig. 3c), Mad2 localizes to all kinetochores, which indicates the activation of the checkpoint. If microtubule dynamics are suppressed with taxol while maintaining kinetochore attachments (Fig. 3b), Mad2 localizes to only a few kinetochores (29). This finding suggests that checkpoint signaling, as determined by Mad2 localization, is sensitive to attachment but does not respond directly to centromere tension. The interpretation of these experiments is complicated, however, because tension required for kinetochores to bind the full complement of microtubules; loss of tension may activate the checkpoint indirectly (32).

Experiments in yeast suggested that a member the Auroa kinase family, p110, is required to activate the spindle checkpoint in response to loss of tension but not loss of microtubule attachments (33). Understanding the function of Auroa kinases is particularly important because they have been linked to oncogenesis, and Auroa kinase inhibitors currently are in development as cancer therapeutics (34, 35). In mammalian cells, the inhibition of Auroa kinase activity with small-molecule inhibitors has been shown to bypass the mitotic arrest induced by taxol but not that induced by nocodazole, which is consistent with the idea that the kinase is required specifically in a tension-sensitive mechanism of checkpoint activation (36, 37). The interpretation of these results is complicated, however, because Auroa kinases are implicated also in regulating kinetochore-microtubule binding (38, 39). An alternative interpretation is that Auroa kinase inhibition overrides the taxol-induced arrest through effects on kinetochore-microtubule attachments.

Correcting errors in chromosome–spindle attachments

Feedback control of anaphase onset, or mitotic checkpoint signaling, is one mechanism that contributes to ensuring accurate chromosome segregation. Delaying anaphase in response to unattached kinetochores, however, is not sufficient. Chromosomes must attach to spindle microtubules in a particular...
orientation. For each replicated chromosome pair, the sister kinetochores attach to opposite poles of the spindle so that when sister chromosomes separate at anaphase, they are pulled to opposite sides of the cell. Other attachment states can occur, for example if both sister kinetochores are attached to the same spindle pole or a single kinetochore is attached to both poles. If these errors are not corrected, sister chromosomes will not segregate properly at anaphase (40).

Error correction is thought to occur by stabilizing correct attachments while destabilizing incorrect attachments (41). Experiments in yeast showed that the inhibition of the Ipl1/Aurora family of kinases prevents error correction by stabilizing incorrect attachments while destabilizing incorrect attachments (38, 42), but how the active kinase corrected attachment errors was not known. This problem was particularly difficult to address because attachment errors are observed infrequently in the presence of active Aurora kinase (43). Experimental approaches that accumulated attachment errors through inhibition of Aurora kinase, for example by genetic mutation (42), did not permit subsequent kinase activation to examine error correction. Reversible small-molecule Aurora kinase inhibitors present a solution to this problem because they can be used to inhibit kinase function and subsequently removed to activate the kinase.

To devise a strategy to address the question of how attachment errors were corrected, several issues needed to be addressed. First, Aurora kinases have been implicated in multiple processes in mitosis (44). Ideally, kinase inhibition temporarily would be controlled to isolate experimentally the error correction process. Second, the microtubules fibers that attach chromosomes to the spindle are highly dynamic, and the error correction likely involves some regulation of these dynamics. Live imaging would permit the analysis of microtubule dynamics with high temporal and spatial resolution. Finally, analysis of microtubule dynamics is difficult if individual fibers are obscured by other microtubules in the spindle. By creating conditions in which the improperly attached chromosomes are positioned away from the spindle body, individual fibers could be observed clearly.

An assay was developed, using several small-molecule inhibitors, in which all of these issues were addressed (Fig 4a). First cells were arrested in mitosis with monopolar spindles using the Eg5 inhibitor monastrol (Fig 4a). In the monopolar spindles many chromosomes have a particular attachment error in which both sisters are attached to the single spindle pole, referred to as synthetic attachment (46). After the removal of monastrol, the spindle becomes bipolar, all attachment errors are corrected, and the chromosomes segregate normally at anaphase. To test if Aurora kinase activity is required for correction of the attachment errors, an Aurora kinase inhibitor was added immediately after the removal of monastrol (Fig 4a ii). The advantage of adding the Aurora kinase inhibitor at this point is that Aurora kinase activity is unperturbed for all the preceding stages of mitosis. This assay was performed with two structurally unrelated Aurora kinase inhibitors, A-K1-3 and hesperadin, to control for possible off-target activities of the small molecules (Fig 4b).

Using cells that express GFP-labeled tubulin, both chromosome and microtubule dynamics were examined at high resolution by multimode fluorescence and transmitted light microscopy during spindle bipolarization in the presence of the Aurora kinase inhibitor. The syntelic attachment errors persisted as the spindle bipolarized, which directly demonstrates that Aurora kinase activity is required for the correction of these errors. Notably, some of the improperly attached chromosomes were positioned away from the spindle body, which allowed clear observation of the attached microtubule fiber, unobstructed by other spindle microtubules (Fig 4c). At this point, the Aurora kinase inhibitor was removed to examine how the active kinase might correct the syntelic attachment errors (Fig 4a iii, iv). Aurora kinase was shown to be fully active in vivo 30–60 minutes after removing the inhibitor, as determined by measuring the phosphorylation of histone H3, a known Aurora kinase substrate. On the time scale of kinase activation, improperly attached chromosomes remained attached to the microtubule fibers and were pulled to the spindle pole as the fibers shortened (Fig 4b). After disassembly of the microtubule fibers, the chromosomes moved to their usual position at the center of the spindle as correct attachments formed. Properly attached chromosomes were not affected, which suggests the local regulation of microtubule dynamics by Aurora kinase activity.

This assay demonstrates some advantages of small-molecule inhibitors, particularly in combination with high-resolution live-cell microscopy. Mitosis is a highly dynamic process with many events occurring on time scales of minutes or seconds. Ideally, an experiment would allow both perturbation of protein function and observation of the effects of the perturbation on similar time scales. The use of reversible small-molecule inhibitors to manipulate protein function, together with live cell imaging, makes this possible. In the assay described here, the inhibitors were used effectively as switches to turn enzymes on and off for both the kinases Eg5 and Aurora kinases. With this high degree of temporal control, a mechanism for correcting chromosome attachment errors could be dissected without perturbing the preceding processes, such as those involved in spindle assembly.

Force generation in cytokinesis

Following inactivation of the checkpoint, the chromosomes separate at anaphase and are pulled in opposite directions by the attached microtubule fibers. At anaphase, the cell physically divides into two daughter cells in cytokinesis. Several key questions in cytokinesis have been addressed by using small-molecule inhibitors. First, how is the force generated to cleave the cell into two parts? Second, what mechanisms determine the position of the cleavage plane? Third, how is the timing of progression through cytokinesis controlled?

Cleavage of a cell into two equal parts is a dramatic event that requires coordinated generation of force around the entire perimeter of the cell (Fig 5a). As a clue to how this might be achieved, a filamentous structure was shown by electron microscopy to lie at the cleavage furrow, just below the plasma membrane (reviewed in Reference 47). These filaments, distinct from microtubules, were called microfilaments. A key
Figure 4  Correction of improper chromosome attachments by activation of Aurora kinase (45). (a) Assay schematic. (i) Treatment with the Eg5 inhibitor monastrol arrests cells in mitosis with monopolar spindles, in which sister chromosomes often are both attached to the single spindle pole. (ii) Hesperadin, an Aurora kinase inhibitor, is added as monastrol is removed. As the spindle bipolarizes with Aurora kinase inhibited, attachment errors fail to correct so that some sister chromosomes are still attached to the same pole of the bipolar spindle. (iii) Removal of hesperadin activates Aurora kinase. Incorrect attachments are destabilized by disassembling the microtubule fibers, which pulls the chromosomes to the pole, whereas correct attachments are stable. (iv) Chromosomes move from the pole to the center of the spindle as correct attachments form. (b) Structures of the Eg5 inhibitor monastrol and two Aurora kinase inhibitors, hesperadin and AKI-1. (c) Spindles were fixed after bipolarization either in the absence (i) or presence (ii) of an Aurora kinase inhibitor. Arrows indicate sister chromosomes that are both attached to the same spindle pole. Projections of multiple image planes are shown, with optical sections of boxed regions (1 and 2) to highlight attachment errors. Scale bars 5 µm. (d) After the removal of hesperadin, GFP-tubulin (top) and chromosomes (bottom) were imaged live by three-dimensional confocal fluorescence microscopy and DIC, respectively. Arrows and arrowhead show two chromosomes that move to the pole (marked by circle in DIC images) as the associated kinetochore-microtubule fibers shorten and that then move to the center of the spindle. Time (minutes:seconds) after the removal of hesperadin. Scale bar 5 µm.
step in understanding the function of microfilaments in cytokinesis and other processes was to observe a correlation between the presence of the filaments, their disruption by the small molecule cytochalasin (Fig. 5a), and the phenotype of cytochalasin treatment. Cytochalasin eliminated the microfilaments at the cleavage furrow and prevented contraction of the furrow at cytokinesis. Cytochalasin also inhibited several other forms of cellular or intracellular force generation, including cell motility, membrane ruffling, and nerve outgrowth (48, 49). Microfilaments were observed in all of these systems, and in every case the microfilaments were disrupted by cytochalasin and returned to their normal state as cells recovered after the removal of cytochalasin. Furthermore, the actions of cytochalasin and colchicine generally were mutually exclusive: Processes dependent on microtubules and therefore inhibited by colchicine were often insensitive to cytochalasin, whereas those inhibited by cytochalasin were generally insensitive to colchicine (49). These observations suggested that the two types of filamentous structures could function independently in the cell. Although the molecular target of cytochalasin was still unknown, the correlative evidence indicated that microfilaments played a fundamental role in the generation of forces at the cellular level.

The evidence seems overwhelming that microfilaments are the contractile machinery of nonmuscle cells" (49). Contractility in muscle was achieved through the action of the myosin motor, which uses energy from ATP hydrolysis to slide filaments made up of polymers of the protein actin. The relevance of this process to other cell types had not been demonstrated. A direct link between cytochalasin and actin was provided by the demonstration that cytochalasin decreases the viscosity of actin filaments purified from muscle (50). This experiment led to two important conclusions. First, cytochalasin interacts directly with actin. Second, "an interaction of cytochalasin with actin or actin-like proteins in vivo could account for the ability of cytochalasin to inhibit various forms of cell motility and contraction" (50). Thus, actin was shown to be the molecular target of cytochalasin and implicated as a critical component of the microfilaments involved in cytochalasin-sensitive processes, including contraction of the cleavage furrow at cytokinesis.

Spatial and temporal control of cytokinesis

The cleavage plane typically is positioned in the center of the cell so that cellular components are divided equally between the two daughter cells. Asymmetric divisions do occur, however, and are particularly important during development, when the location of the cleavage plane can determine the fate of the daughter cells. Models to explain the position of the cleavage plane relied on the presence of the bipolar microtubule array of the mitotic spindle, which would place the division plane in between the spindle poles. To test this idea directly, an experiment was designed using monastrol to determine if cytokinesis could occur in cells with monopolar spindles (25). Because the spindle checkpoint prevents anaphase onset in monastrol-arrested cells, inhibitory antibodies against Mad2 were microinjected to override the checkpoint. The microinjected cells entered anaphase and successfully completed cytokinesis (Fig. 6). This experiment demonstrated that a bipolar microtubule array is not required for cytokinesis. Furthermore, careful analysis of microtubule dynamics showed that a population of microtubules near the chromosomes was stabilized during anaphase in the monopolar spindles at the location where the cleavage plane formed. These findings suggested a model in which microtubule dynamics are regulated through association with chromosomes to determine the position of the division plane.

The monastrol experiment showed that the positioning of the cleavage plane is correlated with the position of a particular population of microtubules. How microtubules generate a signal to recruit components of the contractile machinery remained an outstanding question. It has been difficult to isolate experimentally the molecular events that occur in the short time between anaphase onset and the beginning of cytokinesis. To address this problem, a strategy was devised to arrest cytokinesis at a defined point, before contraction of the cleavage furrow (51). A small-molecule inhibitor of the ATPase activity of nonmuscle myosin II, the actin-based motor that generates the force to contract the cleavage furrow, was identified in a high-throughput screen. This inhibitor, called blebbistatin because it prevents myosin II-dependent membrane blebbing, blocks cytokinesis
This experiment demonstrated that the duration of cytokinesis myosin II at the cleavage furrow, increased substantially (51) the blebbistatin arrest. In the presence of MG132, the time that small-molecule proteasome inhibitor MG132 was added during the blebbistatin arrest is that their effects on a single process could be isolated without affecting the preceding processes. These experiments showed that signals from both Aurora and Rho kinases are required to localize myosin II to the cleavage furrow.

To investigate the timing of cytokinesis, small molecules have been used in several strategies to perturb the cleavage process. If cytokinesis is prevented by perturbing either actin or microtubules with cytochalasin or nocodazole, or by inhibiting myosin II with blebbistatin, a window of approximately 1 hour exists during which cytokinesis can occur if the inhibitor is removed (51–53). The existence of this window suggests that an irreversible step exists that prevents cells from reversing processes. Such irreversible steps can be mediated by the degradation of key proteins through proteolysis. To test whether proteolysis is required for the irreversible exit from cytokinesis, the small-molecule proteasome inhibitor MG132 was added during the blebbistatin arrest. In the presence of MG132, the time that cells remained in cytokinesis, as determined by the presence of myosin II at the cleavage furrow, increased substantially (51). This experiment demonstrated that the duration of cytokinesis is determined by ubiquitin-mediated proteolysis.

**Conclusion**

The experiments described in this review illustrate how small-molecule inhibitors have been used to design strategies to address fundamental questions in cell division. As our understanding of cell division advances, the use of small molecules should complement genetic and RNAi-based approaches. In particular, the temporal control over protein function that is possible with small molecules makes it possible to dissect the functions of proteins that are involved in multiple processes. Part of the complexity of cell division is that many proteins, for example the Aurora and Polo family kinases (44, 54), are implicated at multiple stages in both mitosis and cytokinesis. The perturbation of one stage often affects subsequent events, such as by activation of the spindle checkpoint, which limits analyses by preventing subsequent steps. Small-molecule inhibitors can be used to temporally isolate a specific process without perturbing the preceding events. These strategies will likely make important contributions to future investigations of cell division mechanisms.

It also is important to consider some of the limitations of small-molecule inhibitors, particularly in comparison to genetic approaches. With genetics, any gene can be targeted for mutation or deletion without directly affecting any other gene. The discovery of useful small-molecule inhibitors, however, is challenging. The specificity of small-molecule inhibitors also is difficult to demonstrate convincingly. Testing a kinase inhibitor against over 500 kinases in the human genome, for example, is a substantial undertaking. One way to address specificity is to use small molecules in focused assays, in which a narrowly defined biologic process is examined, so that off-target effects are unlikely to be relevant. In combination with this approach, the effects of different, chemically unrelated inhibitors that target the same protein could be compared, as the off-target activities are unlikely to be similar.

**Future directions**

The use of small-molecule inhibitors is limited by the availability of inhibitors and the assays that can be designed around them. The proteins that currently are known to be targeted by small molecules make up a small fraction of the proteome. The identification of new inhibitors will promote the application of small-molecule-based strategies to an increasing range of biologic problems. As methods are developed to monitor protein function with high temporal and spatial resolution, particularly in living cells, the scope for using small molecules also will increase. With recent advances in fluorescence-based probes, it has become possible to monitor numerous properties of living cells, including protease activity, posttranslational modifications, membrane potential, and pH, as well as mediators of intracellular signaling such as Ca2+ and cyclic AMP (55). The temporal control available with small-molecule inhibitors, combined with these high-resolution readouts, should be a powerful combination for examining dynamic biologic processes in living cells. In vitro methods also have been developed for measuring the enzymatic activities of single protein molecules. Observing the effects of a small-molecule inhibitor both at this level and in a more complex cellular context should provide new insights into protein function.

Both the identification of new inhibitors and the design of increasingly sophisticated assays to examine their effects also will contribute to the drug discovery process in several ways. First, studies with small-molecule inhibitors will advance our understanding of the effects of chemical inhibition, the mode of action of most drugs, which typically does not affect levels of the target protein. Approaches such as RNAi that act by

Assay to examine cytokinesis in the presence of a monopolar spindle (25). Treatment with monastrol, a small-molecule inhibitor of the kinesin Eg5, causes cells to arrest in mitosis with monopolar spindles because of activation of the spindle checkpoint. Microinjection of an antibody against the protein Mad2 inactivates the checkpoint so that cells divide with monopolar spindles.

---
reducing protein levels may have other effects, for example, preventing the formation of a multiprotein complex for which the depleted protein is required. Second, the discovery of new inhibitors may provide leads for drug development. For example, inhibitors that induce a mitotic arrest by targeting a protein that is specific to mitosis are potential leads for anticancer drugs that will have fewer side effects than tubulin poisons such as taxol and the vinca alkaloids. Third, assays that are designed to examine the effects of small molecules on specific cellular processes can be used to screen potential drugs for both on- and off-target activities. Finally, a deeper understanding of the basic molecular mechanisms of key processes should lead to improved therapeutic strategies.

References

Chromosomes are large molecules of DNA that organize genetic materials of an organism. Chromosomes need to be properly organized, packaged, and compacted to ensure their integrity and segregation to daughter cells during mitosis. In eukaryotic cells, chromosomes associate with histones and other proteins to form chromatin within the nucleus. The basic packaging unit of chromatin is the nucleosome. The nucleosome core particle consists of 147 base pairs of DNA that wrap around a core histone octamer. A linear array of nucleosomes is further folded into high-order chromatin structures. In addition, chromosomes are regulated during mitosis by the structural maintenance of chromosomes (SMC) family of proteins. Sister chromatids are physically tethered during DNA replication by the SMC1/3 cohesin complex to ensure equal segregation of chromosomes to daughter cells. These sister chromatids are compacted by the SMC2/4 condensin complex to form metaphase chromosomes.

DNA is the genetic material that encodes all information necessary for life. The DNA molecules that carry this information must be highly regulated to control and protect precisely the information they encode. In addition, cellular DNA needs to be replicated and divided equally to daughter cells during mitosis. For these reasons, DNA is elegantly compacted more than 100,000 times into a nucleoprotein structure known as chromatin. This compaction allows for the protection, regulation, and segregation of the genetic information encoded in DNA.

**Chromatin Structure**

Genomic DNA is organized into subunits called chromosomes (1). The human genome is split into 46 chromosomes. In eukaryotes, DNA is packaged and compacted with histones and other proteins to form chromatin. DNA wraps around core histones to form nucleosomes, the most fundamental level of DNA compaction (2). In addition to compacting DNA, histones also regulate the accessibility of DNA to various biological processes that use DNA as the template, including transcription, DNA replication, and DNA repair.

Nucleosome and chromatin fiber

The nucleosome core particle is the basic building block of chromatin (Fig. 1). It consists of 147 base pairs (bp) of DNA wrapped around the histone core in 1.7 left-handed, nonuniform superhelical turns (3). X-ray crystallography studies have revealed the structure of the nucleosome core particle to a resolution of 1.9 Å (4, 5). Each nucleosome core particle is made up of eight core histone molecules, one histone H3-H4 heterotetramer and two histone H2A-H2B heterodimers (4). Each core histone contains an amino-terminal unstructured tail and a three-helix histone fold (5). The histone folds in each dimer contain three distinct DNA-binding motifs that make extensive contacts with the minor groove of the DNA (4, 5). The helical periodicity or average number of base pairs per helical turn of DNA around the nucleosome core is 10.2bp (5, 6). The minor grooves of DNA wrapped around neighboring nucleosomes line up to form channels through which the flexible histone tails emerge from the nucleosome core particle (5). The major groove of nucleosomal DNA is exposed to allow recognition by nuclear proteins, such as transcription factors (5).

Nucleosomes are connected to one another by linker DNA of variable length and the linker-binding histone H1 protein (Fig. 1) (7). These long arrays of nucleosomes spontaneously condense to form helical arrays of nucleosomes, termed the 30-nm fiber after its apparent diameter (Fig. 1) (8). Additional condensation and compaction of chromatin occur through internucleosomal interactions. One important internucleosomal interaction required for chromatin fiber formation is the interaction of a highly acidic patch of histone H2A with the histone H4 tail (8). Ultimately, these internucleosomal interactions form interphase chromatin with an unknown architecture (Fig. 1) (9).
Histone tails

One striking characteristic of the nucleosome core particle is the protrusion of flexible amino-terminal tails from the core histone proteins (5). These histone tails make ideal targets for the regulation of the nucleosome core particle. During events such as transcription, the chromatin must be opened up to allow the extensive protein machinery to access DNA. A cetylation of lysine residues on the protruding core histone tails is one major posttranslational modification that promotes chromatin opening (10). Lysine acetylation of histone tails is associated with active transcriptional regions of the genome, whereas hypoacetylation correlates with transcriptional repression (11). Histone acetyl transferases (HATs) promote transcription by catalyzing acetylation of histone tails (11). Histone deacetylases (HDACs) mediate histone tail deacetylation and, therefore, repress transcription. In addition to acetylation, core histone tails are posttranslationally modified by a number of other moieties, such as serine/threonine phosphorylation, arginine/lysine methylation, lysine ubiquitination, lysine sumoylation, glutamic acid A DP ribosylation, arginine deimination, and proline isomerization (10). These modifications either promote or suppress access to chromatin during transcription, DNA repair, or chromatin condensation in unique ways (12). Recent work has identified several proteins that catalyze these histone modifications, such as the methyl transferases that methylate lysines and arginines, as well as the demethylases such as Jumonji C (jmc) domain-containing proteins and lysine specific demethylase 1 (LSD1) (13).

Chromatin assembly

Chromatin assembly is coupled with DNA replication. Immediately after DNA replication, the parental histones from the original chromosome are randomly divided between the two daughter strands of DNA (14). The remaining complements of histones are assembled from newly synthesized histones. Newly synthesized histones H3 and H4 are acetylated, and these acety groups are removed after their incorporation into DNA (15). A assembly of chromatin requires the functions of histone chaperones and ATP-dependent chromatin remodeling factors (16). Histone chaperones bind histones and facilitate their proper deposition onto DNA by preventing nonspecific histone-DNA interactions (17). Two major histone chaperones are CAF-1 and NAP-1. CAF-1 localizes to the replication fork by binding PCNA and facilitates the deposition of histones H3 and H4 onto the newly synthesized DNA strands (18, 19). Subsequently, NAP-1 facilitates the deposition of histones H2A and H2B to complete the nucleosome (20). Using in vitro nucleosome assembly and nuclease digestion mapping assays, it was shown that the periodic spacing of nucleosomes requires the function of ATP-dependent chromatin remodeling factors, such as the ACF/ISWI complex (16, 21).

Chromosome Cohesion

The propagation of genetic information during cell division is a complex and highly regulated process that involves extensive changes to the interphase chromatin. The somatic cell cycle is divided into four phases: G1, S, G2, and M. During S phase, DNA is replicated to form sister chromatids (22). Each sister chromatid contains the exact same genetic information. Therefore, it is imperative to ensure equal segregation of sister chromatids to daughter cells during mitosis (M phase). Unequal segregation of chromosomes results in daughter cells with wrong chromosome numbers, a condition known as aneuploidy. One important mechanism that ensures proper segregation of chromosomes to daughter cells is sister chromatid cohesion. The cohesin complex

Sister chromatid cohesion is primarily established by the cohesin complex (23). The cohesin complex is a multiprotein complex that contains the structural maintenance of chromosomes (SMC) family of proteins (24). SMC proteins contain the Walker A motif at their N-terminus and the Walker B motif at their C-terminus (Fig. 2a). These motifs are brought together by an intramolecular coiled-coil domain to form a functional ATPase domain, which is similar to other ATP-binding cas tases (ABC) ATPases, such as RAD50 (25). SMC proteins

Figure 1: Schematic drawing of how chromosomes are formed from nucleosomes to the mitotic chromosome. Double-stranded DNA (black lines) wraps around core histones (gray cylinders) to form the nucleosome. Histone tails (curved lines) protrude from the histone core and can undergo various posttranslational modifications that regulate chromatin state. Helical array of nucleosomes forms the 30-nm fiber. Scaffolding proteins (gray bars), such as condensin, further compact chromatin during mitosis to promote proper segregation to daughter cells.
Chromosome Formation

(a) Architecture of the SMC protein complexes. A functional ATPase head domain is formed by N-terminal Walker A and C-terminal Walker B motifs that are brought together by an intramolecular coiled coil. Two SMC proteins heterodimerize through their hinge domains. Kleisin proteins link the two head domains of the SMC heterodimer. (b) Architecture of the cohesin complex. The SCC1 kleisin protein links together the head domains of the SMC1–SMC3 heterodimer to form a ring. (c) Two models for how cohesin establishes functional sister-chromatid cohesion. Sister chromatids are shown as cylinders.

heterodimerize with one another through their hinge domains to form three unique complexes: cohesin (SMC1–SMC3), condensin (SMC2–SMC4), and SMC5–SMC6 (16, 19, 20). The head domains of the heterodimeric pairs of SMC proteins are linked by proteins known as kleisins (23). In addition to kleisins, SMC complexes contain additional non-SMC proteins. The cohesin complex is a multi-subunit complex that consists of the heterodimeric SMC1–SMC3 core, SCC1/MCD1/RAD21, and SA2 (SCC3 in yeast) (Fig. 2b) (23, 24). The function of SA2 is unknown. SCC1 is the kleisin subunit of the cohesin complex. SCC1 contains a winged helix domain at its C-terminus that mediates binding to the head domain of SMC1 (21). The binding of SCC1 to SMC1 facilitates the binding of SCC1’s N-terminal domain to the SMC3 head domain (26). In so doing, SCC1 links the two head domains of the SMC1–SMC3 heterodimer to form a ring-shaped structure. Cryoelectron microscopy has confirmed the ability of the cohesin complex to form a ring-shaped structure with an internal diameter of 30–40 nm (27).

Sister chromatid cohesion

The cohesin complex is loaded onto chromatin during late G1 phase of the cell cycle (28). The ATPase activity of SMC1–SMC3 is required for cohesin loading onto chromatin (29). The mechanism by which the ATPase activity promotes cohesin loading is unclear. In addition to the ATPase activity of SMC1–SMC3, cohesin loading is dependent on the SCC2–SCC4 complex (30). Both SCC2 and SCC4 contain Huntingtin, elongation A subunit, TOR (HEAT) repeats. The exact mechanism by which SCC2–SCC4 promotes cohesin loading is unclear. It has been proposed that SCC2–SCC4 stimulates the ATPase activity of SMC1–SMC3 (23, 29). The cohesin complex is concentrated around centromeres and at intergenic regions (31–33). Interestingly, in budding yeast, the chromosomal localization of SCC2–SCC4 does not overlap with that of cohesin, suggesting that cohesin redistributes to intergenic regions after SCC2–SCC4 facilitates its loading onto chromatin (27). The enrichment of cohesin at intergenic regions is thought to function in regulation of gene expression by insulating promoters from distant enhancers.

Loading of cohesin onto chromatin is itself insufficient to establish functional cohesion between sister chromatids. Establishment of sister chromatid cohesion occurs subsequent to cohesin loading and is tightly coupled to DNA replication in S phase. Several factors are required for the establishment of functional sister chromatid cohesion after the loading of cohesin onto chromatin. These factors include the acetyl transferase ECO1/CTF7, the replication factor C (RFC) complex (CTF18/CTF8), and the chromatin structure remodeling (RSC) complex (34–36). The precise mechanism by which chromatin-bound cohesin establishes sister chromatid cohesion is unresolved. Elegant studies have shown that cohesin binds chromatin by entrapping DNA within its ring-shaped structure. These studies inserted an artificial tobacco etch virus (TEV) protease cleavage site into
one cohesin subunit to allow inducible cleavage. Upon expression of TEV, the cohesin complex was rapidly removed from chromatin and sister chromatid cohesion was destroyed (27). In addition, using circular minichromosomes in which cohesin is loaded, cleavage of the circular DNA results in the removal of cohesin from these chromosomes (37). These studies show that DNA is entrapped within the cohesin ring. How DNA is encircled by the cohesin ring is unclear. Several possible mechanisms have been proposed, most of which involve the transient dissociation of proteins within the cohesin complex to open the ring structure. These include dissociation of the SMC1 and SMC3 hinge domains, SMC1 head domain and SCC1 C-terminus, or SMC3 head domain and SCC1 N-terminus. A further outstanding question is how cohesin actually mediates sister chromatid cohesion. Two equally viable models have been proposed (Fig. 2c). The embrace model proposes that a single cohesin complex encircles both sister chromatids within its ring-shaped structure as the DNA replication fork progresses (Fig. 2c, left). With a diameter of 30–40 nm, the cohesin ring is large enough to accommodate both sister chromatids (10 nm each) (32). However, it is unclear how the cohesin ring copes with the massive DNA replication machinery that would presumably need to move through the cohesin ring. Alternatively, a cohesin dimerization model proposes that each sister chromatid is trapped by separate cohesin complexes. In this model, the individually trapped sister chromatids are held together by the dimerization of the two cohesin complexes (Fig. 2c, right). However, intermolecular interaction between cohesin complexes has not been detected.

Mitotic Chromosome Condensation

In addition to cohesion between sister chromatids established during the S phase of the cell cycle, chromosomes are further condensed to allow for the movement and segregation of sister chromosomes to daughter cells during mitosis. The formation of stable, rod-like chromosomes during prometaphase of mitosis is mediated by several scaffolding proteins, such as topoisomerase II and the cohesin complex (38, 39).

The condensin complex

Chromosome condensation during mitosis is mediated by the condensin complex. Condensin has two subtypes: condensin I and condensin II (Fig. 3a) (23, 24). Both condensin I and condensin II contain the core SMC2–SMC4 heterodimer (34). Similar to SMC1 and SMC3, SMC2 and SMC4 dimerize through their hinge domains. An intramolecular coiled-coil domain brings together the Walker A and Walker B motifs at the N- and C-termini of SMC2 and SMC4. These functional AT-Pase heads are linked by kleisin proteins, CAP-H for condensin I and CAP-H2 for condensin II (24). The condensin complexes also contain additional non-SMC proteins. Condensin I contains CAP-D2 and CAP-G, whereas condensin II contains CAP-D3 and CAP-G2 (34). The functions of these non-SMC proteins are unclear. Electron microscopy studies showed that the condensin complex can adopt a ring-shaped structure similar to cohesin. Condensin can also adopt a lollipop-like structure, with the coiled-coil and hinge domains of SM C2–SM C4 projecting away from a protein mass that includes the head domains of SM C2–SM C4 and the non-SMC proteins (35). How or whether condensin I and condensin II vary in function is unknown. Both condensin I and condensin II are excluded from the nucleus during interphase. Condensin I associates on chromatin after nuclear envelope breakdown during mitosis, whereas condensin II associates with chromatin before nuclear envelope breakdown (40). By cytological examination, chromosome-bound condensin I and condensin II do not overlap (36). Depletion of condensin I or condensin II causes distinct abnormalities in chromosome morphology (41), suggesting that the two complexes may not be functionally redundant.

Chromosome condensation

The mechanism by which the condensin complex organizes chromosomes during mitosis into their fully compacted and stable structure is currently unresolved. Several studies in multiple organisms have established that inactivation of condensin does not result in completely decondensed chromosomes, but in compacted chromosomes that are not properly structured into rigid rods (42). The identity of those factors that mediate chromosome compaction in the absence of condensin is unknown. These
studies suggest that condensin mediates the organization of compacted chromosomes into higher order structures that give rise to familiar metaphase chromosomes (Fig. 1). Clues into how condensin organizes chromosomes come from its activities in vitro. The addition of DNA to purified Xenopus condensin stimulates its ATPase activity (43). Condensin promotes the positive supercoiling of closed circular DNA when in the presence of topoisomerase I and ATP, but not the nonhydrolyzable ATP analog, AMP-PNP (43). The supercoiling of DNA by condensin could promote mitotic chromosome formation, but whether this activity of condensin occurs in vivo is unclear.

The activity of condensin is cell cycle regulated. Condensin purified from mitotic extracts is much more active in promoting DNA supercoiling than condensin from interphase extracts (43). In yeast, cdc2 stimulates condensin activity by phosphorylation of condensin (44). Furthermore, cdc2 is necessary for chromosome condensation (45). Cell Cycle: Regulation of Topoisomerases, Chemistry of
DNA repair is the elimination of covalent DNA modifications and the correction of base mismatches. There are six basic repair categories: direct repair, base excision repair, nucleotide excision repair, recombination, cross-link repair, and mismatch repair.

**Direct Repair**

In direct repair, the chemical modification that constitutes the lesion is reversed without removing and replacing nucleotides. There are four known direct repair enzymes: photolyase, spore photoproduct lyase, methylguanine DNA methyltransferase, and AlkB family oxidative demethylases (1).

**Photolyase.** Photolyase harnesses blue light (400–500 nm) energy to repair ultraviolet (UV) (200–300 nm)-induced DNA damage. Photolyase is a 55–65-kDa flavoprotein that contains two noncovalently bound chromophores (2, 3). These chromophores are a flavin in the form of FADH− and a pterin in the form of methenyltetrahydrofolate (5,10-MTHF) in most photolyases and in rare cases 8-hydroxydeazariboflavin. There are two types of photolyases: cyclobutane photolyase, which repairs cyclobutane pyrimidine dimers (Pyr−→Pyr−), and 6–4 photolyase, which repairs pyrimidine 6-4 pyrimidone photoproducts. The structures and mechanisms of action of both types of enzymes are similar (2). They bind damaged DNA in a light-independent reaction and carry out catalysis by light-initiated cyclic electron transfer. In cyclobutane photolyase, FADH− transfers an electron to Pyr− to generate a radical pair, FADH− and Pyr−−Pyr−−. The cyclobutane radical undergoes bond rearrangement to yield two canonical pyrimidines concomitant with back electron transfer to regenerate the catalytically competent FADH−. Then the enzyme dissociates from the repaired DNA (Fig. 1). The (6–4) photolyase acts by a similar mechanism except that the (6–4) photoproduct is first converted to a four-membered oxetene ring thermally (1, 3) (Fig. 1). Although humans and other placental mammals do not possess photolyase, they do possess two proteins with a high degree of structural similarity to photolyase but no repair activity (1). These proteins, named cryptochrome 1 and 2, are essential for the regulation of the circadian clock (4, 5).

**Methylguanine DNA Methyltransferase.** Methylguanine DNA methyltransferase (MGMT), which repairs the O6-methylguanine and O6-methylthymine, is a 20–30-kDa protein that has no cofactors and is ubiquitous in nature (1). It recognizes DNA damage either by three-dimensional diffusion or, as recently claimed, by two-dimensional diffusion along the duplex with 3′ scanning bias, and it forms a low stability complex with the backbone of the DNA at the active site (7). It then flips out the O6-methylguanine base into its active site (7). The methyl group is then transferred to a nucleophilic cysteine residue in the active site in a SN2 manner (8). The repair reaction generates methyl-cysteine and inactivates the enzyme (Fig. 3) (9–11). The protein cannot be regenerated and is degraded after acting in the reaction. In the reaction the enzyme acts as an alkyl transfer reagent and not as a true enzyme (12). The MGMT encoded by the ada gene is largely responsible for the so-called “Adaptive Response” in Escherichia coli (13).

**AlkB Family Oxidative Demethylases.** These enzymes repair 3-methylcytosine and 1-methyladenine that are introduced by S9-type methylating agents. They use molecular oxygen, 2-oxoglutarate, and Fe(II) to oxidize the methyl group and release it in the form of formaldehyde. The enzyme is also capable of repairing RNA. It has been shown that the human homologues of AlkB, ABH2 and ABH3, prefer dsDNA and ssDNA, respectively, and that in the case of RNA, ABH2 prefers...
Figure 1: Reaction mechanism of DNA photolyases: (A) mechanism of cyclobutane photolyase and (B) mechanism of (6-4) photolyase. Both photolyases harness blue light energy to remove UV-induced damage and contain two noncovalently bound chromophores. They bind UV-damaged DNA in a reaction that is light independent and carry out catalysis in a light-initiated cyclic electron transfer. In (6–4) photolyase, the (6–4) photoproduct is converted to a four-membered oxetane ring thermally ($kT$) before the photochemical reaction.
double-stranded substrates, whereas ABH3 prefers single-stranded substrates. AikB is widespread in nature, and at least eight genes encoding the enzyme have been identified in humans (Fig. 4) (14).

Base Excision Repair

In base excision repair, the damaged nucleotide is removed in two steps. First, a glycosylase cleaves the glycosidic bond of the damaged base and releases it; then a combination of AP lyase/P endonucleases cleaves the phosphodiester bonds on either side of the resulting abasic site (AP = apurinic/apyrimidinic site) to release the deoxyribose. The resulting gap is filled in by a polymerase and sealed by DNA ligase. Base excision repair as a general rule works on non-bulky DNA lesions that do not cause gross structural alterations in the duplex (15).

Some glycosylases are simple glycosylases, which only catalyze the hydrolytic removal of a base to form an abasic site, whereas other glycosylases cleave off the base using a lyase mechanism and catalyze an AP lyase reaction. In this AP lyase reaction, a Schiff's base is formed from the 1′ aldehyde of the AP deoxyribose. This labilizes the 2′ hydrogen, resulting in a β-elimination reaction, and leaving a 5′-phosphomonoester and a 3′ unsaturated sugar phosphate residue. Lyase reactions are usually associated with glycosylases that remove oxidized bases, but not with glycosylases that remove alkylated or normal bases (15).

Depending on the initial events in the removal of the damage, in humans repair may proceed by two possible mechanisms: short patch repair or long patch repair. In short patch repair, the repair patch is a single base; in long patch repair, it is 2–10 nucleotides long. In the short patch monofunctional glycosylase pathway, APE1 makes a 5′ incision at an AP site and the 5′-baseless sugar phosphate is trimmed by the dRP lyase activity of Polβ to generate a ligatable 5′ end, which is ligated by the Ligase III/XRCC1 complex. Long patch repair occurs when hydrolytic glycosylases or spontaneous base loss generates the AP site. In long patch repair, APE1 cleaves the 5′ phosphodiester bond, and then repair synthesis and nick translation are carried out by DNA Polymerase δ or ε aided by RFC/PCNA clamp loader/polymerase clamp. DNA synthesis displaces several nucleotides. The flap that is generated is

Figure 2. Reaction mechanism of spore photoproduct lyase. Spore photoproduct lyase removes the UV damage spore photoproduct. The enzyme is an iron sulfur protein that uses AdoMet as a cofactor and repairs the damage through a radical mechanism.
Chemistry of DNA Damage Repair

Repair of O₆-methylguanine by methylguanine DNA methyltransferase. Methylguanine DNA methyltransferase has no cofactors and recognizes DNA cooperatively. It flips the O₆-methylguanine into its active site and transfers the methyl group to a nucleophilic cysteine in an SN₂ reaction.

The damage recognition mechanism of DNA glycosylases is similar to the mechanism of recognition of DNA photolyase. The initial recognition by DNA glycosylases is by diffusion. The distortions and H-bond changes that occur as a result of DNA damage are recognized with a low affinity/specificity. This recognition is followed by base-flipping, which forms a high affinity/specificity complex (16, 18). The glycosyl bond is then cleaved off by the Fen1 endonuclease and the repaired DNA is ligated by Ligase I (1, 16, 17) (Fig. 5).

The damage recognition mechanism of DNA glycosylases is similar to the mechanism of recognition of DNA photolyase. The initial recognition by DNA glycosylases is by diffusion. The distortions and H-bond changes that occur as a result of DNA damage are recognized with a low affinity/specificity. This recognition is followed by base-flipping, which forms a high affinity/specificity complex (16, 18). The glycosyl bond is then cleaved off by the Fen1 endonuclease and the repaired DNA is ligated by Ligase I (1, 16, 17) (Fig. 5).

Nucleotide Excision Repair

Nucleotide excision repair is the primary repair system for the removal of DNA damage caused by chemicals that produce bulky adducts or by the UV component of sunlight, which produces cyclobutane pyrimidine dimers (Py4<->Pyr) and (6-4) photoproducts in DNA (1). These lesions, as well as other bulky lesions induced by chemical carcinogens, are removed by the universally conserved repair mechanism called nucleotide excision repair. Nucleotide excision repair can be used to repair almost all single base lesions in DNA. As a result, it recognizes an extremely diverse substrate range, and rather than recognizing the specific damage itself, the excision nuclease tends to recognize the backbone conformations created by the damage (1).

The basic steps of nucleotide excision repair are as follows: 1) damage recognition, 2) dual incisions, 3) release of the excised oligonucleotide, 4) repair synthesis to fill in the gap, and 5) ligation. In E. coli, nucleotide excision repair is carried out by three proteins, UvrA, UvrB, and UvrC, which excise a 12-13 nucleotide-long oligomer containing the damaged base. A (UvrA)₂(UvrB) complex traces along the DNA backbone until UvrA recognizes a damaged base. The complex then binds to the damaged base. This binding activates the helicase function of UvrB, which unwinds the DNA around the damage (about 5 bp on either side of the damage). The resulting single-stranded DNA leads to a tighter binding of UvrB to the single-stranded DNA and a dissociation of the UvrA from the tight UvrB-DNA complex. Therefore, UvrA is referred to as the "Molecular Matchmaker" (1). The resulting UvrB-damaged DNA complex then recruits UvrC, which initiates the dual incisions of the DNA. The 3' incision is performed first at the fourth or fifth phosphodiester bond to the lesion by the GIY-YIC endonuclease domain of UvrC. In a concerted but asynchronous reaction, the second active site in the C-terminal half of UvrC...
Chemistry of DNA Damage Repair

Figure 4. Direct repair through oxidative demethylation by the AlkB protein. AlkB uses molecular oxygen, 2-oxoglutarate, and Fe(II) to oxidize the methyl group and then releases it as formaldehyde.

makes the 5′ incision. Helicase II (UvrD) releases the 12–13 nucleotide-long oligomer carrying the lesion along with UvrC. The dissociation of UvrC leaves a free hydroxyl group at the 5′ incision. DNA Pol I binds to this hydroxyl group and fills in the gap while releasing UvrB. DNA ligase then completes the repair reaction (Fig. 6) (20).

In humans, excision repair is carried out by six factors: RPA, XPA, XPC, TFIIH, XPG, and XPF-ERCC1, which are comprised of 15 proteins. These act in a coordinated manner to make dual incisions bracketing the lesion and remove the damage in 24–32 nucleotide-long oligomers (13). Damage is recognized by RPA, XPA, and XPC acting in a cooperative manner, followed by recruitment of TFIIH by XPA and XPC. The resulting complex is called pre-incision complex 1 (PIC1). Within this complex, the DNA is unwound by about 25 bp around the damage site by the XPB and XPD helicase subunits of TFIIH in a reaction that requires ATP hydrolysis. Then, XPC is displaced concurrent with binding of the XPG nuclease to form PIC2; finally XPF–ERCC1 is recruited to form PIC3. In PIC3, XPG makes the 3′ incision at the 6th ± 3 phosphodiester bond and the excised 24–32 nucleotide-oligomer is released and the complex dissociates. The excision gap is filled in by DNA polymerases and then ligated (21, 22) (Fig. 6).

Both the prokaryotic and the eukaryotic excision nucleases employ thermodynamic discrimination and kinetic proofreading to achieve high specificity. However, despite these elaborate discriminatory mechanisms, excision nucleases do not have absolute specificity and “gratuitous repair” of undamaged DNA occurs at a low but potentially deleterious level (23-25).

Finally, in addition to nucleotide excision repair and base excision repair, an alternative repair pathway exists to remove Pyr→Pyr and (6–4) photoproducts in some organisms, including Schizosaccharomyces pombe. In this alternative pathway, an enzyme called UV dimer endonuclease cleaves DNA immediately 5′ to the damaged lesion. The damage is then removed by a 5′ to 3′ exonuclease (26, 27). Additionally, AP endonucleases, like Nfo in E. coli and APE1 in humans, have the ability to incise immediately 5′ to nonbulky lesions caused by oxidative damage and initiate excision of the lesion by a 5′ to 3′ exonuclease (28).

Double-Strand Break Repair and Recombinational Repair

Double-strand breaks occur naturally in V(D)J recombination to generate antibodies and during the immunoglobulin class switching reaction, but they also occur improperly during replication as a result of the replication fork stalling and collapsing. Double-strand breaks may also be caused by ionizing radiation, chemicals, and reactive oxygen species. Homologous recombination (HR) and non-homologous end joining (NHEJ) are the two mechanisms used to repair double-strand breaks (1).

Homologous Recombination (HR)

In homologous recombination, an intact homologous duplex is used to retrieve information and fix the duplex with strand breaks. The three basic steps in homologous recombination...
Chemistry of DNA Damage Repair

**Figure 5.** Base excision repair in mammalian cells. In base excision repair, the damaged nucleotide is removed in a two-step process. A glycosylase cleaves the glycosidic bond of the damaged base, releasing it, and then AP lyase and AP endonuclease cleave the phosphodiester bonds on either side of the abasic site, which releases the deoxyribose.

are strand invasion, branch migration, and Holliday junction formation (Fig. 7). Strand invasion and branch migration are carried out by RecA in prokaryotes (29) and Rad51 in eukaryotes (30). The Rad51 paralogs (XRCC2, XRCC3, Rad51B, Rad51C, and Rad51D) along with BRCA2 are considered the mediators during homologous recombination in mammalian cells. Before the initiation of strand invasion by Rad51, the Mre11/Rad50/Nbs1 (MRN) complex processes the termini of double-strand break to facilitate strand invasion. After strand invasion and branch migration, the two duplexes are linked through the Holliday junction, which is the key intermediate of homologous recombination. In the Holliday junction, the two strands that are being recombined are joined together covalently by single-strand crossovers. A heterodimeric resolvase, Mus81/Mms4, then cleaves the Holliday junction to separate the two duplexes (31) (Fig. 7). A key feature of HR is that any information that is lost by double-strand break is retrieved using the information from a sister chromatid or homologous chromosome.

**Nonhomologous End Joining**

In NHEJ in eukaryotes, the Ku heterodimer binds to both ends of the double-strand break (32) and recruits DNA–PKcs and the ligase IV–XRCC4 heterodimer. These then ligate both ends of the double-strand break regardless of whether they actually come from the same chromosome (33). In NHEJ, Artemis is the end-processing nuclease (34) (Fig. 8).

HR is important for the rescue of collapsed replication forks. NHEJ is the physiological recombination mechanism in V(D)J recombination and seems to be the major pathway of the repair of double-stranded breaks induced by ionizing radiation and radiomimetic agents in mammals.
Cross-Link Repair

Chemotherapeutic drugs such as cisplatin, psoralen, and mitomycin C and other DNA-damaging agents cause interstrand DNA cross-links. These lesions pose unique problems for the cellular machinery because both base excision repair and nucleotide excision repair rely on the redundant information in the undamaged strand to correctly fill in the gap resulting from the damage removal. However, in cross-linked DNA, both strands are damaged and the genetic information is therefore lost. The cell overcomes this difficulty by using multiple repair systems to repair the damage. Nucleotide excision repair and homologous recombination work either coordinately or in tandem to remove these lesions in E. coli and Saccharomyces cerevisiae (35, 36), and the mechanism of removal of cross-links in mammalian cells is not well understood.

E. coli overcomes the dilemma of cross-link repair by combining nucleotide excision repair with homologous recombination. First, dual incisions are made in one strand by the UvrABC excision nuclease. Second, through homologous pairing of the incised duplex with the intact sister chromosome, a segment of the intact duplex is paired with the gap, generating a three-strand noncovalent intermediate. The transferred strand is ligated to form a three-stranded covalent intermediate. Third, the “excised oligomer” remaining linked to the duplex through the cross-link is recognized as a bulky adduct and is excised by dual incisions. The gaps generated by repair and recombination in the damaged and sister duplex, respectively, are filled in by DNA polymerases and the newly synthesized DNA is ligated (35) (Fig. 9). Genetic evidence indicates that the yeast S. cerevisiae also employs combinations of nucleotide excision repair and recombination to eliminate cross-links (37, 38).
Chemistry of DNA Damage Repair

**Figure 7** Repair of the double-strand break by homologous recombination in mammalian cells. In homologous recombination, an intact homologous chromosome is used to retrieve information and repair double-strand breaks in the duplex. The three basic steps of homologous recombination are strand invasion, branch migration, and Holliday junction formation.

**Figure 8** Repair of double-strand breaks by nonhomologous end joining in mammalian cells. In nonhomologous end joining, the ends of the double-strand break are brought together by DNA–PKcs (light blue rectangle) in conjunction with the Ku70/Ku80 (dark blue circle) heterodimer. After end processing by the Artemis nuclease and some DNA polymerases, the ends are ligated by the XRCC4–Ligase IV complex.

The role of nucleotide excision repair in cross-link repair in humans is not currently clear. Replication fork collapse due to cross-links can induce double-strand breaks during replication both in vivo and in vitro (39). Mutations in XPF and ERCC1 render mammalian cells extremely vulnerable to DNA cross-linking agents (40). This has led to the conclusion that XPF•ERCC1, which is a structure-specific endonuclease, plays a significant role in cross-link repair that is distinct from its role in nucleotide excision repair. At the double-strand break induced by replication, XPF•ERCC1 degrades one of the cross-linked strands 3′ to 5′ though the cross-link (38). Recombination proteins, which include Rad51, Rad52, XRCC2, XRCC3, and RPA then act to generate a Holliday junction intermediate, which would be resolved as described previously (40).

It has been found that patients with Fanconi’s anemia (FA) are extremely susceptible to cross-links. Evidence has been found that suggests that the FA complex (which is composed of FANCA, C, E, and F, 4 of the 12 Fanconi anemia proteins) along with the M/R/N complex and BRAC1/BRAC2 use homologous recombination to participate in both cross-link repair and double-strand break repair (41).
Mismatch Repair

Mismatch repair removes mismatched bases from newly synthesized DNA. The general strategy of mismatch repair follows. The repair reaction is usually coupled to DNA replication and corrects errors introduced by DNA polymerases in the newly synthesized strand. The mismatch is recognized by a mismatch-specific protein, and the mismatched nucleotide in the newly synthesized strand is removed by an exonuclease that initiates hydrolyses of the newly synthesized strand at a nick that may be located up to 1000 nucleotides away from the mismatch and that may be 3' or 5' to the mismatch. Exonucleolytic degradation of DNA past the mismatch is coupled to DNA synthesis to replace the excised DNA and substitute the correct nucleotide in place of the mismatched one. The mismatch repair system is evolutionarily conserved among organisms ranging from E. coli to humans. The mismatch is recognized by M uS in E. coli and by M uS6 in humans (heterodimers of M uS paralogs M SH2 and M SH6 and M SH2 and M SH3, respectively). The strand-discriminating nick is introduced by M uH in E. coli. This enzyme recognizes the transiently hemimethylated GATC sequence in the newly synthesized strand. This sequence is methylated by deoxycytidine methylase (Dam) at the A residue, and shortly after synthesis, the newly synthesized DNA is transiently unmethylated. In a hemimethylated GATC site, M uH makes a nick at the 5' side of G in the unmethylated GATC. In humans, there is no methyl-directed mismatch repair and the enzyme responsible for introducing nicks is not known (42, 43). It is thought that the terminus of the elongating leading strand and the terminus of the Okazaki fragments of the lagging strand may constitute sites of entry of the mismatch removing exonuclease. In both E. coli and in humans, a protein called M uL provides communication between the nick and the mismatch and helps direct the exonuclease degradation from the nick to the mismatch. M uL is a homodimer in E. coli, and there are two heterodimers of three M uL homologs in humans (M uL u = M LH1 plus P MS2 and M uL β = M LH1 plus P MS1). The DNA located between the nick and the mismatch is removed by 3' to 5' or 5' to 3' exonucleases depending on whether the nick is 3' or 5' to the mismatch. The gap is then filled by DNA Pol III in E. coli (Fig. 10) by DNA Pol I in humans and is ligated. Mismatch repair increases the spontaneous mutation rate in E. coli and yeast. Humans defective in mismatch repair exhibit a cancer-prone syndrome called hereditary nonpolyposis colon cancer (HNPCC), and sporadic mutations of mismatch repair genes are also associated with up to 50% of all human cancers (42–44).

Maintenance of genomic stability is essential for the survival of cells, organisms, and species. Genomic stability relies on the complete and accurate transmission of genetic materials from mother cells to daughter cells and from one generation to the next. This task is daunting, however, because the genome is constantly challenged by numerous intrinsic and extrinsic stresses that damage deoxyribonucleic acid (DNA). If left untreated, such damage can destabilize the genome by introducing gene mutations, duplications, and chromosomal rearrangements such as deletions and inversions, which fortunately does not normally happen as cells evolve a complex damage sensing and signaling mechanism named the DNA damage and replication checkpoint. Checkpoint activation effectively pauses the progression of the cell cycle, allowing more time for the removal of DNA lesion. Moreover, activated checkpoint also regulates and coordinates a number of cellular processes including DNA repair, DNA replication, and chromatin remodeling to alleviate the stress on the genome.

The Biology of Checkpoint
Deoxyribonucleic acid (DNA) damage poses a constant and serious threat to the stability and integrity of the genome. DNA damage can develop from exposure to external sources such as chemical carcinogens, ultraviolet (UV) light, or X ray. It can also be caused by sources from within: metabolic byproducts, free radicals, and interference with duplication and segregation of genomic DNA. To maintain genomic stability in the face of DNA damage, an intricate and elaborate signaling pathway called the DNA damage and replication checkpoint is evolved. Remarkably, essential components of checkpoint are largely conserved throughout evolution, underlying the importance of this pathway and making the study of checkpoint simultaneously in different model systems rational. In eukaryotes ranging from human to yeast, two signaling pathways, which are initiated respectively by the ATM (ataxia telangiectasia mutated) kinase and the ATR (ATM- and RAD3-related) kinase, are the major guardians of genome stability (1). Although ATM primarily responds to double-stranded DNA breaks (DSBs), ATR regulates the response to a wide spectrum of DNA damage, especially those interfering with DNA replication (2). Through phosphorylation of signal transducer and effector proteins, ATM and ATR relay the DNA damage signals to downstream cellular processes. The effectors of ATM and ATR include proteins involved in cell-cycle transitions, DNA replication, DNA repair, chromatin remodeling, telomere maintenance, transcription control, and apoptosis. Collectively, the phosphorylation of these effectors enhances the ability of cells to repair and to overcome the encountered DNA damage. When the extent of damage reaches an intolerable level, activated checkpoint can also lead to programmed cell death.

What will happen if cells do not have a functional checkpoint? The ATR checkpoint is essential for the survival of cells and the embryonic development in mammals (3, 4), which is likely a result of the important function of ATR in coping with the intrinsic stresses during DNA replication. On the other hand,
Sensing of DNA Damage

the ATM checkpoint is not essential, but its defects result in phenotypes associated with genomic instability, such as high cancer risk, premature aging, and neuron degeneration (2). Mutations in several other genes involved in the ATM or ATR checkpoint response, such as p53, Brcal, and Nbs1, have also been found to associate with cancer. Thus, it is clear that the ATM and the ATR checkpoint are crucial for survival at both cell and organism levels.

The Chemistry of DNA Damage Sensing

In eukaryotic cells, a prototypical checkpoint cascade consists of DNA damage sensors, signal initiators, signal transducers, and effectors. Similar to many other signal transduction cascades, the signaling of checkpoint pathways is primarily achieved by protein phosphorylation. ATM and ATR are believed to be the signal-initiating kinases in these pathways. Albeit related in sequence, ATM and ATR differ in their DNA damage specificity. ATM responds primarily to DSBs, a rare but acute threat to genomic stability. ATR, on the other hand, is more pleiotropic and indispensable for checkpoint responses to damage caused by disturbance during normal DNA replication. With the help of distinct sets of DNA damage sensors that recognize specific DNA damage-induced structures (see below), ATM and ATR are localized to sites of DNA damage in cells and phosphorylate their substrates at these sites.

Activated ATM and ATR phosphorylate proteins of various functions, two of which are the Chk1 and Chk2 kinases. Chk1 and Chk2 are pivotal signal transducers in the checkpoint pathways (5, 6). Phosphorylation and activation of Chk1 and Chk2 not only allow the checkpoint signals to reach additional effectors, but also provide an additional layer of signal regulation. A group of signal transducers, including Brcal, TopBP1, Claspin, 53BP1, and Mdc1, mediate the signaling from ATM and ATR to Chk1 and Chk2 (7–15). These proteins are often referred to as the mediators. Many of the mediators are substrates of ATM or ATR, and they contain phosphopeptide-binding domains such as the breast cancer C-terminal (BRCT) and the forkhead-associated (FHA) domains. These properties of the mediators enable them to interact with other proteins in a phosphorylation-dependent and damage-regulated manner, thereby allowing the checkpoint signals to be relayed to downstream effectors. As a result of checkpoint activation, the cell cycle can be temporarily halted at the G1/S or the G2/M transitions, or even within the S phase. Furthermore, activated ATM, ATR, and the Chk kinases also phosphorylate proteins involved in DNA repair, DNA replication, chromatin remodeling, and gene expression to facilitate the removal of DNA lesions and to alleviate the stress on the genome.

DNA Damage Sensing by the ATM Pathway

In response to ionizing radiation or certain types of DNA-damaging agents (e.g., cisplatin), the activity of ATM is rapidly stimulated by DSBs (16). In undamaged cells, ATM molecules exist as inactive oligomers. Upon DNA damage, autophosphorylation of ATM on a Serine residue (Ser1981) transforms the latent oligomers into active monomers (Fig. 1) (17), which appears to be an essential step for ATM-mediated checkpoint activation as mutation of this residue renders the kinase functionless. It should be noted that ATM autophosphorylation can be triggered by very low doses of ionizing radiation or disturbance of chromatin structure in the absence of detectable DSBs (17). It was hypothesized that alterations of chromatin structure might partially activate ATM. However, the exact mechanism that leads to ATM autophosphorylation remains unclear.

Activated ATM is capable of phosphorylating non-DNA-bound substrates like p53, but the phosphorylation of other substrates at sites of DNA damage requires actions of the Mre11-Rad50-Nbs1 (MRN) complex (Fig. 1). In cells lacking Mre11 or Nbs1, ATM does not associate with chromatin nor does it phosphorylate its substrates such as Brcal and Smc1 (18). The MRN complex can directly associate with double-stranded DNA ends in vitro (19, 20), and it possesses a 3’ to 5’ exonuclease activity (21). Mre11, the nuclease of the complex, stably associates with Rad50 to form a globular DNA-binding head with two flexible arms comprising the coiled coils of Rad50 (19, 20). The Mre11-Rad50 complex can bind DNA, and this association stabilizes the nuclease and increases its activity (22). The MRN complex interacts with ATM to form the MRN-ATM complex (Fig. 1), which is necessary for ATM activation in response to DNA damage. The MRN-ATM complex stabilizes ATM, allowing it to autophosphorylate and become activated.
Sensing of DNA Damage

to DNA ends and tether DNA fragments through the arms of Rad50 (20, 22). Nbs1 interacts with both Mre11 and ATM, and its ATM-binding domain in the C terminus is critical for the recruitment of ATM to DNA damage (23). Interestingly, a recent study using purified proteins demonstrated that the MRN complex is able to stimulate the phosphorylation of substrates by ATM in the presence of double-stranded DNA ends (24). These findings suggest that the MRN complex, which not only recruits ATM to DSBs but also directly stimulates its kinase activity, is an important DNA damage sensor of the ATM pathway.

The recognition of double-stranded DNA ends is only the first step of the DNA damage sensing by ATM. As soon as ATM is activated at the DNA ends, it phosphorylates the histone H2AX in the adjacent nucleosomes (Fig. 1) (25). Phosphorylated histone H2AX recruits the mediator Mdc1 through an interaction with its BRCT domain (12, 26, 27), allowing Mdc1 to recruit additional ATM molecules with its FHA domain (26). This Mdc1-mediated recruitment mechanism enables ATM to phosphorylate distant histone H2AX molecules farther away from the DNA breaks, and eventually generate a large chromatin region with phosphorylated histone H2AX. Phosphorylated histone H2AX may then bring in additional ATM substrates involved in DNA repair, chromatin remodeling, and checkpoint signaling to facilitate the functions of these proteins at sites of DNA damage (26).

In addition to phosphorylated histone H2AX, methylated histones H3 and H4 are also implicated in checkpoint signaling (28–30). It was shown that the mediator 53 BP1 recognizes methylated histone H3 through its tandem Tudor domains (28). Interestingly, the methylation of histone H3 is not induced by DNA damage, which led to the hypothesis that a change of chromatin structure, which exposes the preexisting methylated site on histone H3, is induced at sites of DNA damage.

It has become clear that the sensing of DNA damage by the ATM pathway is a multistep process involving several independent sensing mechanisms. The ATM pathway recognizes not only DNA breaks but also protein modifications at sites of DNA damage. These distinct sensing mechanisms ensure that the signaling of the ATM pathway is tightly regulated at multiple levels.

Recruitment of ATR to DNA Damage

Unlike ATM, which strongly prefers DSBs, ATR is a broad-spectrum signal initiator. Various types of replication interference, such as those induced by UV irradiation or ribonucleotide reductase inhibitor Hydroxyurea (HU), strongly elicit the ATR pathway. This versatility and the pivotal role of ATR in cell viability and genomic stability has prompted an intensive investigation into the mechanisms by which ATR senses different types of DNA damage and activates the checkpoint.

In human cells, ATR exists in a stable complex with another essential checkpoint protein called ATRIP (3). In budding yeast Saccaromyces cerevisiae, ATR’s homolog Mec1 also functions in a complex with Ddc2; the budding yeast ATRIP homolog (31–33). It has been shown that Mec1 can be activated in the cdc13 temperature-sensitive mutant as well as by the HO endonuclease (34, 35). Cdc13 is a telomere-binding protein. When mutated, telomeres are unprotected and stretches of single-stranded DNA (ssDNA) are exposed because of cleavage by exonucleases (36). In the other scenario, ssDNA is also generated at the exonuclease-processed DSBs induced by HO (37). Increasing amounts of ssDNA and ATR activation were also observed when yeast replication forks are blocked by HU and UV treatments (Fig. 2) (38, 39). All these findings suggested a link between ssDNA and the activation of the ATR pathway.

Replication protein A (RPA), a protein complex with affinity to ssDNA, is a key player in many types of DNA metabolisms such as DNA replication and DNA repair (40). In G2 yeast cells, depletion of RPA abolished the localization of Ddc2 to HU-induced DSBs (41), suggesting that RPA is important for the recognition of ssDNA and ssDNA processing in the activation of the ATR pathway.
the recruitment of Mec1 to sites of DNA damage. The distinct functions of RPA in DNA replication and checkpoint activation were demonstrated in rfa-1L1, an RPA mutant strain proficient in DNA replication yet partially defective in checkpoint activation (41). In the African frog Xenopus egg extract, another model system used in the study of DNA replication and checkpoint, ATR associates with chromatin in a replication-dependent manner (42). Depletion of RPA, however, ceased the association of ATR with chromatin (43). In human cells, RPA is required for the localization of ATR to DNA damage-induced nuclear foci and the efficient phosphorylation of Chk1 (44). Collectively, these findings suggest that ssDNA coated with RPA might be a common structure recognized by ATR and ATRIP.

In a series of in vitro biochemical experiments aimed at recapitulating the initial steps of DNA damage sensing in human cells, the roles of ssDNA and RPA were directly analyzed (41). In these experiments, single- or double-stranded DNA of various lengths was biotinylated and immobilized on streptavidin-tagged magnetic beads. The association of purified ATR and ATRIP with immobilized DNA was analyzed in the presence or absence of RPA. It was found that 1) purified ATRIP protein was efficiently recruited to ssDNA only in the presence of purified RPA; 2) RPA confers ATRIP higher affinity to ssDNA than dsDNA (double-stranded DNA); and 3) the ATR-ATRIP complex, but not ATR alone, binds to ssDNA efficiently in the presence of RPA. Together, these experiments demonstrated that ssDNA coated with RPA is a structure that efficiently recruits ATR-ATRIP (Fig. 2). As RPA-coated ssDNA is commonly generated during different types of DNA repair and when DNA replication was interrupted, it is highly possible that RPA-coated ssDNA is the key structure that enables ATR-ATRIP to respond to a broad spectrum of DNA damage (Fig. 2). These findings, however, do not rule out the possibility that ATR-ATRIP can localize to specific types of DNA damage through alternative protein-protein or protein-DNA interactions.

Roles of Replication Factor C (RFC)- and Proliferating Cell Nuclear Antigen (PCNA)-like Complexes in Damage Sensing

Although RPA-coated ssDNA is critical for the recruitment of ATR-ATRIP to sites of DNA damage, RPA-stained DNA is not sufficient for ATR-ATRIP to elicit a robust checkpoint response. The function of ATR-ATRIP requires additional regulatory proteins including the RFC-like Rad17 complex and the PCNA-like Rad1-Rad11-Hus1 (9-1-1) complex. During DNA replication, the RFC complex recognizes the primer-template junctions (the junctions of ssDNA and dsDNA) at replication forks and recruits ring-shaped PCNA complexes onto DNA in an ATP-dependent manner (44). Once loaded onto DNA, PCNA functions as a sliding clamp allowing DNA polymerases to stably associate with their template. Likewise, the PCNA-like 9-1-1 complex is recruited onto DNA by the RFC-like Rad17 complex (45). However, the recruitment of 9-1-1 occurs only after DNA damage, suggesting that the Rad17 complex can specifically recognize certain DNA structures induced by DNA damage.

Single-strand DNA generated at sites of DNA damage or stressed replication fork is always juxtaposed with junctions of ssDNA and dsDNA (Fig. 2). To investigate whether the Rad17 and 9-1-1 complexes recognize such DNA junctions, these complexes were expressed in engineered insect cells and purified using affinity chromatography. In several in vitro biochemical assays, the Rad17 complex recruited 9-1-1 complexes onto DNA structures with both ssDNA and dsDNA regions (46-49), and this recruitment was enhanced by RPA (48, 49). Interestingly, unlike RFC, which uses only the 3′ double/single-strand DNA junctions to PCNA, the Rad17 complex can use the 5′ double/single-strand DNA junctions to recruit 9-1-1 complexes (48, 49). This finding provides a possible explanation as to how Rad17 and 9-1-1 complexes are recruited to resected DSBs and telomeres that possess only 5′ double/single-strand DNA junctions. As ssDNA gaps are observed at stressed replication forks, both 5′ and 3′ double/single-strand DNA junctions are induced by replication interference (Fig. 2). Together, these experiments suggest that the Rad17 and 9-1-1 complexes are sensors of the double/single-strand DNA junctions at sites of DNA damage and stressed DNA replication forks.

Similar to the DNA damage sensing by the ATM pathway, the sensing by the ATR pathway is also a multistep process. ATR-ATRIP directly recognizes RPA-coated ssDNA, whereas the Rad17 and 9-1-1 complexes recognize the junctions of ssDNA and dsDNA. Additional checkpoint regulators may also contribute to the sensing of different DNA structures at sites of DNA damage. The co-localization of ATR-ATRIP and its regulators on damaged DNA may enable the ATR to be activated by these regulators and phosphorylated by its kinases. Consistent with this idea, TopBP1, a protein that interacts with the 9-1-1 complex, stimulates the kinase activity of ATR-ATRIP in vitro (50). In summary, the ability to recognize certain DNA structures at sites of DNA damage is most likely the key for the versatility of the ATR pathway. Furthermore, the involvement of multiple sensors in this pathway may enable it to distinguish different types of DNA damage and generate a signal accordingly.

Processing of DNA Damage

Many types of DNA damage that efficiently elicit the ATR checkpoint interfere with DNA replication, suggesting that DNA replication forks may play a particularly important role in the processing of DNA damage to structures recognizable to the ATR checkpoint (e.g., ssDNA and junctions of ssDNA and dsDNA). A accumulating evidence has suggested that the uncoupling of DNA helicases and DNA polymerases at progressing replication forks may lead to increased amounts of ssDNA at the forks (51). The stalling of DNA polymerases can directly result from DNA lesions themselves or from those recognized or processed by specific repair proteins. For example, xeroderma pigmentosum group A (XPA), a protein involved in the recognition of UV-induced DNA damage, is required for the activation of ATR checkpoint by UV during S phase (52).

In addition to the DNA damage that interferes with replication, the ATR checkpoint is also elicited by DSBs. These DSBs,
However, need to be first recognized and processed by specific factors. It was recently shown that the activation of ATR by ionizing radiation, but not that by replication stress, requires ATM and the MRN complex, RPA can no longer localize to DSBs, indicating that the formation of ssDNA at DSBs is compromised. The processing of DSBs also require CDK activity and is restricted to the S and G2 phases of the cell cycle. Thus, even with distinct DNA structure specificities, the ATM and the ATR checkpoints may function together to mediate a coordinated response to DNA breaks in the replicating or replicated genome.

**Tools and Techniques**

The sensing of DNA damage by the checkpoint has been characterized both in cells and in cell-free systems by using biochemical approaches. Several methods are commonly used to introduce different types of DNA damage in cells (56). For instance, to generate DSBs in cultured cells, cells can be treated with IR (ionizing radiation), laser beam, or therapeutic compounds such as cisplatin and bleomycin. To introduce replication stress to cells, cells are treated with UV or replication inhibitors such as HU and aphidicolin. It should be noted that the actual DNA damage induced by these methods are likely heterogeneous. For example, IR induces not only DSBs but also single-strand DNA breaks induced by these methods are likely heterogeneous. For example, IR induces not only DSBs but also single-strand DNA breaks and other types of DNA lesion.

Many checkpoint-mediated protein phosphorylation events can be detected by Western blotting with phospho-specific antibodies or mobility shift on protein gels due to the modification. As a result, the phosphorylation status of these proteins has been exploited as markers for checkpoint signaling in cells. Moreover, cell-cycle stage-specific checkpoint responses can now be monitored by stage-specific assays such as the G1, intra-S, and G2/M checkpoint assays (57–59). Checkpoint kinase activities can be measured by using immunoprecipitation and in vitro kinase assays. Immunofluorescence, chromatin fractionation, and chromatin immunoprecipitation are commonly used methodologies to analyze the recruitment of checkpoint proteins to sites of DNA damage.

Several cell-free assay systems have been used to dissect the mechanisms of DNA damage sensing in vitro. The most extensively applied system is the one using Xenopus extracts. As DNA replication can occur efficiently in Xenopus extracts, this system has been used to analyze how replication interference is sensed by checkpoint sensors (60, 61) and how activated checkpoint regulates DNA replication. The checkpoint can also be elicited in a replication-independent manner by various synthetic DNA structures in Xenopus extracts (9, 62). The checkpoint response in Xenopus extracts is often monitored by the phosphorylation of various checkpoint proteins. The association of checkpoint proteins with damaged chromatin or DNA is used to monitor the recognition of DNA damage in Xenopus extracts.

In vitro biochemical assays with purified proteins are developed to demonstrate the direct recognition of damage-induced DNA structures by checkpoint sensors (41). Various checkpoint proteins have been successfully expressed in bacteria, yeast, insect, and mammalian cells and have been purified bioclorically. The association of checkpoint proteins with various DNA structures can be captured and visualized by using biotinylated DNA or DNA labeled with radioactive isotopes. Finally, in vitro kinase assay is performed to measure the effects of DNA on the activity of checkpoint kinases and the phosphorylation of their substrates.

**Future Perspectives**

Since Hartwell and Weinert first observed that DNA damage led to cell-cycle arrest in budding yeast and proposed the concept of the DNA damage checkpoint (63), the checkpoint field has evolved quickly into a leading area of both basic biological research and cancer and disease-oriented research. DNA damage and replication checkpoint, as we now know, is an indispensable and evolutionarily conserved cellular process. In all species, checkpoint is an integral part of cell survival and organism development by maintaining genomic stability against continuous insults from both outside and inside. Instability of the genome in human cells is often both a prelude and a hallmark of cancer, a debilitating disease affecting millions and the leading cause of death in many countries including the United States. In fact, mutations (p53, Brca1, Chk2) or abnormalities of the checkpoint pathway have been found repeatedly to associate with cancer or other cancer-prone genetic disorders. A thorough understanding of the chemical and biochemical steps that lead to checkpoint activation and its impact on other cellular processes will surely generate much insight into tumorigenesis at the molecular, cellular, and organ level. The study of the mechanism of action and specificity of the checkpoint kinases will also help us design safer and better drugs to fight cancer. Indeed, several inhibitors of the checkpoint kinases are already in various stages of preclinical and clinical studies. From a more fundamental standpoint, we still know very little about the actual events leading up to the sensing of DNA damage and the activation of ATM and ATR. The biochemical and functional roles of a number of checkpoint proteins remain virtually unknown. Furthermore, from examining the disease symptoms and phenotypes of knockout mice, it is obvious that defects of checkpoint interfere with development. Yet, how checkpoint influences development and the difference among specific organs and systems is not clear at all. In summary, the DNA damage and replication checkpoint is a fundamental and elaborate cellular process. It protects cells from being genetically compromised by DNA damage. Uncovering the hidden secrets of the checkpoint mechanism will lead us closer to cracking the codes of cancer and other genetic and developmental diseases.

Sensing of DNA Damage

Further Reading
All DNA polymerases share a common two-metal ion catalyzed chemistry of nucleotide incorporation. Structure analysis, however, suggests that DNA polymerases share one of two different ancestors, which converged to employ the same mechanism. *Escherichia coli*, the prototypical bacterium, encodes five different DNA polymerases. The chromosomal replicase functions closely with clamps, clamp-loaders, and other proteins. Oxidative damage to DNA during normal cell growth requires interplay among the several distinct DNA polymerases, which enable the replicase to circumvent these obstacles and complete chromosomal replication. Additional processes involving DNA polymerases are brought into action during heightened levels of DNA damage. We review here DNA polymerase structure, catalytic mechanism, and several pathways in which various bacterial DNA polymerases act.

**Introduction**

*Escherichia coli* DNA polymerase (Pol I) is so named because it was the first DNA polymerase to be isolated and characterized (1). Pol I remains the most intensively studied DNA polymerase, and its general structure and properties generalize to other DNA polymerases. Sequence comparisons of DNA polymerases derived from many organisms indicate the presence of at least five different classes of DNA polymerase (Table 1) (2). For simplicity, we will focus in this review on the DNA polymerases of *Escherichia coli*. *E. coli* contains five different DNA polymerases that assort into four polymerase families (Table 1). Pol I is a member of the A-family; it is ubiquitous among bacteria and plays a major role in DNA repair. Pol II is a B-family DNA polymerase that seems to be involved in repair. Interestingly, eukaryotic and archael chromosomal replicases are all members of the B-family. The C-family of DNA polymerase is specific to bacteria and functions as the chromosomal replicase. *E. coli* contains one C-family polymerase, which is referred to as Pol III. Some bacteria contain two C-family DNA polymerases, which are referred to as Pol C (the replicase) and DnaE polymerase (after the gene encoding it) (3). *E. coli* contains two Y-family DNA polymerases, Pol IV and Pol V. Y-family DNA polymerases have relatively low fidelity and thus differ from typical DNA polymerases, which usually have very high fidelity in DNA synthesis (2, 4). For example, DNA polymerases I, II, and III make mistakes only once every $10^4$–$10^6$ nucleotide additions, and fidelity is assisted in these enzymes by the presence of a 3′–5′ exonuclease, which is referred to as a proofreader that removes most of the mistakes made by the polymerase (i.e., misincorporated nucleotides) (2, 4). In contrast, Y-family polymerases have intrinsically high error rates ($10^{-1}$–$10^{-3}$) and are the only *E. coli* DNA polymerases that lack 3′–5′ exonuclease activity (5, 6). These unique properties allow Pol IV and Pol V to pass over DNA lesions and thus enable chromosome duplication in the face of DNA damage, but they do so at the expense of creating mutations (5, 7). Pols II, IV, and V are induced by DNA damage and are proposed to function collectively and to enable replication over DNA lesions (4, 8–10).

In this review we summarize the general architecture of DNA polymerases and the chemistry of the DNA polymerase and the chemistry of DNA synthesis and 3′–5′ exonuclease activities (see also DNA replication). The ultimate function of DNA polymerases is the duplication of genetic material, and therefore, we also describe how Pol III functions at a replication fork. Lastly, we present a brief overview of the different repair reactions in which the remaining DNA polymerases act.

**Chemistry of DNA synthesis and 3′–5′ exonucleolytic proofreading**

The substrates for DNA synthesis are a 3′ primed site and deoxyribonucleoside triphosphate (dNTP) (see Fig. 2). DNA polymerase catalyzes a phosphoryl transfer reaction that adds a dNMP moiety to a 3′ terminus of an existing DNA strand, releasing pyrophosphate (Fig. 3a). The reaction is catalyzed exclusively by two metal ions (e.g., Mg$^{2+}$) (11, 12). Metal ion A extracts a proton from the DNA primer 3′ terminus using a hydroxyl group to produce an oxyanion nucleophile, which attacks...
the γ-phosphate of the incoming dNTP that is base-paired to the template. Metals A and B stabilize the resulting penta-coordinate transition state, and metal B also stabilizes the pyrophosphate leaving group.

The two metal ions are held in place by three conserved aspartic acid residues. The fact that catalysis is mediated exclusively by metal ions with no direct participation of amino acid side chains suggests that nucleotide polymerization may have originated before the evolution of proteins. Specifically, the two metals may have been chelated by RNA in the primordial "RNA World" that is thought to have operated before the evolution of proteins.

The 3′–5′ proofreading exonuclease is called into action when an incorrect dNMP is added to the 3′ terminus. The 3′–5′ exonuclease is located in a separate domain with a distinct active site. The chemical reaction of the exonuclease proceeds by hydrolysis (see Fig. 2c), but it is remarkably similar to the polymerase reaction. Specifically, two metal ions catalyze the reaction: metal ion A activates water to form a hydroxynucleophile that attacks the phosphodiester bond of the 3′ terminal mismatched nucleotide. Metal A stabilizes the developing charge on the dNMP leaving group.

Structure of DNA polymerases

The crystal structures of multiple representatives of each class of DNA polymerase have been solved and compared (12). In all cases, the overall shape is that of a right hand, and it contains a minimum of three subdomains, which are referred to as the palm, fingers, and thumb. These subdomains are indicated for the structure of Pol I shown in Fig. 2a. Although the chain folding patterns of the fingers and thumb are different among the different polymerase families, the core architecture of the palm domain contains the catalytic site for DNA polymerization and is structurally conserved among the A, B, and Y families. The chain topology of the palm, and the relative location of the three Asp residues that hold the catalytic metal ions in polymerases of the A, B, and Y families, are shown in Fig. 2b. This conservation of structure in the palm suggests that the members of the A, B, and Y family share a common evolutionary ancestor.

Interestingly, C-family DNA polymerases (bacterial replicases) have a different chain topology in the palm, and the location of the Asp residues is also unique (13, 14). The palm architecture is shared by the X-family of DNA polymerases that include eukaryotic Pol β and certain nucleotidyl transferases (Table 1). Presumably X-family polymerases share a common ancestor with DNA polymerases of the C-family.

Figure 1. Chemical mechanism of DNA polymerase and 5′→3′ exonuclease. (a) DNA polymerase reaction. The enzyme chelates two metal ions using three aspartic acid residues (only two are shown). Metal ion A abstracts the 3′ hydroxyl proton of the primer terminus to generate a nucleophile that attacks the γ-phosphate of an incoming dNTP substrate. The phosphorolysis results in production of a pyrophosphate leaving group, which is stabilized by metal ion B. (b) The 3′→5′ exonuclease proofreading activity is located in a site that is distinct from the polymerase site; yet it uses two-metal-ion chemistry similar to DNA synthesis. The reaction type is hydrolysis in which metal ion A activates water to form the hydroxynucleophile. Nucleophile attack on the phosphate of the mismatched nucleotide releases it as dNMP (5′UMP in the case shown).

In all DNA polymerases, the DNA lies on the palm of the polymerase and also interacts with the thumb (see Fig. 2c). The finger domain binds the incoming dNTP for incorporation into the DNA chain. The A–T and G–C base pairs have very similar geometry, and during binding of a dNTP, the fingers domain closes over the palm to match the dNTP to the template strand forming a tight enclosure into which only the geometry of a correct base pair can fit (15). Incorrect base pairs do not have the correct geometry to fit into this tight enclosure and are usually released instead of incorporated. In the rare instance of incorrect nucleotide incorporation, the primed site usually enters the 3′→5′ exonuclease site for excision of the incorrect terminal nucleotide (see Fig. 2c).
kinetic scheme shown in Fig. 3. Most often, the DNA polymerase selects and incorporates the correct dNTP (pathway 1 in Fig. 3). Correct incorporation events are rapid. Incorporation of an incorrect dNTP (pathway 2 in Fig. 3) is slow, several orders of magnitude slower than incorporation of a correct dNTP (16, 17). Misincorporation is slow because the incorrect dNTP does not form a normal base pair with the template strand, and thus, the geometry of the incorrect base pair does not induce the correct fit in the enzyme active site needed to bring the two active site metal atoms into the proper juxtaposition for the chemical step. Furthermore, if the DNA polymerase incorporates the wrong nucleotide, the resulting mismatched 3' terminus presents yet another slow kinetic barrier to the DNA polymerase. The polymerase is very slow to extend the mismatched product by another nucleotide, because the correct geometry of the active site metals depends on the DNA substrate being correctly base paired. Therefore, the slow kinetics of two steps, misincorporation and extension of a mispaired 3' terminus, result in very few mistakes relative to the rapid incorporation of correct dNTP substrates. The kinetic pauses associated with incorporation of an incorrect dNTP give time for a mismatched primed template to melt and reposition into the separate active site of the 3'-5' exonuclease (Fig. 2c and Fig. 3). Once in the 3'-5' exonuclease active site, the proofreading 3'-5' exonuclease rapidly excises the incorrect 3' terminal nucleotide and thereby restores the substrate to one that is fully base paired (dashed arrow in the scheme of Fig. 3). Thus, the slow steps involved in misincorporation, combined with the rapid proofreading exonuclease removal of mismatched nucleotides, provide the DNA polymerase with a second try at chain extension. Most retrials have a positive outcome, which results in the incorporation of a correct nucleotide base.

DNA polymerase III holoenzyme

High-fidelity chromosomal replication in E. coli is executed by a multicomponent complex referred to as DNA polymerase III holoenzyme (see Fig. 4a (18-21)). Pol III holoenzyme consists of three main subcomponents: Pol III core, β-clamp, and γ-complex clamp-loader. Pol III core is the replicative DNA polymerase that consists of three subunits (α, ε, δ): α exhibits DNA polymerase activity, ε performs 3'-5' exonuclease activity necessary for proofreading, and the function of δ is currently unclear. Pol III core requires direct association with the β-clamp to perform processive DNA synthesis. β-tethers the polymerase to its respective template by binding the α subunit of Pol III core while encircling DNA immediately behind the polymerase (see Fig. 4a). Coupling of Pol III core to β results in an increase in both the catalytic rate (~10^7 s^{-1}) and processivity (~50 kb). The structure of the β-clamp resembles a symmetrical ring with sufficient space to accommodate double-stranded DNA (see Fig. 5a). β is composed of a homotrimer with each protomer consisting of three globular subdomains. The structure of the eukaryotic clamp, proliferating cell nuclear antigen (PCNA), is similar to β (23, 24). However, PCNA is composed of a homotrimer with each protomer consisting of three subdomains. The head-to-tail protomer organization of β results in two structurally distinct "faces": the C-terminal face is involved in intermolecular interactions (i.e., binding Pol III core α subunit) (see Fig. 5a and 5b). β also binds Pol I, II, IV, and V and is therefore thought to play a role in polymerase trafficking during transcription synthesis (which is discussed in more detail below). Lastly, recent studies indicate that β interacts with DNA repair proteins M5, M6, and DNA ligase (25). The function of δ in DNA repair is currently unclear.

The γ-complex clamp-loader is a heteropentameric ATPase responsible for assembling β onto DNA at primed sites (26-28). The clamp loading process is illustrated in Fig. 5b. The γ-complex binds and opens the ring-shaped β-clamp in the presence of ATP. The ATP-bound γ-complex selectively binds to a primed site that stimulates ATP hydrolysis and results in release of the clamp-loader and closure of β around DNA (20).
The proteins currently thought to act at the replication fork include two Pol III core molecules, two γ-clamps, γ-complex, DnaB helicase, primase, and single-stranded DNA binding protein (SSB) (see Fig. 4a) (20, 32). Each Pol III core is dedicated to either the leading or the lagging strand and is tethered to its respective template via binding to the γ-clamp. The unwound portion of the lagging strand is thought to form a "trombone" loop that enables bidirectional movement of the lagging strand polymerase and the replisome (33).

The clamp loader acting at the replication fork is thought to be composed of subunits γ, τ, h, l, χ, ψ (32, 34, 35). In this configuration, two γ subunits are substituted by two τ subunits. γ (47 kDa) and χ (71 kDa) share identical N-terminal clamp loading sequences as they are encoded by the same gene, dnaX. However, γ is truncated because of an efficient translational frameshift that produces approximately equal amounts of γ and χ. The χ subunit connects to SSB and is held in the structure by τ (36). The γ-to-SSB connection enhances processivity and enables efficient transfer of RNA primers from primase to the clamp loader (37). Each γ subunit binds to a single Pol III core thereby linking the leading and lagging strand polymerases together (see Fig. 4a) (14, 21, 38, 39).

DnaB is the replicative helicase that unwinds the parental duplex DNA ahead of the replication fork (see Fig. 4a) (40). DnaB encircles the lagging strand as a homohexamer and uses the energy of ATP hydrolysis to unwind DNA with 5'-3' polarity (see also DNA Helicases, Chemistry and Mechanisms of). DnaB is connected to Pol III holoenzyme via its interaction with the χ subunit of the clamp loader (41). This interaction greatly stimulates DnaB activity at the replication fork (42). DnaB also binds to and stimulates primase, which is a specialized RNA polymerase that synthesizes RNA primers approximately 12 nucleotides in length to initiate DNA synthesis (1, 43).

The mechanism of Pol III action at the replication fork is illustrated in Fig. 4. The lagging strand is synthesized as discontinuous sections of 1-3 kb called Okazaki fragments. An Okazaki fragment is initiated by primase action (see Fig. 4a). The clamp loader uses the energy of ATP hydrolysis to assemble β onto the newly synthesized RNA primer (see Fig. 4a). The Pol III core binds β and processively synthesizes the DNA portion of the Okazaki fragment, which creates a DNA loop (see Fig. 4c). The Okazaki fragment is completed when Pol III encounters the 5' end of the previous Okazaki fragment and dissociates from the DNA, which disassembles the loop. Pol I is required for Okazaki fragment maturation and is discussed below.

The leading strand polymerase performs DNA synthesis in a continuous fashion and therefore requires an initial priming event. However, DNA damage or other impediments along the leading strand may block progression of the replication fork and...

Figure 4 Pol III function at the replication fork. Leading and lagging strand synthesis are performed in a continuous and discontinuous fashion, respectively. The lagging strand is synthesized in contiguous sections called Okazaki fragments. (a) An Okazaki fragment is initiated as primase synthesizes a short RNA primer along the lagging strand. (b) The γ-complex clamp loader uses the energy of ATP hydrolysis to assemble β at the newly primed site. (c) The lagging strand polymerase cycles to a newly synthesized primed site after completing the previous Okazaki fragment. (d) The lagging strand polymerase synthesizes the DNA portion of the next Okazaki fragment. (Adapted with permission from Reference 20.)

The repair of arrested replication forks involves two major pathways: recombinational repair and translesion synthesis. Recombinational repair uses RecA and a host of other recombination factors that facilitate strand exchange and non-mutagenic replication across damaged DNA (reviewed in References 48–50). Translesion synthesis employs low-fidelity DNA polymerases that often perform mutagenic replication opposite a damaged template (reviewed in References 5–7).

Translesion synthesis by low-fidelity DNA polymerases Chromosomal DNA is often damaged by exposure to exogenous (i.e., UV irradiation, chemical agents, etc.) and endogenous (i.e.,
Figure 5. Structure and function of β-clamp and γ-complex. (a) The structure of β resembles a ring with sufficient space to accommodate duplex DNA. It is a homodimer in which each protomer contains three globular subdomains. The protomers are arranged in a head-to-tail fashion resulting in two structurally distinct "faces." The C-terminal face is involved in intermolecular interactions. Protomers are indicated in light and dark shades (PDB ID 2POL). (b) γ-complex uses the energy of ATP hydrolysis to assemble β onto DNA at primed sites. γ-complex binds to and opens β in the presence of ATP. The clamp loader selectively binds to primer-template junctions, which stimulates ATP hydrolysis and results in dissociation of γ-complex and closure of β around the DNA. DNA polymerase binds the C-terminal face of β and initiates DNA synthesis at the primed site. (c) Subunit organization of γ-complex clamp loader. The γ-complex is composed of five subunits (γ3, δ′, δ) that are arranged in a spiral-like fashion. γ-complex contains three ATP sites that lie at the subunit interfaces and include an "arginine finger" within a conserved SRC motif. The ATP site organization of the γ-complex is proposed to confer cooperativity between subunits. (Adapted with permission from Reference 20.)

oxidative damage) insults (see also DNA Damage, Chemical Biology of Diseases Related to (51). Spontaneous mutagenesis of nucleotide bases by cytosine deamination to yield uracil also occurs with high frequency in the cell. DNA repair mechanisms have evolved to excise and repair various types of DNA damage (discussed below) (see also DNA Damage Repair, Chemistry of). However, the replication fork sometimes encounters DNA damage that has evaded the repair machinery. Pol III and other high-fidelity DNA polymerases cannot replicate damaged DNA. Thus, the replication fork becomes arrested at the site of DNA damage. Low-fidelity lesion bypass DNA polymerases can extend DNA across various types of damaged DNA, but this often results in a mutation. Thus, switching between high-fidelity and low-fidelity DNA polymerases is thought to facilitate replication through sites of DNA damage (4, 8-10, 52). Pol I and Pol III exhibit high-fidelity DNA synthesis and make mistakes on average of only 1 in 10^10 nucleotides (5, 16, 17). Y-family Pol IV and Pol V misincorporate nucleotides 10 to 1000 times more frequently and are error-prone lesion bypass polymerases that are associated with the mutagenic response of cells to DNA damage (5, 6, 16, 52). Structures of Y-family polymerases suggest that replication of past aberrant nucleotides is likely caused by a highly solvent exposed DNA binding cleft (53, 54). Thus, bulky lesions and nucleotide mismatches are more permissible among this class of enzyme.
Replication fork arrest by DNA damage leads to RecA-mediated induction of the SOS response pathway. The SOS response involves upregulation of over 40 genes that facilitate increased viability during stress (i.e., chemical agents, UV light, and nutrient deficiency) (reviewed in References 5 and 6). The DNA polymerases that are upregulated during the SOS response include Pol II, Pol IV, and Pol V. Pol II is the first DNA polymerase to be induced (∼1 minute). Interestingly, Pol II has been shown to perform high-fidelity DNA synthesis (error rate = 10⁻³ to 10⁻⁴ per base pair) on undamaged templates, but despite this, Pol II seems to be involved in error-prone DNA synthesis in vivo (∼1 minute). Pol II is somewhat of an enigmatic enzyme because it has been implicated in translesion synthesis, adaptive mutation, and recombinational repair (which is discussed below) (∼4–6, 56). Additional study is required to understand the relevant functions of Pol II in the cell.

Pol V is upregulated from ∼15 to ∼200 copies per cell approximately 45 minutes after SOS induction. Pol V is a heterotrimer with a subunit composition of UmuD′C, (see Fig. 6a). UmuD contains the catalytic domain of Pol V. UmuD′ is the product of RecA-modulated proteolytic cleavage of UmuD. Importantly, Pol V function requires RecA, and the mechanism by which RecA stimulates Pol V activity has been under investigation for several years (57). Recent data indicate that RecA-nucleoprotein filaments act in trans to stimulate Pol V (see Fig. 6a) (57, 58). Interestingly, RecA filaments in cis (immediately 5′ to Pol V on the DNA template) do not stimulate Pol V (59). Pol V and SSB may cooperate to displace RecA from DNA (57, 60). Alternatively, recent data indicate that RecA may be removed by UvrD helicase, as UvrD is also induced during the SOS response, but whether UvrD plays a direct role in translesion synthesis is currently an open question (61, 62).

Pol IV and Pol V use the η-clamp (63-66) and are capable of synthesizing DNA opposite various types of lesions (i.e., abasic site, thymine dimer, and benzo(a)pyrene) (see Table 2) (4, 8, 9, 67). Pol IV is expressed constitutively at ∼250 copies per cell, suggesting a role during normal growth, and consistent with the finding that Pol IV is required for adaptive mutation under nonlethal conditions (6). Pol IV is increased 10-fold after SOS induction. Pol IV is less than 200 copies per cell (4, 8, 9). Pol IV is involved in translesion synthesis during translesion synthesis based on structural and biochemical studies is illustrated in Fig. 6b. The dimeric η-clamp can bind both Pol IV and Pol III simultaneously, and it is proposed to hold Pol IV away from the DNA template while Pol III activity synthesizes DNA (68, 69). However, during a Pol III encounter with a lesion, Pol IV is allowed to gain access to the template in place of Pol III. After the lesion is bypassed by Pol IV, the high-fidelity Pol III regains control of the primed site. These events limit the action of the low-fidelity Pol IV to the region in which it is required to bypass a lesion.

DNA polymerase activity during repair

Oxidative damage that leads to replication fork arrest is common during bacterial growth and probably occurs at least once during each cell division even under the most favorable conditions (48, 51). Most lesions are not dealt with by mutagenic polymerases, but instead they are repaired by recombination, which is an error-free process. Recombinational repair can take many different paths and employs several different proteins, but ultimately, it involves high-fidelity DNA polymerases such as Pol I, Pol II, and/or Pol III (6, 49, 56). For additional information, we refer the reader to more thorough reviews of the various recombinational repair pathways (64, 48–50, 70).

Even high-fidelity DNA polymerases sometimes incorporate an incorrect nucleotide. All cells contain a specialized mismatch repair system that catches these errors and corrects them. Mis-match repair involves excision of DNA past the mismatch, and eventually, it allows Pol III to try again (reviewed in References 71 and 72). The process of mismatch repair requires proteins MutS and MutL, among others. Mutations in the human homologues of these proteins lead to a predisposition to development of tumors (73).

Nucleotide excision repair (NER) is responsible for removing a wide array of DNA lesions that predominately occur as a result of exposure to oxygen or UV light (reviewed in Reference 74) (see also DNA Damage, Chemical Biology of Diseases Related to). Unlike mismatch repair, NER employs Pol I to replace damaged DNA. NER also requires the action of Uvr (ultraviolet radiation) proteins that were originally discovered because of their ability to sustain cell growth after exposure to UV irradiation. Like MutS and MutL, mutations in the human homologues of the Uvr proteins predisposes individuals to cancer.

Base excision repair (BER), in which a single damaged base is excised and replaced, also uses Pol I to replace the modified nucleotide. BER is involved predominately in the repair of apurinic and apyrimidinic nucleotides (abasic (AP) sites) that frequently develop from spontaneous hydrolysis (reviewed in Reference 75). Importantly, BER is also responsible for removing uracil from DNA, which is the product of cytosine deamination. Bases modified by oxidation and alkylation are also repaired; however, these modifications occur less frequently.

A recent study suggests that Pol IV and Pol V may also be involved in BER because of their intrinsic lyase activity (76). Shen et al. demonstrate relatively weak 5′-phosphodiester bond cleavage of an abasic site (AP′-dRP activity) by Pol IV and Pol V. Interestingly, several DNA polymerases from the X, A, and Y families exhibit lyase activity. Human Pol η, for example, exhibits strong AP′-dRP activity and is thought to be involved in the excision and incorporation of nucleotides during BER (77, 78). Furthermore, eukaryotic pol ι, which is a Y-family homolog of Pol IV and Pol V, has also been shown to exhibit AP′-dRP activity (79). Additional studies are required to determine whether Pol IV and Pol V are involved in BER.

Lastly, Pol I is responsible for repairing DNA during Okazaki fragment maturation. Pol I replaces the RNA portion of Okazaki
Bacterial DNA polymerases: Chemistry of...

Figure 6. Mechanisms of translesion synthesis. (a) Activation mechanism of Pol V during translesion synthesis. Pol V is a heterotrimer composed of subunits UmuC and UmuD. UmuC is the catalytic domain, and UmuD is the product of RecA-mediated proteolysis. Translesion synthesis by Pol V is activated by the presence of a RecA filament in trans. (b) Model of DNA polymerase switching during translesion synthesis. Pol II* and Pol IV each bind to a β protomer at a conserved hydrophobic protein binding pocket (QL[S/D]LF). 1. Pol III* is arrested at the site of DNA damage, whereas Pol IV is held in an inactive state away from the DNA. 2. Pol IV gains hold of the primer terminus from Pol III* at the stall site; Pol III* is now held away from the DNA. 3. Pol IV extends the DNA past the lesion. 4. Pol III* regains hold of the primer terminus from Pol IV.

fragments using its 5′→3′ exonuclease activity and synthesizes DNA in its place. The remaining nick between adjacent Okazaki fragments is repaired by DNA ligase.

Future perspectives

The work of many laboratories has provided significant insight into the detailed workings of Pol III function at the replication fork. The way in which the replisome interacts with other DNA processes (i.e., DNA compaction, transcription, and recombination, repair), however, is poorly understood. For example, how does Pol III holoenzyme replicate through high-affinity protein-nucleic acid complexes such as RNA polymerase or repressor proteins? What is the fate of the replication components after an encounter with a blocking lesion? Does the replisome directly recruit or interact with recombination factors that repair broken forks? β has been shown to bind mismatch repair proteins MutS and MutL. What is the significance of these interactions?

The presence of five DNA polymerases in E. coli suggests that access to primed sites might be regulated. Indeed, recent biochemical data indicate that β plays a major role in switching between high-fidelity and low-fidelity DNA polymerases during translesion synthesis. High-fidelity DNA polymerases Pol I and Pol II also bind to β and are expressed at relatively high levels relative to Pol III. Do high-fidelity DNA polymerases compete for primed sites during normal growth? Furthermore, we still do not understand the major role of Pol II in the cell.

Lastly, translesion synthesis by Pol V is stimulated by RecA filaments in trans. The presence of RecA filaments in cis (on the DNA template), however, inhibits the activity of Pol V.
Additional work is required to elucidate the exact mechanism and organization of RecA filaments in the cell responsible for Pol V activation. Future studies will likely reveal the answers to many of the questions addressed above.

doi: 10.1002/9780470048672.wecb133

DNA helicases are members of a larger class of enzymes composed of molecular motors that couple the energy of NTP binding and hydrolysis to directional translocation along a nucleic acid lattice. Structurally and mechanistically related helicases perform drastically different roles in DNA metabolism by associating with various macromolecular machineries that orchestrate DNA processing events. Within these macromolecular ensembles, DNA helicase translocation is coupled to separation of duplex DNA into two single strands, which is necessary for DNA replication, repair, recombination and transcription. Translocation by DNA helicases can also result in the disassembly of protein–nucleic acid complexes formed during DNA metabolism. One major consequence of cellular dependence on DNA helicases is that defects in these enzymes result in a broad spectrum of disorders usually characterized by premature aging, susceptibility to cancer, and other diseases normally associated with aging.

We will start this article by discussing the structure–function relationship in the six major DNA helicase families as defined by the presence of distinct sets of helicase signature motifs and conserved structural features. We will then outline similarities and mechanistic differences between DNA helicases and other related motor proteins, as well as describe currently accepted mechanistic models for the mechano-chemical coupling of NTP hydrolysis with DNA translocation and unwinding. Both traditional and developing experimental techniques used to study DNA helicases along with the most important and challenging questions regarding the molecular mechanisms and cellular activities of these enzymes will be also discussed.

DNA helicases are ubiquitous enzymes found in all domains of life. Bona fide helicases use the energy derived from binding and hydrolysis of nucleoside triphosphates (NTPs) or deoxynucleoside triphosphates (dNTPs) to translocate along a nucleic acid lattice (reviewed in Reference 1). Unidirectional translocation provides the duplex separation required for all aspects of DNA metabolism, as well as the disassembly of protein–nucleic acid complexes formed during DNA-manipulation processes. Nucleic acid helicases and related proteins are classified into six superfamilies based on the presence of highly conserved amino acid sequence motifs that define the motor core of these enzymes (1, 2). Despite sharing the highly structurally conserved motor core, the cellular roles of the helicases within the same superfamily are highly specific and determined by unique structural features that are incorporated into the otherwise conserved core or through protein–protein interaction domains that lead to their incorporation into larger macromolecular machineries.

Biological Background

In all cellular organisms, double-stranded DNA (dsDNA) carries genetic information. To access, process, and interpret this information, the double-stranded helix must be separated into its two-component single-stranded DNA (ssDNA) strands. Once the duplex is unwound, DNA processing events such as DNA replication, repair, recombination and transcription may proceed. Both unidirectional translocation of a helicase along the DNA strand and helicase-mediated unwinding of double-stranded DNA by disruption of the hydrogen bonds formed between pairs of complementary bases are energetically unfavorable, and they depend on the energy derived from hydrolysis of the phosphoanhydride bonds of NTP.

Biomedical importance of DNA helicases

Cellular DNA suffers an estimated $1.9 \times 10^5$ modifications per day per cell as a result of environmental stress induced
by ultraviolet light exposure, toxic chemicals, and the byproduct of normal cellular metabolism (3). This constant attack necessitates existence of multiple DNA-repair mechanisms for maintaining genomic integrity. Many cellular DNA repair machineries rely on the strand-separation properties provided by helicases. Therefore, it is not surprising that defects in human helicases are linked to a broad spectrum of disorders, which are usually characterized by premature aging, susceptibility to cancers, and other diseases normally associated with aging, immunodeficiency, or mental retardation (4). Several diseases, for example, are associated with mutations in the nucleotide excision repair (NER) helicases: XPD (ERCC3) and XPF (ERCC2). These diseases include Xeroderma pigmentosum, Cockayne syndrome, and trichothiodystrophy (5). These NER helicases are also involved in protecting cells from retroviral infections (6). Increased susceptibility to breast and ovarian cancer as well as the chromosome instability disorder Fanconi anemia has been linked to mutations in Bach1, which is a helicase that has been implicated in repair of double-stranded breaks in DNA and DNA interstrand crosslinks (7, 8). The precarious aging diseases, Werner’s syndrome and Rothmund-Thomson syndrome, as well as Bloom’s syndrome, have all been associated with mutations in three of the five human RecQ-like helicases [WRN(RecQ3), RecQ4, and BLM, respectively], which are involved in DNA repair through homologous genetic recombination and DNA replication (reviewed in References 4 and 9).

Classifications

Through the use of bioinformatics, helicases are grouped into six superfamilies (SF1–SF6, respectively) that are defined by the presence of so-called helicase signature motifs (for recent review see Reference 1) (Fig. 1). These motifs are the most conserved elements of the helicase motor cores and encode the amino acids involved in the binding of NTP and nucleic acid and are responsible for transduction of the conformational change on NTP binding and hydrolysis. It is important to note that not all proteins that possess the characteristic signature motifs are bona fide helicases. Some of these enzymes act as nucleic acid translocating motors (for example, motor subunits of type I restriction enzymes and viral DNA packaging motors), protein-nucleic acid remodeling machines (such as chromatin remodeling factors) (10), or ATP-induced conformational switches that provide local RNA strand separation (11, 12). Alternatively, we currently lack sufficient predictable power to use an amino acid sequence comparison to determine a correct translocating lattice for a given helicase-like protein. Related enzymes have been shown to translocate on DNA, RNA, or even a polypeptide lattice. Examples of peptide translocases include SccA (13), which is a component of the bacterial protein export machinery that contains motifs characteristic to SF2 helicases, and CtpA (14), which is a member of the AAA + ATPase family (15) that resembles SF3 and SF6 hexameric helicases. Thus, any other classifications of bona fide DNA helicases are possible only when extensive biochemical studies have been carried out. Because the phosphodiester backbone of nucleic acid strands have defined polarity, helicases can be classified based on direction of their translocation along a single strand of DNA. Helicases that move in 3' → 5' direction are designated as "A", whereas 5' → 3' helicases are categorized as "B". A final distinction can be made among related helicases based on their ability to translocate on ssDNA or dsDNA designated as "u" or "p", respectively (1).

Enzymes in the largest superfamilies I and II (SF1 and SF2, respectively) are structurally similar. The motor cores of these helicases are formed by two so-called RecA-like folds shown in (Fig. 1a), and they contain the signature motifs. Although they perform similar functions, the motifs shared among SF1 and SF2 helicases differ in composition and arrangement. High-resolution three-dimensional crystal structures of several members of SF1 and SF2 revealed that the conserved signature motifs are located at the interface between the two RecA-like folds [ternary complex of UvrD helicase with a nonhydrolyzable ATP analog and forked DNA substrate (16) is shown as a typical SF1 representative, whereas N33 dsDNA binary complex (17) represents SF2 helicases in (Fig. 1a)].

Helicases from superfamilies III, IV, V, and VI form ring structures that consist of six protomers (Fig. 1b). Each protomer within the ring contains an AAA + (ATPases associated with multiple cellular activities) fold or a fold similar to the RecA/F7-ATPase (1). These six subunits interact to form six asymmetric nucleotide-binding pockets at the interfaces between adjacent subunits. These enzymes use the sequential ATP hydrolysis mechanism (18), which will be described below. The crystal structure of the E1 helicase from bovine papillomavirus bound to DNA in the central channel and the asymmetric ATP binding sites (19), which exemplifies a hexameric replicative DNA helicase, is shown in (Fig. 2).

Unique features and incorporation into macromolecular machineries

Each cell contains numerous DNA helicases along with a multitude of RNA helicases, nucleic acid translocating motors, and helicase-like molecular switches. Therefore, it is crucial for cellular DNA metabolism that a specific enzyme will interact with the designated DNA-processing intermediate at the appropriate time. Many helicases contain unique (or group-specific) auxiliary domains that enable enzymes with additional functions or alter their mechanistic properties, which makes them suitable for performing a diverse set of activities in various DNA processing pathways (Fig. 2). The unique features of helicases confer on these enzymes the ability to: 1) interact with a particular cognate DNA processing intermediate, which could be either a DNA molecule or a protein-nucleic acid complex; 2) unwind just right amount of DNA; and 3) “hand-out” the transiently separated DNA strands to the next step in the DNA processing event (Fig. 2). Specificity can be achieved in dsDNA through use of auxiliary domains that enable a helicase to bind to its cognate DNA substrates. For example, the archael XPB (Rad25) helicase possesses a domain responsible for the recognition of bulky DNA damage during initiation of NER (20). Another NER helicase, XPD (Rad3), preferentially binds to the ssDNA-dsDNA junction of a forked DNA substrate (21). Similarly to XPD, other members of the Rad3 family (such as Ding (22) and Bach1 (23)) are also structure-specific helicases.
DNA Helicases, Chemistry and Mechanisms of

Figure 1 Classification of helicases and conserved motifs. (a) Nonhexameric SF1 and SF2 helicases. The crystal structures of SF1 UvrD helicase (PDB: 2IS6) bound to DNA and AMPNPP and SF2 HCV NS3 helicase (PDB: 1A1V) bound to ssDNA are shown. The conserved motifs comprising the motor core of the enzymes are highlighted in colors coordinated to the labels bearing the letter or numeral identification of the respective motif. The two RecA-like folds indicated as 2A and 1A (SF1) and 2 and 1 (SF2). The conserved motifs are located at the interface between the folds and are positioned near the ATP binding site as indicated in each structure. (b) Conserved motifs of the hexameric helicases of SF3-SF6. The crystal structure of an SF3 Papillomavirus E1 hexamer helicase (PDB: 2GXA) in complex with ssDNA and ADP. Each protomer within the hexameric ring is depicted in a different color. The signature motifs located at the interface between each pair of protomers with motifs A, B, and C as well as the ssDNA binding loop contributed by one protomer, whereas motifs B' and switch 2 contributed by the adjacent protomer, are shown for one active site. Although the E1 structure was solved in the presence of ADP, the two nucleotide-binding sites within the ring were found in a conformation expected for the ATP-bound state. These sites are indicated as ATP.

Prototypical representatives for each superfamily are listed in the colored circles that schematically depict the relative sizes of the respective superfamilies. The signature motifs for each superfamily are shown by their respective circles.

In bacteria, RuvA specifically recognizes the Holliday junction formed during homologous recombination (HR) and promotes its migration (24). Additionally, several members of the RecQ helicase family also display specificity for various recombinational intermediates (reviewed in Reference 25).

Helicases are often characterized biochemically isolated from their interacting partners. However, in the cells, helicases usually function as integral parts of macromolecular machineries responsible for carrying out DNA metabolism. The presence of the associating proteins can greatly affect the unwinding properties of helicases and can aid in the identification of cognate DNA substrates, which represent the DNA processing intermediates in respective pathways.

An important characteristic of a helicase commonly affected by interaction with accessory proteins is processivity. Processivity is defined as the probability that the helicase will take the next step forward and separate another base pair as opposed to dissociating from DNA. Some helicases are extremely processive for example, the bacterial recombinational helicase UvrB can unwind 30,000 base pairs per binding event (26). Although RecBCD contains two helicase motors and a "built-in" processivity factor (27), other processive helicases require interaction with external processivity factors to unwind long stretches of DNA at a speed comparable with that of the RecBCD. Examples of such enzymes include the Escherichia coli replication helicase, DnaB, which interacts with the \( \tau \) subunit of DNA polymerase. This interaction between DnaB and DNA polymerase increases the rate of movement of the replication fork to over 1000 base pairs per second (28). Interaction with the origin recognition protein RepD makes PcrA a more processive helicase that can sustain rolling circle replication of large plasmids (29).

Although DNA unwinding by a helicase stems from its directional translocation along DNA, many helicases actively separate duplex DNA. These helicases usually have a structure that is driven through the middle of the duplex and serves as a molecular ploughshare that physically separates the two strands. RecG and UvrB have such wedge structures positioned strategically at the ssDNA-dsDNA junction (30, 31). This structure also allows for maintaining separation of the two strands as the displaced strand is directed through a second DNA-binding channel within the enzyme. RecBCD also has a pin structure...
DNA Helicases, Chemistry and Mechanisms of

Figure 2  Accessory elements that allow DNA helicases to perform unique functions in the cell. Co- and trans-acting factors enabling helicases with unique properties are schematically depicted around a conserved motor core, which is involved in coupling of ATP binding and hydrolysis to directional translocation along DNA. These elements include processivity factors, structural features involved in duplex destabilization, factors providing the substrate specificity, stabilization of the nascent ssDNA strands, as well as additional enzymatic activities.

located within the RecC subunit that after binding of the enzyme to duplex DNA splits the two strands into two separate channels within the helicase (27).

A final property of helicases is product stabilization and hand-out of the single DNA strands for the next DNA processing step. Renaturing of nascent single strands after unwinding is often prevented by the ssDNA binding proteins, SSB in E. coli (32), and RPA in eukaryotes (33).

Cellular roles and functions

DNA helicases are integral parts of many cellular machineries that play critical roles in DNA replication, repair, recombination, and transcription. Every stage of DNA replication, which includes initiation, elongation, termination, and restarting of the replication fork after stalling or collapse, involves at least one DNA helicase. Most replicative helicases (for example bacterial DnaB, viral E1, and archaeal and eukaryotic MCM helicases) are ring-shaped hexamers that have been identified as SF3 or SF4 helicases. These enzymes are highly processive and very fast; this attribute is imperative for complete and rapid replication of the genome. Although the closed ring shape is an important determinant of processivity, ring assembly around one strand of the circular bacterial DNA or at the replication origins internal to long eukaryotic chromosomes requires assistance by other proteins. During replication initiation, these helicases are recruited to the replication origin, which results in local helix destabilization and strand separation (reviewed in Reference 34). The helicase rings then translocate away from the origin and unwind the double helix ahead of DNA polymerase and the rest of the replication machinery.

When the replication machinery encounters a site of DNA damage that requires repair, progression of the replication fork stalls or collapses. One of the best-studied helicases involved at this stage is bacterial RecG. This enzyme specifically interacts with and catalyzes regression of the stalled fork, which provides a second chance for cellular DNA-repair machineries to fix the damage (reviewed in Reference 35). Bacterial replication fork restart may also be achieved through a recombination-dependent process that involves the RecBCD helicase/nuclease and the PriA helicase, which is specific for D-loop structures produced by recombinatorial proteins (see Reference 28 for review). WRN, which is a member of the RecQ family of helicases in humans, has also been implicated in progression and restart of the replication after DNA damage or replication arrest (36).

NER and transcription that involves transcription factor IH (TFIIH) in eukaryotes and archaea provides an interesting case of a process that requires the function of two DNA helicases of opposite polarity cooperating in local strand separation at the sites of DNA damage or during promoter opening. TFIIH contains two helicases: a 3′→5′ enzyme XPB (ERCC3 or Rad25) and a 5′→3′ helicase XPD (ERCC2 or Rad3). Cooperating XPB and XPD enzymes separate duplex DNA at the site of DNA damage (37, 38) and hand over the resulting repair bubble to the structure-specific endonucleases that cleave both upstream and downstream of the damaged region, which allows it to be removed and a new strand to be synthesized (39). Notably, interactions with other proteins of the TFIIH complex significantly increase the processivity and ATPase activity of XPB and XPD helicases, and they are likely to be involved in regulating activity of these helicases so that just enough of the duplex is unwound around the damaged site for the repair process to proceed (See References 37 and 39, and the references within). Like many aspects of cellular DNA metabolism, HR requires transient formation of the ssDNA intermediates and therefore the effector DNA helicases (reviewed in Reference 40). Additionally, some steps in HR, which do not require unwinding of a DNA duplex, benefit from the translocate activity of the helicase-like enzymes. The main recombination pathway in E. coli is initiated by the RecBCD complex that, similar to TFIIH, contains two helicase subunits of opposite polarity, a 3′→5′ helicase RecE and a 5′→3′ helicase RecD. In contrast to TFIIH, however, RecE and RecD subunits move along two opposite DNA strands and in conjunction with the third subunit RecC
form an exceptionally efficient machine for processing DNA ends. RecBCD is equipped with all the necessary accessory factors required for recognition of a blunt ssDNA end, fast and processive unwinding of the DNA duplex, recognition of the recombination hot spot, imbedded into the DNA on which the enzyme translocates, \( \gamma \)-regulated nuclease and helicase activities, and the ability to facilitate formation of the active species in HR—which is a nucleoprotein filament formed by RecA recombination on ssDNA.

RecBCD has only a few homologs in bacteria, and no eukaryotic analog of this helicase/nuclease has been identified. In some genetic backgrounds, most RecBCD activities can be performed by the RecQ helicase acting together with RecF nuclease to process the ssDNA ends and the RecFOR proteins, which facilitate loading of RecA recombination on to ssDNA produced by RecQ/RecF activities (reviewed in Reference 41). The RecQ helicases have also been implicated at subsequent steps in HR, which require caretaker functions that involve disruption of the nucleoprotein filaments as well as stabilization of the invading strand, and that facilitate branch migration and resolution of Holliday junctions (reviewed in Reference 9). Notably, whereas all of these activities can be carried out by a single bacterial RecQ helicase, its five mammalian counterparts evolved to perform more specialized tasks.

**Nucleotide Hydrolysis and Translocation**

**ATP (NTP) Hydrolysis**

Most helicases display preference for ATP as an energy source. However, some of these enzymes display a broad specificity for nucleotides or deoxynucleotides, whereas some prefer different nucleotides, such as for example phage T7 helicase, which selectively hydrolyzes dTTPs (42). Although the precise mechanisms for individual helicases differ, all these enzymes generate force through conformational changes within nucleotide binding folds, which allow them to perform active work. Not surprisingly, the highest structural conservation among helicases is observed between the nucleotide-binding and hydrolysis cores. This structure uses Walker A and B motifs (Walker P-loop) observed between the nucleotide-binding and hydrolysis cores. Notably, whereas all of these activities can be carried out by a single bacterial RecQ helicase, its five mammalian counterparts evolved to perform more specialized tasks.

**ATP binding/hydrolysis fold of RecA (see Fig. 1)**

ATP synthase (43) provides an environment where Mg\(^{2+}\) ion is chelated between the phosphate of ATP through its amino group while the threonine (or serine) coordinates the Mg\(^{2+}\) ion. The Walker B box (motif II) contains a characteristic DEAH, DExH, or DExx sequence. The aspartic acid from this motif coordinates the Mg\(^{2+}\) ion through its carboxyl group, and the glutamate serves to activate the water molecule for nucleophilic attack on the \( \gamma \)-phosphate. Additionally, residues in all eight SF1 signature motifs form important contacts with the ATP-Mg complex, and residues in motifs Ia, III, V, and VI form contacts with DNA. All the motifs work in a concerted manner to transduce a conformational change between the nucleotide and DNA binding sites (reviewed in Reference 1).

Hexameric helicases in SF 3-6 also employ the Walker A and B boxes for NTP (or dNTP) hydrolysis (Reviewed in Reference 18). The ATP binding sites are formed with one subunit that provides the Walker A and B motifs and the neighboring subunit providing an arginine finger (Fig. 2). Crystal structures of the E1 helicase from bovine papilloma virus (SF3) (19), and of the gp4 helicase from the T7 bacteriophage (SF4) (44), show that these sites are asymmetric, and they have different affinities for the nucleotide. These sites have been described as ATP binding, ADP + Pi, and empty (apo). The structural data support a sequential ATP hydrolysis mechanism in which ATP binding to the empty site induces a conformational change in the helicase. ATP is then hydrolyzed to create the ADP + Pi state, and then the nucleotide and inorganic phosphate is released, which results once again in an empty state that permits a new molecule of ATP to bind.

**Translocation**

The mechanism(s) employed by helicases to translocate along nucleic acid lattices were the subject of a heated debate over the past decade. In the last few years, however, the models converged, which resulted in the general acceptance of a so-called “inchworm” mechanism (reviewed in Reference 45) (Fig. 3). Evidence to support this mechanism has been found for both SF1 and SF2 helicases and the related DNA translocases of the Swi2/Snf2 family, with the major difference being that SF1 helicases bind to ssDNA through stacking interactions between DNA bases and aromatic residues of the helicase (46) (Fig. 3a). However, SF2 helicases bind the phosphate backbone of a DNA molecule and translocate along the backbone, avoiding significant base interactions (47) (Fig. 3b). While “inning” forward along ssDNA through the use of NTP-induced conformational changes, the helicase unwinds duplex DNA by displacing the complementary strand with the help of one of the structural tools described above. The inchworm mechanism requires that the helicase maintains at least two DNA binding sites that can alternate between two states, one being tightly bound and other a loosely bound state. The alternating DNA-binding sites may belong to different subunits of a helicase ring (as most profoundly illustrated for BPV E1 helicase (19)) or to a single monomer as is the case with SF1 and SF2 helicases. The crystal structures of prototypical SF1 helicases, PcrA (46), and UvD (16) combined with vast biochemical data support this model of translocation and show a single strand of DNA on which the helicase translocates, spanning the region between the RecA-like folds and bound simultaneously to both folds (46). The helicase binds to ssDNA, and after binding to ATP, it undergoes a major conformational change resulting in closing of the cleft between the two RecA-like folds, with the leading fold binding tightly to DNA, and the trailing fold easing its grip. The helicase takes a step forward on the hydrolysis of ATP or on the release of the
DNA Helicases, Chemistry and Mechanisms of

(a) "Inchworm" translocation by the SF1 helicases whereby the helicase binds to and interacts with the bases of ssDNA. In the absence of ATP, the cleft located between the RecA-like folds is apart, and the folds are separated by a single DNA base. After binding to ATP, the cleft closes, and the trailing RecA fold moves one nucleotide closer to the leading fold, which results in displacement of a single base.

(b) SF2 helicases translocate along a nucleic acid lattice through extensive contacts with the DNA backbone also using the inchworm mechanism. Here ATP binding and hydrolysis induces a conformational change that involves closing of the cleft between the RecA-like folds.

(c) Hexameric helicases are believed to translocate by an escort mechanism in which the DNA binding loops located within the center channels of the ring structure for each subunit are linked through the set of helicase signature motifs to the ATP binding pockets located on the outside of the structure. In this staircase mechanism, the loops associated with ATP are located at the top of the channel, bind to the next incoming base, and escort that base through the channel. The loops located in the intermediate positions along the staircase are bound to ADP, and the empty pocket is located at the exit position, where after binding to ATP the loop can return to the top and bind the next entering base.

The mechanism of translocation employed by the SF3, hexameric helicase E1 uses the asymmetry of the ATP-binding sites to escort DNA through the central channel of the ring structure (19) (Fig. 3c). Individual subunits within the hexamer have DNA binding loops that protrude into the central channel. The ATP-bound subunits place their loops at the top of the channel and bind to the DNA backbone of the next entering nucleotide. These subunits maintain contact with this nucleotide and escort the base through the central channel, as ATP is hydrolyzed to ADP + P and ADP and P are released. The loops associated with the empty site are located at the bottom of the channel (exit) and on binding a new ATP, return to the top of the channel and bind a new DNA base for escorting.

The step size of a helicase is one of the more contentious characteristics because of the various ways it can be defined. It may be determined in terms of efficiency, which refers to the number of base pairs unwound or translocated per binding and hydrolysis of 1 NTP molecule. The physical step size of a helicase can be determined based on its ability to traverse discontinuities in the DNA lattice, whereas "kinetic step size" refers to a frequency of kinetically rate-limiting step that occurs during DNA unwinding (48). The three step sizes are rarely identical for a given enzyme. Although SF1 helicases hydrolyze one ATP molecule per one nucleotide they translocate (49), or per one base pair of dsDNA unwound (16), their kinetic step size is much larger (50). Integration into larger macromolecular ensembles may alter the perceived step size even more. For example, when a typical SF1 helicase RecB is incorporated into RecBC enzyme, it displays a physical step size of 23 nucleotides (51).

Depending on the method of analysis, the kinetic step size of SF2 helicase NS3 was estimated as 18 base pairs (kinetic and physical step size on RNA) (52), 11 base pairs (also correlated to a measured physical step size and binding site size) (53), 9 base pairs on DNA (54), and 3–4 base pairs (55). The difference in these step sizes may reflect the two nucleic-acid-binding domains found in SF2 helicases. One RecA-like fold reaches out and binds to duplex nucleic acids about 11 base pairs ahead while the trailing domain follows unwinding the duplex behind the leading domain (53) in discrete steps. The larger apparent 18 base pair step size may reflect either the max step size or the low processivity of NS3 helicase. Recent single-molecule analysis of NS3 helicase connected its kinetic step size of about 3–4 base pairs to smaller substeps associated with ATP hydrolysis. In these experiments, NS3 unwound duplex DNA in three base pair steps by a spring-loaded mechanism, in which the lead binding fold of NS3 moves forward one base pair per ATP hydrolyzed. After three successive steps, enough tension has built up to cause the trailing fold to snap forward, which leads to unwinding and release of three nucleotides (55).

Although SF1 and SF2 enzymes can translocate and some can unwind DNA as monomers, these enzymes show evidence of increased processivity and helicase activity when they act as cooperating monomers, dimers, or oligomers. For example,
the SF1 helicase UvD and the SF2 helicase NS3 both display low processivity at low concentrations; however, at high concentrations or under conditions when more than one helicase can bind in succession to a single strand of DNA, their processivity is dramatically increased (54, 56). The exact mechanisms of duplex unwinding and therefore the nature of oligomerization requirement for SF1 and SF2 helicases remains disputed. According to one model, cooperation between the independent monomers achieves two goals: 1) it allows for exertion of greater forces and 2) it increases the probability of the helicase to take a step forward versus falling off DNA and hence its processivity. An alternative theory is that these helicases form specific higher-order complexes with each other resulting in dimers (UvD) (57) or oligomers (NS3) (58). These structures are necessary for efficient unwinding and may result in activation of latent helicase activity (reviewed in Reference 59). This activation may also be achieved through the protein-protein interactions within respective macromolecular machines. Although evidence supports both models, together these results indicate that protein-protein interactions, and assembly into higher-order structures play an integral role in modulating helicase activity, and they serve to stabilize the helicase when bound to a nucleic acid lattice.

Tools and Techniques Used to Characterize Helicases

The biomedical importance of DNA helicases and their intriguing molecular mechanisms prompted continuous development of assays to monitor interactions between these enzymes and their nucleic acid substrates, translocation, NTP hydrolysis, duplex separation, and remodeling of nucleoprotein complexes. DNA binding and duplex unwinding by helicases is conventionally monitored by gel electrophoresis-based assays. In these assays, DNA substrates are produced by annealing two partially complementary oligonucleotides, one of which is radioactively labeled at the 5' end (Fig. 4a). Several DNA substrates that mimic cellular DNA repair intermediates can be produced in this manner. These substrates can be used to determine the polarity exhibited by a particular helicase and to identify its preferred or cognate substrate. In the binding assays, protein-DNA complexes are separated from the free radioactively labeled substrate taking advantage of the difference in electrophoretic mobility through polyacrylamide gels under native conditions (Electrophoretic Mobility Shift Assays). In the unwinding assay, the DNA substrate is incubated with the helicase, and DNA unwinding is initiated by the addition of ATP. After quenching the reaction, the displaced oligonucleotide can be separated from the intact substrate by electrophoresis through nondenaturing polyacrylamide gel. The relative quantities of the radioactive label in the substrate and product bands can be used to quantify binding and unwinding.

These traditional assays have been adapted to monitor duplex separation by following fluorescence resonance energy transfer (FRET), which is a powerful spectroscopic technique for measuring distances in the 0.7-75 Å range (see Fluorescence Resonance Energy Transfer (FRET) for Proteins for more information). In this assay, two fluorophores, a donor, and an acceptor are incorporated into complementary strands of a DNA duplex (Fig 4b). When the duplex is intact and the donor and acceptor are in close proximity to each other, the excitation energy of the donor fluorophore can be transferred to the acceptor fluorophore (whose emission frequency should correspond to the detection of the donor) via an induced dipole-dipole interaction. As the helicase separates labeled DNA strands, there is a decrease in fluorescence by the acceptor fluorophore and a simultaneous increase in fluorescence by the donor fluorophore.

Both, gel- and FRET-based techniques are discontinuous methods, which means that only complete unwinding of each substrate molecule results in a measurable signal. For the processive enzymes, it is important to monitor duplex unwinding as it occurs. Continuous monitoring of a helicase activity can be achieved through the use of a fluorescence-based helicase assay that exploits the use of several DNA-intercalating dyes that display a measurable increase in fluorescence intensity when bound to ssDNA relative to the unbound state or to the dsDNA-bound form (60) (Fig. 4d). As the DNA molecule is unwound, fluorescence decreases as ssDNA products form and the dye is released.

Translocation assays

Duplex separation and disassembly of the nucleoprotein complexes directly stems from unidirectional translocation of a helicase along DNA. Most commonly, directional translocation is monitored by following displacement of streptavidin from a radiolabeled DNA molecule biotinylated near one of the termini (61) (Fig. 4c). Translocation by DNA helicase results in accelerated dissociation of the streptavidin from biotin. The products of such reaction are then resolved using an electrophoretic mobility shift assay that separates the free oligonucleotide from streptavidin-bound DNA. More quantitatively, translocation can be monitored by following a change in the fluorescence of a dye incorporated into a DNA substrate (62) (Fig. 4c).

Single-molecule techniques

The complex nature of DNA helicase reactions and mechanisms necessitated the development of multiple techniques that allow direct observation of individual protein-DNA complexes. Most groundbreaking insights into helicase mechanisms from single-molecule techniques have come from the use of total internal reflection microscopy (TIRM), magnetic tweezers, and laser tweezers (optical trap) (63). In these approaches, DNA is immobilized either on a surface of a microscope slide, a glass capillary, and/or a polystyrene or magnetic bead using biotin-streptavidin or antibody-antigen interaction.

TIRM allows detection of hundreds of single molecules simultaneously with high sensitivity (Fig. 4d). These single-molecule assays are usually an extension of the FRET-based methods described above. The advantage of this approach over the bulk studies is that single events can be captured, recorded, and visualized as they occur, in contrast to the bulk assays that monitor the ensemble average for all molecules in solution and can obscure key steps in DNA manipulation processes.

WILEY ENCYCLOPEDIA OF CHEMICAL BIOLOGY © 2008, John Wiley & Sons, Inc.
Methods for the helicase analyses. (a) Observation of strand separation through the use of discontinuous helicase assays. A radioactive label ($^{32}\text{P}$) can be used to label one strand and monitor unwinding activity caused by the difference in electrophoretic mobility of the duplex substrate compared with the ssDNA product. The same process can be monitored using a FRET pair of fluorophores, donor (D), and acceptor (A). (b) Continuous unwinding assays can be monitored fluorescently through the use of an intercalating dye that has increased fluorescence when intercalated into duplex DNA. (c) Deposition of transcription DNA substrates and their products. Translocation can be observed by the ability of the helicase to displace streptavidin from a biotinylated oligonucleotide. Other methods include observing the change in fluorescence of a fluorophore incorporated into the DNA lattice or observing the displacement of a triplex forming oligonucleotide by a dsDNA translocating enzyme. (d) For TIRM, single-DNA substrates are attached to a slide through a streptavidin/biotin interaction. The substrates are labeled with a FRET pair of fluorophores. Single unwinding events can be observed through monitoring fluorescence decrease of the acceptor fluorophore and simultaneous increase in the donor fluorophore. (e) Magnetic tweezers can be used to observe helicase binding and unwinding properties through changes in the force-extension properties of DNA. DNA is attached to surface at one end, and tethered to a magnetic bead at the other. The magnetic bead can be manipulated through the application of a magnetic field, and changes in DNA can be monitored. (f) Polystyrene beads attached to one or both ends of a DNA molecule can be trapped by the laser tweezers. Unwinding can be monitored through displacement of an intercalating dye. This technique can also be used to monitor translocation of a fluorescently labeled enzyme.

In magnetic tweezers, one end of the DNA molecule is attached to the surface of the glass capillary and the other end is attached to the magnetic bead (Fig. 4e). The bead can be "lifted" from the surface by applying the electromagnetic field. The magnetic field exerts a constant force, so the resulting extension of the molecule can be measured as a function of the applied force. Using this approach, one can monitor the displacement of the bead in all three dimensions (displacement in the x and y dimensions is monitored directly, whereas the z direction can be estimated from the refraction pattern). DNA helicase activity can be observed from the difference in the force-extension properties between ssDNA and dsDNA.

A rather informative single-molecule technique combines optical trapping and fluorescence microscopy. Here, a long DNA molecule is attached to a polystyrene bead, which can be captured by the laser tweezers (a device that allows trapping of a small semi-transparent object in the focus of a laser beam) (Fig. 4f). Translocation of a helicase along the DNA molecule extended by a flow of buffer can be monitored after displacement of the intercalating fluorescence dye or directly if the fluorescence label is introduced in the helicase. Chemically modified nucleic acids can be used in each technique described above to deduce the mechanisms of helicase translocation and unwinding. Discontinuities can be introduced into the nucleic backbone through nicks and polyglycol linkers to determine whether the continuity of the phosphate backbone is necessary for translocation by the helicase (64). By varying the size of the discontinuity, one can also determine the physical step size of the helicase by testing how large of a gap the enzyme can tolerate (51). Additionally, the nucleic acid moieties can be removed resulting in abasic sites, which may impede the translocation (65). The electrostatics can be interrupted by incorporating a peptide nucleic acid moiety into the sequence or by introducing a methylphosphonate into the backbone (66).
Future Research and Remaining Questions

In addition to identifying new helicases and biochemically characterizing their properties, a major point of emphasis in the future is how these helicases are incorporated into larger complexes and macromolecular machineries involved in DNA metabolism. The protein–protein interactions within these assemblies likely play integral roles in modulating helicase properties. One of the more intriguing questions that remains to be addressed involves the structural characteristics responsible for defining a helicases polarity and translocation lattice.

Genetic recombination is classically manifest as the reassortment of genes during meiosis, where extensive pairing of homologous chromosomes is associated with “crossover” between them to create new derivative hybrid chromosomes. The associated enzymatic pathway, homologous recombination (HR), is now known to execute such exchange not only during meiosis but also between homologous sequences in mitotic cells, for example between sister chromatids. Nonhomologous recombination (NHR), also called illegitimate recombination, was recognized initially and defined as genetic recombination that failed to show this canonical feature of HR, i.e., hybrid derivative chromosomes that lacked extended homology at the junction between parents. Instead, junctions often showed 1-10 bp segments of “microhomology” too short to be used by HR enzymes. Such events seemed to defy the logic and benefits of HR in a chemically distinct alternative reaction that was, on its face, detrimental. In this review, the processes that underlie NHR are placed in context as DNA repair pathways that are in fact associated with genome preservation, but that can secondarily give rise to chromosome rearrangements and other mutations. The biochemical requirements of these reactions are discussed as well as current understanding of how the responsible enzymes have been adapted to meet these requirements.

Biological Background

As might be expected from the fact that both HR and NHR represent new joints between previously separate DNA duplexes, an intimate relationship exists between recombination and DNA double-strand breaks (DSBs) (Fig. 2a). Processes that give rise to DSBs not only underlie meiotic and mitotic HR, but also they predispose cells to NHR. Conversely, deficiency in cellular components required for both HR and NHR causes hypersensitivity to DSBs. Indeed, it may be most accurate from an evolutionary perspective to consider HR and NHR foremost as alternative mechanisms for silent repair of DSBs, with recombination as a secondary consequence. It is thus critical to consider the cell cycle-dependent interplay of homologous and nonhomologous mechanisms at a DSB as the stage on which NHR plays out.

Interplay between homologous and nonhomologous DSB repair

Cells constantly suffer DNA lesions that degrade the genome. Some DSBs are created deliberately and by specific mechanisms (see below), but many result from oxidative, radiation, or physical stresses that occur more randomly (Fig. 2b). When acting as a DSB repair pathway, HR uses a homologous donor chromosome as a template to copy the genetic information required to bridge the broken ends without altering the template itself (Fig. 2c). Such a second intact copy of a chromosome is present in diploid cells, although in large, complex, and repetitive genomes, finding this potential donor is not trivial because chromosome pairs are not associated. A nonideal donor exists when one of a pair of sister chromatids is broken, where
Nonhomologous Recombination

Figure 1  Microhomology use in NHR. (a) Demonstration of microhomology, which is evident as a sequence common to both chromosome substrates (boxed). Note that the position of initiating DSBs cannot be inferred from the product. (b) Possible mechanisms for generating microhomology. If DSB overhangs encompass a microhomology, it can be rejoined directly by NHEJ. Internal microhomologies must be exposed, either by unwinding, as suggested for DNA-PKcs (1), or by 5′ resection, as suggested for deletion MMEJ (2).

Figure 2  Interplay between HR and NHR. (a) When a DSB occurs (top), it can be resected and used to copy a donor chromosome (red) during HR (left) or rejoined directly (right), sometimes inaccurately (jagged line). HR and NHR lead to recombination by crossover resolution and engagement of a different DSB (green), respectively (bottom). (b) A timeline shows a period during which NHEJ may be iteratively attempted before DSB resection; after which, HR is attempted. Alternative pathways (below) might lead to rejoining, but these are often less efficient and uncommon when the above pathways are functioning normally.

the other sister is both physically associated and strictly homologous. This special relationship is strengthened by understanding that replication itself can lead to DSB formation. It is thus both predictable and observed that HR is a principal repair pathway in S or G2/M cell cycle stages after replication but before cell division (6, 7). Given that nonhomologous DSB repair processes are, by definition, not HR, it is in turn predictable and observed that such repair predominates at DSBs occurring randomly outside of replication (6, 7). But what is DSB repair in the absence of a homologous donor? Stated simply, nonhomologous repair is the direct rejoining of DSB ends (Fig. 2a) (5). The details of these mechanisms are addressed below, but simply recognizing that they are executed without an information template correctly predicts that they have a higher error rate. However, when HR is impractical or impossible because of inaccessibility of a homologous template, even error-prone rejoining of DSB ends will yield a relative preservation of the genome as compared with continuing cell division with a broken chromosome. Also, repair of simple DSBs by direct rejoining can be >99% accurate (8, 9), so that nonhomologous repair is often genetically silent.

A major difference between homologous and nonhomologous DSB repair is that HR begins with extensive resection of the 5′ DSB strands, whereas NHR is comparatively duplex preserving. Mounting evidence indicates that the 5′ resection is the regulated step in DSB repair pathway “choice” because it is an essentially irreversible commitment to HR (6, 8). Resection is under direct cell-cycle control, being activated by cyclin-dependent kinases, at least in yeast, and therefore largely inactive in G1 cells (6). Even in replicating cells, resection is delayed, approximately an hour in yeast, before it begins in earnest (10). The basis of these effects is poorly understood, mainly because the mechanism(s) of resection remain enigmatic. Regardless, their net effect is to provide a period during which nonhomologous repair of a DSB might be attempted, with transition to homologous repair of persistent breaks at a pace that is cell-stage dependent.
Nonhomologous repair (15, 16).

NHR events. Potential complexity of the processes giving rise to observed stable resolution (13). These cycles underscore the potential complexity of the processes giving rise to observed NHR events.

Telomeres and breakage–fusion–bridge cycles

The ends of linear chromosomes are a type of “DSB” worth specific consideration. McClintock first recognized that specialized structures called telomeres protect chromosome ends (13, 14). A detailed description of this structure is beyond the scope of this article, but it involves a repeating DNA sequence and multiple proteins that bind to it, including DSB repair proteins (14). The key importance is that when this structure fails, because of loss of telomere proteins or degradation of the DNA repeat, chromosome ends become a DSB target for NHR mechanisms that can fuse sister chromatids by direct joining. The resulting dicentric chromosome is destined to be broken during mitosis if pulled toward opposite spindle poles, which leads to SSBs that might again lead to chromosome fusion, ongoing “breakage–fusion–bridge” cycles, and NHR before ultimate stable resolution (Fig. 3a) (13). These cycles underscore the potential complexity of the processes giving rise to observed NHR events.

V(D)J recombination

Another important context for understanding NHR is a series of genome manipulations in the developing vertebrate immune system where nonhomologous repair mechanisms are co-opted to create deliberate mitotic chromosome rearrangements. In V(D)J recombination, specific variable, diversity, and joining sequences from a collection of such segments in the germline genome are juxtaposed in recombinant chromosomes to create functional immunoglobulin and T-cell receptor genes (Fig. 3a) (15, 16). Both by the reassortment of different coding segments and by maximizing the error-prone nature of nonhomologous junctions, a large repertoire of antigen receptor genes results. V(D)J recombination is initiated by a mechanism-specific recombinase, the RAG1/2 proteins, but it is completed by the same nonhomologous repair mechanisms used in genome preservation, which highlights the potential duplicity of these mechanisms. Although less well defined, immunoglobulin class switch recombination also seem to require nonhomologous repair (15, 16).

Chromosomal instability in cancer

Nearly all cancer cells show deranged chromosomes manifest as translocations, deletions, and amplifications. Some rearrangements likely develop as a consequence of aberrant cell growth, but others are unquestionably causative. In one pattern, which is typical of lymphoid malignancies, specific cancers are associated with recurring, usually reciprocal, translocations between nonhomologous chromosomes. Translocation t(9;22) in chronic myeloid leukemia is a classic example that allows treatment with inhibitors that target the product of the resulting BCR–ABL fusion gene (17). The other main pattern, which is typical of epithelial malignancies, shows massively deranged genomes with multiple, usually nonreciprocal, rearrangements. Extensive efforts continue to identify oncogenes and tumor suppressor genes whose function is affected by these rearrangements. Junctions of rearranged chromosomes in cancer frequently show microhomology in the absence of extended homology and are therefore inferred to originate by direct rejoining/NHR. The lesions and mechanisms that yield these rearrangements are undoubtedly multiple, including both telomere-dependent and telomere-independent events. Some rearrangements represent errors of the V(D)J process because they occur in cells and loci undergoing this targeted recombination (Fig. 3b). This issue provides another caution regarding the multiplicity of NHR mechanisms, because even these errors could represent use of inappropriate loci in the V(D)J reaction, joining of RAG1/2-generated and spontaneous DSBs, or even DSB-independent transposition between chromosomes (15). Other NHR presumably originates from two independent DSBs (Fig. 2a), but the final sequence might have little to do with the configuration of the inciting damage, as elegantly demonstrated in a yeast model (18).

Chemistry of DNA End Joining

The chemical transactions of DNA end joining are predictably similar to other DNA repair pathways and even to replication in that all of these processes manipulate base-pairing and phosphodiester bonds to create intact duplex molecules. However, the direct repair of DSBs presents biochemical challenges unique to these substrates. In this section, I consider both the general and the specific chemical requirements of nonhomologous DSB repair, how they are manifested in the two main pathways of repair, and the sometimes unusual properties of key enzymes that determine their function in these pathways.

Chemical steps in strand break repair

It is important to recognize that although NHR and HR share a substrate, they are mechanistically very different. It is more useful to compare NHR with the direct repair of single-strand breaks (SSBs), which is a subset of the base-excision repair (BER) pathway (Fig. 4a) (19). Three reaction classes might be required for such repair, depending on the specific nature of the break. All DNA repair culminates in ligation of a strand nick bearing 3' OH and 5' P termini. To arrive at that point, it might first be necessary to resynthesize bases missing as a result of the DNA damage. Both polymerization and ligation might also depend on the removal or reversal of blocking nucleotide fragments residual on the break termini. It might include lyase-dependent removal of 5' deoxyribosephosphate deoxyribosephosphate.
Nonhomologous Recombination

Figure 3. Special mechanisms of NHR. (a) Telomere failure unmasks chromosome ends for fusion by NHEJ, which leads to potentially iterative cycles of breakage and fusion before ultimate stable telomere resolution. Oval, centromere; rectangle, telomere. (b) Immune receptor loci contain multiple V, J, and sometimes D segments with signal sequences (triangles) that are cleaved by RAG1/2 and subjected to NHEJ to generate recombined products. Engagement of an inappropriate chromosome can lead to RAG1/2-dependent chromosomal rearrangement.

Nonhomologous end joining

The term “nonhomologous end joining” (NHEJ) initially referred generically to direct rejoining of DSBs, but it is now most commonly used to refer to a specific and dominant pathway of nonhomologous repair defined by both DNA features and protein components (5). Regarding the DNA, NHEJ typically entails little or no nucleotide loss from DSB ends. In the strictest manifestation, which is typified by the behavior of budding yeast NHEJ acts almost exclusively by annealing DSB overhangs (9, 20). Because such overhangs were often paired in the original duplex, overhang joining tends toward accurate repair directly analogous to BER (Fig. 4a). This restriction to overhangs is apparent relaxed in other species, but current evidence nonetheless distinguishes NHEJ and more extensive nucleotide loss (see below). Regarding proteins, NHEJ requires both specific structural proteins to bind and bridge ends and enzymes to catalyze reactions similar to BER (Fig. 4a) (5). Unlike HR, whose genes were first identified by screens in yeast and bacteria, many proteins that catalyze NHEJ were discovered in mammals by observations that their deficiency causes sensitivity to DSBs and V(D)J impairment (4, 5, 16). This observation led to the common notion that mammals and single-cell organisms predominantly use NHEJ and HR, respectively. This notion is misleading, because all eukaryotes maintain complex HR and NHEJ pathways that are highly active in the correct cell states (6, 7).

NHEJ structural proteins include Ku, which is a protein preserved in all organisms that possess NHEJ and whose utilization provides the most specific current definition of this pathway (5). Ku is a heterodimer of the Ku70 and Ku80 proteins in eukaryotes and a homodimer in prokaryotes but in all organisms forms a ring that provides initial lesion recognition by passage of the DSB end through the ring (21). Interestingly, although Ku likely binds all DSBs, it is only required for NHEJ, not for HR. The specific roles of Ku in NHEJ in higher eukaryotes center on its identity as the principal DNA binding component of the DNA-dependent protein kinase (DNA-PK), whose catalytic subunit DNA-PKcs is also required for efficient NHEJ (5). As a kinase activated by DSB ends, DNA-PKcs contributes to NHEJ in part by phosphorylating NHEJ proteins and regulating the ensuing cascade of events. However, in vitro evidence also supports a primary structural role of DNA-PKcs as part of an end bridging complex (22, 23), although cellular evidence that supports this function is needed. Indeed, one key action of activated DNA-PKcs is autophosphorylation, which in some fashion seems to release the DSB ends for access by downstream enzymes (24). Despite this central role, neither lower eukaryotes nor bacteria are known to require a DSB-dependent kinase for NHEJ, which suggests that such regulation was imposed on...
Nonhomologous Recombination

Figure 4  Chemistry of strand break repair. (a) The steps of SSB and DSB rejoining are highly analogous, with an added requirement for end bridging in NHEJ. For simplicity, only select mammalian proteins are indicated. Curved line, terminal damage; red arrow, polymerization. (b) The end-bridging step is realized in unusual ways by NHEJ polymerases (Pol) and ligase (Lig). At 3′ overhangs, polymerases tolerate an incomplete primer–template pair, in part using special protein motifs (cyan loop). Similarly, DNA ligase IV can ligate (carat) across from strand discontinuities. In some yeast, an additional NHEJ requirement exists for the DSB-binding Mre11–Rad50–Xrs2 (MRX) complex (9), which may account for the bridging function in place of DNA-PKcs (26). Consistently, current best evidence does not suggest a role for the analogous Mre11–Rad50–Nbs1 (MRN) complex in vertebrate NHEJ (27), but this is poorly explored because MRN is essential for viability.

NHEJ enzymes include foremost the requisite DNA ligase. In eukaryotes, DNA ligase IV (Lig4) is both strictly required for Ku-dependent NHEJ and largely if not entirely dedicated to this pathway (5). In prokaryotes, the principal NHEJ ligase, called LigD in mycobacteria, is present in an operon with Ku, which again demonstrates a coupling of Ku with a specific NHEJ ligase (28). However, the ligase presents a point of divergence between kingdoms in that LigD is no more related to Lig4 than to other ATP-dependent ligases. LigD does not act alone in support of NHEJ but it interacts via tandem C-terminal BRCT domains with a coiled-coil domain of a protein called XRCC4 (29). XRCC4 itself binds DNA (30) and so is arguably a structural protein that acts as a scaffold between the ligase and the DNA but because of the strength of its association is accurately viewed as a subunit of DNA ligase IV. Strikingly, yet another protein associates with Lig4::XRCC4 called XLF/Cernunnos that is predicted to be structurally similar and evolutionarily related to XRCC4 (31).

Other NHEJ enzymes execute end processing before ligation and are generally less well defined and less strictly required. Nucleases include the protein Artemis in higher eukaryotes, which executes unique NHEJ functions in V(D)J recombination (32) and the slower repair of approximately 10% of irradiation-induced DSBs that correlate with cytotoxicity (33). However, Artemis is absent from most lower eukaryotes, perhaps because of its intimate association with DNA-PKcs and V(D)J recombination (32), and even in organisms that possess it, Artemis is unlikely to account for all end trimming. Thus, some NHEJ nucleases are yet to be described. NHEJ polymerases include select members of the Pol X family of DNA polymerases typified by the BER enzyme Pol β, specifically Pol4 in yeast (20) and terminal deoxynucleotidyl transferase (TdT, used only in V(D)J recombination), Pol λ, and Pol µ in mammals (34). However, like nucleases, these proteins cannot account for all NHEJ polymerization, as demonstrated clearly in yeast (20). Also, deficiency of even both Pol λ and Pol µ leads to only a mild phenotype manifested as altered V(D)J joint spectra but not frank sensitivity to DSBs (35). In prokaryotes, NHEJ end processing remarkably includes two protein domains often fused to the ligase, although these can function independently (28, 36). LigD in particular is a polyfunctional protein that contains polymerase, nuclease, and ligase domains in tandem, so that mycobacterial NHEJ can be transferred with just two polypeptides (37). As with the ligase, the prokaryotic nuclease and polymerase are not particularly related to Artemis or Pol X polymerases (28, 36).
Microhomology-mediated end joining

In early experiments it was observed that DSBs were sometimes repaired by an erroneous mechanism associated with nucleotide loss from the ends (38). In much literature this repair was attributed to NHEJ in its generic sense, but more recent work has continued to refine both NHEJ and this alternative form of repair. A major clue that the latter was a distinct mode of repair was the general observation that joints formed in NHEJ mutants showed more extensive nucleotide loss. This phenomenon has been carefully explored, and data support the notion that Ku-dependent NHEJ is primarily responsible for accurate rejoining (39, 40). One name given to the alternative rejoining pathway is “NHEJ” (41), but this is confusing given the more common convention of using NHEJ to describe Ku-dependent joining. The designation microhomology-mediated end joining (MMEJ) was applied to Ku-independent repair in budding yeast (42). Similar joining, which is typified by microhomology use and substantial nucleotide loss, can also be observed in insects and plants (43, 44), and until additional information suggests a better classification, MMEJ seems a suitable name for all. MMEJ is poorly explored in bacteria.

The mechanisms of MMEJ are not well established and are likely multiple. A unifying feature in all systems is that MMEJ is repressed by Ku in mammals, developing data suggest that poly-ADP-ribose polymerase and DNA ligase III might participate in one subpathway (41). Because these factors are typically associated with BER, the analogy drawn above between the direct repair of SSBs and DSBs might in fact be realized in competing repair pathways. More detailed explorations of MMEJ have been performed in yeast, where a different type of repair was revealed that is not yet possible to describe as a simple linear pathway (2, 42). In Saccharomyces cerevisiae, MMEJ shows only a partial dependence on any factor (42). Interestingly, two of these factors are the NHEJ enzymes Dnl4 and Pol4, even in the absence of Ku. Another dependence is on the 3′→5′ flap nuclease Rad1-Rad10, which is not implicated in NHEJ but does function in HR and, more relevantly, in single-strand annealing (SSA) (3, 4). SSA is a form of repair in which larger internal direct repeats are annealed. SSA is not typically described as NHEJ because these repeats are too big to be considered microhomologies and because it uses the HR protein Rad52 to facilitate annealing. Although Rad52 is not obviously required for MMEJ in S. cerevisiae (42), its homologue in Schizosaccharomyces pombe is, which leads to the designation of MMEJ as “micro-SSA” (2). This finding is compelling as it invokes the most consistent apparent requirement of deletion MMEJ—namely, that strand resection must expose microhomologous sequences for annealing, which is probably common with HR (Fig. 2b, 2, 45). Importantly, NHEJ might sometimes use internal microhomologies close to the DSB ends through the action of proteins such as DNA-PKcs, which are distinct from 5′→3′ resection and MMEJ (Fig. 2b, 1). A fundamental question remains whether MMEJ is a distinct mechanism of DNA repair or simply a different manifestation of previously described pathways. Yeast MMEJ is markedly inefficient and largely irrelevant to basal DNA repair (40, 43), in contrast to HR and NHEJ (6, 8). However, repair consistent with MMEJ can be very efficient in higher eukaryotes, so that although the quality changes, rates of end joining do not necessarily decrease markedly with NHEJ mutation (40, 42). Moreover, even an inefficient pathway might be of relevance to NHR, so it is important to consider which mechanisms actually catalyze rejoining of inappropriate DSB pairs. NHEJ can efficiently mediate nonhomologous integration of transformed fragments in some fungi (46). A low, it was found that some spontaneous yeast nonreciprocal rearrangements depend on NHEJ (47) and that yeast NHEJ can mediate reciprocal translocations between two induced DSBs (48). It is now known how to disable MMEJ specifically, but residual chromosome rearrangement observed in NHEJ mutants indicates that at least one other mechanism, presumably MMEJ, is also at play (47, 48). It is not yet clear how often mammalian NHEJ might execute spontaneous NHR, but it is clearly a net caretaker of the genome whose absence leads to increased chromosome rearrangements by alternative repair mechanisms (49).

DNA ligase IV

Clearly, Lig4 is specifically suited to NHEJ, but why? In part, it is because the DNA ligase IV complex can engage the NHEJ structural machinery by specific protein contacts (25). However, the enzymatic function of Lig4 might also be optimized for NHEJ, because transferring its BRCT domains to a different ligase did not transfer NHEJ capacity (50). This function is not manifested by a notably greater ability of Lig4 to ligate compatible overhangs. Instead, Lig4 has a unique ability to ligate ends that do not align to a simple nick but are incompatible or have a gap (51). Unlike most ligases, Lig4 apparently can bring the 3′→5′ P′ and 5′→3′ P′ into position for catalysis anyway, which requires tolerance for non-duplex DNA (Fig. 4b). This activity would have the tendency to promote rejoining of complex ends and therefore chromosome stability at the expense of potentially less deleterious local mutations. Concerns are that others have not observed markedly different ligation fidelity of Lig4, but importantly this was measured nicks, not DSBs (52). Also, my laboratory has examined many NHEJ substrates in yeast genetic assays and has rarely observed outcomes consistent with promiscuous ligation (8, 20). Other NHEJ proteins might also influence the different types of outcomes. XLF/Cernunnos depletion from extract-mediated NHEJ reactions had a much greater effect on joining of complex as opposed to simple DSB substrates (53). This effect might imply a role for XLF/Cernunnos in promoting either end processing or possibly promiscuous ligation by Lig4 (again, though, XNL), the yeast XLF homologue, is equally required for both simple and complex end configurations (our unpublished results). It is still the early days for these studies, and it is of great interest to determine how important the catalytic properties of the DNA ligase IV complex are beyond its recruitment by NHEJ structural proteins.

Pol X NHEJ polymerases

Strong evidence points to the acquisition of special enzymatic properties in the Pol X family of NHEJ polymerases that allow them to deal with the limiting substrates inherent to DSBs.
Nonhomologous Recombination

The comparison with BER is particularly helpful here. Pol β is similar to Pol4, Pol λ, and Pol µ in that it fills gaps by extending a primer strand, bringing them to ligation readiness (19). However, BER and NHEJ differ markedly in the template strand, which is continuous in BER but discontinuous in NHEJ (Fig. 4). Criticality, the point of template discontinuity in NHEJ depends on the polarity of the DSB (Fig. 4b). At 5' overhangs, the discontinuity is ahead of the primer-template pair, past the gap, and outside of the active site of the enzyme. At 3' overhangs, the discontinuity is behind the point of synthesis, within the active site in the position of primer-template pairing. Numerous findings indicate that Pol X NHEJ polymerases tolerate this latter substrate perturbation, whereas other polymerases cannot. Yeast Pol4 is required for synthesis only at 3', but not at 5', overhangs (20). Pol X NHEJ polymerases also show an unusual propensity toward frameshift mutations that suggest a greater flexibility in use of primer-template pairings (54). Extensive structural data also reveal that contacts with the distal 5' side of a gap are paradoxically more numerous than with the 3' (i.e., synthesis) side (55). Moreover, two protein loops unique to Pol X NHEJ polymerases make variable contacts to, or occupy the position of, the template strand (56, 57). These loops account in part for the stabilization of extrahelical bases during frameshift synthesis, and they might also contribute to stabilization of template discontinuities (Fig. 4b). One loop, in conjunction with a Pol µCFD histidine that bridges the dNTP and primer terminus, also facilitates template-independent synthesis and possibly template-dependent synthesis in the absence of initial primer-template base-pairing, which thus adds base-pairing potential to initially incompatible overhangs (Fig. 4b) (34, 51, 58). A picture emerges in which extended and atypical polymerase-DNA contacts overcome the instability of DSB joints caused by template strand discontinuity.

Tools and Techniques for Studying End Joining

The temporal sequence imposed in vivo on repair of single, often complex, chromatin DSB lesions is difficult if not impossible to recapitulate in vitro. It is thus advisable to take genetic data as a primary reference point for understanding NHR mechanisms. In vitro analyses nonetheless allow focused study of enzymes properties, and structural biology will continue to be irreplaceable in elucidating enzyme-substrate relationships.

Genetic analysis

A first approach to studying DSB repair is to treat cells with DSB-inducing agents such as ionizing radiation. A change in either survival or mutagenesis caused by a gene defect can be taken as evidence for its involvement in DSB repair, especially if supported by epistasis analysis to ascertain which repair pathway is affected. An alternative approach is to express in cells mega-endonucleases that create DSBs specifically at native or engineered chromosomal sites (3). In this way, repair can be tracked not only by survival but also by the status of genetic markers at the cut site. A limitation is that most joints restore the cut site and will simply be recleaved, so that repair outcomes are influenced by the method. Linking DSB formation to termination of endonuclease expression limits this issue (8), but the problem is never completely avoidable. A final approach introduces plasmids that were linearized in vitro into cells, where recircularization is required for plasmid maintenance (9, 20). Although limited by the use of naked DNA, the simplicity of this approach and the tremendous variety of available DSB ends make it common and powerful.

In vitro reconstitution

Two main approaches have been used for studying NHEJ in vitro. In the first approach, crude extracts are prepared from cells and are spiked with DNA fragments whose joining is followed by electrophoretic monitoring or PCR amplification (27, 53). Extracts have a full complement of cellular proteins in appropriate ratios and might therefore provide the best recapitulation of the in vivo situation while allowing manipulation of conditions, DSB ends, and so on. More reports reconstituted the NHEJ reaction from purified mammalian, yeast, or bacterial components (26, 33, 51). Some rejoining can be catalyzed by nothing more than a ligase, but focusing on incremental activity with combined components and complex DSBs gives confidence that results are meaningful to cellular NHEJ. Another concern is that NHEJ reconstitution has always used mass action chemistry with sometimes high concentrations of proteins and DNA, which is in marked contrast to the single pair of ends presented in vivo.

Structural analysis

Crystal structures of many NHEJ proteins have tremendously revealed the overall shape of the large and complex DNA-PKcs structure (23). For most other domains, structural inferences can be drawn by mapping NHEJ proteins onto crystallized enzymes of the same class. However, no published structures show two DSB ends engaged together, which I argue defines the unique functions of NHEJ proteins.1 Similarly, poor insight exists into the interconnected assembly of the full NHEJ repair complex. Furthermore, crystal structures are static, whereas NHEJ is dynamic with multiple different reactions.

Future Directions

Nonhomologous DSB repair has a complex relationship with genome preservation in that it can yield both silent repair and NHR. More understanding of this relationship will require improved genomic systems for monitoring the influence of nonhomologous repair pathways on genome integrity. It will also

1 A recent paper has now reported a structure of ends being bridged by the polymerase domain of the bacterial Lpg enzyme (Brisette NC, Pitcher RS, Juarez R, Pitcher AJ, Green AJ, Dafforn TR, Fox GC, Blanco L, Doherty AJ. Structure of a NHEJ polymerase-mediated DNA synaptic complex. Science 2007;318:856-8).
require delineation of the cell-cycle, checkpoint, and chromatin mechanisms that regulate S’ resection and the interplay of NHR and HR. Better molecular definition of the various nonhomologous repair pathways is needed, especially with regard to NHEJ, in which clear mechanisms are still pending. Pol X polymerases provide a conceptual framework for exploring how individual proteins engage the unstable substrates inherent to a DSB, which could be extended to the ligase and beyond. More interaction mapping and biochemical and structural analyses will be required to understand the assembly of a full NHEJ repair complex and the function of currently enigmatic contributors to it. Specific goals include single-molecule NHEJ reconstitution in vitro, structures with two-sided DSBs, and delineation of dynamic changes and regulatory switches that occur during reaction progression.

Sarco(endo)plasmic reticulum Ca\textsuperscript{2+}-\textit{ATPase} (SERCA) transports Ca\textsuperscript{2+} ions against a concentration gradient using energy derived by the hydrolysis of ATP. SERCA forms an aspartyl phosphorylated intermediate, which is acid stable, thus enabling studies of the reaction mechanism. Methods have been established for a detailed functional analysis of mutants, allowing definition of the roles of the individual amino acid residues in the partial reaction steps, and the mutational studies can now be correlated with the positions of the residues in crystal structures of SERCA in various conformational states. Here, we use the glutamine mutant of Glutamate 183 as an example of the methods and analyses. This mutant exhibits a block of the dephosphorylation of the E2P intermediate, but it is little affected in the E1 state, which is consistent with a key role for Glu183 in positioning the attacking water molecule during the hydrolysis of the acyl phosphate bond in the E2P phosphoenzyme.

Sarco(endo)plasmic reticulum Ca\textsuperscript{2+}-\textit{ATPase} (SERCA) is a prime example of a membrane-bound ion pump. This energy transducer or "nanomotor" transports Ca\textsuperscript{2+} against a steep concentration gradient across the sarco(endo)plasmic reticulum membrane, which uses the energy derived from ATP hydrolysis. Like the Na\textsuperscript{+}, K\textsuperscript{+}-ATPase and several other membrane-bound transport ATPases, SERCA belongs to the family of P-type ATPases that form an acylphosphate intermediate during the reaction cycle. This intermediate is acid stable, thus enabling kinetic studies of its formation and decay by acid-quenching techniques. Examination of the partial reaction steps using isotopically labeled ATP, phosphate, and Ca\textsuperscript{2+} have led to a detailed description of the reaction cycle (see References 1 and 2, and more references in Further Reading). SERCA functions as a single monomeric 110-kDa polypeptide chain; thus, the ability to hydrolyze ATP coupled with the protein conformational changes involved in translocation of bound Ca\textsuperscript{2+} is contained within a single molecule (3). The amino acid sequence was determined by cDNA cloning (4), and the development of a technique for efficient expression of the cDNA paved the way for studies of the structure-function relationship using site-directed mutagenesis (5). The first successful task accomplished by this methodology was the identification of almost all the residues binding the Ca\textsuperscript{2+} ions (6-8), which later was confirmed by the crystal structure (9). To date, several hundred mutant forms have been expressed and analyzed functionally, leading to identification of residues involved in essential steps of the Ca\textsuperscript{2+} transport mechanism, binding of ATP, phosphorylation and dephosphorylation, as well as the transport associated conformational changes (6). A database on all SERCA mutations with functional consequences is available by request to the corresponding author.

Because of the ease with which the SERCA1a isoform of the Ca\textsuperscript{2+}-ATPase can be prepared in almost pure form and high yield from rabbit skeletal muscle, this enzyme has been amenable to a large variety of biochemical and biophysical experiments. In 2000, the atomic structure of SERCA1a with bound Ca\textsuperscript{2+} determined by X-ray crystallography was published as the first high-resolution structure of a P-type ATPase (9). This achievement was followed by crystal structures of the enzyme in several functionally relevant conformations (see References 10-13). Many structural details correlate well with the functional analysis of mutants, thus providing a sound basis for the use of site-directed mutagenesis to obtain additional insight into the structure-function relationship. With detailed structural information now available, mutagenesis of the Ca\textsuperscript{2+}-ATPase entered a new age, in which the task is to explain the functional relevance of the structural features observed rather than to predict structure.

**Background**

**Reaction Cycle**

Figure 1 shows the reaction cycle of SERCA as currently understood. Two Ca2+ ions are translocated in each cycle of ATP hydrolysis in exchange for 1 to 3 protons (2 being illustrated). Four major conformational states can be defined, of which two are phosphorylated and the other two are not. The E1 forms display specificity for reaction with ATP/ADP ("kinase activity") and the binding of Ca2+ with high affinity, whereas the E2 forms react with water/oxygenophosphate (P) instead of nucleotide ("phosphatase activity") and cannot bind Ca2+ with high affinity. During ion translocation, the ions become occluded (i.e., cannot associate with the surrounding media on either side of the membrane) as indicated by the closed boxes (2, 3, 10–12). The E1 form exposes its two high-affinity Ca2+ binding sites to the cytoplasm, and these sites have to be occupied before phosphorylation from ATP can occur. As long as the enzyme has not yet become phosphorylated, the Ca2+ ions can dissociate back toward the cytoplasmic side, although they may be temporarily occluded (the gate closes but is not yet locked, flickering open from time to time). The phosphorylation locks the cytoplasmic gate, and the phosphorylated E1P form, now with occluded Ca2+ ions, subsequently undergoes a conformational transition to E2P—a state where the Ca2+ sites are exposed toward the lumen (the luminal gate opens) and exhibit low affinity. After the luminal release of Ca2+, protons bind at the transport sites from the luminal side, and E2P dephosphorylates by hydrolysis of the aspartylphosphate bond, which leads to occlusion of the protons in E2. As a result of the transition to E1, the translocated protons are released on the cytoplasmic side, which reestablishes the cytoplasmically facing high-affinity Ca2+ binding sites.

Acting as a catalyst at the phosphorylation site, Mg2+ ions are part of the reaction cycle as it coordinates ATP/Pi. Alkali metal ions like Na+ and K+ are also important as they accelerate the dephosphorylation of E2P by binding to a regulatory site in the cytoplasmic part of the protein (14). The whole transport cycle is reversible. Thus, the pump can be phosphorylated by Pi in the E2 form, which predominates at acidic pH in the absence of Ca2+ on the cytoplasmic side. If luminal Ca2+ is present, then it can bind to the luminal facing ion binding sites of the E2P form, and thereby allow backward formation of E1P from E2P. Transfer of the phosphoryl group from E1P to added ADP results in ATP synthesis accompanied by movement of Ca2+ from the lumen to the cytoplasm (1). The two phosphoenzyme conformations E1P and E2P are denoted ADP-sensitive and ADP-insensitive phosphoenzymes, because they are dephosphorylated by reaction with ADP (yielding ATP) and water (yielding Pi), respectively (1, 2).

The E2 form of the enzyme has been shown to be target of the SERCA specific inhibitors thapsigargin, CPA (cyclopiazonic acid), and BHQ (2,5-di-tert-butyl-1,4-dihydroxybenzene), as well as vanadate, which inhibits a large variety of enzymes that interacts with phosphate compounds.

---

**Correlation with Structure**

SERCA consists of a membrane-spanning domain of 10 mostly alpha-helical segments (M1 through M10, numbered from the N-terminal end) and a large cytoplasmic head-piece made up by three distinct domains, named N (nucleotide binding), P (phosphorylation), and A (actuator) (9). Figure 2 shows two examples of SERCA structures determined by X-ray crystallography. The transition state occurring immediately before formation of the E1P state was mimicked by adding AlF4− as phosphoryl analog together with ADP to Ca2+-bound enzyme (left) (10). The E2 state with noncovalently bound Pi, E2P, occurring between E2P and E2 in the reaction cycle, was mimicked using MgF42− as phosphate analog together with the inhibitor thapsigargin that binds in the transmembrane region (right) (11). Three key residues in the Ca2+-transport mechanism are indicated in the figure: Glu309, A3sp351, and Glu318. In the E1 form, two Ca2+ ions are coordinated by residues in the transmembrane segments M4, M5, M6, and M8 (6–10, 15, 16), of which M4 and M6 are unwind in the middle to make space for the Ca2+ ions and allow the side chains to interact with the ions. The glutamic acid residue in M4, Glu309, not only coordinates one of the two Ca2+ ions but also seems to function as a gate at the cytoplasmic entrance of the binding cavity (16). The M1 transmembrane segment is bended in the occluded form, and the part of M1 near the bend approaches Glu309, which thereby contributes to stabilization of the closed state of the cytoplasmic gate (17). A sp351 in the P-domain is the residue that undergos phosphorylation and dephosphorylation during the functional cycle, and no phosphorylation occurs in mutants with alteration to A3sp351 (5). In the E1 and E2P forms, the catalytic site is made up exclusively by residues in the P- and N-domains. During the E1P to E2P transition, the A-domain rotates more than 90° horizontally around an axis perpendicular to the membrane, such that Glu183 of the conserved TGES motif in the A-domain
Functional Analysis of Mutants

For functional studies of mutant enzyme forms, mutated cDNA must be expressed in a suitable system. The mammalian COS cell system was introduced originally for expression of Ca\(^{2+}\)-ATPase mutants by Maruyama and MacLennan (5). This system is advantageous because the microsomal fraction that contains the expressed mutant or wild-type Ca\(^{2+}\)-ATPase exhibits only a very low background of endogenous Ca\(^{2+}\)-ATPase and other enzymes that hydrolyze ATP or form an acid-stable phosphoenzyme. For phosphorylation studies with radioactive (gamma-32P)ATP or 32P, or studies of Ca\(^{2+}\) occlusion (7, 8), conventional transfection methods such as calcium phosphate precipitation and lipofection suffice to produce enough material, whereas, for more demanding measurements of equilibrium binding of Ca\(^{2+}\), adenovirus vectors can be used to increase the transfection efficiency in the COS cells (15). For biophysical studies, yeast expression, which yields more enzyme (but with higher background of other ATPases), is recommended (see Further Reading).

Two basically different types of phosphorylation experiments are employed.

1. Ligand dependency of steady-state or equilibrium phosphorylation—the enzyme is incubated with various concentrations of (gamma-32P)ATP or 32P, or the concentration of Ca\(^{2+}\) is varied in the presence of the phosphorylating substrate, to determine the apparent affinity for the ligands. Likewise, the concentration dependence of inhibition of phosphorylation by vanadate, thapsigargin, or a fluoride phosphor analog such as AlF\(_4^\text{-}\), can be determined by addition of the inhibitor at various concentrations followed by measurement of phosphorylation in the presence of (gamma-32P)ATP and Ca\(^{2+}\) (18, 19).

2. Transient state kinetics—the enzyme is incubated for sequential time intervals with (gamma-32P)ATP or 32P, to allow measurement of the rate of phosphorylation, or the dephosphorylation rate is determined by chasing the phosphoenzyme in conditions that prevent additional phosphorylation. It is possible to design conditions that lead to selective accumulation of each of the four main intermediates, E1, E1P, E2P, and E2, at steady state or equilibrium (18, 20). The transformation of one state to the next in the reaction cycle can then be followed on addition or removal of a ligand. These experiments are carried out either by hand mixing at 0°C or with the use of quench-flow instrumentation that allows measurements of rates under more physiological conditions (25°C, ms to seconds) (20).

Because of the acid stability of the aspartylphosphate bond of the phosphoenzyme, acid is used to quench (i.e., "freeze") the phosphorylated state for quantification of the protein-bound radioactive phosphate. After acid quenching, the protein is washed by centrifugation and isolated by sodium dodecyl sulfate polyacrylamide gel electrophoresis under acidic buffer conditions. Quantification of the phosphatase activity associated with the Ca\(^{2+}\)-ATPase is performed conveniently by quantitative autoradiography ("imaging") of the dried gels.

The Glu183Gln Mutant as Example

Here we illustrate some techniques applied in the functional analysis of mutants using as an example the mutant having Glu183 of the conserved TGES loop of the A-domain replaced by glutamine (Reference 10; see also Reference 19 where the alanine mutant was analyzed with similar results).

Ca\(^{2+}\) affinity

The Glu183Gln mutant is well expressed in the COS cell system, but unlike the wild type it does not possess any ATPase...
activity or ability to transport 
and accumulate calcium into the microsomal vesicles. In panel (a) of Fig. 3, it is demonstrated that Ca\textsuperscript{2+} does not readily bind to the enzyme and activates the phosphorylation process from ATP with an apparent affinity slightly higher than that of the wild type (K\textsubscript{a} for Ca\textsuperscript{2+} activation slightly reduced). Hence, there is no disruption of the function of the Ca\textsuperscript{2+} sites in the E\textsubscript{1} form in this mutant. The slight increase in apparent Ca\textsuperscript{2+} affinity at steady state may be explained by the reduced phosphoenzyme turnover rate (Fig. 3, panels d, e, and f), and because lower Ca\textsuperscript{2+} concentrations are required for the phosphoenzyme to accumulate when the turnover rate is reduced.

**Formation of the E1P phosphoenzyme from E1**

Panel (b) of Fig. 3 depicts the results of a transient kinetic experiment performed using quench-flow instrumentation to determine the time course of phosphorylation from (gamma-32P)ATP of the Ca\textsuperscript{2+}-bound E1 form (step 2 in Fig. 3). The rate constant determined for the mutant by fitting a monoexponential function is 22 s\textsuperscript{-1} versus 35 s\textsuperscript{-1} for the wild type (i.e., a rather moderate difference).

**The Ca\textsuperscript{2+} binding E2 to CaE1 transition**

Taking advantage of the fact that only the Ca\textsuperscript{2+} state can form a phosphoenzyme by reaction with ATP, the rate of the E2 to CaE1 transition (steps 6 and 1 in Fig. 1) can be determined as illustrated in panel (c) of Fig. 3. Ca\textsuperscript{2+}-deprived enzyme (excessing in a Ca\textsuperscript{2+} affinity equilibrium between E1 and E2), see Fig. 1) is incubated with Ca\textsuperscript{2+} for sequential time intervals (t), and the amount of phosphophosphorylated CaE1 accumulated during the Ca\textsuperscript{2+} incubation step is determined in each case by another 34 ms incubation with (gamma-32P)ATP, followed by acid quenching. Because the phosphorylation from ATP (step 2 in Fig. 1) requires the enzyme to be in the CaE1 form and is rapid, as documented in panel (b) of Fig. 3, the amount of phosphoenzyme measured at t + 34 ms follows the same function of t as the appearance of CaE1.

---

**Figure 3**

Functional analysis of mutant Gln185Gln (squares) and the wild-type Ca\textsuperscript{2+}-ATPase (circles). Panel (a): Ca\textsuperscript{2+} dependence of steady-state phosphorylation with ATP. Phosphorylation was performed for 10 s at 0°C by manual mixing in a buffer that contained 40 mM MOPS/Tris pH 7.0, 80 mM KCl, 5 mM MgCl\textsubscript{2}, 1 mM EGTA, 5 (gamma-32P)ATP, and various additions of CaCl\textsubscript{2} to obtain the free Ca\textsuperscript{2+} concentrations indicated on the abscissa. The lines show the best fits of the Hill equation to the data. Panel (b): Quench-flow measurement at 25°C of the time course of phosphorylation with ATP of Ca\textsuperscript{2+}-bound enzyme. The enzyme, preincubated in 40 mM MOPS/Tris pH 7.0, 80 mM KCl, 5 mM MgCl\textsubscript{2}, and 100 nM CaCl\textsubscript{2}, was mixed with an equal volume of the same medium that contained in addition 10 nM (gamma-32P)ATP (final concentration 50 nM), and acid quenching was performed at the indicated time intervals after mixing. Panel (c): Quench-flow measurement at 25°C of the time course of phosphorylation with ATP of enzyme preincubated without Ca\textsuperscript{2+}. The enzyme, which was kept in 40 mM MOPS/Tris pH 7.0, 80 mM KCl, and 2.2 mM EGTA, was mixed with an equal volume of medium that contained 40 mM MOPS/Tris pH 7.0, 80 mM KCl, 10 mM MgCl\textsubscript{2}, 1 mM EGTA, and 1.1 mM CaCl\textsubscript{2} for 34 ms, prior to acid quenching. Panel (d): Turn-over of phosphoenzyme formed from ATP and distribution of E1P and E2P. The enzyme was phosphorylated in the presence of 5 (gamma-32P)ATP for 10 s at 0°C in 40 mM MOPS/Tris pH 7.0, 80 mM KCl, 5 mM MgCl\textsubscript{2}, 2 mM calcium chelator EGTA, 5 mM MgCl\textsubscript{2}, and 0.55 mM CaCl\textsubscript{2} (yielding a free Ca\textsuperscript{2+} concentration during phosphorylation of 10 nM on both sides of the membrane). Dephosphorylation was followed by acid quenching at the indicated time intervals after chase with 6.7 mM EGTA (open symbols, total phosphoenzyme). To determine the fraction of the phosphoenzyme which is ADP-insensitive E2P at the indicated time intervals, ADP-sensitive E1P was removed by inclusion of 0.9 mM ADP for 2 s before acid quenching (closed symbols). Monoexponential decay functions were fitted to the data. Panel (e): Decay of E1P as a result of the E1P to E2P transition calculated as the difference between the two curves corresponding to the open and closed symbols in panel (d). Panel (f): Dephosphorylation of E2P. The E2P phosphoenzyme was formed by incubation with 0.5 mM ATP for 10 minutes at 25°C in 100 mM MES/Tris pH 6.0, 10 mM MgCl\textsubscript{2}, 2 mM EGTA, and 30% v/v DMSO. The reaction mixture was cooled for 2 minutes on ice, prior to a 19-fold dilution into ice-cold dephosphorylation medium that contained 40 mM MOPS/Tris pH 7.0, 2 mM EGTA, 1 mM MgCl\textsubscript{2}, 80 mM KCl, and 0.5 mM nonradioactive Pi, followed by acid quenching at the indicated time intervals.
hydrolysis of E2P to E2 + Pi. The rate of the conversion of E1P during the first 34 ms reaction of Ca^{2+} (type) corresponds to the amount of phosphoenzyme formed during the first 34 ms reaction of Ca^{2+}-deprived enzyme with (gamma-32P)ATP together with Ca^{2+}. This amount depends on the rate of the E2 to Ca^{2+}E1 transition as well as on the relative amount of enzyme that initially is present as E1 and, therefore, reaches the phosphorlylatable Ca^{2+}E1 state faster than E2.

The E1P to E2P transition

Panels (d) and (e) of Fig. 3 show how the rate of the Ca^{2+}-translocating E1P to E2P transition of the phospho-enzyme is determined. The enzyme is phosphorylated with (gamma-32P)ATP under conditions where E1P accumulates as the major steady-state intermediate in the wild-type enzyme [0°C, neutral pH; K+ present to activate dephosphorylation of E2P (14)]. Phosphoenzyme decay in the forward direction of the pump cycle is examined by addition of excess EGTA, which removes Ca^{2+} and thereby terminates phosphorylation from ATP, followed by acid quenching at sequential time intervals (open symbols in panel (d) of Fig. 3). It is observed that the dephosphorylation is much slower in the mutant than in the wild type. The phosphoenzyme determined here is the sum of the ADP-sensitive E1P and the ADP-insensitive E2P (see Fig. 1). To quantify the amount of E2P, ADP is added to remove E1P 2 s before quenching (closed symbols). It is revealed that approximately 60% of the mutant phosphoenzyme is ADP-insensitive E2P at the beginning of the chase, in contrast to the wild type that is 100% ADP-sensitive E1P. The dephosphorylation occurs through the conversion of E1P to E2P followed by hydrolysis of the latter to E2 + Pi (Fig. 3), and the retention of the ADP sensitivity during phosphoenzyme decay in the wild type demonstrates that the E1P to E2P conversion is rate limiting for the dephosphorylation. In the mutant, dephosphorylation is very slow, and the ADP-insensitive fraction of the phosphoenzyme increases with time (panel (d), closed triangles, in Fig. 3), which indicates that the rate-limiting step for the dephosphorylation is not the conversion of E1P to E2P, but the hydrolysis of E2P to E2 + Pi. The rate of the conversion of E1P to E2P is calculated by subtracting the data that corresponds to the ADP-insensitive E2P (closed symbols in panel (d)) from the data that represents the total amount of phosphoenzyme [open symbols in panel (d)]. The results of the calculation shown in panel (e) indicate that the E1P to E2P transition is about threefold slower in the mutant, as compared with the wild type, even though E2P is observed to accumulate in the mutant.

The dephosphorylation of E2P

The reason for the accumulation of E2P in the mutant is clear from the results depicted in panel (f) of Fig. 3, which reveal a block of the hydrolysis of E2P to E2 + Pi. To measure this reaction separately, the E2P phospho-enzyme is formed backward by reacting E2 (accumulated in the absence of Ca^{2+}) with 32P, in the presence of 30% (v/v) dimethyl sulfoxide, which increases the affinity for Pi. The 32P-labeled E2P phospho-enzyme is chased by dilution into a dephosphorylation medium that contains an excess of nonradioactive Pi, and the phospho-enzyme decay is followed by acid quenching at sequential time intervals. The difference in the rates of E2P dephosphorylation of wild type and mutant is conspicuous, amounting to ~100 fold.

Conclusion for Glu183Gln based on the mutational analysis in conjunction with the crystal structures

The results in Fig. 3 demonstrate that the Glu183Gln mutant behaves almost normally in the E1 state, whereas the dephosphorylation of E2P is blocked in the mutant. This finding is consistent with the hypothesis that the catalytic site fluctuates between two major configurations, E1/E1P with “kinase activity” and E2/E2P with “phosphatase activity,” because of the movement of Glu183 into the catalytic site in E2/E2P. The position of Glu183 in the crystal structure of E2 with AlF4− bound as phosphoryl transition state analog (12) suggests that the role of Glu183 in the dephosphorylation of E2P is to position the attacking water molecule, see Fig. 4. The explanation of the distinct reactivities of E1P and E2P toward ADP and water is simply that in E2P the TGES loop with Glu183 occupies the position that ADP has in E1P (10, 11).

Furthermore, the rates of the conformational changes E2 to E1 and E1P to E2P are reduced about threefold in the mutant, which indicates that the rate-limiting step for the dephosphorylation is not the conversion of E1P to E2P, but the hydrolysis of E2P to E2 + Pi. The rate of the conversion of E1P to E2P is calculated by subtracting the data that corresponds to the ADP-insensitive E2P (closed symbols in panel (d)) from the data that represents the total amount of phospho-enzyme [open symbols in panel (d)]. The results of the calculation shown in panel (e) indicate that the E1P to E2P transition is about threefold slower in the mutant, as compared with the wild type, even though E2P is observed to accumulate in the mutant.

The dephosphorylation occurs through the conversion of E1P to E2P followed by hydrolysis of the latter to E2 + Pi (Fig. 3), and the retention of the ADP sensitivity during phosphoenzyme decay in the wild type demonstrates that the E1P to E2P conversion is rate limiting for the dephosphorylation. In the mutant, dephosphorylation is very slow, and the ADP-insensitive fraction of the phosphoenzyme increases with time (panel (d), closed triangles, in Fig. 3), which indicates that the rate-limiting step for the dephosphorylation is not the conversion of E1P to E2P, but the hydrolysis of E2P to E2 + Pi. The rate of the conversion of E1P to E2P is calculated by subtracting the data that corresponds to the ADP-insensitive E2P (closed symbols in panel (d)) from the data that represents the total amount of phospho-enzyme [open symbols in panel (d)]. The results of the calculation shown in panel (e) indicate that the E1P to E2P transition is about threefold slower in the mutant, as compared with the wild type, even though E2P is observed to accumulate in the mutant.
which suggests that Glu183 is involved in interactions that facilitate these conformational changes. In some E2 crystal structures (e.g., Protein Data Bank ID 1XP5 and 1WPG), Glu183 is within hydrogen bond distance of Thr352 in the P-domain, and such interaction might facilitate both the insertion of the TGES loop in the catalytic site during the E1P to E2P transition and the disengagement during the E2 to E1 transition (19).

Final Remarks on the E1-E2 Model for The Reaction Cycle

The "E1-E2" two-state nomenclature ("E-E" in the earlier Ca2+-ATPase literature) was introduced solely on the basis of functional measurements (1), and its relevance has been questioned, although a similar "Post-Albers scheme" has also been useful in the functional analyses of the Na+/K+-ATPase (see Further Reading). With the determination of atomic structures of the various conformational states and the supporting functional evidence from mutagenesis, the two-state nomenclature has turned out to have a sound structural basis, even though at least 4 different conformations exist. Hence, in all forms referred to as E1 (E1, E1P, and transition states between them) the TGES loop with Glu183 is separated from the catalytic site (Fig. 2), and the Ca2+-bound residues are in position to bind the ions with high affinity. The same set of residues is involved in Ca2+-binding in all E1 states, irrespective of whether the sites are occupied or not, as the occlusion depends on the position of M1. On the other hand, all E2 forms (E2, E2P, and transition states between them) have the A-domain rotated with Glu183 approaching the catalytic site, and these structures show the Ca2+ binding sites to be disrupted (either facing the lumen, as in E2P, or rearranged to occlude protons as in E2 and E2P).

Chemistry of Bacteriorhodopsin

Janos K. Lanyi, University of California, Los Angeles, California
doi: 10.1002/9780470048672.wecb035

Thirty years of research with bacteriorhodopsin has provided answers to many questions about how protons are transported by transmembrane pumps. In this small seven-transmembrane protein, absorption of light by the retinal chromophore initiates a reaction cycle in which the initial state recovers through multiple conformational changes of the retinal and the protein, and a proton is translocated stepwise from one side of the membrane to the other. Spectroscopy, extensive use of site-specific mutations, and crystallography have defined the photocycle reactions in atomic detail and provide a step-by-step description of the proton transfers, the transient local and global perturbations in the protein and how they arise, and the energy flow through the system, which add up to the mechanism of the pump.

Membrane proteins perform some of the most topologically complex and important functions in biology, such as translating small and large molecules into and out of cells and organelles, coupling energetic functions through the generation and the discharge of transmembrane ion gradients, initiating signaling cascades in cells, and inserting and folding of polypeptides into the lipid bilayer. Bacteriorhodopsin belongs to the heptahelical membrane-protein family that also includes a wide variety of receptors for biological signals. As a light-driven pump for protons in halophilic archaea (1, 2), it generates the inwardly oriented transmembrane electrochemical proton gradient used for synthesis of adenosine triphosphate (ATP) and the uptake of nutrients by the cells. Illumination causes isomerization of the purple retinal chromophore from all-trans to 13-cis,15-anti, and the ensuing sequence of thermal reactions regenerates the initial state in ca. 10 ms, through protein conformational changes and internal proton transfers that translocate a proton across the membrane. Interest in bacteriorhodopsin has been renewed in the last few years because many bacteriorhodopsin-like photoreactive proteins are now found also in eubacteria and eukaryotes, and thus, it is becoming clear that the use of retinal for light-sensing and energetics is more widespread in biology than ever imagined. In addition to the already well-known chloride pump of the archaea, halorhodopsin, these newly discovered proteins include the proton pumps proteorhodopsin and xanthorhodopsin, and various sensory rhodopsins.

Background

As an active transporter, bacteriorhodopsin functions as a biological energy transducer. Proteins of this kind move ions against their electrochemical potential across the membrane barrier, using energy generated by a chemical reaction or from light. Such ion pumps are necessary for muscle contraction (Ca\(^{2+}\) transport), nerve conduction (Na\(^{+}\) and K\(^{+}\) transport), as well as ATP synthesis in mitochondria and photosynthetic systems (H\(^{+}\) transport). Because of their large size and in most cases complex multi-subunit structure, progress in understanding the mechanism of the transport and how it is coupled to the driving reaction in the pumps has been slow.

The conceptual and methodological advantages of bacteriorhodopsin have made it possible to gain insights into its structure, reaction cycle, and function as an ion pump in far more detail than for other membrane proteins. The outstanding questions concern the interhelical interactions that fold the protein and confer stability to the seven-helical bundle immersed in the lipid bilayer, the identity and location of functional groups in the protein interior, the nature of the perturbation of the retinal chromophore upon photoisomerization, the propagation of conformational changes from retinal to near and far regions of the protein, the kinetics and energetics of the reaction cycle in which a proton is transferred from group to group inside the protein, the proton release and uptake at the membrane surfaces, and the nature of the protonation switch that confers directionality on the pump. Answers to such questions are sought for many ion pumps, but in bacteriorhodopsin, the large amount of information now available gives a vivid picture of the molecular events that accomplish the transport.
Structure and Mechanism

The protein (26 kDa) is a bundle of seven helices, A through G, with three helices normal to the membrane plane and the rest inclined at small angles to the normal. The retinal is covalently bound through a protonated Schiff base to Lys-216 at the middle of helix G, and it lies nearly parallel to the membrane in the space surrounded by the seven helices. The protein forms in vivo a homotrimer, and the trimers are assembled into an extended hexagonal lattice (P3 symmetry), the "purple membrane." Protein-protein contact in these patches is through a continuous boundary layer of lipids no more than one lipid wide, at the monomer periphery. The interhelical loops as well as the N- and C-termini are short, with the exception of the connection of helices B and C through a structured as the N- and C-termini are short, with the exception of the wide, at the monomer periphery. The interhelical loops as well as the N- and C-termini are short, with the exception of the connected by a continuous boundary layer of lipids no more than one lipid wide, at the monomer periphery.

At the active site, the positively charged protonated retinal Schiff base donates a hydrogen bond to a water molecule (wat402) that donates in turn to the extracellular side, and the E–F interhelical loop with a twist, on the cytoplasmic side.

In the L-state, the retinal is still somewhat twisted but the Schiff base regains a hydrogen bond. There is disagreement over the partner in this hydrogen bond. In the highest resolution X-ray structure (9), it is wat402 (still to the extracellular direction), but in others, it is wat402 moved to the cytoplasmic side (10). In the latter case, rotation of the C15=N–H bond disconnects the Schiff base N–H bond from the extracellular side, and the E–F interhelical loop with a twist, on the cytoplasmic side.

Chemistry of Bacteriorhodopsin

Absorption of a photon by the purple all-trans retinal chromophore (with a single broad absorption band with a maximum at 568 nm) initiates the reaction sequence BR \( \rightarrow \) K \( \leftrightarrow \) L \( \leftrightarrow \) M \( \rightarrow \) N \( \rightarrow \) O \( \rightarrow \) BR (7, 8), where each state and substate is well defined by spectroscopic and crystallographic means. Although a kinetic scheme that rigorously fits all data into a linear sequence has not yet been produced, the proton transport mechanism can be understood by the molecular properties of the intermediate states and by their interconversions.

The first stable state, the K-intermediate, contains a highly twisted 13cis,15-trans retinal, with prominent hydrogen-out-of-plane (HOOP) bands, particularly at 320 nm. A nomalous Schiff base C=\( \leftrightarrow \)N stretch frequency, lesser \( \rightarrow \)N chemical shift, and the X-ray diffraction structures of K indicate that rotation of the C15=N bond disconnects the Schiff base N–H bond from wat402. At this stage, the overall contour of the all-trans retinal is maintained despite the isomerization. In the states that follow K, the retinal gradually relaxes, and deprotonation of the Schiff base as well as an increasingly accommodating binding site allow it to assume the bent configuration expected for a 13-cis,15-trans retinal.

In the L-state, the retinal is still somewhat twisted but the Schiff base regains a hydrogen bond. There is disagreement over the partner in this hydrogen bond. In the highest resolution X-ray structure (9), it is wat402 (still to the extracellular direction), but in others, it is wat402 moved to the cytoplasmic side (10). In the latter case, rotation of the C15=N–H bond disconnects the Schiff base N–H bond from the extracellular side, and the E–F interhelical loop with a twist, on the cytoplasmic side.

As the retinal relaxes, C13 and the 13-methyl group moves in the cytoplasmic direction toward Trp-182. The resulting
displacements of side chains between helices F and G, and the breaking of the connection between helices F and G through the hydrogen bonds of wat501 to Trp-182 and Ala-215 (Fig. 2), separate helices F and G. The link of Lys216 to wat502 and thereby to the peptide segment of Thr-46 propagates perturbation from the retinal to the Asp-96/Thr-46 pair. Entry of water and growth of water clusters creates a hydrogen-bonded chain of four water molecules between Asp-96 and deprotonated Schiff base (6). The increase of hydration at Asp-96 lowers its initially high pK_a and the aqueous chain conducts the proton to the Schiff base. The M-to-N reaction corresponds to this proton transfer, followed by reprotonation of Asp-96 from the cytoplasmic surface that produces N' from N. Crystallographic evidence and much non-crystallographic data indicate that these photocycle steps are accompanied by the outward and inward tilts of the cytoplasmic ends of helices F and G, respectively. The tilt of helix G arises from rearrangement of hydrogen bonds that eliminate, partly, the n-bulge in this helix at Lys-216. The tilt of helix F is a consequence of the separation of helices F and G and the repacking of side chains between them. There is reason to believe that it is the tilts that loosen the structure and allow the entry of water.

Reprotonation of Asp-96 allows the thermal re-isomerization of the retinal to all-trans, through another long-range coupling mechanism (12), which probably involves the hydrogen-bonded chain of water that bridges them. This produces the red-shifted O-state, where the retinal is, once again, twisted. Transition to the initial relaxed all-trans isomeric state occurs as the protonated Asp-96 loses its proton to the vacant proton release site at Glu-194/Glu-204, thereby recovering the initial electrostatic environment of the extracellular region and completing the cycle.

Key Experimental Methodology

The current understanding of how bacteriorhodopsin transports protons is the result of the use of an unprecedented variety of biophysical methods in many laboratories. Indeed, in many cases, the methods were developed with bacteriorhodopsin as the test subject. There is room to discuss only the most important of these methods.

Transient and low temperature spectroscopy in the ultraviolet/visible and infrared [Fourier transform infrared (FTIR) and resonance Raman] have yielded spectra of the intermediate states and provided many insights, even if not a fully satisfactory solution, to the kinetics of their interconversions. Transient spectroscopy in the visible (7) makes use of following absorption changes at selected single wavelengths, over as many as six orders of magnitude of time after flash photolysis, as well as an optical multichannel analyzer to obtain complete spectra at selected times after the flash. Alternatively, the intermediates can be trapped at cryogenic temperatures, after producing photostationary states (13). Both methods produce characteristic difference spectra and are well suited for identifying which of the various states is produced, as their single absorption maxima for the most part are well defined. Quantification of these states and calculation of a kinetic model from the observed succession of time-resolved spectra is more difficult, because the spectra are broad and several overlap one another. Furthermore, the reaction scheme is more complex than what is expected from a linear sequence in which each state arises by unidirectional transition from the preceding one. Multiple rise and decay components have been interpreted as evidence for back-reactions that lead to transient equilibration of states, and as multiple parallel photocycles. If present, the latter could arise from conformational heterogeneity, interactions within the bacteriorhodopsin trimers, and heterogeneous protonation states near the pK_a for the proton release group. Infrared and Raman spectroscopy is performed along the same lines, but the vibrational spectra (14–16) provide essential molecular level information about changes in the isomeric state of the retinal, the protonation states of dissociable residues, the strength of hydrogen bonds, and backbone conformation. An additional information on these spectra comes from the use of D_2O, H_2^18O, as well as 13C-, 18O-, and 15N-labeled amino acids, and polarized infrared beam for measuring linear dichroism, as well as single-site mutations to change the photolysis and to assign the positive and negative difference bands to specific amino acid residues.

Solid-state nuclear magnetic resonance (NMR) spectroscopy of bacteriorhodopsin is with the membranes either uniformly oriented relative to the magnetic field (17) or nonoriented but with "magic angle" spinning (18). In either case, the samples are enriched with 1H_2O or 12C isotopes in the examined parts of the molecule. The chemical shifts identify the protonation states of acidic groups, their hydrogen-bonding status, and the electrostatic environment. Dipolar interactions provide accurate...
interatomic distance and dihedral angle. Importantly, like FTIR, this method does not average structural information in the case of conformational heterogeneity. Difficulties include a requirement for large amounts of specifically labeled bacteriorhodopsin and problems of thoroughly illuminating a nearly opaque sample to trap the photocycle intermediates.

The purple membrane is isolated as an extended two-dimensional array of bacteriorhodopsin and lipids and, after some manipulation to increase the size of the patches, is an ideal material for cryo-electron microscopy. The maps produced to 3.5-7 Å resolution (19) identifies the positions of the seven-transmembrane helices, the retinal, and some bulky side chains. The latter helped to establish the rotational position of most helices in the seven-helical bundle, and thus, it yielded the first useful structural model. In the last decade, it has been possible to grow well-diffracting three-dimensional crystals. Bacteriorhodopsin crystals are usually thin (10-15 µm) hexagonal plates, 100-150 µm in diameter. X-ray diffraction of crystals produced reflections complete to 1.4-1.5 Å resolution, and the resulting model (3) defines the locations of water molecules bound in the protein interior and the hydrogen bonds relevant to the function and the stability of the structure. The highest crystallographic order is in crystals grown with the cubic phase method (20). The protein forms trimers in the same extended P3 sheet as in the native purple membrane, but the stacking of these sheets to produce the P63 symmetry is not with uniform orientation and the crystals usually show merohedral twinning. This problem is absent in crystals grown by other methods (10), but they are less ordered and the resolution is poorer. Many mutations of functional interest apparently disrupt the structure in subtle ways and make the protein unstable in detergent or do not allow the growth of crystals.

The cubic phase for the crystallization (20) is formed by a roughly 1:1 mixture of mono-olein and bacteriorhodopsin solubilized in octylglucoside. In a process not well understood, salts such as KCl or Na phosphate cause the conversion of the cubic phase with the incorporated bacteriorhodopsin into a lamellar phase and condensation of the protein into crystals. A related method, based on bicelles, adds phospholipids to the mixture. Conventional vapor phase crystallization in the presence of detergent yields bacteriorhodopsin crystals with a somewhat different packing arrangement. The crystals in general are suitable for the trapping of most (K-, L-, various M-, and N-) but not all (N and O), intermediate states (9). The M-state(s) can be accumulated with greatest ease because its absorption band is far removed from the initial state and its decay can be slowed by suitable mutations. Depending on their spectral overlap with the non-illuminated state, the quantum yields for the forward and back photo reactions, the wavelength of illumination, temperature, and mutations (if any), the other intermediates accumulate up to 60% in the photostationary states. Difficulties are measured at 100 K, where the intermediates are thermally stable and damage from the X rays is minimized.

Some movements at specific locations in the protein, for example, at the cytoplasmic surface in the M- and N-states, can be determined with site-specific spin-labels. This method is of particular value for intermediate states that do not accumulate in illuminated crystals. The paramagnetic probes are covalently linked to engineered cysteines, and the erythrocyte sedimentation rate (ESR) spectra of single or pairs of labels, determined statically in photostationary states or dynamically during the photocycle initiated by flash photoexcitation, reveal conformational shifts as changes in environmental restrictions on motion or changes in inter-spin distance with two labeled sites (21, 22). As in other proteins, a complementary method is to follow the reactivity of cysteine residues, placed one by one, along appropriate segments of the protein, such as interhelical loops.

Energetics of the Pump

The quantum yield of the photoisomerization from all-trans to 13-cis,15-trans is 0.60. From calorimetric measurements, the enthalpy gain in the first ground-state intermediate, K, is ca. 45 kJ/mol (23). Part of this will be used for proton transport, the rest is dissipated in the photocycle. One proton is translocated in each cycle across the membrane dielectric, against a proton gradient as high as 200 mV. The pump efficiency (the free energy of the transported proton vs. the energy gain in the K-state) is ca. 50%, and the overall efficiency of use of the energy input (the free energy of the transported proton vs. the energy of the absorbed photon) is ca. 10%.

In the K-state, the energy gain is conserved in bond torsions of the retinal from steric constraints, and electrostatic potential from loss of the Schiff base—counterion interaction and the resulting rearrangement of charges in the extracellular network. As the retinal Schiff base protonates Asp-85 in the L-to-M reaction so as to lose their electrostatic interaction, the binding site relaxes, stepwise, to accommodate the changed shape of the retinal, and free energy is passed from the chromophore to the protein. Most photocycle steps occur without a net free energy change, i.e., near equilibrium (8). The physiological pH (7.5) is well above the pKsa of the extracellular proton release complex (ca. 5.0), and the proton release constitutes one of the two steps where energy is dissipated, here as dilution entropy. In contrast, the pH where proton is taken up at the cytoplasmic surface is about the same as the pKsa of Asp-96 (ca. 7). The last step in the cycle is where the greatest part of the free energy gain is lost, resulting in a strongly unidirectional reaction that fully recovers the initial state from O. Loss of free energy in this step occurs most likely from proton transfer from Asp-85 to the proton release complex after these regain their low and high proton affinities, respectively (where the pKsa are 2.5 and ca. 9.5).

Drug Transport in Living Systems

Yael Elbaz and Shimon Schuldiner, Alexander Silberman Institute of Life Sciences, Department of Biologic Chemistry, Hebrew University of Jerusalem, Jerusalem, Israel

doi: 10.1002/9780470048672.wecb143

Living organisms are constantly assailed by a host of harmful chemicals from the environment. Because of the diversity of these “xenobiotics”, cellular survival mechanisms must deal with an immense variety of molecules. Polyspecific drug transporters supply one such strategy. They recognize a wide range of dissimilar substrates that may differ in structure, size, or electrical charge, and they actively remove them from the cytoplasm. As such, these transporters provide an essential survival strategy for the organism. However, given that the substrates of these multispecific transporters include many antibiotics as well as antifungal and anticancer drugs, they are associated with the phenomenon of multidrug resistance (MDR) that poses serious problems in the treatment of cancers and infectious diseases, and some of them are coined multidrug transporters (MDTs). As expected from their central role in survival, these transporters are ubiquitous, and in many genomes, several genes coding for putative MDTs have been identified. MDTs are found in evolutionary unrelated membrane transport protein families, which suggests that they might have developed independently several times during the course of evolution. In this review, we discuss some basic concepts regarding drug transport from bacteria to humans.

Drug elimination in living systems is a multistep process that may involve metabolism, binding to proteins in the circulatory system and binding to specific receptors and excretion processes. A common way by which living organisms, from bacteria to humans, protect themselves against the harmful effect of a toxic compound is the removal of these molecules from the cell, which thus reduces the amount of drug that reaches its target site of action. Membrane transport proteins recognize these drug molecules and in an energy-dependent manner transport them across the plasma membrane and away from the target, either out of the cell or into subcellular organelles. The scope of this review encompasses numerous biologic networks and a variety of transport systems operating in concert. We will only discuss some major systems involved in transport of so-called drugs across biologic membranes in organisms from bacteria to humans. We chose to focus on polyspecific drug transporters, and by examination of some of the best characterized, we extract some general concepts.

Multidrug Transporters (MDTs)

The discovery of P-glycoprotein (P-gp/MDR1) in the mid 1970s introduced the concept of a single protein that can confer resistance to a relatively large number of structurally diverse drugs (1). In the following decades it has become clear that all living cells, be it a bacterial cell avoiding the deleterious effect of an antibiotic, a kidney cell eliminating an environmental toxin such as nicotine from the body, or a cancerous cell evading chemotherapeutic agents, express multidrug efflux transporters. Multidrug transporters (MDTs) recognize a wide range of dissimilar substrates that may differ in structure, size, or electrical charge, and they actively remove them from the cytoplasm. As such, these transporters provide an essential survival strategy for the organism. However, given that the substrates of these multispecific transporters include many antibiotic, antifungal, and anticancer drugs, they are associated with the phenomenon of multidrug resistance (MDR) that poses serious problems in the treatment of cancers and infectious diseases (2-4). The phenomenon of multidrug transport is an intriguing one because it seems to challenge the basic model of an enzyme
binding specifically to a single substrate in an optimized set of interactions as a prerequisite to efficient catalysis. MDTs, on the other hand, are polyspecific proteins that recognize a remarkably broad array of substrates. The occurrence of MDTs in evolutionary unrelated membrane transport proteins families indicates that they have originated independently several times during the course of evolution (5, 6). MDTs have been identified in several families, based on their amino-acid sequence similarities ([References (7) and (8); Table 1](9–16)].

### ATP binding cassette (ABC) superfamily

This superfamily contains primary active transporters that couple ATP binding and hydrolysis to substrate translocation across the lipid bilayer. This superfamily of transporters will be reviewed in a different chapter in this encyclopedia and will not be discussed here (see the article ATP binding cassette (ABC) Transporters in this encyclopedia). One of the many families included in the MFS is the SLC (solute carrier) superfamily. The SLC superfamily represents approximately 300 genes in the human genome that encode for either facilitated transporters or secondary active symporters or antiporters. Members of the SLC superfamily transport various ionic and nonionic endogenous compounds and xenobiotics. The SLC22 family includes anion and cation transporters (Organic Anion Transporters, OCTs; Organic Cation Transporters, OCTs). The SLC22 family shares a common theme with the MDTs discussed above. These polyspecific transporters handle an impressive broad substrate range. Many substrates are noxious to the organism, and these transporters actively remove them. The reasons they are not considered MDTs are therefore probably just historic.

### Resistance–nodulation–cell division (RND) superfamily

RND is a large ubiquitous superfamily of transporters with representations in all domains of life. Composed typically of about 1000 amino-acid residues, they are arranged as 12 transmembrane helices proteins with two large hydrophilic extracytoplasmic loops between helices 1 and 2 and helices 7 and 8. It has been postulated that these proteins developed from an internal gene duplication event. The members of the RND family are also secondary active transporters that catalyze the proton-motive-force driven transport of a range of substrates, including hydrophobic drugs, bile salts, fatty acids, heavy metals, and more ([12].

### Small multidrug resistance (SMR) family

One of the many families included in the MFS is the SLC (solute carrier) superfamily. The SLC superfamily represents approximately 300 genes in the human genome that encode for either facilitated transporters or secondary active symporters or antiporters. Members of the SLC superfamily transport various ionic and nonionic endogenous compounds and xenobiotics. The SLC22 family includes anion and cation transporters (Organic Anion Transporters, OCTs; Organic Cation Transporters, OCTs). The organic anion and cation transporters of the SLC22 gene family share a common theme with the MDTs discussed above. These polyspecific transporters handle an impressive broad substrate range. Many substrates are noxious to the organism, and these transporters actively remove them. The reasons they are not considered MDTs are therefore probably just historic.

### Multidrug and toxic compound extrusion (MATE) family

This newly identified family of MDTs called MATE includes representatives from all domains of life ([17]). These transporters contain 12 putative transmembrane helices. This family of MDTs was first identified with the characterization of NorM, which is a Na+/drug antporter from Vibrio parahaemolyticus ([18, 19]).

### Major facilitator superfamily (MFS)

The MFS is one of the largest and most widespread families of transporters and is composed of numerous subfamilies of diverse functions. This superfamily consists of single-polypeptide transporters from bacteria to higher eukaryotes involved in the symport, uniport, or antiport of a variety of small solutes. Among the various transporters of MFS transporters are sugars, drugs, neurotransmitters, Krebs cycle metabolites, amino acids, and many more ([20, 22]). Most MFS transporters are about 400–600 amino acids in length and possess either 12 or 14 transmembrane helices. Most proteins in this superfamily are secondary-active transporters that couple ion gradients to the translocation of a substrate. Evidence demonstrating that proteins within several MFS families consist of duplicated six transmembrane units supports the possibility that MFS permeases developed by an internal gene duplication event ([20].

systems that function as heterooligomers are encoded by a pair of genes that belong both to the SMR family and are located in close proximity or even in an overlapping region in the genome. The only heterodimer characterized thus far is the EmrE transport system from Bacillus subtilis (25).

Members of several RND, MFS, and ABC subfamilies have been proposed to function in combination with a periplasmic membrane fusion protein (MFP) and an outer membrane protein (OMP) to generate a single energy-coupled tripartite efflux system across both membranes of the gram-negative bacteria. The best characterized tripartite systems are MexAB-OprM from Pseudomonas aeruginosa and, by far, AcrAB-ToIC from Escherichia coli.

Insights Into Structures of MDTs

Much research is directed toward deciphering the mechanisms by which MDTs confer resistance against cytotoxic drugs. Such understandings hold promise for tremendous clinical implications. Our current knowledge of the multidrug transport mechanism is based on a wealth of data obtained from extensive research using biochemical and genetic approaches and on recently achieved structural data. In our attempts to understand how these transporters confer multidrug resistance, several questions should be addressed. The first and most obvious question regarding this class of transporters is the question of substrate recognition: What is the architecture of a binding site that enables the binding of numerous dissimilar drugs? Next to be answered are questions regarding the drug translocation pathway across the membrane, the coupling of ion/drug fluxes and conformational changes that must occur throughout the transport cycle. Acquisition of high-resolution structures of membrane proteins using X-ray crystallography is not an easy task, and so, to date, reliable high-resolution structural models were obtained only for a few ion-coupled transporters from the MFS and RND families. No structural information exists to date for transporters from the MATE family. A low-resolution (7 Å) projection map of 2-D crystals of EmrE is the closest to atomic resolution data that exists for the SMR class (26). Based on the combined evidence gathered up to date, several general perceptions can be drawn as to the function mechanism of MDTs.

The first structural evidence that approaches atomic resolution of an MFS transporter was supplied by the interpretation of the three-dimensional structure of the oxalate transporter, OxlT, obtained at the low resolution of 6.5 Å (27, 28). Later on, structures of two proteins from this superfamily were achieved at higher resolution: LacY, the lactose permease (29), and GlpT, the glycerol-3-phosphate transporter (30). While LacY and GlpT are both MFS members, they share a mere 21% sequence identity and differ in their mechanism of function. Although LacY acts as a symporter of pyridine nucleotides and protons across the membrane, GlpT is an organic phosphate/inorganic phosphate (Pi) antiporter. Surprisingly, despite these differences, both structures present a highly similar overall fold. In addition, also the general overall structure of OxlT seems to be very similar to the LacY and GlpT structures. The finding that the fold might be better conserved than the sequence suggests the possibility that a general architecture exists for the 12 transmembrane MFS proteins and that the specific function of each transporter is achieved by subtle changes in the substrate binding site and translocation pathway. Following this line of thought, various structural representations of MFS transporters have been generated based on structural homology to LacY and GlpT, among which we can find models of VMA T (31), TetAB (31), MdfA (32), and rOCT1 (33).

Thus, although neither one of the solved MFS structures is a multidrug transporter, it is reasonable to assume that general insights can still be extracted and applied.

Recently, another structure of an MFS multidrug transporter, the structure of EmrD from Escherichia coli, solved to a 3.5 Å resolution, was published (34). Regrettably, the structure was solved without any substrate bound, and, to date, no biochemical data exist to support the mechanism speculated by the authors. On the other hand, two newly solved structures of AcrB, which is a well-characterized RND multidrug transporter from Escherichia coli, with and without bound substrate, provide valuable information regarding transport mechanisms of tripartite multidrug efflux systems, alongside newly arising questions (35, 36). Functional implications arising from these publications will be discussed in more detail.

Substrate Recognition: Multiple Drug Binding Proteins

Substrate recognition by MDTs is the first and most obvious puzzle that arises when considering the remarkable broad-ranged substrate specificity of these proteins. How can a binding pocket accommodate so many structurally dissimilar substrates? This characteristic of MDTs has long been consid- ered paradoxical because of its ostensible contradiction to basic dogmas of enzyme biochemistry (37, 38).

Soluble regulatory proteins

The first structural information to shed light on the nature of the multi-specific binding pocket came from the solved 3-D structures of soluble multidrug-recognizing proteins. As membrane proteins are not easy to crystallize, the focus of structural analysis attempts has been directed also to the soluble drug-binding proteins that regulate the expression of MDR proteins. The underlying rationale is that the regulatory proteins and the transporters share some substrates, and so the information obtained from these structures would be applicable to the binding sites of the MDTs. BmrR, which is a transcription regulator from Bacillus subtilis, promotes the expression of Bmr, which is an MDR transporter of cationic lipophilic drugs. The structure of BmrR bound to TPP⁺, which is an analog of the coactiva- tor TPP⁺, reveals the drug-binding domain. The drug-binding pocket contains hydrophobic and aromatic residues that inter- act with the drug molecule. The phenyl rings of the substrate molecule interact via van der Waals and stacking interactions with aromatic residues, and an essential electrostatic in- teraction takes place between a negatively charged residue and the...
positively charged substrate. Complementory electrostatic interactions are found between TPSs and carbohydrate groups of several acidic residues positioned in close vicinity (39). Valuable information was also achieved from the solved structures of QacR, which is a Staphylococcus aureus multidrug binding protein that represents the transcription of the QacA multidrug transporter gene. Structures of QacR were obtained in complex with six different lipophilic drugs, both monovalent and bivalent cations and many of them substrates of QacA (40). The structure of QacR exhibits a large drug-binding site with several aromatic residues forming stacking interactions with the substrate’s rings, and several polar residues that mediate drug-specific interaction through hydrogen bonds. Four glutamate residues within the binding pocket maintain electrostatic interactions with the substrate’s positively charged moiety. The different structures of QacA–drug complexes reveal a large, multifaceted drug-binding pocket in which different drugs can bind to different and partially overlapping sets of residues.

**Transport proteins**

With MDTs the only detailed structural evidence is provided by AcrB. The recent structure of AcrB in the presence of substrates reveals a substrate binding pocket in each of the three protomers (35). Bound antibiotic–drug molecules, minocycline and doxorubicin, are observed only in one of the three protomers. The substrate binding pocket is rich in aromatic amino-acid residues, mostly Phe residues. Such aromatic side chains may interact with the drug molecules through hydrophobic or aromatic interactions. Several polar residues located in close vicinity may form hydrogen bonds with the drug molecules. The structure implies a voluminous binding pocket in which different sets of residues are used for binding of the different kinds of substrates. Such a strategy is similar to that previously observed in the regulatory protein QacR.

The critical role of aromatic side chains in the binding of lipophilic substrates is also demonstrated by site-directed mutagenesis studies of other MDTs. Three aromatic residues (Tyr 40, Tyr60, and Trp63) in EmrE, which is an extensively characterized SMR transporter from Escherichia coli, play a role in substrate recognition (41, 42). The importance of aromatic side chains in the equivalent positions has been demonstrated for other SMR proteins as well (43).

A distinguishing feature of MDTs that recognize cationic drugs seems to be the presence of a membrane-embedded negatively charged residue, namely glutamate or aspartate, that neutralizes the positively charged moiety of the drug. EmrE, which is a proton-coupled SMR transporter, has only a single membrane-embedded charged residue, Glu14. Through site-directed mutagenesis studies, Glu14 has been shown to be an essential part of the binding site of both substrate and protons (44, 45). In LmrP, which is an MFS multidrug transporter from Lactococcus lactis, two acidic residues have been shown to be essential for the recognition of the monovalent cation Hoechst 33342, whereas a single negatively charged residue in the binding pocket is sufficient for recognition of the monovalent cation ethidium (38). Also in the soluble regulatory proteins the equivalent of such a buried residue has been visualized. Glu253 of the transcription factor BmrR contributes to the protein–drug interaction through its carboxylate group (39, 47). In QacR, which is another regulatory protein, four partially buried glutamates in the drug-binding site exist, at positions 57, 58, 90, and 120, that surround the drug-binding pocket and interact with the positively charged moieties of the substrates (40).

Another structure of the soluble regulatory protein QacR, this time in complex with bivalent diamidine substrates, reveals a novel manner of drug binding through electrostatic interactions. In these structures the electrostatic neutralization of the positively charged substrate was achieved through drug interactions with the negative dipoles of several oxygen atoms from nearby side chains and the peptide backbone, and not through interaction with the carboxylate of an acidic residue (48). QacA and QacB are both MFS transporters from Staphylococcus aureus that are closely related. Although QacA confers resistance to both monovalent and bivalent cations, QacB confers resistance to monovalent cations only. Site-directed mutagenesis studies provided evidence that the substrate specificity differences are caused by the presence of an acidic residue at position 323 in QacA that plays a critical role in conveying resistance to bivalent cations (8).

In MdfA, however, an MFS multidrug transporter, it has been demonstrated that no single acidic residue plays an irreplaceable role, and although efficient transport of positively charged substrates does require a negative charge at position 26 (either Glu or Asp),-neutralization of this position does not necessarily abolish the interaction of MdfA with cationic drugs (49, 50). In the recently solved structure of AcrB in complex with minocycline and doxorubicin, no acidic residues seem to participate in cationic-substrate binding, and this finding may be a reflection of the fact that substrates of AcrB can be also uncharged and negatively charged (35).

The organic anion (OA Ts) and cation (OCTs) and multidrug transporters share a fundamental trait of polyspecificity. It is interesting to compare, from the knowledge that has accumulated so far, the strategy adopted by each such group of multispecific transporters that allows for broad-range substrate recognition.

The OCTs transport various small amphiphilic organic anions, uncharged molecules, and even some organic cations that are usually around the molecular weight of 400–500 Da and include clinically relevant drugs such as anti-HIV therapeutic agents, anti-tumor drugs, antibiotics, anti-hypertensives, and anti-inflammatories (11). OCTs substrates are organic cations and weak bases that are positively charged at physiologic pH, as well as noncharged compounds, with molecular mass of < 500 Da. Among transported substrates of OCTs are endogenous compounds, drugs, and xenobiotics (12). Many SLC22 family members are expressed in the boundary epithelia of the kidney, liver, and intestines and play a major role in drug absorption and excretion. Substrate translocation by most OCTs is energized by coupling the uptake of an organic anion into the cell to the extrusion of another organic anion from the cell; thus, OCTs use the existing intracellular versus extracellular gradients of anions, such as α-ketoglutarate, as a driving force (11). Similarly, OCT1-3 from the SLC22 family are exchangers of organic cations (12). Several OCT members have been identified and cloned from various eukaryotic origins. Human OCT1-4 and Uralot were more thoroughly studied. 

**Drug Transport in Living Systems**
than others, and so knowledge regarding substrate specificity, drug transport, regulation, and overall characteristics has accumulated. In contrast, a description regarding the functional characteristics of OA T5-9 is still lacking.

In the organic anion transporter rOA T3, site-directed mutagenesis studies lead to the proposal that rOA T3 contains a large binding pocket with several interaction domains responsible for the high-affinity binding of structurally diverse substrates. Two essential membrane-embedded basic residues (Arg 454 and Lys 370) attract negatively charged substrates through electrostatic interactions, but their role in determining specificity is not identical. Interestingly, replacement of the basic amino acids at positions 370 and 454 with the corresponding residues of OCTs, thus generating the mutant R454DK370A, changed the charge selectivity of the protein that could now transport the cation MPP⁺. Several conserved aromatic residues that have been shown to be important for the transport of different substrates by rOA T3 are assumed to mediate substrate recognition through aromatic interactions that could include π–π interactions with aromatic residues. A conservative replacement of Asp475 in rOCT1 to glutamate yielded a protein that exhibited higher affinities for some of its cationic substrates but also impaired transport rates. The authors suggested that the mutation at position 475 from Asp to Glu alters the structure of the cation binding site and harms the translocation step, thus altering the selectivity of rOCT1. Additional studies of the binding site of rOCT1 reveal six more amino acids critical for substrate affinity, among which are aromatic and polar amino acids.

The general feature emerging is that of a multifaceted binding pocket, in which different drugs bind to separate, yet overlapping, sets of residues, many of them aromatic.

**Transport Mechanisms of MDTs**

**AcrB**

Structures of the RND transporter AcrB suggest a possible mechanism for this class of transporters. AcrB functions together with the auxiliary MFP AcrA and the OMP TolC as a tripartite transport system. The AcrB structures reveal an asymmetric trimer, in which each protomer adopts a different conformation according to its proposed role in the catalysis of the transport reaction. The "binding" protomer is occupied by bound substrate, and the "extrusion" protomer is outwardly open in a way that suggests it is the form present just after the extrusion of the substrate through the TolC funnel; the "access" protomer seems to be in the state just before substrate binding. The three different protomer conformations are suggested to represent consecutive states of the transport cycle that result in the guiding of the substrate through AcrB toward TolC. How is the proton gradient coupled to the drug efflux and to the conformational changes that shift the transporters between states? In AcrB it seems that the proton translocation pathway is separate from that of the substrate translocation pathway. Site-directed mutagenesis studies in AcrB and MexB, which is an AcrB homolog from Pseudomonas aeruginosa, show that any replacements of either of the three transmembrane charged residues Asp407, Asp408, and Asp409, and completely abolishes the ability of the protein to confer drug resistance [55, 56]. No other charged residues reside within the transmembrane domains making this triplet the most likely proton translocation pathway. The structure reveals that in the "access" and "binding" protomers Lys940 is adjusted by salt bridges with Asp407 and Asp408, whereas in the "extrusion" protomer, Lys940 is turned toward Thr978 and the salt bridges are eliminated. Additional studies identify also Thr978, which is close to the essential Asp-Lys-Asp network, as important for AcrB's function and as a putative part of the proton relay network [57]. Some unanswered questions remain on the way to grasp fully the AcrB transport mechanism, among which is how this movement caused by protonation and deprotonation is transmitted to the large conformational changes that must occur throughout the transport cycle. Also, the essential role of AcrA and the interaction with TolC have yet to be decoded.

**MFS transporters**

In the case of MFS transporters (Fig. 1), it is tempting to speculate that they may be acting by an alternative access mechanism similar to that suggested originally by Lardéčsky [58] and recently supported for the extensively characterized MFS transporter Lacy, which is a lactose permease that cotransports protons and sugar [28]. The substrate and proton binding sites and translocation pathways are proposed to be separate, and the coupling is transmitted by a series of conformational changes induced on substrate binding. The sugar-binding site located in the approximate middle of the molecule at the apex of a deep hydrophilic cavity has alternating access to either side of the membrane as a result of reciprocal opening and closing of hydrophilic cavities on either side of the membrane.

**EmrE**

The simplest coupling mechanism between drug and proton transport has been described for the MDTs from the SRM family (Fig. 1). A single membrane-embedded charged residue, Glu14 in the case of EmrE, an E. coli SMR, is evolutionarily conserved throughout the SMR family and is essential for function. This residue provides the core of the coupling mechanism because its deprotonation is essential for substrate binding [59, 60]. Conversely, substrate induces proton release, and both reactions (substrate binding and proton release) have been observed directly in the detergent solubilized preparation of EmrE [61]. The estimated pKₐ for Glu14 is unusually increased (about 8.3–8.5) compared with 4.25 for the same carboxyl in aqueous environment. The fact that the binding sites for both substrates and protons overlap is that the occupancy of these sites is mutually exclusive provides the basis of the coupling mechanism [45, 59]. The fine-tuning of the pKₐ is essential because replacement of Glu14 with Asp results in a decrease in the pKₐ of the carboxyl and generates a protein that at physiological pH has already released the previously bound protons, can still bind substrate but cannot longer couple the substrate flux to the proton gradient [44, 61].
SMR proteins function through a binding site shared by protons and substrates, which can be occupied in a mutually exclusive manner and provide the basis for the simplest coupling of two fluxes (15, 59).

Physiologic Roles and Natural Substrates

MDTs provide a survival strategy for living organisms that are constantly assailed by a host of harmful chemicals from the environment. Because of the diversity of these “xenobiotics”, cellular survival mechanisms must deal with an immense variety of molecules. MDTs supply one such strategy. The patterns of abundance of drug efflux systems in different organisms do not correlate directly with the above-suggested role. Although MDTs are highly abundant in the soil and environmental bacteria, they exist in relatively large numbers in other organisms as well, such as intracellular bacteria (5). It is not clear, however, whether this is the primary function of all of those identified as MDTs. It is also not clear why so many different ones are required and why there is such a high redundancy in substrate specificities among different MDTs within the same genome. This may be from the necessity to cover a range as wide as possible of substrates, and overlapping provides a backup strategy in case of failure of one of the systems.

In some cases, a direct correlation is found between MDTs and adaptation to specific environments. The natural environment of an enteric bacterium such as E. coli is enriched in bile salts and fatty acids. Bile acids are amphipathic molecules that...
Drug Transport in Living Systems

Figure 2 The structure of the AcrB-drug complex and proposed mechanism of drug transport (from Reference 54). (a) The complex is observed from the side, with the drug shown as a red hexagon. The dotted line indicates a possible pathway for substrates moving from the cytoplasm. The complex contains three molecules of AcrB, Acr accessory proteins, and the TolC channel to the exterior. The drug is proposed to enter AcrB when it is in the access (A) conformation before binding more closely to the porter domain of AcrB in the binding (B) conformation. It is then transported to the opposite face and is released from the extrusion (E) conformation of AcrB. Transport of the xenobiotic is powered by the proton (H\(^+\)) gradient across the membrane. (b) The proposed ordered multidrug binding change mechanism of the three-unit AcrB complex.

act as emulsifying agents, thus possessing antimicrobial activity. Deletion of the acrAB operon leads to increased susceptibility to bile acids and fatty acids, such as decanoate, which suggests that efflux of these compounds may be one of the physiologic roles of the AcrAB efflux system in E. coli. Consistent with that, the expression of AcrAB was increased by growth in the presence of 5 mM decanoate (62). In another study, both bile and mammalian steroid hormones (estradiol and progesterone) have been shown to be substrates of the two major efflux systems of E. coli, AcrAB-TolC and the MFS EmrAB-TolC (63). CmaABC, which is a tripartite efflux pump from Campylobacter jejuni, was also shown to contribute to the bile resistance of the bacterium (64) and so have similar efflux systems from other bacteria, including Salmonella typhimurium (65) and Vibrio cholerae (66). In some cases, deletion of MDTs decreases the pathogenicity of given microorganisms, most likely because of their impaired adaptability (67). It has been suggested that some bacterial MDTs might be involved in export of signals for cell-cell communication (68). For some MDTs, a specific function has been well documented. BLT, which is an MFS multidrug transporter of Bacillus subtilis, has been shown to function as a substrate-specific transporter of the polyamine spermidine, which is a natural cellular constituent. BLT is encoded in an operon with BltD, a spermidine/spermine acetyltransferase, which emphasizes its possible physiologic role in downregulating cellular spermidine levels through efflux, in concert with an enzyme that chemically modifies spermidine (69).

The vesicular monoamine transporters (VMATs) from the SLC18 family provide another example of polyspecific proteins with a very defined physiologic role. These essential proteins are involved in the storage of monoamines in the central nervous system and in endocrine cells in a process that involves exchange of 2H\(^+\) with one substrate molecule. The VMATs interact with various native substrates and clinically relevant drugs, and they display the pharmacologic profile of multidrug transporters (70).

More recently possible roles in supporting pH homeostasis and alkali tolerance have been suggested for TetL, which is a tetracycline efflux protein from Bacillus subtilis, and the multidrug transporter MdfA (71).

In higher multicellular organisms, the strategy for drug elimination is a multistep process that may involve metabolism, binding to proteins in the circulatory system and binding to specific receptors and excretion processes. A variety of polyspecific transporters (from the ABC, MATE, RND, and MFS superfamilies) are expressed throughout the organism. Some of these transporters provide mechanisms that protect the brain and other sanctuaries from exposure to toxins, both endogenous and exogenous. Others are found in the boundary epithelia of kidney, liver, and intestine and play a major role in drug absorption and excretion.

The discussion of the role of MDTs is tightly connected with the question of the evolution of polyspecificity. One can suggest two possible paradigms of multidrug transporter evolution: The first one states that because MDTs confer broad-range drug
resistance, they evolved to protect cells from environmental "xenobiotics." A second possible scenario is that each MDT has evolved as a substrate-specific transporter, and its ability to transport toxins is only an opportunistic side effect (72).

These issues and the others discussed above provide us with a glimpse of this fascinating and complex world of polyspecific proteins. These ubiquitous proteins in many cases play central roles in survival of organisms by providing the means to remove "xenobiotics" away from their targets. On the other hand, in some cases, they present a serious threat for treatment of drug-resistant cancers and infectious diseases. Understanding of the molecular mechanisms that underly the mechanism of action of these proteins is therefore highly relevant.

Our current understanding of ion channels has been made possible by techniques such as electrophysiology and molecular biology, but genetics-based approaches inspired by associated diseases have pointed to regions of functional significance on the ion channels. The ion channelopathies are caused by mutations of corresponding genes or autoantibodies. Although the channels form a highly diverse group (cation, anion, voltage-gated, ligand-gated) and are expressed in excitable and nonexcitable tissues, underlying mutations show recurrent patterns within functionally essential protein parts and lead to common clinical features and almost predictable mechanisms of pathogenesis. This knowledge will prove useful for development of treatment strategies for individuals with various genetic backgrounds and will contribute to both the effectiveness and safety of drugs in the future.

Life’s chemistry of aqueous solutions employs ions as carriers of cell signals. To overcome the impermeable lipid bilayer membrane, the cell invented transporters, channels, and pumps. Ion gradients are established by pumps and serve as batteries of potential energy. Ion channels are membrane-spanning proteins that possess a selectivity filter and a pore that usually is closed by gates in the resting state. The discharge occurs when ion channels open their gates and allow ions to flow down their electrochemical gradients. The cells depolarize when cations diffuse inward or when anions diffuse outward; the cells repolarize when the opposite occurs. Precise control of channel opening and closing is necessary for proper cell excitability and for the production of electrical signals and particularly the action potentials of nerve and muscle. Structures of importance like pore, selectivity filter, voltage sensors, ligand-binding sites, and opening and closing gates were highly conserved for more than 600 million years. Therefore, it is no surprise that an alteration of such functionally important structures can cause a disease.

The episodic clinical features are provoked by environmental factors and caused by abnormal cell excitability, whereas the progressive manifestations that occur in some diseases (periodic paralysis, epilepsy, ataxia, and nephrocalcinosis) are caused by secondary cell degeneration.

### Ion Channels in Disease

The link to human disease came from applying electrophysiological in vitro measurements on diseased muscle cells. These studies showed that an ion channel malfunction could cause a disease (1, 2). Later, the term ion channelopathies was introduced to define this class of diseases characterized by increased or decreased electrical cell excitability (3).

Most channelopathies known to date do not lead to death, but rather they require an abnormal situation, a so-called trigger, to present with recognizable symptoms. Frequently, the attacks can be provoked by rest after physical activity or by exercise itself, hormones, stress, and certain types of food. Most channelopathies have a certain clinical pattern in common: Typically, the symptoms occur as episodic attacks lasting from minutes to days that show spontaneous and complete remission, onset in the first or second decade of life, and—for unknown reason—show amelioration at the age of 40 or 50 years. Surprisingly, many patients with channelopathies respond to acetazolamide, a carbonic anhydrase inhibitor. Most channelopathies show no chronic progression; however, a few exceptions exist. Channelopathies are caused by mutations or by autoantibodies. Although rare, they are important models for frequent disorders.

As the hereditary channelopathies form a group of diseases too diverse to discuss in this short review, we refer to Table 1. In addition, we will describe in more detail some diseases of the largest group of hereditary voltage-gated cation channelopathies, the voltage-gated Na⁺ channelopathies of skeletal muscle, brain, and heart. Furthermore, we will give an example for an autoimmune ligand-gated cation channelopathy and an anion channelopathy.

Abbreviations: *G*, gain; L, loss; D, dominant; R, recessive.

The names of the genes and their chromosomal location are given in column 1 and 2; the names of the corresponding proteins are listed in column 3 for voltage-gated (indicated by a subscribed "v") and ligand-gated channels. Columns 4 and 5 list the diseases and their inheritances. The effects of the mutations on the function of the channel complex are categorized in column 6 as gain or loss of function. Gain stands for a gain that leads to a depolarization block. In general, gain-of-function mutations exert dominant effects if they dominate cell function, whereas loss-of-function mutations only cause dominant inheritance if the channel complex is multimeric (dominant negative effect) or if the second gene cannot compensate for it (haploinsufficiency).

Biochemistry of Voltage-Gated Cation Channels

Basic motif of the main cation channel subunit, the so-called α subunit, is a tetrameric association of a series of six transmembrane α-helical segments, numbered S1-S6, connected by both intracellular and extracellular loops, the interlinkers (Fig. 1). The α subunit contains the ion-conducting pore and therefore determines main characteristics of the cation channel complex conveying ion selectivity, voltage sensitivity, pharmacology, and binding characteristics for endogenous and exogenous ligands. Although for Ca²⁺ and Na⁺ channels the α subunit consists of a monomer, K⁺ channels form homotetrmers or heterotetramers because each α subunit consists only of one domain with six transmembrane helices. Accessory subunits termed β, γ, or δ do not share a common structure; some have one to several transmembrane segments and others are entirely intracellular or extracellular. Functionally, they may influence channel expression, trafficking, and gating.

Voltage-sensitive cation channels have at least one open state and at least two closed states, one from which the channel can be activated directly (the resting state) and one from which it cannot (the inactivated state). This implies that least two gates regulate the opening of the pore, an activation and an inactivation gate, both of which are usually mediated by the α subunit. Although activation is a voltage-dependent process, inactivation and the recovery from the inactivated state are time dependent. The voltage sensitivity of cation channels is conveyed by the S4 segments that are thought to move outward on depolarization and channel opening (4). During channel closing, not all voltage sensors move back at once, which generates a variety of closed states that explain the distribution of voltage sensor mutations to...
Voltage-gated Na\(^+\) channel and associated disorders. The \(\alpha\) subunit consists of four highly homologous domains (repeats I–IV) that contain six transmembrane segments each (S1–S6). The S5 loops, S6 loops, and the transmembrane segments S6 form the ion selective pore, and the S4 segments contain positively charged residues that confer voltage dependence to the protein. Note the small, modulatory \(\beta\) subunit. Mutations associated with channelopathies are indicated by conventional 1-letter abbreviations for the replaced amino acids.

Phenotypes in Na\(^+\) channels. The ion-conducting pore is thought to be lined by the S5-S6 interlinkers that contain the selectivity filter. Although the localization of the activation gate may be within the pore, the inactivation gate has been shown to be located in different regions in the Na\(^+\) and K\(^+\) channels.

The crystal structure of a channel clarified the basis for selection of ions that can pass through the open channel pore and the mechanism by which the channel proteins sense changes in transmembrane voltage that control the open or closed conformational states of the channel (5). Thus, investigations of ion channel proteins employ fundamental physics to study the function of biologically critical proteins.

Physiology of Voltage-Gated Cation Channels

At the resting potential, the open probability of voltage-gated cation channels is extremely low, which indicates that very few channels open randomly. Depolarization causes channel activation by markedly increasing open probability. During maintained depolarization, open probability is reduced time-dependently and not voltage-dependently by channel inactivation, which leads to a closed state from which the channels cannot be reactivated immediately. Instead, inactivated channels require repolarization and a certain time for recovery from inactivation. On the other hand, repolarization of the membrane prior to the process of inactivation will deactivate the channel (i.e., reverse activation that leads to the closed resting state from which the channels can be activated). In this simple, approximate model, transitions from one state into another are possible in both directions, which permits also the transition from the resting to the inactivated state at depolarization as well as the recovery from inactivation via the open state (for review see Reference (6)). Forward and backward rate constants for the transitions determine the probabilities of the various channel states.

Hereditary Voltage-Gated Cation Channelopathies

Hereditary diseases of voltage-gated ion channels cover the diverse fields of medicine, myology, neurology, cardiology, and nephrology. As ion channels do not come alone, but rather in whole families of related proteins that conduct each ion type with slightly modified function and varying tissue expression patterns, the underlying mutations are restricted to single genes expressed in a specific tissue such as brain, skeletal muscle, cardiac muscle, sensory tissues, and secretory tissues (Table 1). Examples are myotonia, periodic paralyses, cardiac arrhythmia, long QT syndrome, migraine, episodic ataxia, epilepsy, and nephrocalcinosis. This trick is evolutionary: On one hand, it mediates many functions with the aid of one basic mechanism. On the other hand, it compensates for an eventually disturbed function by closely related channel siblings. The localization of the disease-causing mutations in the various channel proteins and their functional consequences can be similar in these disorders.
Skeletal muscle voltage-gated Na\textsuperscript{+} channelopathies

Clinically, skeletal muscle Na\textsuperscript{+} channelopathies appear as recurring episodes of muscle stiffness or weakness triggered by typical circumstances such as cold, exercise, oral K\textsuperscript{+} load, or drugs. Muscle stiffness, termed myotonia, ameliorates by exercise and can be associated with transient weakness during quick movements that lasts only for seconds. It is the clinical phenotype brought about by uncontrolled repetitive firing of action potentials that lead to involuntary muscle contraction. On the other hand, the weakness is characterized by lack of action potentials or inexcitability.

Several types of inherited myotonias have been observed because of mutations in the Na\textsuperscript{+} channel gene, SCN4A (Table 1, Fig. 1). Potassium-aggravated myotonia (PAM) may be distinguished clinically from other more frequent forms of Na\textsuperscript{+} channel myotonia by its sensitivity to K\textsuperscript{+}. On the other hand, paradoxical myotonia or paramyotonia (PC) worsens with exercise and cold, and it is followed by long spells of limb weakness that last from hours to days. Two other Na\textsuperscript{+} channel disorders are characterized by episodic types of weakness, with or without myotonia, and are distinguished by the serum K\textsuperscript{+} level during attacks of tetraplegia: hyperkalemic or hypokalemic periodic paralysis (HyperPP and HypoPP). All are autosomal and are transmitted dominantly.

For PAM, PC, and HyperPP, the underlying Na\textsuperscript{+} channel pathogenesis mechanism is the same; mutations are present that cause a gating defect of the Na\textsuperscript{+} channel, which leads to slow or incomplete inactivation—a so-called "gain of function" mutation (normally, Na\textsuperscript{+} channels are inactivating rapidly). This mutation results in an increased tendency of the muscle fibers to depolarize. Although Na\textsuperscript{+} influx at slight depolarization generates repetitive muscle action potentials and myotonia, stronger depolarizations lead to general inactivation of Na\textsuperscript{+} channels and to abolition of action potentials, which causes muscle weakness. Heterozygotes have both mutant and wild type channels, but the mutant channel determines the change in cell excitability, and hence, these disorders are dominant. The mutations (Fig. 1) are located mainly 1) in the voltage sensing S4 segment of domain IV, which is suggested to couple the inactivation to the activation process (PC; [7]); 2) in the III–IV interlinker, which is known to contain the inactivation gate (PC and PAM; [8]); and 3) at several intracellular-facing positions involved potentially as acceptor for the inactivation particle (Fig. 2) or involved in steric hindrance of the binding of acceptor and inactivation particle (PAM and HyperPP; [9, 10]). Overlapping clinical phenotypes of the three disorders probably are caused by a similar increase in channel open probability (Fig. 3). The more severe membrane depolarization found in PC and HyperPP correlates with the higher transient intracellular Na\textsuperscript{+} accumulation, whereas depolarization and accumulation are small in PAM ([11]).

Local anaesthetics and antiarrhythmic drugs of Class I, such as mexiletine and lidocaine derivatives, are useful antimyotonic agents for therapeutic treatment of PAM and PC. Their antimyotonic action occurs because they stabilize the inactivated state, which leads to a use-dependent block. The spontaneous weakness typical of HyperPP is not affected by mexiletine because no repetitive action potentials occur. However, for HyperPP, diuretics such as hydrochlorothiazide and acetazolamide can be useful; these drugs decrease the frequency and severity of paralytic episodes by lowering serum K\textsuperscript{+} and by other unknown mechanisms, perhaps, for example, by affecting pH or K\textsuperscript{+} channels.

Voltage-gated Cation Channel

Figure 2 : Hinged-lid model of fast inactivation of Na\textsuperscript{+} channels. Bird’s eye view of the channel that consists of four similar repeats (I–IV). The channel is shown cut and spread open between repeats I and IV to allow a view of the intracellular loop between repeats III and IV. The loop acts as the inactivation gate whose hinge GG (a pair of glycines) allows it to swing between two positions: the open channel state and the inactivated closed state where the inactivation particle IFM (the amino acids isoleucine, phenylalanine, and methionine) binds to its acceptor.
The disease in which mutations have only been found in voltage sensors, are hypokalemic periodic paralyses (HypoPP) types 1 and 2. In both types, episodes of generalized muscle weakness occur occasionally, often during the second half of the night after a day of intensive exercise. Another trigger is a carbohydrate-rich meal. Glucose and released insulin induce a rapid uptake of K⁺ into the muscle fibers. The resulting hypokalemia correlates with the clinical expression of the paralytic attack and gave the disease its name. If no K⁺ is substituted, the weakness can last several hours or days until the serum level is normalized by a hypokalemia-induced rhabdomyolysis or K⁺ retention. As muscle strength is normal between attacks, at least in young patients, the underlying ion channel defect must be well compensated. The intermittent attacks of weakness in HypoPP lead to the requirement of trigger mechanisms. Insulin secretion, as after carbohydrate-rich meals, is one such trigger. Insulin activates the electrogenic Na⁺/K⁺-ATPase; insulin per se and the resulting decrease in [K⁺]o normally lead to a membrane hyperpolarization. In contrast to normal muscle, HypoPP-1 and HypoPP-2 muscle fibers depolarize to ~50 mV at a reduced [K⁺]o of 1 mmol/L and loose force (12). This explains the hypokalemic weakness of the patients.

In HypoPP-1, mutations have been identified in the Caα1.1 voltage sensors (54 segments of repeats II or IV (13, 14). HypoPP-2 mutations are located in 54 segments of Naα1.4 repeats II and III (Fig. 1; (12, 15)). The resulting changes in the pore currents were minor for HypoPP-1 and showed reduced function for HypoPP-1/2 rather than gain of function. Recent results on K⁺ and Na⁺ channels indicate that voltage sensor mutations may create an accessory ion pathway that generates a hyperpolarization-activated cation leak independent of the main channel pore, and that this leak current is responsible for the pathogenesis of the disease (16–18).

Neuronal voltage-gated Na⁺ channelopathies

Of the many neuronal voltage-gated Na⁺ channelopathies (Table 2), only generalized epilepsy with febrile seizures plus (GEFS⁺) and severe myoclonic epilepsy of infancy (SMEI) will be described in more detail. GEFS⁺ is an autosomal dominant childhood-onset syndrome that features febrile convulsions and a variety of afebrile epileptic seizure types within the same pedigree (19). SMEI is characterized by clonic and tonic-clonic seizures in the first year of life that are often prolonged and associated with fever. Developmental stagnation with dementia occurs in early childhood. In contrast to GEFS⁺, the syndrome usually is resistant to pharmacotherapy. Sometimes, patients with SMEI have a family history of febrile or afebrile seizures, and families exist in which GEFS⁺ and SMEI overlap, so that SMEI can be regarded as the most severe phenotype of the GEFS⁺ spectrum (20).

The first genetic defect in this group of diseases was discovered in a large GEFS⁺ pedigree (19). The authors identified a C121W mutation that disrupts the disulfide bridge of the β₁-subunit extracellular loop and leads to a loss of β₁-subunit function.
function. Subsequently, several groups found linkage to a cluster of genes that encode neuronal Na+ channel α-subunits on chromosome 2q21-33 (Table 1). The first two point mutations were detected in SCN1A to predict amino acid changes within the S4 segments of domains II and IV (T875M, R1648H; (21)). Many more SCN1A mutations have been described since then in addition to the mutations in the GABA_A receptor (Table 1). A few of the Na+ channel mutations were expressed in human embryonic kidney cells or Xenopus oocytes that revealed both gain- and loss-of-function mechanisms. Gain-of-function alterations were an acceleration of recovery from inactivation that shortened the refractory period after an action potential for R1648H (22), increased persistent sodium currents predict membrane depolarization for T875M, W1204R, and R1648H (23); a hyperpolarizing shift in window current for W1204R (24); and a reduced channel inactivation upon high frequency depolarizations for D188V (25). Whether the S4 mutations generate a reduced channel inactivation upon high frequency depolarization shift in window current for W1204R (24); and a reduced channel inactivation upon high frequency depolarizations for D188V (25). Whether the S4 mutations generate a hyperpolarization-activated cation leak through an accessory ion pathway has not yet been studied. In contrast, loss-of-function mechanisms were described in part for the same mutations such as enhanced fast and slow inactivation for T875M and R1648H (22, 24) or a depolarizing shift of the steady-state activation curve for I1656M and R1657C (26), which all reduce the amount of available sodium channels. A complete loss-of-function was described for two other GEFS+ point mutations, V1255L and A1685V (26). Hence, loss-of-function mechanisms seem to predominate for GEFS+, which is in agreement with the genetic findings in SMEI as will be outlined below. In contrast to the point mutations found in GEFS+ families, most SMEI patients carry de novo nonsense mutations that predict truncated proteins without function (27). One SMEI point mutation was also shown to yield nonfunctional channels when expressed in human embryonic kidney cells (26). The sodium channel blocker lamotrigine, which is the only drug of this class that is in use in patients with idiopathic generalized epilepsies, is considered the only effective therapy to terminate channel reopenings (33) whereas beta blockers are not effective (34).

Mutations in SCN5A have also been associated with idiopathic ventricular fibrillation and with Brugada syndrome (35). A family history of sudden unexplained death is typical. Individuals with Brugada syndrome often exhibit a characteristic ECG pattern that consists of ST elevation in the right precordial leads, an apparent right bundle branch block, and normal QT intervals. They have an increased risk for potentially lethal polymorphic ventricular tachycardia. Administration of Class I antiarrhythmics and local anesthetics can expose this ECG pattern in latent cases. Accordingly, the proposed cellular basis of Brugada syndrome involves a primary reduction in myocardial sodium current. In fact, most Brugada mutations cause premature stop codons, frameshift errors, and splice site defects, and they are expected to cause nonfunctional channels. Heterologous expression of missense mutations revealed a reduced channel open probability also in agreement with a reduced channel function. Currently, an implantable cardioverter-defibrillator is considered the only effective therapy to terminate ventricular arrhythmias in symptomatic patients with Brugada syndrome (36).

### Acquired or autoimmunecation channelopathies

Many years before the term channelopathies had been established, muscle diseases were identified to be caused by autobody antibodies against ligand- or voltage-gated ion channels. Often, these disorders occur in association with malignancy. For example, many patients with thymoma develop autobody antibodies to the nicotinic acetylcholine receptor (nAChR) of the skeletal muscle.
neuromuscular junction. Normally, ACh molecules can bind to nAChR, which is situated in the neuromuscular junction of the muscle cell membrane and is the first cation channel cloned (37). ACh binding triggers opening of the ion channel and elicits an inward Na\(^+\) and Ca\(^2+\) current with fast rising and decaying phases. The inward current elicits with a high safety factor an action potential that propagates along the muscle fiber membrane and activates excitation-contraction coupling. The Lambert-Eaton syndrome is associated with small cell lung cancer and is caused by antibody binding to specific extracellular epitopes on the voltage-gated P/Q-type calcium channel glycocalyx of the peripheral motor neuron terminus. It is characterized by muscle fatigue (38). Peripheral nerve hyperexcitability (PNH) is a malfunction of the peripheral nerve and leads, in addition to other symptoms, to spontaneous skeletal muscle overactivity. In some patients, PNH is hereditary, whereas in most patients it is acquired and often an autoimmune disorder caused by serum antibodies to voltage-gated, desorbin-in sensitive K\(^+\) channels of peripheral nerves (40). As these autoimmune disorders fulfill the criteria of channel disorders, this group of diseases has been included recently in the broader classification of channelopathies.

Hereditary Anion Channelopathies

Cystic fibrosis (CF) is one of the most frequent genetic diseases with one case in 2000 to 4000 live births. It is a very serious disease with a mean life expectancy of 20 to 40 years. The patients suffer mostly from chronic pulmonary infections that lead to lung destruction, right heart insufficiency, and heart failure. The defective gene product, the cystic fibrosis transmembrane conductance regulator (CFTR), was identified in 1991 (41). The complex molecule functions as Cl\(^-\) channel and as a regulator of other ion channels and transporters. A defect in CFTR leads to reduced NaCl and water secretion in the airways and in other epithelia. In addition, NaCl absorption is enhanced. As a result, the clearance of the airways is impeded, and chronic colonization by pathogenic bacteria such as Pseudomonas aeruginosa leads to airway destruction. CF is one of the first genetic diseases in which genetic therapy is being attempted. However, the initial enthusiasm has been spoiled by the very limited success in animal models and the lack of convincing benefit for the patient. Currently, new approaches for gene and even more so for “classic” therapy are under study. In addition, the CFTR molecule with all its complex functions is target of basic research. It is entirely feasible that the closer understanding of this molecule, its synthesis, maturation, and interaction with other transporters will lead to new and maybe unexpected therapeutic strategies.

Tools and Techniques Used for the Study of Ion Channels

The patch clamp technique

Hodgkin and Huxley unraveled the ionic basis of nerve excitation in the squid giant axon by the first detailed description of the processes of activation and inactivation of voltage-gated sodium and K\(^+\) currents that use the voltage-clamp technique (42). After this technique had become the principal tool for the study of channels for decades, a more recent development has revolutionized this field. The patch clamp technique, developed by Hamill et al. (43), is a specific application of voltage clamp developed to record the current through a membrane patch conducted by a single channel molecule. The patch clamp technique allows for the direct electrical measurement of ion channel currents while simultaneously controlling the cell’s membrane potential. It uses a fine-tipped glass capillary to make contact with a patch of a cell membrane to form a GΩ seal. Originally, this high resistance seal was yielded on skeletal muscle fibers by enzymatic treatment that removed the basal membrane, the glycocalyx, and the connective tissue. Thus, the treated preparation allowed Hamill et al. (43) to attach the glass pipette to the plasma membrane with a leak resistance of 10 to 50 MΩ. Suction resulted in a GΩ seal and enabled the measurements of currents in the sub-pA range with a small noise. Current variants of this technique make possible the application of solution on the exterior and interior of whole cells and on the membrane patches torn from the cell (outside-out or inside-out)—every thinkable configuration of solution and ion channel orientation craved by the ion channel researcher. Usually, primary cultured cells or cell lines are preferred as they reveal a relatively clean surface membrane (44) and require no enzymatic treatment that damages the plasmamembrane. The patch clamp technique is now the gold standard measurement for characterizing and studying ion channels and is one of the most important methods applied to physiology. Single-channel recordings have shown that many channels (e.g., the voltage-gated Na\(^+\) channel) possess only two conductance levels: zero when the channel is closed and a constant conductance when the channel is open. After depolarization, a brief delay occurs before channels open. The intervals are not identical during each depolarization; in fact, the opening and closing of a given single channel is a random process even though the open probability depends on the voltage and is more sensitive to the voltage than an electronic device such as a transistor. After a subsequent short interval, the open time, the current jumps back to zero as the channels close. The stochastic nature can be understood by certain energy barriers that must be overcome before a channel can flip from one conformation (e.g., open) to another (e.g., closed). The energy needed for this purpose comes from the random thermal energy of the system. One can imagine that each time the channel molecule vibrates, bends or stretches, it has a chance to surmount the energy barrier. Each channel is like a binomial trial with a certain probability of success. Clearly, because the protein movements are on a picosecond time scale, the chance of success at each trial must be small, and many trials will be needed before the channel shuts. Usually, a normal Na\(^+\) channel does not reopen even though the depolarization may be retarded by the
Drug Treatment

The functional expression of the mutations in “expression systems” allows one to study the functional alterations of mutant channels and to develop new strategies for the therapy of ion channelopathies (e.g., by designing drugs that specifically suppress the effects of malfunctioning channels). The limitations in throughput are overcome by the automation of the patch clamp technique by which it will become both cost-effective and fast and, at the same time, will enable the highest sensitivity and most accurate description of drug effect compared with any other ion channel drug screening method. Several strategies for the automation of the patch clamp technique have been pursued with set ups already available on the market.

Currently, ion channel modulator drugs account for several billion U.S. dollars in worldwide sales, such as Ca2+ channel blockers (verapamile-type anti-arrhythmics), Na+,K+ channel blockers (lidocaine-type anti-arrhythmics), and Na+ channel blockers (sulphonylurea antidiabetics, amiodarone-type anti-arythmics). Ca2+ channel blockers (verapamile-type anti-arythmics) and Na+ channel blockers (sulphonylurea antidiabetics, amiodarone-type anti-arythmics) are the most accurate description of drug effect compared with any other ion channel drug screening method. Several strategies for the automation of the patch clamp technique have been pursued with set ups already available on the market.

Further Reading

Mechanosensitive (MS) channels function as molecular transducers of mechanical forces into electrical and/or chemical intracellular signals in living cells. These channels play a major role in the physiology of mechanosensory transduction encompassing cellular processes that range from regulation of cellular turgor and growth in microorganisms to touch, hearing, and blood pressure regulation in vertebrates. Together with the recent work on MS channels in eukaryotic cells studies of prokaryotic MS channels using a multidisciplinary approach based on the patch-clamp recording, X-ray crystallography, computer simulations, and electronparamagnetic resonance and fluorescence resonance energy transfer spectroscopy, have significantly contributed to our understanding of the relationship between the structure and function in these membrane proteins. In particular, experiments employing chemical manipulation of the physical properties of the membrane lipid bilayer have shed light on 1) how MS channels detect physical forces in cellular membranes, and 2) what causes structural conformational changes in MS channels in response to membrane tension.

Mechanosensitive (MS) channels are the main signaling molecules of mechanosensory transduction. They convert mechanical forces acting on cellular membranes into electrical and/or biochemical signals in various types of nonspecialized cells as well as specialized mechanoreceptor neurons (1). The patch-clamp technique, which allows electrophysiologists to study the activity of single-channel molecules, allowed the first recordings of MS channel currents in real time some 20 years ago (2). Although at some point MS channels were considered to be a possible patch-clamp recording artifact, our knowledge of their structure and function has grown to the point that nowadays these channels are central players in our understanding of protein–lipid bilayer interactions. The cloning of the bacterial MscL and MscS channels, the elucidation of their 3-D crystal structures (Fig. 1a and b), and the demonstration of their physiologic role in bacterial osmoregulation (3) have provided a basis for intensive research and rapid progress in studies of the structure and function in the MS class of ion channels. Furthermore, the cloning and genetic analysis of the mec genes in C. elegans (4), genetic and functional studies of the TRP-type MS channels (5), as well as molecular biologic and functional studies of the TREK-1 family of 2P-type potassium channels (6) have also contributed to our understanding of the role of MS channels in the physiology of mechanosensory transduction and in the pathology of several major human diseases (2). The major aim of this article is to summarize recent developments regarding MS channels, with a major focus on the physico-chemical principles that can account for the stretch sensitivity of these membrane proteins.

### Biologic Background

Living cells are exposed to a variety of mechanical stimuli acting throughout the biosphere. The range of mechanical stimuli extends from thermal molecular agitation to potentially destructive cell swelling caused by osmotic pressure gradients. Since cellular membranes present a major target for mechanical stimuli, MS ion channels are the main signaling molecules designed to detect and translate these stimuli into biologically meaningful signals as illustrated by several examples given below:

1. In their natural environment, bacterial cells need to adapt to a wide range of osmotic conditions. Escherichia coli cells exposed to hypo-osmotic shock respond by a rapid release of cellular osmolytes such as proline, potassium glutamate, trehalose, and ATP. This ability prevents the cells from lysis by decreasing the turgor pressure on the challenge of a sudden shift in osmolarity. Bacterial MS channels, MscL and MscS (Fig. 1a and b), are major components of adaptation mechanisms to hypo-osmotic shock. Being located in the cytoplasmic membrane, MscL and MscS are activated by an increase of membrane tension.
Mechanosensitive Channels

2. Genetic screens of the nematode C. elegans have identified several membrane proteins being required for touch sensitivity of this worm. Four of these proteins, MEC-2, MEC-4, MEC-6, and MEC-10, form a mechanically gated ion channel complex (4). These proteins belong to the DEG/ENaC superfamily of amiloride-sensitive Na⁺ channels of the transporting epithelia with many of them suspected to be gated directly by mechanical stimuli. MEC-2, MEC-4, MEC-6, and MEC-10 proteins have been shown to underlay mechanoreceptor currents in this nematode. Consistent with the role of these channels in mechanotransduction in C. elegans is the finding that mutations in MEC-4 result in touch insensitivity, and dominant mutations in the same gene result in swelling-induced degeneration and lysis of the mechanosensory neurons.

3. TREK-1 channels belong to a superfamily of 2P-domain K⁺ channels. They are polymodal (i.e., gated by a variety of chemical and physical stimuli) K⁺ channels. They are opened by both physical (stretch, heat, voltage, cell swelling, and intracellular acidosis) and chemical stimuli (lysophospholipids, polyunsaturated fatty acids, membrane crenators, and volatile general anesthetics) (Fig. 2). Their main function is to maintain the resting level of membrane potential. Recent studies using TREK-1 knockout mice suggest a central role for TREK-1 in anesthesia, neuroprotection, pain reception, and depression (6).

4. TRPC1 is a member of the canonical TRP (transient receptor potential) subfamily of another large and diverse family of ion channels. TRP channels are expressed in many tissues in numerous organisms where they function as cellular sensors mediating responses to a variety of physical (e.g., light, osmolarity, temperature, and pH) and chemical stimuli (e.g., pheromones, odors, and nerve growth factor) (3). TRP channels function as specialized biologic sensors that are essential in processes such as hearing, vision, taste, and tactile sensation. Several TRP channels may be inherently mechanosensitive, including the TRPC1 channel, which has been identified as MscCa, the Ca⁺ permeable M5 channel in Xenopus oocytes (2).

Figure 1 Physical and chemical stimuli affecting the gating of bacterial MS channels. (A) The structure of the pentameric MscL channel (left) and a channel monomer (right) from E. coli based on the 3-D structural model of MscL obtained by X-ray crystallography has revealed that the channel folds as a homopentamer (7). MscL is activated by membrane stretch, amphipaths (e.g., lysophospholipids, chlorpromazine, and triiodothyronine) and parabens. The channel activity is inhibited by Gd³⁺ and high hydrostatic pressure (HHP) and is modulated by temperature and intracellular pH (3). (B) The structure of the MscS heptamer (left) and the channel monomer (right) from E. coli based on the 3-D structural model of MscS (8) most likely depicting an inactive or desensitized functional state of the channel (3). MscS is activated by membrane stretch, amphipaths, and parabens and is modulated by voltage. The activity of the channel is inhibited by Gd³⁺ and high hydrostatic pressure (HHP) (3). The amino acid point in membrane structures (i.e., channel protein and/or lipid bilayer) affected by the specific stimuli.

Chemistry, structure, and gating mechanism

MS channels are composed of amino acids, which are the building blocks of all proteins. The number of amino acids varies largely between different types of MS channels. For example, a single monomer of the bacterial channel MscL of E. coli is made of 136 amino acids folded in several α-helices connected by loops. A short N-terminal α-helix of the MscL monomer is followed by two transmembrane helices TM1 and TM2 and a C-terminal cytoplasmic α-helical domain (Fig. 2a). The TM1 helix is connected to TM2 by a loop that extends into the pore region and lines the periplasmic side of the channel. A 3-D structure of MscL obtained by X-ray crystallography has revealed that the channel folds as a homopentamer (Fig. 1a) (7).

Diversity and heterogeneity of the MS class of channels is well illustrated by the fact that MscS, the second type of MS channels found in bacteria, differs significantly from MscL in its primary as well as quaternary structure. Each channel belongs to a separate subfamily of the large family of prokaryotic MS channels (3). A monomer of MscS is a small membrane protein of 286 amino acids. A 3-D crystal structure of MscS shows that the functional channel is a homohexameter having a large, cytoplasmic region (Fig. 2b) (8). Each of the
Mechanosensitive Channels

Figure 2. Polymodal activation of TREK-1 by physical and chemical stimuli. TREK-1 is opened by stretch, heat, intracellular acidosis, depolarization, lipids, and volatile general anesthetics, and it is closed by protein kinase A (PKA) and protein kinase C (PKC) phosphorylation pathways. TREK-1 is inhibited tonically by the actin cytoskeleton. The cytosolic carboxy C-terminal domain has a key role in the regulation of TREK1 activity. Phosphorylation of Ser333 by PKA and phosphorylation of both Ser333 and Ser300 by PKC in this region arrest TREK-1 opening. cAMP, cyclic AMP; DG, diacylglycerol; pHi, internal pH (reproduced from Reference 6, with permission).

seven MscS subunits contains three transmembrane domains, TM1–TM3, with N-termini facing the periplasm and C-termini at the cytoplasmic end of the channel. According to the crystal structure, the TM3 helices line the channel pore, whereas the TM1 and TM2 helices constitute the sensors for membrane tension and voltage (3).

Eukaryotic MS channels are far more diverse than the prokaryotic MS channels suggesting that various types of MS channels known today may have become adapted independently and at several occasions during the evolution to specific tasks in mechanosensory transduction of living organisms. In other words, the evolution of MS channels likely converged from independent genetic origins toward a common function of transducing mechanical stimuli into meaningful biologic signals. For example, a monomer of the TREK-1 channel consists of 411 residues. Since its quaternary structure has not been determined experimentally, the functional channel is thought to be composed of two, most likely identical 2P-domains (6). Each 2P domain has four transmembrane segments, an extended extracellular loop, and intracellular N- and C-termini. Although structurally very different from MscL and MscS, the TREK-1 channel functionally closely resembles the bacterial channels. The modality of stimuli that affect its activity (Fig. 2) is very similar to the modality of stimuli affecting the activity of other bacterial channels (Fig. 3a and b). The mechanosensitivity of MscL, MscS, and TREK-1 have been well characterized (3, 6). Consequently, one would expect that a fundamental question on the extent to which the mechanism of gating by physical and chemical stimuli characteristic of prokaryotic and archaean MS channels has been conserved and adapted to gating of MS channels in eukaryotes can be answered fairly by comparing mechanosensitive properties of the bacterial MS channels with TREK-1.

Currently two basic models describe gating of MS channels by mechanical force: the bilayer and the more speculative tethered model (3). A third model of indirect gating of MS channels by mechanical stimuli, which combines elements of the bilayer and tethered models and requires an intermediary mechanosensitive membrane protein to interact with an ion channel, has also been considered (2, 9). According to the bilayer model, the tension in the lipid bilayer alone is sufficient to gate directly the MS channels. This model was proposed initially for the gating of bacterial MS channels. To date, it has been documented in a large number of MS channels from both prokaryotic and eukaryotic organisms (Table 1). Purified MscL, MscS, and other prokaryotic MS channels remain mechanosensitive when reconstituted into artificial liposomes (3). Several eukaryotic MS channels including 2P-type potassium channels TREK-1 and TRAAK, TRP-type channels TRPC1, as well as calcium-dependent stretch-activated potassium channels (SAKCa) have also been shown to be gated by the bilayer mechanism (Table 1). In contrast, the tethered model invokes direct connections between MS channels and cytoskeletal proteins and/or extracellular matrix (ECM) and requires relative displacement of the channel gate with respect to the cytoskeleton or ECM for channel gating. Originally proposed for gating of MscS channels in hair cells and chick skeletal muscle, this model should apply to eukaryotic MS channels in specialized mechanoreceptor cells (2, 10).

The evidence showing that lipids play an essential role in opening and closing not only of prokaryotic MS channels but also of the MS channels of fungi, plants, and animals has led recently to a proposal of a possible unifying principle for mechanosensation based on the bilayer mechanism (11). The main idea of the unifying principle is that forces from lipids gate MS channels independently of their evolutionary origin and
4 results from the bilayer–protein interaction. The hydrophobic mismatch between the protein and the bilayer, which bilayer of artificial liposomes requires energy because of hy-

Notes: The bacterial MS channels, MscL and MscS, are the only MS channel proteins whose 3-D structure has been determined. The gating mechanism and/or physiologic function of some MS channels have not been characterized fully. Note that in contrast to the bilayer mechanism, no single experimental result provides direct support for the tethered model of MS channel gating (1). NT indicates that the effect of amphipaths (CPZ and TNP) has not been tested in the particular type of MS channels (adopted from Reference 10, with permission).

A likely gating mechanism or physiologic function that has not yet been established firmly.

Notes: The bacterial MS channels, MscL and MscS, are the only MS channel proteins whose 3-D structure has been determined. The gating mechanism and/or physiologic function of some MS channels have not been characterized fully. Note that in contrast to the bilayer mechanism, no single experimental result provides direct support for the tethered model of MS channel gating (1). NT indicates that the effect of amphipaths (CPZ and TNP) has not been tested in the particular type of MS channels (adopted from Reference 10, with permission).

A likely gating mechanism or physiologic function that has not yet been established firmly.

Mechanosensitive Channels

Chemical Tools and Techniques

Several experimental techniques have proven extremely useful in studies of MS channels. Besides the already classic patch-clamp technique used for functional studies of ion chan-

thickness of the bilayer adjacent to the membrane protein will tend to match the length of the protein’s hydrophobic exter-

Fig. 3 because any uncompensated mismatch will add a high energetic cost by exposing hydrophobic groups of amino acid residues to water. The energetic cost of transferring a hydrophobic protein surface from an organic solvent to an aque-
ous environment is approximately 17 mJm$^{-2}$ (1). Hydrophobic matching can be achieved by stretching and/or tilting of the lipid chains, which are more flexible than relatively rigid pro-

tens. Localized changes in bilayer thickness and curvature may also compensate for the mismatch (Fig. 3) (1). Consequently, bilayer dilation/thinning or changes in local membrane curvature could affect an MS-channel protein by shifting the equilibrium between the closed and the open channel conformations. This process has experimentally been demonstrated by reconstituting the MscL channel into phospholipid bilayers of different thick-

ness and examining the channel function by the patch clamp as well as examining its structure by EPR spectroscopy. The experiments showed that although hydrophobic mismatch was not the driving force that could trigger the channel opening, the MscL reconstitution into thin bilayers (e.g., PC16, 16:1 di-
palmitoylphosphatidylcholine) decreased the energy required to open the channel, whereas reconstitution into thick bilayers (e.g., PC20, 20:1 eicosenoylphosphatidylcholine) increased the energy (13). Consequently, although thinning the bilayer is not sufficient to fully open the channel, it contributes to decreasing the energy barrier that has to be overcome to open the channel.

The second possibility of gating MS channels by bilayer tension takes into consideration changes in intrinsic bilayer cur-

vature as a possible trigger for the channel opening (Fig. 3). Experiments on bacterial MS channels suggested that a diverse group of substances with amphiphilic or amphiphilic properties
Mechanosensitive Channels

Hydrophobic Mismatch

Intrinsic Curvature

Figure 3 Possible mechanisms of MS channel activation by bilayer deformation forces. Hydrophobic mismatch and bilayer curvature are considered as deformation forces of pressure-induced changes in the lipid bilayer causing conformational changes in MS channels as indicated by the example of MscL (13). These changes were studied experimentally by reconstituting purified MscL proteins in liposome bilayers prepared from synthetic phospholipid/cholesterol lipid of well-defined composition. The changes in functional properties were examined by the patch-clamp technique, whereas the structural changes were determined by EPR and FRET spectroscopy. (Reproduced from Reference 12, with permission).

such as trinitrophenol (TNP), chlorpromazine (CPZ), local anesthetics, or lysophospholipids (LPC) could trigger gating in these MS channels in the absence of externally applied membrane tension (14). This finding was subsequently confirmed on several prokaryotic (3) and eukaryotic MS currents (10, 15–17). Experiments examining the effect of amphipaths on an MS channel structure and function by EPR spectroscopy and patch-clamp recording side by side were undertaken using again MscL as a model MS channel. Addition of LPC to one monolayer of liposomes reconstituted with MscL generated local stresses leading to redistribution of the transbilayer pressure profile in the lipid bilayer and causing the channels to open without applying membrane tension. These studies thus showed that by chemically modifying membrane lipid content, one could stabilize multiple conformational states in MS channels for a time sufficiently long for biophysical studies of membrane proteins. Furthermore, in contrast to hydrophobic mismatch, insertion of an amphipath into only one monolayer of the membrane bilayer is sufficient to activate fully an MS channel. Together, these findings support theoretical considerations, which suggested that variations in the lateral pressure within lipid bilayers of cell membranes could serve as a mechanism for modulation of protein function (18).

Practical Applications

The following examples illustrate the practical applications in nanotechnology and medicine that have resulted from the basic research on structure and function of MS channels:

1. A light-driven nanovalve was constructed using the MscL channel of E. coli as a template (19). The nanovalve is opened by long-wavelength ultraviolet radiation and can be closed by visible light. For this purpose, MscL was modified by attaching light-sensitive synthetic compounds that undergo light-induced charge separation causing reversible opening and closing of the channel. Such a light-driven nanovalve can, for example, be used in liposome-based drug delivery systems.

2. Bacterial MscL and MscS channels have been shown recently to have potential as selective targets for
novel types of antibiotics (20). Namely, both channels are not only opened by amphipaths (3) but also by parabens, the alkyl esters of p-hydroxybenzoic acid, which seem to interact directly with the gate of the channels (20). The novel antibiotics based on parabens as lead compounds would, therefore, work as openers of MscL and MscS and thus compromise cellular turgor of bacterial cells, which inhibits cell growth and proliferation. In particular, MscL, identified to date in many bacterial pathogens, seems to be an ideal target for the novel antibacterial agents because MscL is highly conserved in prokaryotic cells, but its homologues have not been found in animal and human cells (1). Consequently, an antibiotic targeting MscL could be broad-spectrum and selective, potentially targeting a range of pathogenic bacteria with expected minimal side effects to infected patients.

3. The growing number of human diseases, including cardiac arrhythmias, polycystic kidney disease, Duchenne muscular dystrophy, and tumorigenesis, to name a few, have been associated directly with changes in expression and/or gating of Msc channels (2). The spider venom peptide GsMtx-4 seems to apply to several channels from evolutionary diverse origins. Additional questions to address will be on the structural origins of both diseases.

Mechanosensitive Channels

This article deals with the passive transport of electrolytes, water, and small organic molecules across biologic membranes (cell membranes and membranes that confine cellular compartments). Passive transport may be classified into diffusion, facilitated diffusion, and bulk flow. The focus in the current article is on simple diffusion, a process described by the random movement of solutes that results in the net transport (flux) along a concentration gradient. This process, at first, may be described by the first law of Fick. More detailed models take into account the partitioning of solutes between the aqueous media and the barrier itself, as well as the flux resistance that arises from water layers adherent to the barrier, which results in the second law of Fick. The actual extent of the diffusion of molecules across biologic membranes is caused by the interaction between the composition and the structural arrangement of the membrane and by the physico-chemical characteristics of the permeant. For the sake of simplification, the primary structural element of a biomembrane, which is a phospholipid bilayer, can be considered a continuous, lipophilic phase between two aqueous compartments. Commonly used permeability screening approaches include in silico modeling, liposome-based experimental models, cell culture models, and in situ perfusion.

The permeability of compounds through cell membranes is of great interest and importance for the elucidation of many biologic cell functions. Most metabolically important substances are transported across membranes by active transport. Many other intrinsic compounds, as well as most drugs, are known to pass the membrane by passive diffusion.

Biologic Background

Biologic membranes as transport barriers

The most prominent function of biologic membranes is to control selectively the molecular transport into and out of cells. The ability of certain molecules to traverse such biologic barriers depends on their composition as well as their structural and functional features. These features are discussed in more detail on a molecular level elsewhere in this encyclopedia. In brief, the plasma membrane of a cell, as well as any other biologic membrane, is organized basically as a bilayer structure of two sheets composed of phospholipids and neutral lipids, like cholesterol, in which membrane proteins are embedded. The polar head-group of the phospholipids is facing toward the aqueous phases, which are the cytosol on the one side and the medium around the cell on the other, whereas the lipophilic chains of the sheets face to one another to form the center of the membrane.

At first glance, such a membrane might be assumed to be a tight barrier that separates the cell interior from its surrounding or cellular compartments from each other, not allowing for any transport of compounds across this barrier. However, particular molecules need to pass through cell barriers to maintain continuously the basic functionality of the cells; they need to introduce and load substrates as well as remove and discharge toxic compounds. Furthermore, overall cell volume, osmotic pressure, intracellular pH, and ionic composition are controlled by the passage of molecules through the cell membrane.
Types of transport processes across cell membranes

Transport of molecules across biomembranes can be classified mechanistically into the following types: 1) active transport via carriers, 2) passive transport, which comprises a) simple diffusion and b) facilitated diffusion, and 3) endocytosis/transcytosis. Active transport consumes energy through coupling with cellular metabolism. It is accomplished typically via substrate-specific carrier proteins. Therefore, active transport can be maintained against a concentration gradient, which means, for example, certain substances selectively can be picked up independently of their concentration in the cell. Also, a toxic substance may be removed completely from the cell while an appreciable concentration of the same substance still exists in the surrounding medium.

In contrast to active transport, passive transport as a whole does not involve energy consumption and, therefore, only can work down a concentration gradient (or other types of gradients, such as electrochemical potential, thermal, or pressure gradients). In other words, passive transport of molecules equilibrates their chemical potential on both sides of the membrane. The process of passive transport can be subdivided into two different mechanisms: passive diffusion and facilitated transport. Passive diffusion is a physico-chemical process, whereas in facilitated transport, molecules pass through the membrane via special channels or are translated via carrier proteins. Both passive diffusion and facilitated transport, in contrast to active transport, follow a gradient, where facilitation merely lowers the activation energy for the transport process.

In contrast to the above-discussed molecular transport mechanisms, endocytosis, exocytosis, and transcytosis represent the transport of compounds across plasma membranes along with the bulk of their surrounding aqueous medium through vesicle formation (invagination), translocation of the vesicle, and subsequent membrane fusion, a process that also requires energy. These topics are not covered in this article.

Transport across epithelial barriers

Transport across epithelial barriers, such as the gastrointestinal (GI) wall or the blood/brain-barrier, is the result of a series of different, sequential, and parallel processes. Nevertheless, they may be modeled in many cases in the same way as transport across a single membrane.

As a class of tissue, epithelium demarcate body entry points, predisposing a general barrier function with respect to solute entry and translocation. The intestine is lined with enterocytes, which are polarized cells with their apical membrane facing the intestinal lumen that is separated by tight junctions from the basolateral membrane that faces the subepithelial tissues. In addition to their barrier function, the epithelium that line the basolateral membrane that faces the subepithelial tissues.

Passively absorbed compounds diffuse either through the cell itself (transcellular pathway) or in between cells (paracellular pathway). The lipid bilayers of which the mucosal and basalateral epithelial cell membranes are composed of, define the primary transcellular diffusion resistance to solute transport across the intestinal barrier. Transcellular permeability, particularly of lipophilic solutes, depends on their partitioning between intracellular membrane and aqueous compartments (Fig. 3).

Physico-Chemical Approach to Passive Transport

Passive transport is the process of mass transfer across any separating barrier, diaphragm, membrane, or partition “wall” toward equilibrating any differences in chemical potential because of gradients of concentration, electrostatic potential, thermal, or (partial) pressure gradient.

Individual molecules and/or ions (if we, for the moment, disregard the solvation shell) traverse the barrier to equilibrate the gradient. The velocity of the passage of individual molecules affects the overall kinetics of transport with respect to both the lag time (time until steady-state of transport is reached), the time period after which the equilibrium is reached, and—in the case of non-symmetrical systems like cell membranes—the equilibrium state. Properties of both the barrier (membrane) and the diffusant (traversing molecule) are of importance for the mechanism of passage, particularly their interaction on the molecular level. Here, solvation shells and energies of solvation/resolvation play a major role. Solvation states and intermediate states affect activation energies for the passage of the molecules.

Quantitative description of the diffusion process

Let us consider diffusion of molecules between two compartments in the first place, for the sake of simplicity, without a (rate-influencing) barrier between them (Fig. 2, Scheme 2a).

The donor compartment contains a higher concentration of diffusant \( C_D \) compared with the concentration in the acceptor compartment \( C_A \). In other words, a concentration gradient exists. Furthermore, also for the sake of simplicity, we consider transport along a one-dimensional direction.

Definitions

**Flux \( J \)** of a species is the mass \( M \) (or number of molecules of this species) transported per unit time across the barrier, normalized by the cross-sectional surface area \( A \) of the barrier:

\[
J = \frac{\text{d}M}{\text{d}t} \cdot \frac{1}{A} \tag{1}
\]

(dimensions of \( J \): g sec\(^{-1}\) cm\(^{-2}\))

A plot of the mass transported versus time is linear if the donor concentration is virtually constant and the acceptor concentration is virtually zero; the flux is constant when the...
system has reached the equilibrium called steady state (i.e., the linear part in Fig. 3):

$$M = J \cdot A \cdot t$$  \hspace{1cm} (1a)

The slope of the curve corresponds to $J \cdot A$. In most experimental setups, the surface area $A$ is known and flux $J$ can be derived. Constant flux is maintained as long as $C_D$ is much larger than $C_A$ and as long as both are practically unchanged. In biologic systems, a good example for such conditions may be the uptake of xenobiotics from the GI-trait, where the GI tract acts as a reservoir for the molecules, which are transported through the intestinal epithelium into the blood, which acts as a sink.

The quantitative value of flux is widely dependent on the concentration in the donor compartment $C_D$ (figuratively spoken, the pressure). Ideally, $C_D$ should not change over the period of observation; if $C_D$ is not constant, its change with time needs to be considered, which in many cases applies to real situations. However, the concentration in the acceptor compartment should be kept negligibly small (sink conditions) to make calculations easier. Fortunately, in biologic systems, this scenario is very often the case and experimental conditions in most cases can be chosen accordingly. It is handy to define permeability $P$ as the inverse of the resistance of the membrane, which is the flux normalized by the concentration in the donor compartment.

$$P = J / C_D$$  \hspace{1cm} (2)

Permeability, therefore, comes in the dimension of cm/sec, a self-explanatory unit.

Combining Equation 1 and 2 reveals:

$$\frac{dM}{dt} = P \cdot A \cdot C_D$$  \hspace{1cm} (3)

In cases where $C_D$ is not constant over time, the flux $J$ also changes with time. Exchanging mass by concentration, $M = C_D \cdot V$, where $V$ is the concentration of the donor phase, reveals:

$$\frac{dC_D}{dt} = \frac{P \cdot A}{V} \cdot C_D$$  \hspace{1cm} (4)

Setting $k = P \cdot A / V$, integration of Equation 4

$$\int_{C_{D0}}^{C_D} \frac{1}{C_D} \, dC_D = k \int_{0}^{t} \, dt$$  \hspace{1cm} (5)
Passive Diffusion Across Membranes

**Figure 2** Schematic illustration of concentration gradients. \( C_D \) concentration in the donor compartment; \( C_A \) concentration in the acceptor compartment. Scheme 2a: without a physical barrier; Scheme 2b: lipid barrier-controlled; Scheme 2c: water layer-controlled; and Scheme 2d: combined lipid- and water layer-controlled.

**Figure 3** Diagram illustrating mass transport versus time, lag time, and steady-state flux.

The sigma minus plot (i.e., plotting \( \ln C_D \) vs. time) yields permeability as the slope \( k \), where still \( k = P \frac{A}{V} \).

A similar general expression also can be used under non-sink conditions. Here it is useful to describe the velocity of transport (i.e., flux \( J \) ) expressing the effect of the concentration gradient (\( \Delta C \)) and the length of the dimension along the line (\( \Delta x \)), as well as to introduce the diffusion coefficient as the proportionality constant (the Fick law).

\[
J = -D \frac{\Delta C}{\Delta x} \quad (7)
\]

This description is particularly useful because the diffusion coefficient is reasonably well defined in aqueous solutions, it is related to molecular properties in aqueous solutions, and it can be predicted. However, in biologic systems, the observed length \( x \)—for a single transport step—will be widely unchanged. Preferably, steady state and sink conditions are studied, which simplifies the Fick law and focuses on permeability as stated above.

Let us now consider a barrier between the donor and the acceptor compartment, where the barrier has different properties in terms of the solvation of the traversing molecules, as a simplification of a biomembrane. Such a model is shown in Fig. 2, beginning with Scheme 2b, where a homogeneous lipid barrier between the donor and the acceptor compartment is...
Passive Diffusion Across Membranes

introduced. The permeability also is defined in this case as described above and as indicated in the Scheme. Looking closer into the system, the diffusant will partition into the lipid barrier according to the ratio of solubility both in the aqueous phases and in the lipid phase (the partition coefficient, i.e., the ratio of chemical potentials in the two phases). The concentration ratios in the two interfaces will be equal, but not the absolute concentrations, as the concentration in the donor compartment is higher than in the acceptor compartment. The gradient between the two interfaces will make the diffusion occur (see Fig. 2).

The diffusion coefficient in the aqueous phase (donor and acceptor phase) would not play a role if practically no concentration gradient exists within these compartments, in other words, if the diffusion in the aqueous compartments is not rate determining. The partition coefficient between the lipid phases and aqueous phases, $K$, determines whether $C_{D}$ and $C_{A}$, are higher or lower than $C_{L}$ and $C_{A}$, respectively.

If the diffusion of the permeant in the lipid barrier phase is rate determining, then the thickness of the barrier has to be taken into account as well. Here, the permeability coefficient is proportional to its diffusion coefficient $D$ in the membrane (slow diffusion in the membrane).

\[ \text{lag time} = \frac{D}{K C_{D} h} \]  
\[ \text{M} = k \cdot t \]  

Also in this example, flux $J$ is constant during the steady state and permeability $P$ can be revealed. However, here we have to consider a lag time $t_{L}$. For a constant flux, we have to wait until the lipid barrier is saturated and shows a constant gradient of the diffusant according to the partition coefficient. The lag time that represents the intercept with the time axis is found by extrapolating the linear part of the curve (Fig. 3).

\[ \text{lag time} = \frac{D}{K C_{D} h} \]  
\[ \text{M} = k \cdot (t - t_{L}) \]  

Diffusion with respect to physico-chemical characteristics of the permeate

In the beginning of the last century, it was observed that the permeability of a substance across a cell membrane is proportional to the relative partition coefficient of the permeating substance between phases of oil and water. In later years, it was found that the product of the permeability coefficient $P$ and the square root of the molecular weight of a permeant shows a better correlation with the partition coefficient than does permeability alone. This correlation has lead to the idea that permeation is limited not only by the lipid solubility of the permeant but also by a "screen-like" property of the membrane because small molecules penetrate faster than would be predicted from their oil-water partition coefficients. For larger molecules, however, one would expect a product of permeability with the cube root, rather than the square root, of the molecular weight to be more closely correlated with the oil-water partition coefficient. Likewise, the apparent partition coefficient to the membrane plays a major role for the transport processes across the membrane. In strict physico-chemical terms, a membrane is not a phase, but it is most common to treat it as such anyway.
