Partitioning of a substance between two phases (e.g., the aqueous phase and the membrane) may be expressed by the difference in Gibbs free energy between the two phases. Major energy differences of the permeant between the two phases are because of the hydrogen-bonding abilities of the substance and the energy of hydration and/or solvation. In addition, nonpolar molecular interactions and entropy terms also contribute to the energy difference. A plot of the logarithm of the partition coefficient versus the number of hydrogen bond donors and acceptor of the permeant gives a straight line (3, 4). The partitioning of a molecule at the water-membrane interface is greatly dependent on its polar nature. The more polar a substance, the higher are the energy expenses for the substance to enter into the membrane phase. For example, the permeability and partition into the membrane decrease approximately exponentially with the number of OH groups of the permeating molecule (3, 4).
Membrane uptake of the noncharged form of a solute is favored over its charged form. As a result, solute membrane permeability versus pH curves is shifted toward the right for weak acids and toward the left for weak bases. This condition also explains the irregular permeability behavior of ion pairs.

**Passive transport of water and protons**

The movement of water and protons/hydroxyl ions across the cell membrane is of particular importance for the existence of the cell (6). Two passive processes move water through membranes: diffusion and hydrodynamic flow. A semipermeable membrane is a membrane that will allow certain molecules (i.e., water) or ions to pass through it by diffusion. If the concentrations of a substance for which the membrane is impermeable are different on the two sides of the membrane, then water will be transported to equilibrate concentrations, for example, a stream of water toward the higher concentration is driven by osmotic pressure.

For the permeation of protons and hydroxyl ions, it has been shown that a prerequisite is the formation of membrane spanning water aggregates in which just the electrons are switched between water molecules. This prerequisite is in contrast to what is found for other ions.

**Simple diffusion of nonelectrolytes**

In the case of nonequilibrium spatial distribution of a certain species, characterized by a nonuniform distribution of chemical potential, diffusion of this species will occur in accordance with the gradient of its chemical potential. If a gradient exists in the chemical potential for one of the species, then a statistical force will be exerted on the particle distribution. The average velocity of a particle will be given by the product of its mobility and the sum of the forces acting on it (4). During the transport of a substance across a membrane, it must move through phase boundaries, such as aqueous phase/membrane/aqueous phase. As mentioned before, the substance has different affinities to each phase encountered. In most cases, the diffusion within the membrane is much slower than in the liquid phase.

So, permeability is proportional to the diffusion coefficient in the membrane and the partition coefficient between the membrane and aqueous phases, while being inversely proportional to the thickness of the membrane. The molecular weight and shape of the permeant are related closely to all of those characteristics.

It is reasonable to expect that nonelectrolytes normally have limited partitioning readily into the lipid barrier. Biologic fluids contain a variety of such charged species that originate from the dissociation of salts, acids, and bases. Another kind of transport, facilitated diffusion, is prevalent for them because their permeation via simple diffusion is rather limited because of limited partitioning into the biomembrane. Facilitated diffusion is a process where permeants diffuse across membranes with the aid of transport proteins. Water-filled pores in the membrane formed by proteins are the main pathway for ions. These pores may be gated so that they can open and close, thus regulating the ion flux. Another kind of membrane proteins, carrier proteins that change shape as the molecules are being carried through, are responsible for the facilitated transport of larger molecules like glucose and amino acids. In contrast to active transport, facilitated diffusion does not require energy and only can carry molecules or ions down a concentration gradient. The transport proteins involved are intrinsic, that is, they span the membrane. They are solute-specific, for example, they have binding sites for the specific molecule or ion that they transport. They also have a defined capacity of how many solutes they can transport. An example of facilitated diffusion is glucose that permeates through cell membranes rather slowly via conventional diffusion because it is not soluble in the membrane. However, glucose passes quickly across a cell membrane via facilitated diffusion.

**Tools and Techniques to Study Diffusion Across Membranes**

Both the prediction and the studying of transport processes through biologic membranes are of great interest in many fields. For example, in drug development, permeability across the intestinal barrier is of essential importance for the destiny of a drug candidate and in molecular biology, knowledge about the pathways in cells of endogenous compounds is of interest. Many different techniques to study such phenomena, thus, have been developed during the years. The complexity of the used techniques ranges from chromatographic systems with covalently bound membrane phospholipid to in situ studies with segments of animals.

**Prediction of diffusion based on experimentally determined physico-chemical characteristics**

Chromatographic methods

Chromatography also can be used to predict permeability. The most widely used methods are immobilized artificial membrane chromatography (IAM) and immobilized liposome chromatography (ILC).

Immobilized artificial membrane chromatography (IAM)

IAM chromatography is a reverse-phase liquid chromatography method that emulates the lipid environment of cell membranes.
by using a chromatographic surface prepared by covalently immobilized cell membrane phospholipids. The technique is experimentally simple and can screen many compounds within a short time. The predominant factor that regulates the passive diffusion across a membrane is its ability to pass through the lipid cell layer, and the capacity factor log K, determined by this technique shows reasonable correlation with permeability across cell monolayers and partitioning into liposomes (8, 9).

Immobilized liposome chromatography (ILC)

Compared with IAM, which uses a monolayer of phospholipid, the liposomal phospholipid bilayers in ILC have the advantage of closely resembling biologic membrane bilayers and constitute a 2-D fluid in which lipid molecules and other components are free to diffuse (10). With this technique, the phospholipid composition can be changed to mimic the membrane of interest. Membrane lipids extracted from human cells also can be used; the technique then is called immobilized biomembrane chromatography (IBC) (11).

Partitioning and distribution (log P/log D)

The lipophilicity of a drug is the most-used single physicochemical property to predict permeability across biologic membranes (12). The most common distribution model is octanol/water (log P) or octanol/buffer (log D, at fixed pH).

Several experiments have demonstrated that a correlation exists between log P and the degree of transcellular absorption of a homologous series of compounds. However, for structurally different compounds, such correlation could not be shown. The lipidosome partitioning system is employed increasingly as an alternative to the IAM approach (13, 14).

In vitro artificial membrane methods

Phospholipid vesicle-based methods

Liposomes

Liposomes can be used to investigate the passive diffusion of compounds across a membrane. Unilamellar liposomes (Fig. 4) can be loaded passively with the compound of interest, the external water phase replaced by an acceptor medium, and the concentration of this compound measured in the medium as a function of time. Liposome studies allow a complete manipulation of solute environment both inside and outside of the vesicles, thus making it a suitable system for passive mechanistic absorption studies. The so-called “stopped-flow technique” can be used to study permeability through liposome bilayers. The major advantage with this technique is that even very rapid permeation processes can be measured.

The distribution coefficient between a liposome phase (see above about the membrane phase) and a water phase also has been used instead of an octanol/water partition coefficient (log P). The liposome phase provides a biomimetic environment to a much larger degree compared with the octanol phase and has shown to the ability to predict in vivo permeability more precisely (13). Lipid bilayer-containing partition systems thus have been considered to model the hydrogen-bonding ability of biologic membranes better than bulk solvents. Biologic lipid membranes are composed of charged lipids that provide a polar environment at the membrane surface, which in biologic systems, often holds a negative charge. A strong attraction of positively charged molecules, thus, is observed. Liposome partitioning, in contrast to octanol/water partitioning, can take into account hydrogen bonding and electrostatic effects. However, the partition coefficient measured in liposome systems may not reflect permeation always. In some cases, it may reflect more drug interactions with the membrane surface (10, 12).

The phospholipid vesicle-based barrier

The phospholipid vesicle-based barrier is a novel predictive medium-throughput screening method for drug permeability, with the use of a tight barrier of liposomes on a filter support (Fig. 5). The liposomes are deposited into the pores and onto the surface of a filter support by centrifugation. Solvent evaporation and freeze-thaw cycling then are used to promote the fusion of liposomes, and a tight barrier is obtained as shown with calcin permeability and electrical resistance (16). The technique is much less labor intensive than comparable cell-based methods and seems, therefore, appropriate for screening of a larger number of drug candidates in earlier stages of drug development. The advantage of this model compared with the parallel artificial membrane permeability assay (PAMPA) models is that the use of liposomes instead of a mixture of phospholipids in an organic solvent leads to a model that resembles the biologic membrane to a larger extent.

Parallel artificial membrane permeability assay (PAMPA)

The PAMPA model is a simple model for fast determination of transcellular in vivo drug absorption. Coating a hydropho-
models are that they underestimate the permeability of actively transported drugs and hydrophilic molecules with low molecular weight and that the use of UV detection excludes drug compound that do not display UV absorbance (8, 9, 20),

Cell-based tools

Isolated membrane vesicles

Cell homogenates precipitated by centrifugation and resuspended in a buffer result in the formation of vesicles, which are mixed with the permeant in the buffer and filtrated after a fixed time. The amount of permeant taken up by the vesicles then is determined. Vesicles offer a unique opportunity to study the properties of drug and nutrient transport at the cellular level. In addition to offering a possibility for separating the brush border and basolateral membranes, membrane vesicles studies allow a complete manipulation of the solute environment both inside and outside the vesicle, thus making it an ideal system for mechanistic absorption studies. Uptake studies can be performed with a small amount of the substance to be tested. A unique advantage for this technique is that the vesicles can be cryopreserved and used for a long duration. The drawbacks are that membrane vesicles are used primarily for studying concentrative processes, for example, active carrier-mediated transport, the need for radiolabeled compounds, and day-to-day variations in the preparation (8, 22, 23).

In vitro cell models

In vitro techniques for the measuring of permeability are less labor- and cost-intensive compared with the more complex in situ and in vivo models. In addition, they are more suitable as screening models because they require smaller quantities of test compound. The capacity of an in vitro system to predict permeability across a biologic barrier depends on how closely the model resembles the in vivo system (8, 23).

Single-cell studies

Cells from animal or human origin can be isolated from different tissue and used as uptake systems. Normally, the isolated cells are suspended in a buffer under O2/CO2 in the presence of the permeant and shaken well. After a certain time period, the cells are separated from the buffer and extracted to determine the amount of permeant inside the cells. Because of the low volume of the cells, the assay is based mostly on use of radiolabeled compounds (23). Cells can be isolated from different origin, and every animal can give rise to experiments with many different compounds or conditions. However, many disadvantages exist as well, like the lack of reproducibility with large variations in viability, because of the chemical or mechanical stress during isolation. This method also only allows for uptake, not transport or permeability, to be studied, but the polarity of the uptake; whether a compound is taken up on the apical or basolateral side cannot be decided (22).

Cell monolayer studies

Several different cell monolayer models that mimic in vivo barriers have been developed and are very popular models in industry as well as academia. The ideal model would be a monolayer of polarized normal human enterocytes, but attempts to isolate and grow them have failed because of the low viability and the complicated requirement for attachment, monolayer formation, and differentiation. However, tumor cells grow

Passive Diffusion Across Membranes

![Diagram](image3.png)
than tissue models, but their culture can be labor-intensive and relatively accessible and more amenable to higher throughput. Caco–2 assays are used. The system also is amenable to automation. The major drawback of cell monolayer models is the intrinsic variability that can be seen in permeability data. The results obtained in several laboratories can differ by more than an order of magnitude, probably because of the underlying variability in, for example, culturing techniques, genetic drift, and variable architecture is preserved and closely resembles the in vivo situation and the viability of the tissue can be monitored closely by electrical parameters during the experiment. However, because these techniques also involve the determination of the active transport and efflux mechanisms, we leave these topics to other parts of the encyclopedia.

In vivo and in situ models In vivo studies are performed in unanesthetized animals or humans. Epithelial permeability has been studied in vivo mainly by perfusion techniques such as double balloon catheter. In situ perfusion methods involve a surgical procedure on anesthetized animals whereby a segment of the intestine is isolated and perfused with drug solution. In situ perfusion of intestinal segments frequently is used to study the permeability and absorption kinetics of drugs. The biggest advantage of the in situ system compared with the in vitro tissue systems is the presence of an intact blood and nerve supply in the experimental animals (8). But because these models are dealing with active transport mechanisms, a more detailed presentation would be beyond the scope of this article.

Lipid metabolism encompasses a large part of intermediary metabolism and includes highly dynamic processes, which are subject to regulation at transcriptional and enzymatic levels. The maintenance of lipid metabolism or lipid homeostasis is multilayered and includes biosynthesis and degradation, the impact of external stimuli proceeding through signal transduction, the function of lipid-responsive transcription factors, and lipid trafficking. It also includes the production of bioactive lipids, which have regulatory roles in different lipid metabolic pathways, effect specific transcription factors, and influence a myriad of cellular processes.

Lipid metabolism is responsive to external supplies of fatty acids and other precursors required for neutral lipid, glycerol phospholipid, and sphingolipids synthesis. In some cell types, fatty acid composition within membrane lipids must necessarily adapt to changes in temperature to maintain appropriate fluidity essential for biologic activity. Finally, lipids are diverse in both structure and abundance and differ among animals, plants, fungi, and bacteria. This article will focus on the fatty acid metabolism and, to some extent, its relationship to sterol metabolism, which underpins lipid homeostasis.

Lipid homeostasis is maintained through a complex network of hormonal, neuronal, and environmental regulators. Inability to modulate lipid metabolism to maintain homeostasis is a hallmark of many disease states, including metabolic syndrome, obesity, diabetes, cardiovascular disease, and some cancers. Together, these diseases are the leading causes of morbidity and mortality in the United States and most other developed countries. It is hypothesized that high circulating levels of free fatty acids, occurring as a result of various metabolic disturbances, lead to excessive fatty acid internalization and the resultant lipotoxicity of normal cells and tissues. Furthermore, free fatty acids and activated fatty acids (fatty acyl-CoAs) are toxic to cells because of their hydrophobic properties, which dissolve membranes. These compounds interfere with enzyme function and, when in excess, serve to increase both oxidation rates and the synthesis of ceramide, which in turn leads to increases in cell death by apoptosis. The correlation between chronically increased plasma free fatty acids and triglycerides with the development of obesity, insulin resistance, and cardiovascular disease has led to the hypothesis that decreases in pancreatic insulin production, cardiac failure, and cardiac hypertrophy are from aberrant accumulation of lipids in these tissues (1).

Biologic Background

Lipids represent a diverse group of compounds, which are readily soluble in organic solvents such as chloroform or toluene and are essential for the structure and function of all living cells. Lipids include oils, fatty acids, waxes, steroids (e.g., cholesterol and steroid hormones), and other related compounds. Specific classes of lipids are the primary structural components of membranes, provide sources of metabolic fuel, and function as bioactive signaling molecules.

Classes of lipids

Fatty acids, the simplest class of lipids, are carboxylic acids containing a long aliphatic tail generally consisting of an even number of carbon atoms, which are either saturated or unsaturated (Table 1). Natural fats and oils generally have
fatty acids with at least eight carbon atoms [e.g., caprylic acid (C8:0, n-octanoic acid)]. Saturated fatty acids (SFAs) lack double bonds and, as a result, can form straight chains, which can be tightly packed. Common SFAs include butyric (C4:0, n-Butyanoic acid), lauric (C12:0, n-Dodecanonic acid), myristic (C14:0, n-Tetradecanonic acid), palmitic (C16:0, n-Hexadanonic acid), stearic (C18:0, n-Octadecanonic acid), and arachidonic (C20:0, n-Eicosanonic acid). Monounsaturated fatty acids (MUFA’s) contain one double bond along the chain, which generally occurs in a cis-configuration. Although some monounsaturated fatty acids have a trans-configuration, most found in nature are cis. This cis-configuration results in a fatty acid, which when part of a phospholipid molecule functions to increase membrane fluidity. Common MUFA’s include palmitoleic acid (C16:1n7), cis-9-Hexadanonic acid and oleic acid (C18:1n9), cis-9-Octadecanonic acid. Polyunsaturated fatty acids (PUFA’s) contain two or more double bonds, each in a cis-configuration. These fatty acids include the essential fatty acids in humans, linoleic acid (LA, C18:2n6), cis-9,12-Octadecatrienic acid, and α-linolenic acid (LNA, C18:3n3). Monounsaturated fatty acids (MUFA’s) and polyunsaturated fatty acids (PUFA’s) are the primary dietary sources of essential fatty acids. Essential fatty acids support the cardiovascular, reproductive, immune, and nervous systems, including the production of prostaglandins, which regulate body functions such as heart rate, blood pressure, blood clotting, fertility, and conception, and are essential in the inflammatory response.

Fatty acids can be esterified to glycerol to form diglycerides, which can enter the phospholipid biosynthetic pathway or, with the addition of a third fatty acid, can be converted into triglycerides (TAG). TAGs are the predominant storage lipid but are also present in blood plasma and, in association with cholesterol, are components of lipoprotein particles. sphingosine backbone can be O-linked to a charged head group such as choline. Fatty acids are attached through an amide linkage to sphingosine. Ceramides, sphingomyelins, and glycosphingolipids, which differ in their head groups, are the predominant forms of sphingolipids and function as structural components of membranes and in signal transmission and cell recognition. Finally, fatty acids are stored esterified to cholesterol in lipoprotein particles. Cholesterol is the major sterol found in plasma membranes and, in addition, provides essential functions in lipoprotein metabolism and lipid trafficking and bile acid metabolism. Readers are directed to Vance and Vance (2) and to the section entitled “Lipid Synthesis” in this series regarding the details of phospholipid, sphingolipids, and lipoprotein synthesis, including structure.

Fatty acid and fatty acid derivatives function as signaling molecules

Some of the earliest indications that fatty acids and fatty acid derivatives function as signaling molecules come from studies using the gram-negative bacterium Escherichia coli. The long chain acyl-CoA (LC-CoA) formed as a consequence of coupled transport-activation serves primarily as a substrate for β-oxidation, although it can be incorporated into membrane phospholipids. One particular feature of LC-CoA is that it functions as a bioactive lipid that governs the DNA-binding properties of a specific transcription factor (FadR), which negatively regulates genes required for fatty acid degradation and positively regulates key genes required for fatty acid biosynthesis. Studies summarized by DiRusso and Black (3), which culminated in three crystal structures of FadR, alone in the presence of DNA with the consensus-binding site and in the presence of myristoyl-CoA, clearly defined the bioactive role of LC-CoA as an important effector governing lipid metabolism in E. coli.

In mammalian systems, the HUFA s derived from LA and LN yield an array of compounds with unique roles in a variety of cellular metabolic and signaling events (see “Prostaglandins” in this series). AA and EPA-derived eicosanoids mediate pleiotropic responses including, for example, pain, vasodilatation, vasodilation, inflammation, and bronchoconstriction. Some HUFA s and eicosanoids are ligands for transcription factors, particularly members of the peroxisomal proliferator activated receptor family (PPAR) involved in fatty acid and triacylglycerol metabolism and adipocyte differentiation. Certain classes of highly unsaturated fatty acids also decrease the activity of the Steroid Receptor Element-Binding Protein (SREBP) family members, which activate genes required for LDL uptake, cholesterol, and fatty acid synthesis.

Dynamics of Fatty Acid Homeostasis

Lipid homeostasis is maintained through the multilayered regulatory networks of lipid metabolism, transport, and signal transduction. These processes are dynamic and respond to nutritional and environmental cues, which includes interplay between fatty acid synthesis, fatty acid degradation, and complex lipid and cholesterol synthesis, which are influenced by numerous cellular processes. Metabolic output to maintain homeostasis must be quickly adjusted to meet and adapt to the nutritional needs of the cell. In the context of lipid metabolism, it includes well-defined regulatory processes at both the enzyme and transcriptional levels. Inability for a cell or organism to maintain lipid homeostasis has been suggested to cause a number of diseases, including obesity, diabetes, atherosclerosis, and some cancers.

Fatty acid synthesis

Mammalian fatty acid synthesis is a complex process being partly governed by de novo pathways and also requiring essential dietary contributions (Fig. 1a). Quantitatively, de novo mammalian fatty acid synthesis produces primarily palmitate (C16:0) and oleate (C18:1), which constitute the bulk of the side chains of membrane lipids, storage TAGs, and sterol esters. Short and medium chain fatty acids are synthesized in lesser amounts but have some essential functions in cellular metabolism and growth. For example, myristate (C14:0) is added to proteins in posttranslational modification reactions and is often required for membrane association of proteins, many of which are involved in complex signal transduction events. Very long chain fatty acids (VLFA; ≥ C20) are essential components of sphingolipids, glycosylphosphoinositides, and the lubricating waxes of skin and hair. The essential dietary fatty acids include linolenic acid (LA, C18:3 ω3), linoleic acid (LN, C18:2 ω6), and alpha-linolenic acid (LN, C18:3 ω3). Mammals are missing a fatty acid desaturase capable of introducing a double bond between C9 and the methylene end of the fatty acid. Hence, to synthesize essential HUFA s, LA and LN are both required in the diet (Fig. 1b). LA is the precursor to arachidonic acid (AA, C20:4 ω6) and derivative eicosanoids, whereas LN is the precursor to eicosapentaenoic acid (EPA, C20:5 ω3), docosahexaenoic acid (DHA, C22:6 ω3), and ω3-derived derivatives (Fig. 1b).
ecosanoids, sometimes called resolvins (4). EPA and DHA are required in large quantities during embryonic and neonatal development, particularly for the formation of neural tissues (5). Some current evidence indicates the de novo synthetic pathway for DHA and EPA may be too limited to meet the growth and development requirements of infants and dietary supplementation is recommended for nursing mothers and synthetic formulas.

Four enzyme families are required for fatty acid synthesis. The first, acetyl-CoA carboxylase (ACac), synthesizes malonyl-CoA from acetyl-CoA and CO₂. Malonyl-CoA is the substrate for two other protein families, the fatty acid synthases (Fasn) and the fatty acid elongases (Elovl). The length of the acyl chain is determined by the specificity of the terminal reaction catalyzed by the thioesterase active site of Fasn. The mammalian liver Fasn synthesizes primarily palmitate. The palmitate prolongs the steps to condense and reduce each 2-carbon unit added (7).

The HUFAs (AA, EPA, and DHA), required by mammals, are synthesized by the microsomal elongases and Δ5 and Δ6 desaturases (8). The substrates for synthesis, LA and LN, are obtained primarily from vegetable oils in the diet. Elongation and desaturation of LA produces AA, whereas elongation and desaturation of LN produces EPA and DHA. Synthesis of DHA, which is concentrated in the brain, proceeds through the elongation and desaturation pathways to the product C24:6ω3, which is then the substrate for one cycle of peroxisomal β-oxidation to yield C22:6ω3 (8).

The liver is quantitatively the most important site of de novo fatty acid synthesis and processing and modification of dietary fatty acids. In liver, fatty acids are incorporated into phospholipids, triglycerides, and cholesterol esters, packaged in very low density lipoproteins, and exported to blood. Uptake of fatty acids in extrahepatic cells requires degradation of the complex lipids into component parts by lipases. Fatty acids are then imported by protein-mediated transport mechanisms involving fatty acid transport protein (FATP), fatty acid translocase (FAT/CD36), and long chain acyl-CoA synthetase (A-ACS) (9). This process is poorly understood, although efforts are underway to define the components and mechanisms mediating the selectivity and efficiency of uptake into cells and tissues (10). Fatty acids are incorporated into complex lipids through de novo synthetic and remodeling pathways. As detailed below and shown in Figure 2a, intracellular pools of acyl-CoA are involved in processes outside of lipid metabolism and, in many instances, function as important regulatory molecules. Figure 2b illustrates an overview of glycerol phospholipid synthesis and how fatty acids in the form of acyl-CoA enter these metabolic pathways. Readers are referred to the article entitled “Lipid Synthesis” in this series for specific details regarding these pathways.

β-oxidation of fatty acids

Fatty acids represent an important source of metabolic fuel, especially for cardiac and skeletal muscle, and are degraded by β-oxidation. Before β-oxidation, fatty acids are first activated by acyl-CoA synthetase (A-ACS). This activation step proceeds through an acyl adenylate intermediate and results in the formation of acyl-CoA. These molecules must first traverse the mitochondrial membrane before further metabolism. Acyl-CoA is converted to acyl carnitine by carnitine palmitoyltransferase 1 (CPT 1) on the inner surface of the outer mitochondrial membrane, which is then transported across the inner mitochondrial membrane by carnitine-acylcarnitine translocase into the exchange for carnitine. Carnitine palmitoyltransferase 2 (CPT 2), located on the matrix side of the mitochondrial inner membrane, converts acylcarnitine back to acyl-CoA, which then enters the β-oxidation cycle. During each cycle of β-oxidation, the products are acetyl-CoA, NADH, and FADH2. The first step in β-oxidation is an oxidation step, which is catalyzed by acyl-CoA dehydrogenase (ACD) and yields FADH2. This step is followed by a hydration step catalyzed by enoyl-CoA hydratase and a subsequent oxidation step catalyzed by hydroxyl acyl-CoA dehydrogenase yielding NADH. A acyl-CoA is liberated by ketolactone after cleavage of the bond between the ω-2 and γ-carbons with the addition of CoA to the shortened fatty acid, which undergoes another round of β-oxidation. Regulation of β-oxidation is largely controlled by the concentration of free fatty acids available. Malonyl-CoA, a key intermediate in fatty acid biosynthesis, inhibits CPT 1, thereby inhibiting the transport of acyl-CoA into mitochondria, which represents an important metabolic regulatory switch and functions to modulate the fatty acid biosynthetic and fatty acid oxidative pathways in such a manner that these processes will not occur together. Very long chain fatty acids are initially oxidized in the peroxisome where the initial oxidation step is catalyzed by acyl-CoA oxidase and the subsequent steps in β-oxidation are catalyzed by a multi-enzyme complex with hydratase, dehydrogenase, and thiolase activities. Unsaturated fatty acids require additional enzymatic activities, including enoyl-CoA isomerase and dienoyl-CoA reductase. Readers are directed to Vance and Vance (2) for additional details regarding β-oxidation, including the details of the metabolic reactions.

Fatty acid trafficking

Fatty acids are very apolar compounds and readily partition into a lipid bilayer and biologic membrane. Given the expense to synthesize fatty acids, most cell types will take up exogenous fatty acids, which as acyl-CoA, enter pathways of β-oxidation and complex lipid and TAG synthesis. The concentration of free fatty acids in the circulation, extracellular milieu, and within cells is extremely low as a consequence of their relative insolubility under aqueous conditions. Cells with high levels of fatty acid metabolism (either degradation or storage) transport exogenous fatty acids at higher rates when compared with those with low levels of lipid metabolism. In a number of cell types, fatty acid transport is inducible and commensurate with the expression of specific sets of proteins thought to participate in this process (11). Insulin regulates fatty acid uptake.
Figure 2  (A) Acyl-CoA metabolism within the cell. Fatty acids must be activated to acyl-CoA before metabolism. As shown, acyl-CoA pools derive from vectorial acylation [import/activation], lipolysis of triglyceride stores, chain turnover from complex lipids, and de novo biosynthesis. Acyl-CoAs are important signaling molecules, incorporated into complex lipids and triglycerides, are substrates for energy production through β-oxidation, and are substrates for protein N-myristoylation and palmitoylation. Acyl-CoAs are also subject to chain modification, including desaturation and elongation. Acyl chains in complex lipids serve both structural and regulatory roles. (B) Overview of glycerol lipid metabolism in eukaryotes, with an emphasis on how fatty acids as acyl-CoAs enter these pathways. Glycerol-3-phosphate is converted into phosphatidic acid (PA) through a two-step process, with the intermediate monoacylglycerol phosphate (MAG-P). PA serves in the synthesis of diacylglycerol (DAG) or CDP-diacylglycerol (CDP-DAG). The former is required in the CDP-choline (CDP-C) and CDP-ethanolamine (CDP-E) pathways in the synthesis of phosphatidylcholine (PC) and phosphatidylethanolamine (PE). DAG also serves in the synthesis of triacylglycerol (TAG). PE is converted into phosphatidylycerine via phosphatidylethanolamine-serine transferase; the reverse reaction requires phosphatidylycerine decarboxylase. CDP-DAG is involved in the biosynthesis of phosphatidylinositol (PI), phosphatidylglycerol (PG), and cardiolipin (CL). The asterisks show where acyl-CoA is a substrate in the reaction, including the conversion of lysoPC (LPC), lysoPE (LPE), and lysoCL to PC, PE, and CL, respectively. Also shown is the requirement of acyl-CoA for the generation of cholesterol esters (CHO-FA) from cholesterol (CHO).
is some indication that FAT/CD36 deficiency contributes to the etiology of hereditary hypertrophic cardiomyopathy (14). Genetic linkage studies suggest a deficiency of FAT/CD36 is associated with hypertriglyceridemia and hyperinsulinemia in the spontaneously hypertensive rat. The most informative data on FAT/CD36 derives from studies of transgenic overexpressing and knockout mice. The over expression of FAT/CD36 in transgenic mice results in slightly lower body weight than control litter mates, reduced levels of triglycerides (LDL fraction), and elevated levels of circulating fatty acids. Mice with engineered deletions in the gene encoding FAT/CD36 are viable, yet have a significant decrease in binding and uptake of oxidized low density lipoprotein in peritoneal macrophages. These animals also have significant increases in fasting levels of cholesterol (HDL fraction), nonesterified free fatty acids, and triacylglycerol (LDL fraction). Each of these phenotypes is consistent with alteration in lipid trafficking pathways but do not necessarily indicate a deficiency in cellular uptake of free fatty acids.

Fatty acid transport protein 1 (FATP1) and long chain acyl-CoA synthase 1 (ACSL1) were identified as components of a fatty acid transport system in expression cloning experiments, which specifically targeted cellular fatty acid uptake (15). A sub set of FATP and ACSL 1 were selected in these experiments, it was suggested that fatty acid transport occurred by a coupled transport-activation (15). This mechanism was first shown to occur in gram-negative bacteria and is referred to as vectorial acylation (16). Six different isoforms of FATP have subsequently been identified experimentally in mice, rats, and humans (e.g., in mice, mmFATP1-6).

The mouse FATP1 structural gene contains a peroxisome proliferator-activated receptor response element (PPRE) from -456 to -474; FATP1 expression is induced fourfold and 5.5-fold, respectively, by PPARα and PPARγ in the presence of their respective activators in a PPRE-dependent manner (16). FATP1 expression is down regulated by insulin in cultured 3T3-L1 adipocytes and up regulated by nutrient depletion in murine adipose tissue (17). An insulin response sequence has been identified in the mouse FATP1 structural gene, which is also found in the regulatory region of other genes negatively regulated by insulin, including those encoding phosphoenolpyruvate carboxykinase, tyrosine aminotransferase, and insulin-like growth factor-binding protein 1 (16).

Knockout mice have been generated for FATP1 (18), FATP2 (19), FATP4 (20), and FATP5 (21), which have provided some insights into the roles of these proteins in fatty acid trafficking. Deletion of FATP1 protects animals from developing insulin resistance on a high fat diet and during chronic lipid infusion (18). Animals with a deletion in the gene encoding FATP2 were only evaluated for changes in very long chain acyl-CoA synthetase activity, which was partially diminished, and for accumulation of very long chain fatty acids, which were unchanged. The animals have not been evaluated for fatty acid uptake and no other phenotypes were noted (19). Deletion of FATP4 results in neonatal lethality (20), which is believed to be due to a restrictive dermopathy that prevents expansion of the diaphragm upon birth. Deletion of FATP5 in the mouse results in aberrant bile acid conjugation, which in some manner is linked to the regulation of body weight (21).

Bioactive fatty acids and cellular signaling

Work describing the transcriptional control of fatty acid metabolism in E. coli set the stage showing LC-CoA is an important regulatory molecule that influences a number of different metabolic processes (Fig. 2a).

A noted above, fatty acids also serve as important bioactive fatty acids, which impact on a number of cellular processes related to and distinct from lipid homeostasis (22). In mammalian systems, the highly unsaturated fatty acids derived from LA and LN yield a range of compounds with unique roles in a variety of cellular metabolic and signaling events. AA and EPA-derived eicosanoids mediate pleiotropic responses including, for example, pain, vasoconstriction, vasodilation, inflammation, and bronchoconstriction. Some HUFA and eicosanoids are ligands for transcription factors, particularly members of the peroxisomal proliferator activated receptor family (PPAR) involved in fatty acid and triacylglyceride metabolism and adipocyte differentiation. Certain classes of HUFA also decrease the activity of the SREBP family members, which activate genes required for LDL uptake, cholesterol, and fatty acid synthesis (23). Numerous studies have implicated HUFA in the prevention and management of diabetes, cardiovascular disease, and metabolic syndrome, although the mechanisms are largely undefined (24). Current evidence indicates eicosanoids derived from EPA may counter some effects of eicosanoids derived from AA (22). Hence, there is much interest in establishing a balanced ratio of ω6:ω3 fatty acids, generally recommended to be 2:1 (26, 27).

Lipid-responsive transcription factors and fatty acid homeostasis

The peroxisomal proliferator activated receptors (PPAR) are considered to be internal fatty acid sensors. To date, three distinct PPARs have been discovered, α, γ, and δ, each encoded by a separate gene with distinct tissue specific distributions. PPARα is primarily found in the liver and is involved in regulating the genes involved in fatty acid catabolism whereas PPARγ is primarily involved in the adipocyte differentiation and fatty acid storage. PPARα has a wide range of tissue distribution, but its specific role in the regulation of fatty acid metabolism in the liver has not been well elucidated. The natural ligands for the PPARs are ω3 and ω6 PUFA ω6 fatty acids, HUFA s, and fatty acid-derived metabolites (e.g., leukotriene B4, and 5(S)-hydroxy-eicosatetraenoic acid (29, 31)). Recent work has shown that very long chain fatty acids, including C20:4-ω6 and C22:6-ω3 are potent activators of the PPARα/δ heterodimer and have been shown to induce target genes associated with fatty acid and cholesterol uptake and metabolism (32). PPARγ is primarily expressed in adipose and muscle tissue and is involved in the transcriptional regulation of genes involved in fatty acid and cholesterol synthesis and storage (33). PPARγ is activated by drugs such as thiazolidinediones (34), which are used to treat type II diabetes. The PPARα/γ heterodimer is also important in the transcriptional regulation of genes involved in fatty acid and cholesterol synthesis and storage.
C20:5 ω-3, C22:6 ω-3, and branched-chain fatty acids are potent activators of PPARα (31). Although there is some disagreement whether PUFA or HUFAs are more potent PPAR α agonists, HUFAs are more potent toward PPARγ (32). PPARα regulates genes involved in mitochondrial β-oxidation, including those encoding straight-chain acyl-CoA dehydrogenase (ACDH) and carnitine palmitoyl transferase (CPT1 and 2). PPARα also regulates key peroxisomal genes, including those encoding acyl-CoA oxidase (AOX), L-bifunctional protein, and 3-ketoacyl-CoA thiolester (33), involved in the β-oxidation of very-long chain fatty acids (VLCFAs), which is required in the synthesis of DHA.

Sterol regulatory element-binding proteins (SREBP1α, SREBP1c, and SREBP2) are transcription factors that control both cholesterol and fatty acid biosynthesis. SREBP-1c regulates genes involved in fatty acid synthesis and storage, whereas SREBP-2 regulates genes involved in cholesterol and bile acid synthesis. SREBP-1a is thought to regulate both fatty acid and cholesterol biosynthesis. SREBPs are regulated by intracellular oxysterol levels such that when elevated, their proteolytic cleavage and subsequent activation is prevented. SREBPs serve to balance PPAR-regulated fatty acid oxidation. PUFA and HUFA are believed to suppress fatty acid synthesis by decreasing the activities of SREBP1c and LXR (34). The active form of SREBP is negatively regulated by PPAR, PUFA, and HUFA (22, 35, 36). In addition, SREBP transcription is controlled by LXR demonstrating crosstalk between PPARs and LXR (35). More specifically, PPAR competes with LXR for their shared heterodimer partner, RXR, thereby decreasing LXR activity. The balance between fatty acid biosynthesis and breakdown is important in many disease states and all of the above-mentioned transcription factors play a role in maintaining this balance.

Chemical Tools and Techniques For Studying Lipid Metabolism

Extraction of lipids and the foundations for current analytical studies

The fundamental step in all analytical studies on lipids and lipid metabolites begins with extraction methods. Two papers, Folch et al. (37) and Bligh and Dyer (38), are routinely cited methods describing lipid extraction and should be consulted as general guides. Details of these methods can be found in the Lipid Library (http://www.lipidlibrary.co.uk/topics/extract/index.htm) and in Cyberlipids (http://www.cyberlipid.org/extract/extract0002.htm).

Thin layer and high performance liquid chromatography

Early studies employed thin layer chromatography (TLC) in the separation, identification, and quantification of individual classes of lipids. These techniques have been optimized for different classes of glycerol phospholipids, neutral lipids, sphingolipids, and fatty acids. Methods and general references to TLC can be found in the Lipid Library (http://www.lipidlibrary.co.uk/topics/tlc/index.htm) and in Cyberlipids (http://www.cyberlipid.org/fraction/fraction0005.htm). High performance liquid chromatography (HPLC) has now become routine in the separation and quantification of lipids. Given the optical properties of lipids, the use of evaporative light-scattering detectors is most optimal for detection and quantification. The most comprehensive information on the use of HPLC in analytical lipid studies can be found at Cyberlipids (http://www.cyberlipid.org/index.htm).

Gas chromatography and mass spectrometry

The identification of individual classes of fatty acids has relied on the use of gas chromatography (GC), equipped with a flame ionization detector. Lipids are saponified after extraction and the fatty acids converted to methyl esters. The fatty acid methyl esters (FAME) are separated using GC. The use of standards allowed for the identification of individual species of fatty acids based on retention time. The method is quite sensitive and permits the quantification of fatty acid species. The mode of detection has been enhanced with the use of mass spectrometry (MS), which allows for the detection and quantification of unknowns, thus increasing the utility of these methods. The Lipid Library section on the gas chromatography of lipids (http://www.lipidlibrary.co.uk/GC/lipid0003_index.html) provides a comprehensive description of these methods.

Fluorescent fatty acids using fatty acid trafficking and signaling

A number of different fluorescent fatty acids are in use to investigate various aspects of fatty acid homeostasis. Among these are the C18, C16, and C12 fatty acid-5-aminofluorescein conjugates octadecylaminofluorescein (OAF), hexadecylaminofluorescein (HAF), and dodecylaminofluorescein (DAF), which have been used to study membrane dynamics in gram-negative bacteria. Studies on the intracellular fatty acid-binding proteins have employed anthroloxy-labeled fatty acids, whereas biophysical studies addressing fatty acid transport have used the naturally occurring cis-paranaric acid. Many of the current studies addressing fatty acid trafficking use BODIPY (4,4-difluoro-5-methyl-4-bora-3a,4a-diaza-s-indacene)-labeled fatty acids, which has been adapted for high throughput technologies to select for small molecules that inhibit one or more steps in fatty acid trafficking (39). The BODIPY-derived fatty acid molecules can be visualized using fluorescence microscopy, which provides a tool to monitor intracellular trafficking.

Research Directions—2007

High resolution studies using LC-MS/MS

The identification and quantification of lipids, particularly minor species that are likely to have bioactive roles, has lagged behind...
their hydrophilic counterparts. Understanding these minor lipid compounds is essential to have a complete picture of all of the factors involved in governing lipid homeostasis. With the advent of developing analytical tools that combine HPLC with tandem mass spectrometry, we are now in a position to acquire a significant and novel body of information on complex lipids and lipid metabolites, and to determine how these compounds fit into larger metabolic schemes essential for addressing issues of health and disease.

**Lipid maps**

The emerging field of metabolomics is defined as the study of metabolites and metabolic interrelationships and encompasses the global analysis of the plethora of small molecules generated in the process of metabolism. To effectively use this information for understanding both normal physiology and pathophysiology, we must first have a firm grasp on the interrelationships between metabolic enzymes and the pathways in which they participate. The study of the metabolic intermediates of lipid metabolism and the enzymes participating in these metabolic pathways comprise the field of lipidomics (see "Lipidomics" in this series). A new resource in lipidomics is the Lipid MAPS ([LipidMaps.org](http://www.lipidmaps.org/)), which has been established to aid investigators. Lipid MAPS serves 1) to separate and detect all of the lipids in a specific cell and discover and characterize any novel lipids that may be present, 2) to quantify each of the lipid metabolites present and the changes in their levels and location during cellular function, and 3) to define the biochemical pathways for the synthesis of each lipid and develop lipid maps that define the interaction networks ([40]). This consortium is directed to finding and cataloging the myriad of lipid compounds, including those that are least abundant, those that are transient intermediates in the metabolic pathways, and those with pronounced biologic activity. The consortium is establishing a comprehensive database available to researchers addressing questions within the lipidomics field (e.g., see Reference [41]). Independent researchers and smaller research consortia of investigators with common interests in lipidomics, such as those described within this proposal, can access these databases and, as importantly, can provide information to be cataloged within Lipid MAPS.

Electron Transfer Chemistry in Photosynthesis

Art van der Est, Department of Chemistry, Brock University, Ontario, Canada
doi: 10.1002/9780470048672.wecb450

In oxygenic photosynthesis, light-induced electron transfer reactions occur in two photosystems embedded in the thylakoid membrane. These complexes bind many cofactors and are among the handful of membrane proteins for which the X-ray crystal structures have been determined. The availability of this structural information, in combination with advanced spectroscopic techniques, has allowed the electron transfer reactions to be studied in detail. This work has revealed the pathways, rates, and yields of the electron transfer reactions but has also raised several intriguing questions about how these properties are governed by the protein–cofactor interactions. In this article, a brief overview of the main features of these very complex reactions is given, along with a summary of some techniques used to study them. A short survey of some recent advances in our understanding of the chemistry of electron transfer in photosynthesis is given.

The energy needed by all living organisms is derived ultimately from the sun. However, most energy contained in sunlight is dissipated as heat, which is insufficient to break and form all but the weakest chemical bonds. Hence, to use the energy of the sun, living organisms require a mechanism for capturing individual photons and storing the energy they contain. Moreover, a system that can perform multiple turnovers is required, because even the energy contained in a single photon of visible light is not sufficient for many biochemical reactions. Photosynthesis is the process by which this energy storage is achieved, and because all living organisms are dependent on it, it is arguably the most important biologic process.

Biologic Background

At the heart of this solar energy conversion process are two light-induced electron transfer reactions that generate oxidizing and reducing agents and a transmembrane proton concentration gradient. The nature of this reaction and the type of oxidant it produces distinguishes the various types of photosynthetic organisms.

Occurrence of photosynthesis in the three domains of life

Photosynthesis is most commonly associated with higher plants, which are eukaryotes. However, in terms of photosynthetic electron transfer chemistry, a wider variety of species exists among the bacteria. Indeed, eukaryotic photosynthesis is believed to have evolved through a symbiotic relationship between a non-photosynthetic eukaryote and an oxygenic photosynthetic bacterium. Hence, a complete classification of the various types of photosynthetic electron transfer apparatus can be performed within the domain of the bacteria.

Types of photosynthetic organisms

Photosynthetic bacteria can be divided into two classes: anoxygenic and oxygenic. The anoxygenic bacteria are thought generally to have evolved before the advent of oxygenic photosynthesis, and in these species, the electron transfer oxidizes electron-rich compounds such as thiols. The limited availability of such compounds strongly restricts the environments in which anoxygenic bacteria can survive. In contrast, the oxygenic organisms can live in a much wider variety of habitats because they have evolved the ability to oxidize water, which is much more abundant. Although considerable diversity exists, both at a cellular and molecular level between the various photosynthetic organisms, all of them possess photosynthetic reaction centers, which are membrane-bound oxidoreductase enzymes in which the light-induced electron transfer takes place. The reaction centers are divided generally into two classes on the basis of the terminal electron acceptors, and all known reaction centers can be placed into one of these two types. A unique feature of oxygenic organisms is that they have two different reaction centers, one of each type. Hence, the oxygenic photosynthetic bacteria provide a convenient framework within which most features of photosynthetic electron transfer can be discussed.
Components of the photosynthetic apparatus in oxygenic photosynthesis

The two different reaction centers in oxygenic species seem to have evolved so that they can generate the very positive oxidation potential needed to split water without sacrificing the reducing potential generated on the other side of the membrane. In both reaction centers, an extensive network of chlorophyll molecules, used to capture light, is housed in the same complex as the electron transfer catalysts, and hence, these complexes are called photosystems. The two photosystems are called more correctly light-driven oxidoreductases, and they are referred to as Photosystem I (PS I) and Photosystem II (PS II) or plastocyanin:ferredoxin oxidoreductase and water:plastoquinone oxidoreductase, respectively. In addition to the photosystems, the cyanin:ferredoxin oxidoreductase and water:plastoquinone oxidoreductase participate in the electron transfer in oxygenic photosynthesis. The proton gradient generated by these enzymes is driven by ATP synthase to phosphorylate ADP. These components make oxygenic photosynthesis one of the best characterized biologic pathways.

Electron Transfer in Oxygenic Photosynthesis

The electron transfer pathway shown in Fig. 1 is driven by light-induced charge separation in the two photosystems. The first of these systems is PS II, shown on the left of Fig. 1. In PS II, the radical cation generated by the charge separation extracts electrons from a manganese cluster located on the lumen side of the membrane. After four turnovers of PS II, the manganese complex can remove four electrons from two water molecules to produce molecular oxygen and four protons. On the stromal side of the complex, four turnovers of the complex reduce two molecules of plastoquinone to plastoquinol, which diffuses into the membrane. The plastoquinol is then reoxidized to plastoquinone in the cytochrome b6f complex. The electrons and protons released in this process are both transferred to the stromal side of the membrane. The electrons reduce the soluble protein plastocyanin, whereas the two protons are released into the stroma. In the second photosystem, PS I, the radical cation generated by light-induced charge separation reoxidizes reduced plastocyanin. The electrons transferred through PS I reduce ferredoxin, which is a soluble protein located in the stroma. Ferredoxin is then reoxidized by ferredoxin:NADP+ reductase (FNR), which converts NADP+ to NADPH. The oxidation of water in PS II and the conversion of plastoquinone to plastoquinol and back again lead to the accumulation of protons in the lumen, which creates a proton gradient across the thylakoid membrane. Cyclic electron transport, in which reduced ferredoxin passes electrons to the cytochrome b6f, also can contribute to establishing a difference in H+ concentration across the membrane. This proton gradient is used to drive the ATP synthase enzyme shown on the right, which converts ADP to ATP on the stromal side of the membrane. The final step of photosynthesis, the production of carbohydrates from CO2 via carbon fixation, derives its energy from ATP and NADPH. This step is not shown in Fig. 1.

The Z-scheme

The elucidation of the overall mechanism of photosynthesis described above is the product of many years of intense research. Initially, the focus of most of this work was to determine the nature of the light-induced reactions and their energetics. In 1960,
Hill and Bendall (10) presented a hypothesis that suggested that two light-induced steps were involved and showed a diagram in which the energy was plotted along the horizontal axis. Because the two reactions in this diagram resembled the letter “Z,” it became known as the Z-scheme. Now it is drawn according to the more usual convention of energy as a vertical axis, and many details of the electron transfer reactions have been added (11). This scheme is shown in Figure 2. The vertical axis in the figure indicates the midpoint potential for oxidation or reduction for the various species. The two vertical steps indicate the absorbance of light by PS I and PS II, and it is apparent that the midpoint potentials of the two photosystems are shifted by ~0.8 V with respect to one another. Because of this shift, PS II can use 680 nm photons to generate an oxidizing potential of ~1.0 V, while PS I uses photons of similar energy (700 nm) to produce a reducing potential of ~0.7 V. The various steps after light absorption by PS I and PS II refer to electron transfer along the chain of acceptors in the two systems. Here, we will focus on the details of these electron transfer reactions. Electron transfer in the cytochrome b6f complex is a multistep process also, but these steps are not shown in Figure 2 and readers are referred to a recent review (12) for details.

Photosystem II and type II reaction centers

PS II is representative of the Type II class of reaction centers, and in these systems, the primary acceptor is pheophytin (shown in blue and labeled Pheo in Figure 3, left). A problem that has intrigued researchers in the field for many years is the fact that despite the apparent symmetry of the complex, the electron transfer occurs exclusively to Pheo, on the left in Figure 3 (13). The exact nature of this initial charge separation remains a subject of debate. In purple bacteria, the chlorophyll dimer acts as the donor and the electron transfer is known to proceed via the accessory chlorophyll Chl+$\text{ }^\ddag$ (shown in light blue in Figure 3 (14)). However, in PS II, recent evidence suggests that the initial charge may occur between ChlA and Pheo, and that the oxidized Chl$^+$ then is reduced rapidly by the special pair, P$_{680}^\ddag$ (15). After this initial charge separation, the electron is transferred to the neighboring quinone Q$_{A}$ and then across the complex to quinone Q$_{B}$ (both shown in red in Figure 3). The nature of the quinone varies slightly between various organisms. In PS II, it is plastoquinone, but other quinones, such as ubiquinone, are found in anoxygenic organisms with Type II reaction centers.

In the latter organisms, the oxidized donor is re-reduced by a cytochrome whereas in PSII and P$_{680}^\ddag$ is reduced by the neighboring tyrosine $Y_{Z}$, which in turn is reduced by the oxygen-evolving complex (OEC) (represented by the four Mn atoms shown in green in Figure 3). A second turnover of the enzyme removes a second electron from the OEC and leads to double reduction and protonation of Q$_B$ to its quinol form. The quinol does not have a high affinity for the Q$_B$ site and diffuses out of the reaction center to be replaced by a quinone. The complex can then undergo two more turnovers that produce another quinol and extract an additional two electrons from the OEC. The OEC then has sufficient oxidizing potential to extract four electrons from two water molecules and release four protons and an oxygen molecule in the process.

Figure 2 shows the lifetimes for the various electron transfer steps along with the midpoint potentials for the acceptors, as indicated by the vertical axis. The charge separation to Q$_{A}$ ...
A rapid transformation into S0 accompanied by the release of O2 than maximal energy efficiency. As can be observed from the moving reaction becomes, and the forward reaction rate, therefore, can be slower. The price for the high quantum efficiency is less a quantum yield of close to unity. To achieve this extremely high quantum yield, the rates of forward electron transfer have been optimized, thus avoiding nonproductive recombination. The further the electron is from the donor, the slower the back reaction becomes, and the forward reaction rate, therefore, can be slower. The price for the high quantum efficiency is less.

The further the electron is from the donor, the slower the back reaction becomes, and the forward reaction rate, therefore, can be slower. The price for the high quantum efficiency is less.

The energetics of electron transfer in reaction centers and the factors governing the rates are discussed in Reference 17. One of the most interesting and intensively researched aspect of the electron transfer chemistry in PS II is the function of the OEC. This function is also the most poorly understood part of the PS II enzyme because of its complexity and the difficulty in obtaining spectroscopic signatures that can be interpreted unambiguously in terms of a mechanism. Here, only a basic outline of our current understanding of the water-splitting process is given, and readers are referred to several recent and excellent reviews for more detail (18–21). As successive electrons are removed from the OEC, it passes through a series of five states labeled S0 through S4. The S0 state is not stable and rapidly transforms into S1 accompanied by the release of an O2 molecule. This sequence of steps is known as the Kok cycle, named after Bessel Kok (22) who first observed that oxygen was evolved after every fourth flash of light given to dark-adapted PS II samples. As successive electrons are removed from the OEC, it passes through a series of five states labeled S0 through S4. The S0 state is not stable and rapidly transforms into S1 accompanied by the release of an O2 molecule. This sequence of steps is known as the Kok cycle, named after Bessel Kok (22) who first observed that oxygen was evolved after every fourth flash of light given to dark-adapted PS II samples.

The geometric arrangement of the redox active cofactors in Photosystem I and Photosystem II as given by the X-ray crystal structures: PS I pdb entry 1B80 (2) and PS II pdb entry 2AK7 (3). One of the most interesting and intensively researched aspect of the electron transfer chemistry in PS II is the function of the OEC. This function is also the most poorly understood part of the PS II enzyme because of its complexity and the difficulty in obtaining spectroscopic signatures that can be interpreted unambiguously in terms of a mechanism. as is apparent in Fig. 2, the distance between the primary acceptor (A0A,B) and PheoA takes place with an overall lifetime of ~200 ps and a quantum yield of close to unity. To achieve this extremely high quantum yield, the rates of forward electron transfer have been optimized, thus avoiding nonproductive recombination. The further the electron is from the donor, the slower the back reaction becomes, and the forward reaction rate, therefore, can be slower. The price for the high quantum efficiency is less.

primary role of PS I is to produce a strong reducing potential. From this point of view, it is surprising that PS I contains two phytoquinone molecules on its acceptor side, because quinones generally behave as oxidants and semiquinones behave as weak reductants. Thus, in PS I, the environment clearly has a strong impact on the redox properties of the acceptors. A comparison of the electron transfer rates given in Fig. 2 also shows that the electron transfer times generally are faster than in PS II. Presumably, the reason for this is because no need exists for multiple reduction of the acceptors. Therefore, the quinone can be placed closer to the primary acceptor and can pass the electron to $F_X$ faster than $Q_A^-$. As in all reaction centers, the initial charge separation is extremely fast and it has been assumed generally that it occurs between the chlorophyll dimer ($P_{700}$) and $A_0$. However, as in PS II, this assumption is being challenged by recent data, which suggest that the initial charge separation may occur between the accessory chlorophyll(s) and $A_0$, followed by rapid donation from $P_{700}$ (16).

An unusual feature of the electron transfer in PS I is the fact that it is heterogeneous. Many steps, for example, from $A_1$ to $FX$ and the absorbance is measured using a probe pulse at a known delay after the pump pulse. The time resolution of this method can be as short as $10^{-13}$ seconds. Transient fluorescence methods involve detecting emitted photons and correlating the time at which the photons arrive at the detector with the time of the excitation pulse. The ultrafast techniques are usually limited to times less than a few nanoseconds. To study electron transfer steps with lifetimes longer than this, a continuous detection beam and a fast digitizer can be used to follow the absorbance changes or the emitted light. These methods have provided most lifetimes given in Fig. 2.

Electron paramagnetic resonance methods

The electron transfer in reaction centers generates a series of radical pairs that can be detected by electron paramagnetic resonance (EPR) spectroscopy (see Reference 27 for a review). The advantage of this method is that only paramagnetic species are detected. Hence there are fewer background signals and less chance of errors when subtracting them. However, the method is limited to a time resolution of $\sim 10^{-9}$ seconds. Therefore, it only can be used to study the secondary electron transfer steps. A crucial advantage of magnetic resonance techniques in general is that they depend on tensorial properties and therefore give information such as the relative orientation of the radicals and their spin density distributions along with the rates of electron transfer. For photosynthetic systems, EPR has been used most widely to study trapped paramagnetic intermediates generated by the electron transfer at low temperature. In such experiments, all kinetic information is lost; however, the properties of the individual radicals can be studied in detail, and the pathway can be deduced from the species observed.

Recent Advances

Directionality of electron transfer in photosystem I

One peculiarity of PS I is that the two branches of electron cofactors converge at $F_X$, so that a priori reason exists for why electron transfer should use only one of them. On the other hand, no obvious need exists for both branches to be active. This problem has been addressed by a number of researchers in recent years by using the known structure of PS I to identify specific amino acid residues close to the cofactors in one branch or the other and making point mutations at these locations. Although no consistent picture of the electron transfer pathway in PS I has been developed yet, much of the data provide evidence that both branches may be active. If this model is correct, some data also suggest that it may be possible to influence the extent to which electron transfer occurs in a given branch (24).

Water oxidation and the structure of the water-splitting complex

As discussed, the holy grail of much research on PS II has been to elucidate the mechanism for water splitting. A major hurdle...

With the development of systems biology, several approaches have been developed to profile a tier of organization in a cell, tissue, or organism globally. Metabolomics, also referred to as metabonomics, is an approach that attempts to profile all the small-molecule metabolites in a biological matrix. One major challenge of this approach, as with other “-omic” technologies, is that the metabolome is context dependent and varies with developmental stage/age, genetic modification, disease, and environment. Thus, by definition, the metabolome of an organism must take into consideration all the effects of these manipulations. Despite these challenges, the approach has already been applied to understand metabolism in a range of animal models and has more recently started to be applied to clinical studies. In this article, we will discuss some common approaches currently used in metabolomics and the results that they have produced. In particular, we will focus on the two most common analytical approaches, nuclear magnetic resonance (NMR) spectroscopy and mass spectrometry, and some biological problems they have been used to address.

The postgenomic era seeks to define the biological function of genes and how these translate to define an organism’s phenotype. Unlike genome sequencing projects, the effective study of functional genomics necessitates a plethora of multidisciplinary techniques (1). The development of analytical tools that enable the high-throughput measurement of gene products has provided a comprehensive signature of the physiological state of the cell at several levels (Fig. 1). Metabolomics describes the large-scale analysis of endogenous metabolites that comprise the entire collection of small molecules in a cell, tissue, organism, or biofluid, and includes sugars, organic acids, amino acids, and nucleotides (2, 3).

Benefits of a Metabolomic Approach

A metabolomic approach has several advantages for use in functional genomics. Firstly, as with transcriptional and proteomic analyses, the technique is context-dependent, such that the metabolite complement varies according to the physiological, developmental, or pathological state of the cell, tissue, organ, or organism, which makes it a highly potent tool for measuring changes in phenotype. Secondly, the importance of metabolites in biological control and communication, as building blocks for complex macromolecules and energy transporters, makes them effective markers of cellular function. Indeed, metabolites constitute molecular endpoints farther down the line from gene to function. Thirdly, metabolic control analysis suggests that, although changes in the quantities of individual enzymes are expected to exert little influence on metabolic fluxes, they can and do have a significant impact on metabolite concentrations, even when changes in flux are negligible. Fourthly, metabolites span the species barrier because they have the same chemical structure irrespective of the organism. Metabolomics is therefore a universal “omic” technology in contrast to transcriptomics and proteomics in which a priori knowledge of DNA and protein sequences from each organism is required. Little time is required for reoptimizing protocols for a new species. Finally, metabolomics presents several practical benefits, including cheap cost on a per sample basis, high throughput, and full automation. For example, after the initial purchase of a nuclear magnetic resonance (NMR) spectrometer or mass spectrometer (MS), samples can be analyzed at a cost in the region of £~1.00 per sample, in terms of consumables, with analytical acquisition times typically taking 10 min (NMR) to 70 min (GC–MS). This cost compares very favorably with transcriptional and proteomic analyses.
Terminology

The terms metabolomics (2) and the related term metabonomics (3) were coined in the late 1990s to describe the use of global profiling tools combined with pattern recognition to define a metabolic phenotype of a cell, tissue, or organism. The confusion over what to call the field is still a persistent problem, and new researchers to the field should be aware of both terms. Many people use the terms metabolomics and metabonomics interchangeably (4, 5). However, Nicholson and coworkers state that metabonomics is the “quantitative measurement of the time-related multiparametric metabolic response of living systems to pathophysiological stimuli or genetic modification,” whereas metabolomics is the “measurement of metabolite concentrations and fluxes and secretion in cells and tissues in which there is a direct connection between the genetic activity, protein activity and the metabolic activity itself” (6). To add more confusion, additional terms have been put forward dependent on the analytical techniques adopted. "Metabolic profiling" has been proposed to refer to the detailed analysis of metabolites by hyphenated techniques such as gas chromatography-(GC)-MS and liquid chromatography-(LC)-MS. In contrast, "metabolic fingerprinting" is thought to measure a subset of metabolites and uses techniques such as NMR and direct infusion electrospray-MS to create a barcode of metabolism (7). The term “metabolomics” will be employed in this article throughout.

Analytical techniques

Metabolomics is challenged by the remarkable heterogeneity and complexity exhibited by metabolites. Metabolites span concentration ranges of the order $10^9$, polarity ranges of $\sim 10^{20}$, and mass ranges of the order of 1500 amu. Moreover, most extraction procedures do not provide complete representations, which results in only a portion of the metabolome being analyzed. A truly comprehensive coverage of the metabolome, therefore, necessitates multiple techniques and different sample preparation strategies to encompass such diversity. The principal analytical platforms for metabolomics include 1H NMR spectroscopy and
Figure 2. The two most frequently used approaches for metabolomics are NMR spectroscopy and mass spectrometry. To maximize the coverage of the metabolome, these techniques can be combined. This figure shows the analysis of the aqueous fraction of a section of heart tissue that uses NMR spectroscopy, gas chromatography mass spectrometry and liquid chromatography mass spectrometry. Although mass spectrometry approaches are inherently more sensitive than NMR spectroscopy, metabolite identification becomes more difficult.

GC- and LC-MS (Fig. 2), although others have also used other techniques including Fourier transform infrared spectroscopy, thin layer chromatography, high-pressure liquid chromatography, and Raman spectroscopy. The major techniques as judged by current number of publications will be discussed below.

Nuclear magnetic resonance spectroscopy

High-resolution $^1$H nuclear magnetic resonance (NMR) spectroscopy is a relatively rapid technique and is highly robust in terms of reproducibility of results. The ubiquity of protons in cellular metabolites and the fact that other nuclei are observable by NMR (e.g., $^{2}$H and $^{13}$C) mean that a relatively large number of different metabolites can be detected. Furthermore, the technique requires minimal sample preparation, and its nondestructive nature allows for more analyses to be conducted. However, $^1$H NMR is an inherently insensitive analytical tool that only measures high-concentration metabolites. Typically, using a simple one-dimensional pulse sequence, $^1$H NMR can measure 30–100 metabolites in urine, 20–30 metabolites in blood plasma, and 10–30 metabolites in tissue extracts (8). Despite this, however, $^1$H NMR has proved highly discriminatory for liver toxins in rats (9, 10), mouse models of cardiac and neurological diseases (11, 12), and silent phenotypes in yeast (13). It has been suggested that this finding may be because of the high-concentration metabolites that represent central hubs of metabolism, whereby a perturbation at one point in a metabolic network would be transferred to other pathways through these highly connected hubs (14, 15). However, restriction the coverage of the metabolome to 30 or so metabolites may hinder the isolation of metabolites as unique biomarkers for disease processes and confound the deduction of which pathways are perturbed during a given modification. Strategies are being...
developed to make NMR a more sensitive approach, including the use of cryoprobes and hyphenated techniques. Cryoprobes use liquid helium to cool down the NMR coil assembly and preamplifier to ~4 K, which, by reducing thermal noise, results in a three- to four-fold increase in the signal-to-noise ratio. Hyphenated techniques involve first separating out high and low concentration metabolites using liquid chromatography. This separation improves sensitivity by reducing the likelihood of corsonant peaks and improves the dynamic range of the NMR experiment (16).

Other NMR-based techniques allow the quantification of metabolite concentrations in intact tissue, either in vivo or ex vivo. For example, magnetic resonance spectroscopy (MRS) allows the noninvasive interrogation of metabolite concentrations directly in vivo within a specific localized region. The technique has proved invaluable in the investigation of Alzheimer’s disease (17, 18), traumatic brain injury (19), multiple sclerosis (20), and many brain tumors (21). However, one disadvantage of MRS is that it is compromised by low spectral resolution, partly as a result of the lower fields used in vivo but also founded by dipolar couplings, chemical shift anisotropy, and bulk magnetic field inhomogeneity effects, which act to broaden spectral resonances. These effects can be reduced dramatically by spinning the sample at the “magic angle” (54.7°).

In vivo spectroscopy, it is possible to produce high-resolution spectra in rat heart mitochondria that were not NMR-visible (22). Demonstrated subcompartments of acetoacetate and glutamine of investigating metabolic compartmentation. A recent study compared metabolites with those in commercially available mass spectral databases (e.g., http://www.nist.gov). Although this approach generally works well, distinction between sugar diastereomers is conditioned by both species having identical fragmentation patterns. In such cases, retention times of standards are imperative for accurate assignments. Furthermore, spectral databases are not exhaustive, and so not all peaks can be assigned. Currently, efforts are being made to create metabolomic-specific mass spectral libraries (26). More detailed characterization of unknown peaks can be conducted by running the same samples using chemical ionization as opposed to electron impact ionization or using ion trap mass spectrometers. Chemical ionization is a less energetic method of ionization and so produces less fragmentation. This method increases the probability of observing the molecular ion and so can facilitate compound identification.

The sensitivity of the GC-MS approach is impressive. Using a simple single quadrupole GC-MS, Frieh and coworkers working on Arabidopsis thaliana reported the detection of 326 metabolites, a number that has since increased to over 1000 using a Time of Flight GC-MS (25, 27). Furthermore, the technique has benefited from recent technological advances in two-dimensional GC (28).

LC-MS provides metabolite separation by LC before detection by MS. Sample derivatization is generally not required because no prerequisite for volatility is necessary. Moreover, LC-MS can analyze a wider array of metabolites relative to GC-MS because it is not limited to volatile compounds or molecules that can be rendered volatile. In particular, thermolabile or large molecules such as di- and triphosphates, CoA adducts, peptides, and lipids are all amenable to analysis by LC-MS (29). Following separation by LC, the compounds are ionized, typically using electrospray ionization (26). The sample is passed through a thin metallic capillary tube that contains positively or negatively charged ions, dependent on the solvent used. Electrospraying of the sample creates a cloud of charged droplets, and desolvation of these droplets results in ions that are sampled by the MS. Because electrospray ionization causes minimal fragmentation of the molecular ion, direct metabolite identification by comparison of mass spectra is often not possible. Structural information can be gained, however, by using tandem MS technologies, whereby sequential and selective fragmentation can be carried out. Moreover, compounds that contain a particular functional moiety can be analyzed by conducting neutral loss experiments.

Mass spectrometry

Mass spectrometry (MS) allows the analysis of lower-concent ration metabolites compared with 1H NMR spectroscopy. However, a comprehensive metabolic analysis by MS often requires sample prefractionation, the most common being gas chromatography (GC) and liquid chromatography (LC). Although this prefractionation improves the resolution of the technique and reduces ion suppression, adding a chromatographic step can introduce variability into a data set. In GC-MS, volatile and thermally stable compounds are first separated by GC and the eluted compounds detected by MS. To maximize the range of compounds that are volatile and thermally stable, samples are usually derivatized before analysis for metabolomic experiments. Methoximation in combination with trimethylsilylation is the most predominant protocol for examining aqueously soluble metabolites (25). Methoximation reduces the number of isomers present for sugars, with the number of isomeric forms being reduced from 5 to 2, which thereby dramatically simplifies chromatograms. Trimethylsilylation replaces exchangeable protons with silyl groups to make compounds less polar and therefore more volatile and to improve chromatography. The derivatized samples are vaporized within an inlet port and injected onto the column where they are carried by an inert gas. Compounds are separated according to their partition between the mobile gas phase and the column-bound stationary phase, and the eluted compounds are subsequently ionized within the ion source. The most frequently used ionization method is electron impact in which a beam of electrons ionizes the sample molecules, which concomitantly fragment. Because the energy of these electrons is preselected, the fragmentation pattern is reproducible and effectively provides a near-unique metabolite fingerprint. Metabolites, therefore, can be identified easily by comparing spectra with those in commercially available mass spectral databases (e.g., http://www.nist.gov). Although this approach generally works well, distinction between sugar diastereomers is conditioned by both species having identical fragmentation patterns. In such cases, retention times of standards are imperative for accurate assignments. Furthermore, spectral databases are not exhaustive, and so not all peaks can be assigned. Currently, efforts are being made to create metabolomic-specific mass spectral libraries (26). More detailed characterization of unknown peaks can be conducted by running the same samples using chemical ionization as opposed to electron impact ionization or using ion trap mass spectrometers. Chemical ionization is a less energetic method of ionization and so produces less fragmentation. This method increases the probability of observing the molecular ion and so can facilitate compound identification.

The sensitivity of the GC-MS approach is impressive. Using a simple single quadrupole GC-MS, Frieh and coworkers working on Arabidopsis thaliana reported the detection of 326 metabolites, a number that has since increased to over 1000 using a Time of Flight GC-MS (25, 27). Furthermore, the technique has benefited from recent technological advances in two-dimensional GC (28).

LC-MS provides metabolite separation by LC before detection by MS. Sample derivatization is generally not required because no prerequisite for volatility is necessary. Moreover, LC-MS can analyze a wider array of metabolites relative to GC-MS because it is not limited to volatile compounds or molecules that can be rendered volatile. In particular, thermolabile or large molecules such as di- and triphosphates, CoA adducts, peptides, and lipids are all amenable to analysis by LC-MS (29). Following separation by LC, the compounds are ionized, typically using electrospray ionization (26). The sample is passed through a thin metallic capillary tube that contains positively or negatively charged ions, dependent on the solvent used. Electrospraying of the sample then creates a cloud of charged droplets, and desolvation of these droplets results in ions that are sampled by the MS. Because electrospray ionization causes minimal fragmentation of the molecular ion, direct metabolite identification by comparison of mass spectra is often not possible. Structural information can be gained, however, by using tandem MS technologies, whereby sequential and selective fragmentations can be carried out. Moreover, compounds that contain a particular functional moiety can be analyzed by conducting neutral loss experiments.
This article, but we refer the reader to several excellent reviews of triglyceride in the heart. Similar modulations of cardiolipin in the myocardium following streptozotocin-induced diabetes proceeding accumulation of proatherogenic lysophosphatidylcholines and decreases in the antioxidant ether phospholipids, which suggests that in these obese individuals the lipid profile was already such that it would promote atherosclerosis, inflammation, and insulin resistance. LC-MS has also been used to follow changes in the aqueous fraction of tissue extracts (31), blood plasma, and urine (30) from rodent models of type II diabetes, but here the largest challenge is identifying the metabolites detected, and often such data has been largely used to classify samples as part of a metabolic fingerprinting study rather than to carry out biomarker identifi-

Relative to GC-MS, the application of LC-MS within the metabolomics field is still at a preliminary stage. Reproducibility is a major concern, and true quantification can be hindered by ion suppression effects whereby one co-eluting metabolite affects the ionization of another (26). The lack of electrospray ionization mass spectral libraries also makes identification by LC-MS a particularly challenging problem. Nevertheless, the technique is developing fast and has benefited from several tech-

nological advancements such as the acquisition of accurate mass data by the use of ion cyclotron resonance Fourier transform MS (26).

It is possible to bypass the chromatography stage and use direct infusion of lipid extracts into the mass spectrometer as part of an approach referred to as shotgun lipidomics. Han and colleagues (32) using this approach demonstrated a profound decrease in cardiolipin in the myocardium follow-

ing streptozotocin-induced diabetes proceeding accumulation of triglyceride in the heart. Similar modulations of cardiolipin metabolism were observed in the ob/ob mouse. Note that an integral part of the metabolomic approach is the application of pattern recognition techniques to deduce what variation in a data set is associated with a given disease, genetic modification, or other manipulation of the system. Because of space limitations, it is not possible to discuss this area as part of this article, but we refer the reader to several excellent reviews (33, 34).

Applications of Metabolomics

Metabolomics has proved extremely versatile with a diversity of applications including the study of gene function, toxicology, plant metabolism, environmental analysis, clinical diagnostics, investigation of disease, and discrimination of organism geno-

types. It is not possible to create a definitive list given the huge number and range of approaches that have now been published, but we have set out some key publications below to demonstrate the potential uses of metabolomics.

Study of gene function

One of the first major successes of metabolomics has been the definition of silent phenotypes in yeast where conventional growth rate analyses failed to distinguish different yeast mu-

tants (12). By using 1H NMR spectroscopy, it was apparent that “silent” yeast mutants have compensatory changes in intracellular metabolites to allow the cells to grow at a normal rate. Mutants deleted for genes of related biological activ-

ity resulted in similar metabolite perturbations and, hence, metabolic profiles, as did strains deleted for genes related to mitochondrial metabolism (12). The authors coined the term FANCY for functional analysis of coreponses in yeast (12) to describe this comparative metabolomics approach. Currently, FANCY is being used to predict gene function. Metabolic pro-

files of strains deleted for known genes are being compared with those deleted for unknown genes in the hope of assigning biological roles.

Plant metabolism

Some of the most significant developments in metabolic profi-

ling, particularly those involving GC-MS, have been made in the plant sciences discipline (35) (Fig. 3). Plants are thought to be exceptionally metabolite-rich relative to mammals and yeast. This richness stems not only from the size of their genomes, which ranges from 20,000 to 50,000 genes, but also from multiple substrate specificities for many enzymes, subcellular compart-

mentation, and nonenzymatic reactions. Currently, 50,000 different compounds have been elucidated in plants (36), and the final number is set to increase to approximately 200,000 (28). Concomitantly, the tools and analytical techniques used in metabolomics have been advanced rapidly by researchers within this field. One major goal of plant metabolomics is to expand the information about how plant biochemistry is composed and controlled. Metabolic profiles have been conducted on a diverse array of plant species, including Arabidopsis thaliana (25), tomato (37), potato (38), and rice (39). Efforts are being focused on characterizing silent plant phenotypes and trying to elucidate biological rules for genes of unknown function. For example, a modified potato plant line suppressed in expres-

sion of sucrose synthase isoform II displayed no overt pheno-
type in terms of morphology, yield, or growth rate compared with parental lines. However, by using GC-time-of-flight MS to analyze the metabolic profiles, approximately 1000 com-

pounds were quantified, and plant varieties were successfully discriminated (38). Similarly, other researchers have integrated transcriptomic and metabolomic analyses to investigate global responses to nutritional stress in Arabidopsis thaliana and have demonstrated that the genes and metabolites involved in glu-

cosinolate metabolism are coordinately regulated in response to either sulphur or nitrogen deficiency (40). Metabolomics has also been employed in characterizing the regulatory synthesis of novel plant products: for example, modified health-related carotenoid and flavonoid-based antioxidants have been isolated by the Metabolic Profiling Laboratory and have been commercialized.

Metabolomics: Topics in Chemical Biology
in transgenic tomatoes (41). Plant–host interactions are also a popular target for metabolomic studies (42, 43).

Environmental science

Metabolomics has made remarkable inroads into the environmental research community. Here, a major emphasis is to understand the impact that environmental stress, such as pollution and climate change, has on wildlife. Indeed, many government organizations monitor the prevalence of pollutants in certain species of wildlife as indicators of the exposure risk within the environment. Studies of Japanese medalia have been conducted to investigate the effects of trichloroethylene, a common environmental pollutant, and the pesticide dinoseb, on the development of fish embryos (44, 45). Similarly, cadmium toxicity has been examined in the bank vole and rat and has revealed changes in lipid metabolism that preceded classical nephrotoxicity (46, 47). A further study investigated the effects of environmental toxins on earthworms (48). In particular, the analysis of earthworm tissue extracts by 1H NMR spectroscopy identified maltose as a potential biomarker for ecotoxicity within a metal-contaminated site.

Clinical diagnostics

Metabolomics is well suited to clinical trials, and as more efficient and comprehensive analytical tools become available, a wealth of additional information can be gathered from costly clinical trials without increasing the level of discomfort to the patient or decreasing the practicality to the physician. The fact that all the technologies involved in metabolomics are relatively high-throughput means that large-scale clinical studies can be performed. Makinen and coworkers (49) examined the use of 1H NMR spectroscopy of blood serum to diagnose diabetic nephropathy in 182 sufferers of type 1 diabetes. This approach relied, in part, on modeling the different distributions of lipoprotein fractions and produced a test approximately as good as that used clinically. The group has since developed a Bayesian Markov chain Monte Carlo approach to modeling the constituents of the saturated lipid profile in blood serum of α null mice. Metabolites are identified from exact retention times and comparison of corresponding mass spectra with those in the NIST database. 97 metabolites were quantified.

Figure 3 An example of the use of GC-MS for metabolic profiling. Left: A section of the total ion chromatogram from the analysis of TMS-derivatized aqueous tissue extracts from the liver of PPAR-α null mouse. Metabolites are identified from exact retention times and comparison of corresponding mass spectra with those in the NIST database. 97 metabolites were quantified. Right: Summary of metabolite differences in the tissues of the PPAR-α null mouse. Red: increased relative to control, blue: decreased relative to control. The increased/decreased width of certain arrows reflects relative increased/decreased concentrations across these pathways, respectively.
Metabolomics is becoming a prominent phenotyping aid to the investigation of animal models of disease and discrimination of organism genotypes. Metabolomics is ideally placed as a phenotyping tool in the exploration of naturally occurring and transgenic disease models. The refinement of knockout and knockin strategies combined with accumulating sequence data has accelerated the generation of accurate disease models. Moreover, large-scale mouse mutagenesis programs have been set up, which have produced thousands of mutants in need of analysis (57). Screening for congenital malformations and biochemical, hematological, and immunological defects is extremely labor-intensive and time-consuming. Furthermore, many models do not express the same phenotype as humans and often display a milder pathology such that it is difficult to assess the effects of genetic perturbation. This situation, in part, reflects the shorter life span of model organisms such as mice when compared with humans.

Metabolomics is becoming a prominent phenotyping aid to characterize tissues and organisms rapidly within a biological context. For example, using a metabolomics-guided screen of mutant mice, a mouse model with a novel enzyme deficiency that resembles human maple syrup urine disease has been isolated (58). Mice were identified as having elevated levels of branched chain amino acids in blood and increased concentrations of branched chain u-keto acids in urine. Mere observation correlated these results with a deficiency in branched chain amino-transferase. Other researchers have used metabolomics to characterize the metabolic deficits associated with a particular disease process, for example, human metabolic syndrome. For example, the systemic effects of the PPAR**α** mutation, a gene important in regulating the feeding/fasting response, have recently been defined; using a combination of **1**H NMR and GC-MS, metabolic changes have been followed in the heart, liver, skeletal muscle, and adipose tissue of the PPAR**α** null mouse (31). Similar metabolic profiling approaches have also been conducted to investigate cardiac disease in the mdx mouse (10) and atherosclerosis in the ApoE3-Leiden mouse (59).

Metabolomic techniques have also been used widely to phenotype neurological disorders, with a diverse array of applications including the characterization of regional variation, brain tumors, and neurological disorders (60-64). Because the brain is heavily compartmentalized, a recent study used metabolic profiling to characterize distinct neuroanatomical regions in rats ex vivo by high-resolution magic angle spinning **1**H NMR (61). Such lipids are easily detectable in vivo by magnetic resonance spectroscopy and could be used to monitor the efficacy of gene therapy in patients with glioma. As a complement to this study (65), the low molecular weight intermediate composition of the same rat gliomas was quantified subsequently, and it was demonstrated that myo-inositol, glycine, and taurine concentrations correlated with tumor cell density, whereas the
Conclusions and Future Trends

Although the coinage of the term metabolomics has been relatively new, an explosion of publications has occurred in this field plus a realization that many researchers already were doing similar studies, albeit without an “-omic” tag before the word. It has not been possible to review all the applications of metabolomics fully, and the applications will increase. In addition to the development of new applications, the development of the analytical approaches will also take center stage as researchers push back the limits of detection of NMR spectroscopy, mass spectrometry, and other analytical approaches. In addition to these “wet lab” developments, both the pattern recognition approaches used to process metabolomics and the metabolomic databases used to identify metabolites need to be developed or expanded. In this respect, an excellent place to start on the arduous journey to biomarker discovery through metabolomics is the current metabolomic databases found on the web that make standard spectra freely available (68–70).

The Pentose Phosphate Pathway: An Overview

John F. Williams, Research School of Chemistry, Institute of Advanced Studies, The Australian National University, Canberra, Australia
doi: 10.1002/9780470048672.wecb433

The elementary textbook treatment of the pentose phosphate pathway (PPP) describes its nature and occurrence in the cytoplasm of most cells. The reaction scheme is of two segments, oxidative and nonoxidative. The reactions of the oxidative segment are few and involve the decarboxylation of glucose 6-phosphate (Glc 6-P) to ribulose 5-phosphate (Ru 5-P) and CO₂ via 6-phosphogluconolactone and 6-phosphogluconate (6-PG). Concomitant production of two moles of NADPH and H⁺ for each mole of Glc 6-P converted to Ru 5-P. The nonoxidative reactions are depicted classically with an ordered reaction sequence of reversible steps for the interconversion of other pentose phosphate products that originate from Ru 5-P by epimerase and isomerase enzymes. The reactions of the PPP also link the formation of sugar phosphate intermediates (glycolyl units) containing 3–7 carbon atoms that are generated by freely reversible equilibrium reactions catalyzed in fixed order by Transketolase and Transaldolase. These reactions permit the following three biosynthetic PPP functions to emerge: cellular energetics, growth, and repair. Specifically via 1) the contribution by the oxidative segment of a high NADPH / NADP⁺ redox potential that provides electrons for most reductive anabolic processes; 2) the formation of ribose 5-phosphate (Rib 5-P) for all nucleotide and nucleic acid biosynthesis, which is a demand that does not usually exceed 2% of all Glc metabolized by PPP activity; and (c) a storage pool of diverse phosphorylated glycolyl units that may be used directly or as signals for biosynthetic and energy-yielding reactions by other pathways. Finally, selected reactions of the nonoxidative segment are also part of the most extensive synthetic and life-sustaining event on the planet, namely the photosynthetic reductive path of CO₂ assimilation in all C-3 plants.

The Reactions and Significance

The Reactions and Significance of the Oxidative Segment

The first step in the discovery of the PPP commenced in the autumn of 1929 when Otto Warburg, a German biochemist and Nobel Laureate, was the dominant figure in the unravelling of the chemistry of the PPP (Fig. 1) reactions. Bernard L. Horecker, an American enzymologist, who had unjustifiably claim much of that distinction for the scheme (2).

The Pentose Phosphate Pathway: An Overview

The Oxidative Segment of the Pentose Pathway

to witness a demonstration of some remarkable and puzzling results that Barron and Harrop had published recently (3). The demonstration involved a simple system, namely, the reaction of glucose with non-nucleated erythrocytes in the presence and absence of methylene blue (MeB). Methylene blue is one of a large number of organic dyes that form electromotively active oxidation–reduction systems. MeB had been used successfully by Torsten Thunberg, during the previous decade, for the identification of many dehydrogenase reactions. However, considerable diplomacy was needed for a peaceful presentation of the Barron reaction system because Warburg had been publicly scathing in condemnation of biochemical reactions that included MeB. Notwithstanding this prejudice, when Warburg observed the outcome of the Barron experiments, he was truly astonished. In 1929, it was accepted that all glucose metabolism in erythrocytes was by glycolysis with the formation of two equivalents of lactate, which were diffused by the cells. Contrary to this expectation, the Barron data with MeB as a reactant showed a 50% suppression of the extent of glycolysis and lactate formation while the rate and extent of glucose utilisation was maintained and accompanied by a rapid oxygen uptake. Florink (4) wrote, "In Baltimore Warburg clearly saw, for the first time in his experience, a dehydrogenase at work even though methylene blue was involved."

Warburg returned to Berlin where, with his colleague W. Christian, he repeated and extended the Barron work and over the next 18 months showed that the phenomenon, which was first witnessed in Baltimore, comprised the following sequence of reactions (reactions (1)–(5)).

D-glucose 6-P + H2O + 2 NADP+ → CO2 + pentose-5-P + 2 NADPH + 2 H+ (1)

2 NADPH + 2 H+ + 2 FMN → 2 NADP+ + 2 FMNH2 (Rapid reaction) (2)

2 FMNH2 + O2 → 2 FMN + 2 H2O (Slow reaction) (3)

2 FMNH3 + 2 MeB → 2 FMN + 2 MeB H+ + 2 H+ (Fast reaction) (4)

2 MeB H+ + 2 H+ + O2 → 2 MeB + 2 H2O (Very fast reaction) (5)

Reactions (1)–(5) encompass the disclosure of 1) the reactions of the oxidative segment of the PPP, 2) the discovery of a new pyridine nucleotide-NADP+ and 3) the detection of a flavin mononucleotide (FMN) flavoprotein (initially called "Old yellow enzyme") and the recognition of its role as a catalytic carrier of reducing equivalents from reduced pyridine nucleotide to molecular oxygen via MeB. No contradiction can exist that the unravelling of the reactions of reactions (1)–(5) marked a historic moment of high achievement in biochemical research. The achievement was to lead Warburg and Christian to discover and characterize glucose 6-phosphate dehydrogenase (Zwischenferment) (Glc 6-PDH) (EC 1.1.1.49) and NADP+ (Wasserstoffübertragenden).

In 1931, Warburg and Christian (5) reported the first discoveries on Glc 6-PDH and the conversion of glucose 6-phosphate (Glc 6-P) to 6-phosphoglucono-δ-lactone, $K_{eq} = 6 \times 10^7$ (Fig. 1). Warburg thereby established the existence of new reactions for the oxidative metabolism of glucose that differed from those of the Emden-Meyerhof glycolytic pathway. During the next decade, Warburg, Dickens, Lipmann, Diche, and others showed, among other things, that the above lactone, a potential acid, was hydrolyzed by lactonase (EC 3.1.1.17) to form 6-phosphogluconic acid (6-PG). The thermodynamic constants for the combined actions of Glc 6-PDH

to witness a demonstration of some remarkable and puzzling results that Barron and Harrop had published recently (3). The demonstration involved a simple system, namely, the reaction of glucose with non-nucleated erythrocytes in the presence and absence of methylene blue (MeB). Methylene blue is one of a large number of organic dyes that form electromotively active oxidation–reduction systems. MeB had been used successfully by Torsten Thunberg, during the previous decade, for the identification of many dehydrogenase reactions. However, considerable diplomacy was needed for a peaceful presentation of the Barron reaction system because Warburg had been publicly scathing in condemnation of biochemical reactions that included MeB. Notwithstanding this prejudice, when Warburg observed the outcome of the Barron experiments, he was truly astonished. In 1929, it was accepted that all glucose metabolism in erythrocytes was by glycolysis with the formation of two equivalents of lactate, which were diffused by the cells. Contrary to this expectation, the Barron data with MeB as a reactant showed a 50% suppression of the extent of glycolysis and lactate formation while the rate and extent of glucose utilisation was maintained and accompanied by a rapid oxygen uptake. Florink (4) wrote, "In Baltimore Warburg clearly saw, for the first time in his experience, a dehydrogenase at work even though methylene blue was involved."

Warburg returned to Berlin where, with his colleague W. Christian, he repeated and extended the Barron work and over the next 18 months showed that the phenomenon, which was first witnessed in Baltimore, comprised the following sequence of reactions (reactions (1)–(5)).

D-glucose 6-P + H2O + 2 NADP+ → CO2 + pentose-5-P + 2 NADPH + 2 H+ (1)

2 NADPH + 2 H+ + 2 FMN → 2 NADP+ + 2 FMNH2 (Rapid reaction) (2)

2 FMNH2 + O2 → 2 FMN + 2 H2O (Slow reaction) (3)

2 FMNH3 + 2 MeB → 2 FMN + 2 MeB H+ + 2 H+ (Fast reaction) (4)

2 MeB H+ + 2 H+ + O2 → 2 MeB + 2 H2O (Very fast reaction) (5)

Reactions (1)–(5) encompass the disclosure of 1) the reactions of the oxidative segment of the PPP, 2) the discovery of a new pyridine nucleotide-NADP+, and 3) the detection of a flavin mononucleotide (FMN) flavoprotein (initially called "Old yellow enzyme") and the recognition of its role as a catalytic carrier of reducing equivalents from reduced pyridine nucleotide to molecular oxygen via MeB. No contradiction can exist that the unravelling of the reactions of reactions (1)–(5) marked a historic moment of high achievement in biochemical research. The achievement was to lead Warburg and Christian to discover and characterize glucose 6-phosphate dehydrogenase (Zwischenferment) (Glc 6-PDH) (EC 1.1.1.49) and NADP+ (Wasserstoffübertragenden).

In 1931, Warburg and Christian (5) reported the first discoveries on Glc 6-PDH and the conversion of glucose 6-phosphate (Glc 6-P) to 6-phosphoglucono-δ-lactone, $K_{eq} = 6 \times 10^7$ (Fig. 1). Warburg thereby established the existence of new reactions for the oxidative metabolism of glucose that differed from those of the Emden-Meyerhof glycolytic pathway. During the next decade, Warburg, Dickens, Lipmann, Diche, and others showed, among other things, that the above lactone, a potential acid, was hydrolyzed by lactonase (EC 3.1.1.17) to form 6-phosphogluconic acid (6-PG). The thermodynamic constants for the combined actions of Glc 6-PDH
The F-type Pentose Pathway

![Diagram of the F-type Pentose Pathway]

The sum reaction for the oxidative segment of the PPP is

$$\text{Glc 6-P} + \text{NADP}^+ + \text{O}_{2} \rightarrow \text{G6P} + \text{NADPH} + \text{H}^+$$

The cellular oxidant/antioxidant balance is also dependent on the oxidative damage to DNA, lipids, and proteins. The regulation of the following reactive oxygen system (ROS) enzymes: glutathione reductase, glutathione peroxidase, catalase, superoxide dismutase, NADPH oxidase, and nitric oxide synthase depend on the high value of the NADPH/NADP⁺ ratio (approximately 80/1, compared with 8.6 × 10⁻⁴ for the cytoplasmic NADH/NAD⁺ ratio) as the source of cytoplasmic reducing power (electrons) for biosynthetic and other reactions that require reducing equivalents in aerobic organisms. A reducing equivalent is equal to one electron or one hydrogen atom. Although the PPP is the most usual source of biosynthetic reducing power in cytoplasm, a singular outstanding exception to this generality was found in adipose tissue by Flatt and Ball (12), who showed that 50% of the very large demand for NADPH was supplied by the action of L-malate:NADP⁺ oxidoreductase (oxaloacetate decarboxylating [EC 1.1.1.40]), and the remaining half was supplied by the PPP.

Glc 6-P DH exists in multiple molecular forms and is subject to wide genetic, endocrine, and nutritional variability. Its deficiency is the most common enzymopathy in humans. It is also the most sensitively regulated enzyme in the whole array of reactions comprising the oxidative and nonoxidative segments of the PPP (Figs. 1 and 2). More than a dozen pathways of biosynthesis use NADPH as a substrate (e.g., synthesis of fatty acids, steroids, some photosynthetic products, isoprenoids, sphingosines, phenylalanine and tyrosine, seminal fructose, 3-hydroxykynurenine, and NAD⁺). A high level of unbound NADP⁺ is mandatory for the reductions of oxidized glutathione, dihydrofolate, D-glucuronate, ribonucleotides, cytochrome P450, nitrate and nitrite, glucose production from pyruvate via malate, and the hydroxylation of some fatty acids. The cellular oxidant/antioxidant balance is also dependent on NADPH production principally derived from PPP activity. The regulation of the following reactive oxygen system (ROS) enzymes: glutathione reductase, glutathione peroxidase, catalase, superoxide dismutase, NADPH oxidase, and nitric oxide synthase depend on the high value of the NADPH/NADP⁺ redox couple. Thus, Glc 6-P DH has a pivotal role in the management of oxidative stress and its consequences in normal physiology and pathophysiologic events such as carcinogenesis and aging. Consult Reference 13 for a review of Glucose 6-phosphate dehydrogenase and Reference 14 for a brief review of all other enzymes shown in Figs. 1 and 2.
The Reactions of the Nonoxidative Segment

A synoptic survey of the unravelling of the nonoxidative segment is presented in the latest comprehensive review of the PPP (1). The treatment covers the chemistry of reactions, enzymes, methods, tissue distributions, and the mathematical theory for the quantitation of metabolism by a theoretical connection of the pathways of Figs. 1 and 2 into a pentose phosphate cycle (PC).

Early Discoveries

The initial investigations that lead to chemical knowledge of the pathway of Fig. 2 were indirect and not planned to that end as the following narration will show. Warburg's proposition linking NADPH and respiration (reactions (2)-(4)) was shared by Erwin Haas who was a member of Warburg's Berlin-Dahlem laboratory. Haas departed Germany in 1938 and proceeded to the laboratory of Professor T. R. Hogness (University of Chicago), where he met Bernard Horecker, who had just completed Ph.D. training in enzymology. Haas was a meticulous scientist who possessed much of Warburg's data and methods (of which he was something of a master) and a plan of research to test the proposed role of NADPH in respiration. Haas and Horecker set out to isolate a putative NADPH-cytochrome reductase (reaction (6)) in order to demonstrate the existence and nature of an enzyme that was hypothesized to be the missing link in a respiratory pathway between reduced pyridine nucleotide and oxygen via the cytochrome system (reactions (7) and (8)).

NADPH + H+ + Cyt-C Fe3+ → NADP+ + Cyt-C Fe2+ + 2H

Cytochrome Oxidase (EC 1.9.3.1)

2H + Cyt-C Fe2+ + 0.5O2 → H2O + Cyt-C Fe3+ (8)

Sum Reaction

NADPH + H+ + 0.5O2 → NADP+ + H2O

The search for an enzyme activity was successful, and a reasonably pure flavoprotein, NADPH-cytochrome c reductase (EC 1.6.2.4), was isolated from yeast (15). It was then 1940, and basic research was interrupted and not taken up again until the end of the Second World War. During that interval, Horecker worked on war-related programs, was appointed to the staff of the National Institutes of Health, and in 1945 returned to basic research in enzymology. He proceeded to isolate NADPH-cytochrome c reductase from acetone-dried extracts of pig liver (16), at a time that was almost coincident with the report of Lehninger (10) that NADH was the substrate of respiration. As listed above, the true acceptor for NADPH-cytochrome c is cytochrome P450. This natural disappointment drew attention to a much larger problem, namely an inquiry into the chemistry, enzymology, and metabolic fate of the pentose phosphate product of Fig. 1. The British biochemist, Frank Dickens (Courtauld Institute, London U.K.), had been making pioneering investigations on this topic since 1936. However, a solution of the problem was going to be made in the United States, where metabolic biochemistry and enzymology flourished in the post-war vigour of the 1950s. It is helpful to note the intense interest at the time in the nature and significance of the new pathway of Glc 6-P oxidation. Important findings were going to be made in the laboratories of Bernard Horecker, Ephraim Racker, Seymour Cohen, Bernard Axelrod, and Gilbert Ashwell. Moreover, a most promotive stimulus was the outstanding investigation then being made by Melvin Calvin and colleagues at UC Berkeley. Their work was to lead to a Nobel Prize and to our current chemical appreciation of the path of reductive carbon fixation by photosynthesis (PS). Calvin’s great progress, during 1950-1955, was heavily dependent on success by the above biochemists to solve the chemical and enzymological problems posed by the reactions of Fig. 2. A notable number of the intermediates and enzymes of Fig. 2 were identified as reactants in the path of carbon in PS (17). Also, Horecker made early and successful attempts to compete with Calvin in the quest to map the enzymology of the carbon reduction cycle. By 1950 all investigators possessed strong clues that were to serve as signposts for an ultimate elucidation of a PPP reaction scheme. These signposts were 1) clear evidence that an alternative path of Glc 6-P oxidation existed in yeast, some bacteria, red cells, liver, and other animal tissues. 2) Dickens (18) had confirmed that 6-PG was decarboxylated oxidatively at carbon one to yield ribose 5-phosphate (Rib 5-P) and other sugar phosphate products (all unresolved), including a putative tetrose P. He also demonstrated that Rib 5-P was oxidized at five times the rates of arabinose 5-phosphate (Ara 5-P) and xylose 5-P, both of which are theoretical products of 6-PG decarboxylation. 3) Finally, Dische (19) reported that inosine monophosphate was oxidized to xanthosine by xanthine oxidase. This last important finding of possible end products of Rib 5-P dissimilation was confirmed by Waldvogel and Schlenk (20) who showed Glc 6-P formation from Rib 5-P using rat liver extracts.

Post-1950 Discovery of Reactions for the Nonoxidative Segment of the PPP

With the above background, between 1950 and 1955, a breathing-taking series followed of discoveries of enzyme and substrate reactivities that were destined to be incorporated into a reaction scheme (mechanism) for the classic nonoxidative PPP (Fig. 2). The Fig. 2 diagram has also been given the prefix F-type (for fat-cell) PPP. Williams et al. (1), because its ordered reaction sequence was later shown to measure uniquely a large contribution (50%) to metabolism when Glc was converted to fatty acids.
acids and triglyceride by insulin-stimulated adipocytes (12, 21, 22). An assembly of reaction steps for the scheme of Fig. 2 may be theorized using the conjunction of results from the following temporal list of events. In 1951, Cohen’s group (23) showed that Rib 5-P and Ara 5-P were formed from 6-PG oxidation. Rib 5-P formation was confirmed by Horecker et al. (7) who also proved unequivocally that Ru 5-P was the first pentose-P formed when 6-PG was decarboxylated. A new enzyme, Ribose 5-phosphate isomerase (R 5-P I) (EC 5.3.1.6), that catalyzed the interconversion of the two pentose phosphates was also proposed (7) (Fig. 2). A very active preparation of R 5-P I from Alfalfa (24) was used to demonstrate its reaction and equilibrium. Horecker and Smythidios (25) used a liver enzyme preparation with Rib 5-P to note the formation of an initially high concentration of se-dihydroxyacetone 7-phosphate (Seh 7-P). This seven-carbon ketulose ester had been found originally and was characterized by Andy Benson et al. (26) in Calvin’s laboratory, and it was shown to be an early product of PS carbon fixation. Seh 7-P was formed by the action of Transketolase (TK) (EC 2.2.1.1) (Fig. 2). TK was discovered by Racker and his collaborators (28–29) who demonstrated that it catalyzed the transfer of a two-carbon fragment (an active glycolaldehyde group) from appropriately structured ketulose-sugar donors to a wide selection of aldo-sugar acceptors (Reference 1, p. 754). Two of its donor transfer actions, using different aldo-acceptors, are shown as blue rectangular panels in Fig. 2. TK requires Mg2+ and thiamine pyrophosphate (TPP) as a coenzyme, and a two-carbon group is transferred to its acceptor via an hydroxyethyl-TPP intermediate. A list of 15 of its glycolaldehyde acceptor substrates is tabulated (Reference 1, p. 754). Horecker’s group (30) discovered a second broad specificity group transferring enzyme, namely Transaldolase (TA) (EC 2.2.1.2), which catalyzed the reversible transfer of a three-carbon dihydroxyacetone-enzyme-bound moiety (shown as red panels in Fig. 2) from Seh 7-P to glyceraldehyde-3-phosphate (Gra 3-P). This reaction formed Fru 6-P and a presumed tetrose phosphate that owed its assigned identity more to biochemistry because it was neither isolated nor identified. The availability of synthetic erythrose 3-phosphate (Ery 4-P) enabled Kornberg and Racker (31) to demonstrate the reversal of the TA reaction [reaction (9)]; thus, an authentic reason for its inclusion as an intermediate in the reaction scheme of Fig. 2 was provided. Ery 4-P probably only exists in exceedingly low concentration in any tissue, and to date, no evidence exists that it has ever been measured correctly in, nor isolated from, any preparation carrying out PPP or PS metabolism in vivo or in vitro (32, 33).

Fru 6-P + Ery 4-P ←→ Seh 7-P + Gra 3-P (9)

A third ketopentulose ester, xylulose 5-phosphate (Xlu 5-P) (Fig. 2), was isolated as a product of Rib 5-P metabolism by Ashwell and Hickman (34). It was also shown by Srere et al. (35) that Xlu 5-P, rather than the earlier assigned Ru 5-P, was a definitive substrate of TK. Ribulose 5-phosphate-3′-epimerase (Fig. 2) catalyzed the formation of Xlu 5-P and imparted the transconfiguration to the hydroxyls at carbons 3 and 4, which is a necessary stereochemical condition for substrate reactivity with TK. The 3′-epimerase was purified from a bacterial source by Stumpf and Racker (36) and from muscle by Dickens and Williamson (37). In summary, the above research seemed to uncover an array of substrates and enzymes that satisfied a minimum requirement for inclusion in a new pathway that connected the product of 6-PG decarboxylation with the formation of hexose and triose phosphates. A prescient Racker (38) was the first to present Fig. 2, a theoretical cyclic metabolic pathway with stoichiometry for an ensemble of the above reactants and enzymes.

Search for an Order of Reactions in the Nonoxidative PPP

It is possible to draw various theoretical schemes that oblige the arithmetic conjuction of five-carbon sugars with a summary outcome of sugar products that contain six-carbon and three-carbon atoms, respectively (39). That variety is greatly enhanced if reactions catalyzed by aldolase (Ald) (EC 4.1.2.13) are included. Aldolase occupies the same cellular compartment as all other enzymes of the PPP; it is a dihydroxyacetone 3-phosphate (DHAP) group transferring enzyme, with a catalytic capacity that is usually much greater than TK or TA (a notable exception is adipose tissue where Ald activity is low (21, 22) and only approximates the activity of TK and TA). Ald also has a broad substrate array of aldo-sugar phosphate acceptors (Reference 1, p.754), most of which are the same substrates as those involved in TK and TA reactions. It has never been clear why the pioneering investigators of the nonoxidative PPP assigned aldolase a role of catalytic silence.

The results of the only foundational experiments that explored the identity of a reaction sequence (mechanism) for the PPP were published by the Horecker group (40, 41). Detailed treatment of the conduct and conclusions of these important, but rarely discussed, experiments is given in References 1 and 42. A predication labeling technique that used (1-14C) and (2,3,4-14C)-Rib 5-P as substrates was adopted. These substrates were reacted with fractionated enzyme extracts of acetone powder preparations from rat liver, pea leaf, and pea root tissues and formed, among other intermediates, C14-labeled Glc-6-P (Fig. 3). It was anticipated that both the position and the amount of 14C-label imparted to the Glc 6-P formed by the above substrates would reveal the nature and order of the reactions involved in its formation. Because the enzyme extracts were made from acetone-dried powders, they were free of all nucleotides (40, 42). This strategy confirmed the dissimilation of labeled Rib 5-P to a hexose 6-P end point. Glc 6-P could not recycle, and the labeled prediction pattern was not scrambled. Mg2+ was also omitted from the reaction mixture to inhibit the activity of Fructose bisphosphatase (EC 3.1.3.11) and production of a contaminating 6-P from 1,6-P2 formed by aldolase and the triose-P products of the TK reactions. It is curious that Fru 1,6-P2, which is an Ald product, was formed (Fig. 3) by the liver and pea tissue reaction mixtures but was omitted from the final construction of the scheme for Fig. 2. The experiments with liver enzyme preparation were of a 17-hour duration (Fig. 3). Ribose 5-P was used rapidly during the experiments.
with a C-1/C-3 isotope ratio of 3 (74% of the C-14 isotope in C-1 and 24% in C-3) (40). With a sense of caution, Horecker (40) proposed an tentative chart of the PPP or pentose cycle (PC). It is astonishing that such substandard and unacceptable disagreement between practice and theory was so uncritically ignored by the general community of biochemists. Harland Wood (46) was an exception: he reported a tolerant suspension of the [1-14C]-Rib 5-P data and total rejection of any claim for predictive value by the [2,3-14C]-Rib 5-P results. It was suggested (46) that an as yet unidentified pathway was operated by the above enzyme fractions. Notwithstanding the rejection by Wood (46), without anymore revision, a placid acceptance followed as well as an equally prompt inclusion of F-type PPP into the canon of metabolic biochemistry. Two independent investigators did test the mechanism of the PPP; the first by Katz et al. (47) used [1-14C]-Rib metabolism in liver slices, and the other by Hiatt (48) used the same labeled substrate in mouse liver in vivo. These investigators did not find 14C distributions in the glucose product with twice as much isotope in C-1 as C-3, but instead they found these carbons were equally labeled. These independent failures to confirm the predictions of Fig. 2 were also ignored. Finally it is important to note that inclusion of several PPP enzymes and reactants in the Path of Carbon in P5 gratuitously added an aura of confidence and prestige to the status of the tentative PPP. Thus, 1955 marked an end of the second contentious period in the unraveling of the pathway.

Other than immensely valuable research by Patricia McLean and her collaborators at the Courtauld Institute, U.K., and investigations by Karl Brand at the Max Planck Inst, Dortmund, Germany, fundamental research on the mechanism of the PPP essentially ceased by 1957 and was not resumed for another decade. Instead the era of the quantitative measurement of pathways of carbohydrate metabolism had dawned and PPP measurements featured hugely. This emphasis on quantitation is best summarized in the following quotation from H. G. Wood (46): “The determination of the relative role of different pathways in normal living cells is without doubt of the greatest fundamental importance to our understanding of life processes and will in the future require more attention in all fields of metabolism.” Later Wood and Katz collaborated (49, 50) and during the next eight years developed theory and methods for the measurement of an entity denoted by Wood (46) and later stringently defined by Wood and Katz (49) as PC. The PC definition directed the following set of ordered events: (i) the entry of three moles of Glc 6-P into metabolism by the oxidative

Pentose Cycle

The Pentose Phosphate Pathway: An Overview

Measurement of the Pentose Cycle: Theory and Practice

Search for an Alternative Reaction Scheme for the Pentose Pathway

A detailed treatment of this topic, including the derivation of some important mathematical expressions is given in Reference 1 (pp.753–762), and only a summary of the essentials will be presented here. Between 1958 and 1979, a dozen theoretical papers were published that provided the mathematical basis and formulas for measuring the F-type PC by the application of 14C-specifically labeled substrates. The method of measurement depended on an exact solution of the problem posed by the recycling and, thus, changes to 14C isotope distributions in Glc 6-P, which emerge from the metabolism of the substrates (2,14C)-glucose or (3,3-14C)-glucose in PC. Calculating the different distributions of labeled carbon to infinite cycles, for all percentage contributions of PC, is a difficult mathematical problem that was solved entirely by Joseph Katz. Katz is not only a gifted biochemist but also an equally talented mathematician and innovative metabolic theorist. The acceptance of a PC definition imposed an agreement that all 14C-labeled Fru 6-P formed by the reaction sequence is converted to Glc 6-P and recycled again through the oxidative segment reactions. The quintessence of all measurement methods has involved the development of mathematical expressions that describe the mathematical and ordered redistributions of either carbons 2 or 3 from labeled substrate glucose, into positions 1, 2, and 3 of the hexose 6-P products for any percentage contribution of PC. Such a theoretical distribution is a unique property of the PC. Experimental data for the C-1/C-2 and C-3/C-2 ratios, which have definite limits and values imposed by Katz and Wood theory (49, 50), are used in specially derived equations that calculate the PC contribution relative to the total metabolism of glucose. The above statements cannot be qualified. They derive from the fixed order of the reactions of Fig. 2, which is the mechanistic basis for all the formulas of all the measurement papers (Reference 1, p. 753). The amounts of 14C in C-1, C-2, and C-3 are derived from their earlier reservation and criticism of the substandard evidence for the reaction sequence of PPP (48) and the failure (by JK) to confirm its presence in liver (Reference 1, p. 766). Liver is a very rich source of the enzymes of the PPP (6, 14, 42, 52), and it provides, among other things, a ready display of the reactions of Figs. 1 and 2. Thus, the failure by all measurement investigations to find an F-type PC in liver was mystifying. The mystery deepened when it was noted that the formulation of their elegant measurement theory required Katz and Wood to abandon, indeed fail to mention, their earlier reservation and criticism of the substandard evidence for the reaction sequence of PPP (48) and the failure (by JK) to confirm its presence in liver (47).
The L-Type Pentose Cycle

The following three sets of findings summarize selected aspects of progress in the unraveling of a new PPP reaction sequence in liver that was found to measure 20-30% of total glucose metabolism. The experimental history of these events is fully recorded by Williams et al. in References 42 and 53 and in Reference 1 (pp. 766-798).

First, the foundational experiments that established the F-type PPP were repeated using [L-14C]Rib 5-P and the same rat liver enzyme preparation. However, the reaction mixture was sampled for the labeled Glc 6-P product at a series of much shorter time intervals and right up to the 17-hour termination point that was described for the original work. The results (Table 2) showed a patterned assortment of label distributions in Glc 6-P, which drifted from 8 hours to 17 hours toward the isotope composition in C-1 and C-3 that was noted originally by Horecker et al. (40). However, in this study, the C-1:C-3 ratio at 17 hours was the prized value of 2. Moreover in the seven time samples, which commenced at 1 minute, Glc 6-P was heavily labeled in C-2, C-4, and C-6, whereas C-1 and C-3 only began to accumulate 14C-isotope after 3 hours of reaction. Although this was a study in vitro, it is obvious that liver cells in vivo do not take between 3 and 17 hours to elaborate a path of metabolism and that more enlightening events were being revealed by the isotope distributions in the samples analyzed between 1 minute and 30 minutes of reaction. Second, a carbon balance analysis of all compounds in the various reaction mixtures showed that the intermediates of Fig. 2 only accounted for 80% of the carbon in the Rib 5-P substrate (42). The compounds comprising the missing 20% were identified as sugar phosphates, mostly ketolases (Fig. 4). These new reactants were isolated, shown to be radioactive, and identified as Seh 1,7-P2, D-manno-Heptulose 7-P, D-glycero-d-altro-Octulose 1,8-P2, (D-g-D-a-Oct); D-glycero-d-idulo-Octulose 1,8-P2, (D-g-D-i-Oct) and a small amount of Ara 5-P (42). Octulose monophosphates and bisphosphates and Seh 1,7-P2 were measured in fresh liver by Paoletti et al. (54) and in spinach chloroplasts by Flanagan et al. (33). Last, the structures and order of the reactions of these sugar esters in a new and much modified reaction scheme for the PPP in liver are shown in Fig. 4. The new intermediary compounds were isolated easily from all incubations from 30 minutes to 17 hours. The scheme of Fig. 4 shows the new PPP with prediction 14C-labeling patterns in the intermediates and products of the reactions. The reaction scheme of Fig. 4 was formulated initially from the distributions of 14C in the labeled Glc 6-P (42) and D-g-D-a-Oct 1,8-P2 (55) formed from [L-14C]Rib 5-P during the early intervals of the repeat of the foundational experiment (42). The new pathway, called L-(liver) type PPP, is distinguished from depictions of the classic F-type PPP by the inclusions of Seh 1,7-P2 and octulose-(D-G)-monophosphates and bisphosphates together with Ara 5-P as new intermediates. Aldolase, phosphotransferase (PT), and D-Arabino-s-phosphate ketol isomerase (EC 5.3.1.13) are new enzymes. The effects of mass transfer catalysis by TA were TA-exchange reactions (TA-ex.), which contributed the [4,6-14C]-labeling pattern to Glc 6-P during the first 8 hours were active (1, 42, 56). The TK reaction forming hexose 6-P in the L-type PPP (Fig. 4) used D-g-D-i-Oct 1,8-P2 as substrate. TK and Ald were also very active exchange catalysts (57-59).

A clear demonstration that aldolase is a mandatory catalyst in liver PPP involved the immunochromic evidence of Bleakley et al. (43) who showed the total cessation of hexose 6-P formation when liver aldolase antibody titrated the removal of aldolase from the system where Rib 5-P was reacted with the same rat liver enzyme preparation that established the Fig. 2 scheme. Irrespective of the other contrary data, this evidence alone showed another reaction mechanism involved Ald in liver PPP. The claim that aldolase is an essential enzyme in the PPP was also supported by data of (60) in which, using an in vitro construction of a PPP preparation for the complete oxidation of Glc, noted the formation of Oct-P and the need to include aldolase and sedoheptulose 1,7-bisphosphatase for the construction system to work.

Exposing the Problem of Assigning a Reaction Scheme to the Nonoxidative PPP

The reactions and enzymes shown in Fig. 4 occur in liver cytoplasm and are expected items in the soluble enzyme compartments of most animals. Aldocyclases as well as perhaps the lactating mammary gland and some microorganisms may be exceptions. However, the failure to find incontrovertible evidence for both F-pathways and L-pathways that permitted the placement of C-3 to C-8 glycolyl phosphates in a reaction order and with stoichiometry that satisfied flux demands of a metabolic pathway or cycle is the crux of this 50-year-old enigma. Finding an answer to the problem proved to be quick, obvious, and simple. Uncovering irrefutable evidence and proof for the explanation was a more pressing task that was solved by Flanagan et al. (61). It was the universal use of 14C isotopes in prediction-labeling experiments to both inquire into mechanism and predicate theories for quantifying the F-type and L-type PPP that was the first fundamental error. The second misjudgment was lack of practical attention to the consequences of the glycolyl-group exchange reactions that are actively catalyzed by TK, TA, and Ald. The subscript X is used to distinguish exchange catalysis from the mass transfer activity of these enzymes. Despite some anecdotal warnings by the authors of References (49-51) that both exchange and mass transfer activities could be anticipated in PPP and PS investigations, the warnings were unheeded by the PC measures. A rare exception, in which an exchange-enzyme control accompanied measurements of the L-type PC, is discussed by Williams (1) and Longnecker and Williams (62).

13C-NMR spectroscopy was used by Flanagan et al. (61) for the kinetic investigations of exchange reactions by group-transfer enzymes. Adoption of NMR technology silenced the unfailing criticism of 14C labeling patterns that were measured by wet chemical methods. The maximum catalytic capacities for exchange by the three enzymes were all quantified in reaction mixtures at mass-transfer equilibrium. TA was measured by the

Figure 4  L-type pentose phosphate pathway reactions. The [1-$^{14}C$] ribulose 5-P substrate is the product of reactions shown at Fig. 1. The reaction sequences illustrate the distinctive distribution of $^{14}C$ in hexose 6-P and the following new intermediates: octulose monophosphate, sedoheptulose and octulose bisphosphates. Transaldolase exchange reactions involving ribose and arabinose 5-phosphates are shown. Other detail of the L-type pathway is given in the text. exchange rate of the 13C-TA dihydroxyacetone group with unlabeled Seh 7-P. TKx was measured by the rate of incorporation of a (2-13C)-TK glycolaldehyde group to unlabeled Fru 6-P and Ald, by the exchange of an unlabeled DHAP-Ald group from D-g-D-a-Oct 1,8-P2 to [1-13C]-Rib 5-P and measurement of the rate of formation of [4-13C]-D-g-D-a-Oct 1,8-P2. A comparison of the exchange capacities of these enzymes with the maximum nonoxidative PPP flux rates in three liver preparations showed that TKx and Aldx exceeded flux by 9-19 times in liver cytosol and acetone powder enzyme preparations in vitro and by 5 times in hepatocytes. TAx was less effective in exchange, only exceeding the flux rate by 1.6 times and 5 times in liver cytosol and acetone powder preparations, respectively. Values for the ratios of the rate of group exchange and pathway fluxes in liver are important because of the feature roles of hepatic tissue and of these preparations in the establishment and status of the Fig. 2 and Fig. 4 schemes in biochemistry. The prevalence of exchange activity was also investigated using the dominant TKx rates relative to the maximum PPP flux rates of normal diemal adipocytes. TKx rates in these preparations exceeded melarona, colonic epithelium, spinach chloroplasts, and epi-
didymal adipocytes. TKx rates in these preparations exceeded PPP flux by 5-600 times (61).

Conclusion

A surfeit of evidence has accumulated slowly during the last 53 years to show that predictions and calculations based on their distributions in PPP and PS products and intermediates are pointless and misleading. The isotope patterns cannot reveal the order of the reaction sequences, which can only be measured by an uncompromised net flow of carbon. Instead the 14C-patterns are used by measurement theoreticians, in the PC reaction mechanism and rigorous chemical procedures. Since its first appearance in biochemical texts. The network structure of pathways can be studied from two complementary viewpoints: as networks of enzymes or as networks of chemical compounds. This structure enables more in-depth analysis into metabolic pathways. From these networks, new features regarding pathways on both the local and the global levels can be detected. On the one hand, global features such as the scale-free property of pathways have attracted much attention from the bioinformatics community. On the other hand, local features of networks such as pathway modules can retrieve and characterize subnetworks of related genes that are potentially involved in a particular function of the metabolic pathway. Systems analysis of metabolic pathways must focus not only on existing pathways, but also on reconstructing pathways for new genomes or filling in information regarding missing enzymes. By using the vast amounts of genomic data available, it is possible to reconstruct the metabolic maps of new genomes. Such genomic information has proved useful to refine prediction methods, and they can be complemented with chemical-based information that is inherent in the same network. Overall, a systems approach to metabolism covers the realm of both the genomic and the chemical worlds in an integrated manner. We will show that the concepts of local network features in terms of both these worlds produce modules that can be integrated such that the global view of metabolism can be grasped. The current findings will be described systematically while also involving manual curation such that biologically accurate systems can be produced for analysis.

In bioinformatics, the term “systems approach” is often contrasted to the reductionist approach, in which a large system is broken down into its parts and the parts are studied individually. That is, based on systems theory, a network is studied from the perspective of the organization (relationship) of its parts, from which patterns may emerge. Therefore, we look at the metabolic network in an integrated manner covering the realm of both the genomic and the chemical worlds to identify features that emerge from the network. We will show that the concepts of local network features in terms of both these worlds produce modules that can be integrated such that the global view of metabolism can be grasped. The current findings will be described systematically while also involving manual curation such that biologically accurate systems can be produced for analysis. The recent advancements in systems analysis of metabolic pathways will be introduced.

**Systems Analysis of Metabolic Pathways**

Metabolic pathways have been illustrated using simple diagrams since before the human genome project and related bioinformatics projects had begun. With the involvement of computer science techniques, however, systematic approaches to modeling metabolic pathways have progressed quickly, with various aims that range from metabolite analyses to pathway prediction and reconstruction (1–3). Systems analysis has come to incorporate...
graph-theoretic techniques on the one hand, and physics on the other hand, in the attempt to elucidate the complex functioning of the cellular system. In terms of graph theory, in particular, the network structure of pathways has been studied with complementing views by considering them as networks of enzymes or as networks of chemical compounds to capture more and important information. From these networks, new features regarding pathways on both the local and the global levels have been detected. On the one hand, global features such as the scale-free property of pathways have attracted much attention from the bioinformatics community. These properties have shown that metabolic networks are not so different from other well-known networks such as social networks and the Internet. They also helped to characterize networks in a systematic manner such that particular enzymes that are either undefined (missing) or have important roles in the network could be identified and studied in more depth. On the other hand, local features of networks such as pathway modules can retrieve and characterize subnetworks of related genes that are involved potentially in a particular function of the metabolic pathway. This latter approach of characterizing modules has been supplemented with gene expression information and analyses of chemical reaction patterns not only to infer the function of the genes involved in the particular module, but also to infer the evolution of pathways.

Systems analysis of metabolic pathways needs to focus on existing pathways; it can also be used to reconstruct pathways for new genomes or to fill in information regarding missing enzymes. By using the vast amounts of genomic data available, it is possible to reconstruct the metabolic maps of new genomes. Information of orthologous groups of genes combined with pathway data enables such predictions. Furthermore, the integration of data from a variety of resources such as microarray expression data and localization data can be incorporated in new advanced models to predict and to fill in the gaps in pathways for missing enzymes (3–5). Such genomic information is useful to refine prediction methods, and they can be complemented with chemical-based information that is inherent in the same network (6). Methods for pathway prediction can use a systematic approach to classify chemical reactions based on the specific structures of the chemical compounds involved. Because computer science techniques from graph theory can and have been applied directly for these analyses, some methods will be described later.

**Network Structure**

The analysis of network structure from the viewpoint of computer theory requires an introduction to some background information, which will be provided here. We will introduce the data involved for modeling metabolic pathways and the KEGG pathway database in particular. Furthermore, a basic introduction to graphs as used in computer science will be provided.

**Background: data models**

Several databases for metabolic pathways are available currently from the Internet, and some major representatives are listed in Table 1. KEGG (Bioinformatics Center, Institute for Chemical Research, Kyoto University, Kyoto, Japan), BRENDA (Institute of Biochemistry, University of Cologne, Germany), and other database systems have been applied directly for these analyses, some methods will be described later.

The reaction formulas (chemical equations) in the ENZYME information, which consists of REACTION, RPAIR, and ENZYME, is the KEGG COMPOUND database of chemical compounds. Compounds have been manually curated from the literature. Such biologic information, but also on pathway information that has orthologous groups of genes that are based not only on sequence similarities but also on pathway information. This results in orthologous groups of genes that are based not only on sequence information, but also on pathway information that has been manually curated from the literature. Such biologic information incorporated into the data means that the resulting catalog of gene groups is truly meaningful.

A another resource that is useful in metabolic pathway analysis is the KEGG PATHWAY database of chemical compounds. This database is supplemented by the database of reaction information, which consists of REACTION, RPAIR, and ENZYME. The reaction formulas (chemical equations) in the ENZYME nomenclature as well as those taken from the KEGG pathways are stored in the REACTION database, which contains, among others, the stoichiometry of substrates and products in an enzymatic reaction. To trace the atomic changes of substrates and products, the RPAIR database is constructed by decomposing each chemical equation into a set of substrate-product pairs.

The RPAIR database contains chemical structure alignments of substrate-product pairs (reactant pairs) and chemical structure transformation patterns, which were generated computationally and curated manually from all known enzyme-catalyzed reactions. These patterns are called RDG patterns, which describe biochemical structure transformations and represent KEGG atom type changes in a reaction. KEGG atom type changes are defined at the reaction center atom (R atom), its neighboring atoms in the different (mismatched) region (D atom), and the matched region (M atom), based on a graph-based alignment of the compounds involved in the reaction. The definition of a graph-based alignment between two compounds is described in the next section. Figure 1 illustrates these RDG atoms. Because these transformation patterns generalize complex enzymatic reactions, given a new set of chemical compound structures, the reactions that could possibly take place between them can be predicted.

**Background: algorithms**

The bioinformatics field has enabled the use of algorithmic techniques from computer science to analyze vast amounts of data efficiently and accurately. For the study of networks, graph models are most appropriate, and numerous algorithms exist for studying graph objects. A graph is defined as a set of nodes connected by edges, in which a node represents a specific object such as a particular chemical compound or a particular enzymatic protein, and an edge represents the relationship between two different nodes, such as the catalysis of one compound into another or a protein–protein interaction. Thus, a graph can be defined as a set of nodes V = {v1, v2, v3, ..., vn} and a set of edges E = {e1, e2, e3, ..., em} in which any edge in E connects exactly two nodes in V and no two edges share the same pair of nodes. A directed graph is a graph whose edges define a source and a target; the direction of the graph is defined, such as the direction of an irreversible reaction from substrate to product. In contrast, an undirected graph does not define any direction on the edges. The degree of a node is defined as the number of nodes with which it shares an edge. A subgraph of a graph is a graph that contains a subset V′ of the nodes in V and all those edges in E that connect those nodes in V′. Consequently, a subnetwork is a subgraph of a network modeled as a graph. We will also define here NP-completeness. A problem is NP-complete if it is known that the problem can be verified quickly, but a solution itself is difficult to find efficiently. For example, the Hamiltonian path problem is a well-known NP-complete problem. Given an undirected graph, the problem is to find a path in the graph that passes through all nodes exactly once. This path is most difficult to find, but given a path, it is easy to verify whether the given path in the graph solves this problem. Efficient methods exist to test whether two graphs are similar (or isomorphic). However, the problem of deciding whether a
One of the earliest features that characterizes metabolic compound networks is the scale-free property, which was derived from the finding that the probability that a node can interact with other nodes, which is the degree distribution $P(k)$ of a metabolic compound network, decays as a power law $P(k) \sim k^{-\gamma}$ with $\gamma \approx 2.2$ in all organisms (12–14). This scale-free property ultimately illustrated that biologic networks were not as different from other nonbiologic networks as thought previously, and that metabolic compound networks of almost all organisms thus exhibited robust and error-tolerant properties as a result. Moreover, an analysis of the scale-free properties of the line graphs of metabolic compound networks (that is, the properties of the metabolic enzyme networks) was performed (15). The network properties of the metabolic enzyme networks are not exactly one-to-one to the metabolic compound networks because several reactions may have common products, which reduce effectively the number of edges in the transformed network. Nevertheless, it was found that the scale-free power-law distribution was still preserved in the metabolic enzyme network, with only a small (less than one) difference between the exponents.

However, it was also found that “hubs” of highly connected nodes, such as pyruvate and coenzyme A, also existed in metabolic compound networks, in which these nodes were highly connected and interacted with many other nodes. It was proposed that these metabolic networks were actually arranged in a hierarchical manner (16), where highly connected modules would be connected to one another in a scale-free manner. These modules would in turn form clusters that would then be connected to other clusters at a higher level, and so on. Such properties can be taken advantage of to infer the function of the genes involved in each corresponding module at various levels of the hierarchy. This method would actually correlate well with the fact that networks of genes are not necessarily working alone, but function in concert with other proteins and complexes at higher levels. This finding in fact correlates surprisingly well with results published recently based on graph-theoretical analysis of gene regulatory networks in Bacillus Subtilis (2). That is, because only a subset of genes is actually active at any one time, the dynamic topology of gene regulatory networks was taken into consideration in this work, as opposed to the full static network. As a result, a hierarchical scale-free network emerged.
Local network features

Commonly occurring patterns in metabolic networks, or network motifs, which can be found using building blocks for finding frequent subgraphs, have shown promise of functional inference (17). Recently, however, critiques have been raised saying that such functional inferences must also take into consideration evolution (18). As such, work on extracting phylogenetic modules from metabolic enzyme networks demonstrated that such functional units are indeed conserved across evolution (19). In this work, phylogenetic profiles were constructed for all the enzymes in the metabolic reference map of KEGG. Using the Jaccard coefficient as a similarity measure, all enzymes were clustered hierarchically based on phylogenetic profiles. Then, edges between the enzymes were added based on the edges in the metabolic network. Finally, clusters were created within each cluster based on these new edges between enzymes. These small clusters were thus defined as phylogenetic network modules, in which enzymes that have similar phylogenetic profiles are close to one another in the metabolic network. In preliminary studies, the enzyme clusters were constructed using only the similarity between phylogenetic profiles differed from those that resulted from the final network modules that metabolic network connectivity, which indicates that phylogeny should indeed be incorporated in metabolic module analysis. These phylogenetic modules also demonstrated that this final network possessed hierarchical network features, such that hubs of important genes exist, but that these hubs are connected by more sparsely linked genes that work as linkers between these hubs to connect the entire network as a whole.

The concept that modules comprise the traditional pathways is gaining more focus as basic functional building blocks (20). Gene expression patterns in pathways and their formation of modules have been an intense topic of study (21, 22). These pathways combined with flux balance analysis have also provided interesting results about the metabolic pathway of yeast (23) and Escherichia coli (24). The latter involves steady-state analysis using reaction stoichiometry information, such as those stored in the KEGG REACTION database, and it is gaining renewed interest for systematic analysis of metabolic networks (6).

Functional Network Inference

In addition to the topological features of networks, other sources of information can and should be incorporated to take a step further into inferring function from the hierarchically organized modules of metabolic networks.

Metabolic reconstruction: genome to pathway mapping

The term metabolic reconstruction refers to the process of linking the genomic repertoire of enzyme genes to the chemical repertoire of metabolic pathways. That is, a metabolic enzyme pathway can be inferred given a set of enzymes (25). This task can be done by first referring to the existing pathway maps in which the involved genes are known. By using the genomic information of multiple (related) species and comparing them against these pathways, ortholog groups involved at specific nodes in the pathways can be identified. This method is the basis of the K.O system. Correspondingly, the entire metabolic pathway of an organism can be inferred given its genome. That is, the K.O system can be used to reconstruct a metabolic enzyme network by first referring to the genes known to be in a particular organism. Once the K.O groups in which these genes are involved are identified, the nodes in the metabolic pathway in which these genes participate can be reconstructed. Thus, new sets of genes can then be compared against the K.O groups to reconstruct the metabolic pathways in which the input genes may be involved.

Integration of heterogeneous datasets

Because the metabolic pathway is in fact a complex process of various degrees of interactions between biomolecules, the integration of the main components and their fundamental interactions are important for the extraction of the functional modules and the identification of their roles in the network. For example, information on cellular components and their interactions can be incorporated to reconstruct metabolic networks more accurately compared with genome annotation and/or sequence information alone (4). This involves the incorporation of data from multiple data sources, such as KEGG (for pathway and genomic data) and PSORTdb (for subcellular localization data). In addition, work has been done to integrate stoichiometric and bibliometric data for reconstructing the human metabolic network (3). To incorporate an even wider variety of biologic data for predicting missing enzymes in metabolic enzyme networks, kernel methods are used. A kernel is a mathematic function that can take as input a variety of data for a specific set of entities and transform it such that the input entities can be classified as distinctly as possible. This method consists of two steps: a training phase and a test phase. The training phase consists of using data for which the properties are known in advance. Then, the test phase can be used to assess the applicability of the properties to new input data sets.

In terms of a metabolic network inference that uses multiple sources of data, as an example, for a given set of genes, expression, genomic context, chemical, and phylogenetic information can be used to train a kernel function to infer a metabolic network. This task is done by developing the kernel function such that a score is obtained for every pair of genes. If this score exceeds a particular threshold, the corresponding genes are considered to be related, and an edge can be drawn between them to form the inferred network. The incorporation of chemical information in this work was attempted in two ways: preintegration and postintegration, to enforce chemical restraints in an indirect and direct manner, respectively. In the indirect manner, all input sources are compared and contrasted with the chemical restraints, whereas in the direct approach, the chemical restraints are applied after an initial network is obtained. This latter approach ensures that chemical compatibility is maintained. A as a result, several enzymes were identified to fill in the missing nodes of the metabolic enzyme network for yeast (26).
Compound scope

Metabolic pathways may also be analyzed from a chemical standpoint, and it has been surmised that the array of concentrations of relatively simple chemicals in pathways may provide information for biologic processing (27, 28). Thus, the study of the metabolic reactions that take place in the metabolic compound network comes naturally.

The idea of the “scope” of a chemical compound was defined recently to characterize metabolic compound networks systematically. This idea developed from the fact that the occurrence of a metabolic reaction generally requires the existence of other reactions that provide its substrates, which generates a series of metabolic reactions. In each step of the corresponding expansion process, those reactions whose substrates are available are incorporated (29). Thus, starting with one or more seed compounds, an expansion can result in a final network whose compounds define the scope of the seed. Using all the metabolic reactions in the reference pathways of the KEGG PATHWAY database, the scopes of all metabolic compounds were calculated, and it was found that large parts of cellular metabolism could be considered as the combined scope of simple building blocks. Analyses of various expansion processes revealed that the incorporation of key metabolites such as adenosine tri-phosphate and coenzyme A would increase the network complexity. It was also shown that the outcome of network expansion is in general very robust against the elimination of a single or few reactions, although the elimination of a key reaction would result in a dramatic reduction of scope sizes. As a result, it was hypothesized that the expansion process displays characteristics of the evolution of metabolism, in that the emergence of metabolic pathways over time could be estimated from the systematic analysis of metabolic compound networks (30).

From this work on compound scope, an interesting analysis of the effect of oxygen on metabolic networks and the evolution of life was made possible (31). Recent evidence suggested that the increasing importance of molecular oxygen to metabolic pathways eventually replaced the enzymatic reactions central to anaerobic metabolism in aerobic organisms (32). Thus, by comparing metabolic compound networks under anaerobic and anaerobic conditions, the effect of the presence or the absence of oxygen on the complexity of specific seed compounds could be determined. Based on the reference pathways for metabolism in KEGG, O_2 was found to be among the most used compounds, superseding even adenosine tri-phosphate. Their analyses revealed four subnetworks of increasing complexity, which form a hierarchy such that certain reactions allow transitions between the subnetworks at different levels. Among these four subnetworks, molecular oxygen was required for transition into the largest network. Furthermore, in another analysis of the enzyme distribution across different organisms, it was found that the distributions of enzymes that catalyze anaerobic networks were not necessarily consistent with the tree of life, which indicates that the adaptation to O_2 had occurred throughout the tree of life. These results were supported by data from geologic and molecular evolutionary analyses indicating that all three domains of life appeared by the time oxygen became widely available (33).

Pathway prediction using RDM patterns

The study of the chemical reactions involved in metabolic compound networks and their scopes can help to predict new pathways. In this case, the RDM patterns defined in KEGG can be used. In fact, an analysis of the RDM patterns in KEGG in the context of their frequency of appearance in the KEGG PATHWAY categories was performed. In particular, the more than 2000 RDM patterns that appear in the metabolic pathways of KEGG were analyzed. Because RDM patterns themselves do not indicate the direction of the reaction, when a reaction in the pathway was defined as reversible, two reactions were generated for the corresponding RDM pattern. The number of unique patterns was counted for each pathway category, and it was found that the reactions in the xenobiotics biodegradation pathways in particular were most distinct compared with the other categories of pathways. In fact, roughly 80% of the RDM patterns were unique to this category. Thus, an attempt was made to use RDM patterns to predict a biodegradation pathway of a new xenobiotic compound.

This task was done by comparing the new compound first against the KEGG COMPOUND database to retrieve a list of candidate compounds that are most similar to the query. The matched compounds are then queried against the RDM pattern library to retrieve a list of putative RDM patterns. In the third step, the query compound is transformed into new possible compounds based on the retrieved transformation patterns. These newly generated compounds are then used iteratively as a new query to repeat the prediction cycle until no new transformations can be found. This approach retrieved successfully the degradation pathway for 1,2,3,4-tetrachlorobenzene (34).

Similar research has attempted to gain insight into protein function prediction based on information hidden in the molecular structure of metabolites (35). Such work may eventually identify the relationship between metabolic structure and protein function, thus possibly improving techniques in the prediction of enzyme function and novel metabolic pathways (36).

Discussion

It may now be generally believed that both metabolic networks can be characterized as hierarchically organized networks of modules that have scale-free properties. Several methods for the analysis of metabolic pathways are actively being developed to understand these functional modules found among them. The results, of course depend greatly on the data being used to find them. It has been shown that the incorporation of genomic and phylogenetic information aids the identification of functionally important modules. In turn, these data can aid phylogenetic analysis and functional annotation of the biologic entities involved.

Work in chemical reaction characterization and analysis enables the prediction of missing enzymes and pathways. The concept of modules of compounds, or compound scopes, defines the extent to which a particular chemical compound plays a role in the metabolic compound network. This research aids
in evolutionary analysis of modules as the importance of specific compounds can be directly analyzed based on its scope and the effect it has on the scope sizes of other compounds in the network.

We have illustrated that metabolic enzyme networks and metabolic compound networks are in fact two sides of the same coin. The global analysis of metabolic networks using the line graph transformation illustrated this point nicely. Thus, it is natural to pursue the relationships between those modules found in the original metabolic enzyme network and in the line-graph-transformed metabolic compound network to ascertain their functions. Such integration of knowledge from various aspects is crucial to gain a true understanding of the biologic processes of life.

We note that metabolic systems are studied often in systems biology using dynamics analysis such as flux balance analysis and differential equations. However, discussion regarding system dynamics is beyond the scope of this current manuscript, and we refer the interested reader to the relevant literature (37, 38). This limitation, however, does not preclude these analyses from the standpoint of integrated systems analysis for understanding the metabolic pathway.

Systems analysis approaches such as those presented in this manuscript have illustrated the importance of systematic and integrated methods of analyzing metabolism. It can be expected that multidimensional data will continue to play an important role in such approaches. Because the consistency of such data will determine the accuracy of the predictions, a balance between the speed of computational techniques and the accuracy of manual curation must be maintained. As long as an over-dependence does not exist on either approach, systems approaches for the study of metabolism should prove to be fruitful.

doi: 10.1002/9780470048672.wecb628

Humans are exposed continuously and unavoidably to a myriad of potentially toxic chemicals that are inherently lipophilic and, consequently, very difficult to excrete. To effect their elimination, the human body has developed appropriate enzyme systems that can transform metabolically these chemicals to hydrophilic, readily excretable, metabolites. This biotransformation process occurs in two distinct phases, Phase I and Phase II, and involves several enzyme systems, the most important being the cytochromes P450. The expression of these enzyme systems is regulated genetically but can be modulated also other factors, such as exposure to chemicals that can either increase or impair activity. Paradoxically, the same xenobiotic-metabolizing enzyme systems also can convert biologically inactive chemicals to highly reactive intermediates that interact with vital cellular macromolecules and elicit various forms of toxicity. Thus, xenobiotic metabolism does not always lead to deactivation but can result also in metabolic activation with deleterious consequences.

It is unlikely that the human body could survive and thrive in the chemical environment it lives in if it were not endowed with effective means to protect itself from the adverse effects of the myriad of chemicals to which it is continuously and unavoidably exposed. Although scientists focus on anthropogenic chemicals, humans are exposed to even more naturally occurring chemicals, mostly phytochemicals that, like their man-made counterparts, have the potential to induce toxicity. Both anthropogenic and natural chemicals are referred to as xenobiotics (Gr. foreign to life). Humans are exposed to huge numbers of xenobiotics, in the order of 5000 to 10,000 per day, most of which emanate from the diet. Of the chemicals that humans ingest, 99.9% are natural, largely of plant origin (1).

Biologic Background

Most chemicals to which humans are exposed cannot be exploited by the body either to generate energy or to use as structural blocks to build new tissue; they cannot be used as essential cofactors for enzyme reactions nor as chemical messengers. During the last three decades, however, it has become evident that some dietary phytochemicals possess biologic activity and have the potential to afford protection against major degenerative diseases of high morbidity, such as cancer and cardiovascular disease; this protection may explain the epidemiological findings that populations that consume diets with high vegetable and fruit content are less susceptible to these fatal diseases. Because most of xenobiotics offers no benefit to the human body, its immediate response is to prevent exposure and/or eliminate them. For this objective to be achieved, the body has developed as a first line of defense several transporter systems, such as the P-glycoprotein, which prevent the absorption of chemicals through the gastrointestinal tract by facilitating their efflux from the enterocytes into the intestinal lumen (2). For chemicals that at least partly overcome this obstacle and reach the blood circulation, its immediate response is to excr...

Phase I metabolism

During Phase I metabolism, also referred to as functionalization, the xenobiotic acquires a functional group such as –OH, –COOH, and –NH₂; alternatively, such functional groups may be unmasked, for example, an alkoxy (–C–OR) group can be dealkylated to unmask a functional group (–C–OH). For example, 7-hydroxycoumarin can be formed either by the hydroxylation of coumarin (insertion of an oxygen atom) or by the deethylation of 7-ethoxycoumarin (unmasking) (Fig. 1). Phase I metabolism involves oxidation, reduction, and hydrolysis reactions and is catalyzed by various enzyme systems (Table 2). The predominant reactions are oxidations, and the most important system catalyzing these is the cytochromes P450 (vide infra). Reductions are catalyzed by reductases, which are not very active in mammalian cells but are very active in gut bacteria that, consequently, may contribute extensively to the metabolism of orally administered drugs and other xenobiotics; the most common reductions are azo- and nitroreductions. The enzymes catalyzing hydrolysis reactions are esterases.
Xenobiotic Metabolism

and amidases that hydrolyze esters and amides, respectively (Table 2).

Phase II metabolism

During Phase II metabolism, also referred to as conjugation, the metabolites generated during Phase I metabolism combine with endogenous substrates, such as sulphate, glucuronic acid, glutathione, and amino acids, to form highly hydrophilic metabolites that are excreted with ease in the urine and feces. As an example, 7-hydroxycoumarin, formed from Phase I metabolism, forms a sulphate and a glucuronide conjugate (Fig. 1). Sulphation is catalyzed by the sulphotransferases and glucuronidation by the glucuronosyl transferases that attach glucuronic acid to the substrate. Chemicals, such as the drug paracetamol (acetaminophen) that already possesses a functional group, may bypass Phase I metabolism and be metabolized predominantly through conjugation (Fig. 2). Conjugation with glutathione represents an effective cellular defense mechanism that neutralizes toxic chemicals that otherwise would cause toxicity. Another Phase II pathway, usually minor, is conjugation with amino acids, the most common being glycine. Finally, methylation and acetylation are unusual pathways in that the generated metabolites are less polar than the parent compound; in this case, metabolism hinders rather than facilitates excretion and additional metabolism is required for eventual elimination.

Enzyme Systems that Catalyze Phase I Metabolism

Although several enzymes contribute to the Phase I metabolism of xenobiotics (Table 2), by far the most prominent are the cytochromes P450, so called because in the reduced state they form a complex with carbon monoxide that is characterized by an absorption maximum at 450 nm.

Cytochromes P450

A widespread enzyme system in nature, cytochromes P450 are found in both prokaryotic and eukaryotic cells and, with the exception of striated muscle and red blood cells, are encountered in every tissue but predominately in the liver, which, as a result, is the principal site of xenobiotic transformations. However, cytochrome P450 enzymes also are active in portals of xenobiotic entry, such as the lungs, the gastrointestinal tract, and the nasal mucosa. Although the cytochrome P450 enzyme system can function as a reductase under anaerobic conditions, its main role is to facilitate the oxidation of a myriad of structurally diverse xenobiotics. It is a haem-containing, membrane-bound enzyme that requires molecular oxygen and NADPH and inserts an atom of oxygen to the xenobiotic (X) while the other is reduced to water.

NADPH + H+ + XH → XOH + NADP+ + H2O

The flavoprotein cytochrome P450 reductase channels the electrons from NADPH to the cytochromes P450, which function as a terminal oxidase (Fig. 3).

Figure 2 Metabolism of paracetamol (acetaminophen).

A principal attribute of the cytochrome P450 system is the unprecedented broad substrate specificity it displays, which explains its pivotal role in xenobiotic metabolism. It catalysts efficiently the metabolism of thousands of structurally diverse chemicals with markedly different molecular shape and size. It achieves this very broad substrate specificity by existing as a "superfamily" of enzymes. Each family is subdivided further into subfamilies that may contain one or more enzymes. Enzymes that share a structural similarity of at least 40% belong to the same family, which is indicated by Arabic numbers, whereas, if the structural similarity exceeds 55%, then they are classified within the same subfamily, which is denoted by capital letters; finally, enzymes belonging to the same subfamily are denoted by Arabic numbers. For example, the CYP family comprises two subfamilies, namely CYP1A and CYP1B; the former consists of two enzymes, CYP1A1 and CYP1A2, whereas within the

Figure 3 Cytochrome P450 electron transport system. S, Substrate.

The fact that some xenobiotic-metabolizing cytochrome P450 isofoms are expressed polymorphically (vide infra) and that individuals may lack totally a certain isoform without any detriment to health indicates that the role of these cytochromes P450 in endogenous metabolism is far from life threatening. Cytochromes P450 are believed to have evolved from a common ancestor some three thousand million years ago. The function of the earliest forms is thought to have been in the metabolism of essential endogenous chemicals, such as steroid hormones, and then to have evolved to enzymes capable of metabolizing foreign compounds. As a result, their initial narrow substrate specificity toward steroids was lost and, to cope with the new, increasingly chemical environment, they developed into broad-specificity enzymes that could metabolize the diverse chemicals to which they now were exposed. It has been proposed that what forced the evolution of these proteins was the necessity to develop defense mechanisms to protect against plant toxins present in the food chain that were produced to discourage predators (5).
## Enzyme Systems that Catalyze Phase II Metabolism

Conjugation reactions of xenobiotics or their metabolites with endogenous substrates produce highly hydrophilic metabolites; however, to a lesser extent functional groups may be also methylated or acetylated to produce less hydrophilic compounds.

### Glucuronide conjugation

Glucuronide conjugation is a frequently used route of conjugation by xenobiotics where glucuronic acid, in its active form, uridine diphosphate glucuronic acid (UDPGA), is added to the molecule (Fig. 1). Some drugs like oxazepam and morphine are catalyzed predominantly by glucuronidation because they do not require prior Phase I metabolism to generate a functional accepting group. The most readily conjugated functional groups are phenols and alcohols, which yield ester glucuronides, and carboxylic acids, which form ether glucuronides.

### Sulphate conjugation

Conjugation with sulphate, catalyzed by cytosolic sulphotransferases, is also a major route of Phase II metabolism, where inorganic sulphate, made available in the activated form of 3′-phosphoadenosine-5′-phosphosulphate (PAPS), is added to the molecule (Fig. 1). This is the most important pathway in the metabolism of phenols and is a very efficient conjugating system as long as inorganic sulphate is available.

### Glutathione conjugation

Glutathione conjugation is an important pathway of metabolism that allows the cell to defend itself from chemical insult. It uses the nucleophilic tripeptide glutathione, which possesses a nucleophilic sulphur atom, to detoxify chemically reactive metabolites, preventing them from interacting with critical cellular macromolecules with adverse consequences and, thus, preserves cellular integrity. This reaction is catalyzed by the ubiquitously distributed glutathione S-transferases, which transfer a molecule of reduced glutathione to the toxic chemical that results in its neutralization. Glutathione conjugates additionally are processed further metabolically in the body are excreted and result in its neutralization. Glutathione conjugates additionally are processed further metabolically in the body and, usually as N-acetylcysteine conjugates (mercapturates).

### Amino acid conjugation

In this minor route of xenobiotic metabolism, the carboxylic group of organic acids may conjugate with amino acids, glycine being the most common. The carboxylic group of the xenobiotic forms a peptide bond with the α-amino-group of the amino acid. Initially, in an ATP-dependent reaction, the carboxylic group reacts with CoA to form an α-acyl-CoA thiolster derivative, which then interacts with the amino acid to form the conjugate.

### Hydration

Hydration involves the addition of water to epoxides to form dihydrodiols and is catalyzed by microsomal epoxide hydrolase that displays, broad substrate specificity. As epoxides are generally toxic entities, this is a very important route for their detoxification.

### Methylation

Methylation, as well as amino and thiol groups, may be metabolized through methylation, the methyl donor being S-adenosyl methionine, the product of the interaction of ATP with methionine. Usually, it is a minor metabolic route in xenobiotic metabolism, but it plays a major role in the metabolism of endogenous substrates such as noradrenaline (norepinephrine). Methylation is catalyzed by methyltransferases located in the mitochondria.

### Acetylation

Acetylation is an important metabolic route for aromatic and heterocyclic amines, hydrazines and sulfonamides. An amide bond is formed between the amino group of the chemical and the acetate. This reaction is catalyzed by acetyltransferases, the acetyl group being donated by acetyl-CoA.

### The First-Pass Effect

If an orally taken drug is not absorbed, then there will be no pharmacological effect and the drug will be excrated in the feces. However, it is conceivable that a drug is very well absorbed and yet fails to manifest the expected pharmacological effect. Following oral administration, drugs are absorbed through the intestine into the portal circulation that takes them to the liver and then to the systemic circulation. A drug may undergo metabolism either in the intestine and/or through its first passage through the liver to such an extent that very little remains available for distribution to the other tissues, including the site of action, and, consequently, biologic activity is either not manifested or attenuated. In the intestine, metabolism may be catalyzed not only by intestinal enzymes, such as cytochromes P450 and Phase II conjugation enzymes, but also by microorganisms. This phenomenon is known as the first-pass effect or presystemic metabolism. Thus, poor response to drug treatment after oral intake may be due to the fact that, despite complete absorption, only a small fraction of the drug reaches systemic circulation intact because of extensive metabolism in the intestine or liver.

First-pass metabolism, therefore, will decrease the pharmacological effect of the drug, and if the metabolism is extensive, the pharmacological effect may be abolished completely as a result. Drugs that are subject to first-pass metabolism are administered through alternative routes or at higher doses to compensate for the loss during presystemic metabolism. Glyceryl trinitrate, a drug used in the treatment of heart angina, when taken orally undergoes >99% of first-pass metabolism being denitrated in the liver, and, as a result, it is never administered through this
route but is taken sublingually to bypass the intestine. The patient places a tablet under the tongue, and because of the good network of blood vessels, the drug is absorbed very rapidly and the patient benefits from it within a few minutes.

**Factors that Influence Xenobiotic Metabolism**

Several factors can modulate the activity of xenobiotic-metabolizing enzymes, such as age, the nature of diet, and the presence of disease, but the most important appear to be genetic makeup and concurrent or prior exposure to chemicals (enzyme induction and enzyme inhibition).

**Polymeric expression of xenobiotic-metabolizing enzyme systems: clinical implications**

The presence of xenobiotic-metabolizing enzymes and this level of expression are governed by our genes. Xenobiotic-metabolizing cytochromes P450 may be polymorphically expressed, and if this is not appreciated and the necessary steps taken to adjust drug dosage accordingly, it may have a dramatic impact in clinical therapeutics (5, 6). It is recognized now that xenobiotic-metabolizing enzymes, both in Phase I and Phase II, are polymorphically expressed, resulting in inter individual differences in metabolic capacity, so that drug dose regimens are unlikely to be optimal for all patients. For a certain drug, some individuals are poor metabolizers, whereas others are extensive metabolizers. Furthermore, polymorphic expression affects not only drug efficacy but also the appearance of adverse effects. The etiology of adverse effects experienced by some patients exposed to the therapeutic doses of drugs, especially of drugs with a narrow therapeutic index, i.e., drugs whose plasma concentrations must be maintained within a narrow range to achieve the desired pharmacological effect, may be attributed to their individual enzyme profile (7).

One of the first polymorphisms to be identified involved acetylation (N-acetyltransferase) and the antitubercular drug isoniazid. Several people are slow acetylators, the proportion being race related and varying from about 10% in the Japanese to 70% in Caucasians. Acetylation of isoniazid results in loss of pharmacological activity because acetylisoniazid is devoid of antibacterial activity, but it provokes toxicity that occurs more frequently in slow acetylators. Since acetylation is not catalyzed efficiently, isoniazid blood levels are high and the drug interacts with pyridoxal 5-phosphate, the active form of vitamin B₆, resulting in its depletion; this vitamin deficiency causes neuropathy that leads to seizures. This situation can be avoided by the concurrent administration of the vitamin to patients treated with isoniazid. Genetic polymorphism in other conjugating systems that result in metabolic deficiencies also can lead to predisposition to the toxicity of chemicals that rely heavily on these enzymes for their deactivation. Gilbert’s syndrome is a condition where the patient experiences intermittent jaundice because of reduced capacity in eliminating bilirubin through glucuronide conjugation. The produg irinotecan, used in the treatment of advanced colorectal cancer, provokes severe gastrointestinal toxicity in these patients because of suppressed glucuronidation (8, 9). The active metabolite (SN-38) that is generated metabolically cannot be detoxicated by glucuronidation and consequently accumulates. Another early example of polymorphism involves the drug succinylcholine (suxamethonium), a muscle relaxant used primarily during surgery. Its action lasts only a few minutes because it is very efficiently metabolized by cholinesterases present in the liver and plasma. A few people, about 1 in 3000 who genetically lack this enzyme, develop sustained apnoea as a result of paralysis because its effect is prolonged from 30 minutes to hours.

Genetic polymorphism in cytochromes P450 is believed to be responsible for many adverse effects associated with drug intake. The first cytochrome P450 protein to be recognized as being polymorphically expressed was CYP2D6, an enzyme that catalyzes many current psychoactive drugs, such as tricyclic antidepressants; subsequent studies have revealed that polymorphism may involve also the CYP2C9 and CYP2C19 enzymes. Persons lacking an active gene, i.e., a gene that can generate a functional protein, when exposed to drugs relying on this enzyme for their metabolic deactivation will show exaggerated adverse effects as a consequence of accumulation, and ideally should be prescribed lower doses. One such drug is the antihypertensive debrisoquine, which in normal individuals undergoes extensive CYP2D6-mediated 4-hydroxylation that leads to loss of activity. About 10% of European Caucasians and 1% of Japanese have been identified as poor metabolizers because of the lack of a functional CYP2D6. Subjects with poor metabolism inherited two copies of a gene that encodes either an enzyme with low activity or one with no activity. When exposed to dose regimens of debrisoquine developed for normal metabolizers, as a consequence of diminished metabolism, the drug accumulates on repeated administration and adverse effects commensurate with overdose are experienced, such as sustained drop in blood pressure. A number of individuals are classified as intermediate metabolizers, having one copy of the inactive gene; they display CYP2D6 activity but at low level. As a result of CYP2D6 polymorphic expression, the dose required to produce the same plasma levels may differ by as much as 20-fold among individuals. Similarly, the β-blocking agent timolol is metabolized largely by CYP2D6; when exposed to this drug, poor metabolizers experience a prolonged, more intense pharmacological effect (10). If one is dealing with a produg, however, where metabolism leads to the production of the pharmacologically active form, a less intense or a complete loss of the pharmacological effect may occur in poor metabolizers. The analogic effect of codeine is associated with morphine, which is formed because of CYP2D6-mediated metabolism. In poor metabolizers, the drug displays poor efficacy, and the lack of analgesia is due to the active metabolite is not being produced; indeed, morphine plasma levels are extremely low (11, 12).

Polymorphism also can enhance the metabolism of a drug in persons carrying multiple copies of a cytochrome P450 gene, for example, as a result of gene amplification and duplication, so that a drug may be deactivated more rapidly through
metabolism, leading to a less intense or totally absent pharmacological effect because therapeutic plasma levels are not achieved. Such individuals are known as ultrarapid metabolizers and require far higher doses than normal to achieve therapeutic response. However, in the case of intake of a prodrug, the dose should be decreased to prevent an exaggerated effect and toxicity. Ultrarapid metabolizers show symptoms of codeine intoxication, such as severe abdominal pain, when they take a normal therapeutic dose (13).

**Cytochrome P450 regulation by chemicals and clinical consequences**

The levels of cytochrome P450 are not only genetically determined but may be modulated also by factors such as age, nutritional status, and the presence of disease. The most important factor, however, is previous exposure to xenobiotics, either natural or synthetic, that either can induce, largely as a result of enhanced enzyme synthesis, or impair cytochrome P450 activity; both can lead to serious consequences during multiple drug intake. Such drug interactions involve in particular, CYP3A4, as this enzyme is the most active cytochrome P450 in drug metabolism and, moreover, is the dominant form in the liver and intestine, the principal site and the first site of metabolism following oral drug intake, respectively.

Cyclosporin is an immunosuppressant drug taken chronically by organ transplant patients. It has a narrow therapeutic index, and plasma levels have to be maintained within a narrow range to ensure efficacy and to avoid the appearance of serious adverse effects that can be life threatening. The principal catalyst of its metabolism is CYP3A4, and even small changes in the activity of this enzyme can have major impact on its efficacy. The antifungal drug ketoconazole is a potent inhibitor of CYP3A4, and, as a result, it increases plasma levels of cyclosporin leading to toxicity when coadministered with it (14). Similarly, serious interactions can occur with prodrugs that necessitate CYP3A4-metabolism to generate the pharmacologically active form. Terfenadine underdose nearly complete first-pass effect in the liver; it is metabolized by CYP3A4 to generate a metabolite, fexofenadine, which possesses antihistaminic activity. Normally, terfenadine is never seen in the blood of patients because of the extensive first-pass metabolism. When, however, it is taken together with ketoconazole, its metabolism is impaired and terfenadine can escape into the systemic circulation causing cardiotoxicity (14). To avoid such complications, the active metabolite fexofenadine has replaced the original formulation that necessitate CYP3A4-metabolism to generate the pharmacologically active form.

be critical. Pulmonary cytochrome P450 activity is more likely to be increased when exposure to the inducing agent occurs by inhalation; smokers, for example, display higher pulmonary cytochrome P450 activity (CYP1) compared with nonsmokers, which is ascribed to the inhalation of polycyclic aromatic hydrocarbons.

**Bioactivation of Xenobiotics**

A striking paradox that was first recognized in the 1970s was that the xenobiotic-metabolizing enzyme systems, long regarded as being exclusively involved in the deactivation and elimination of chemicals, such as the cytochromes P450, could in fact assume the reverse role, i.e., they could convert innocuous, chemically inert xenobiotics to highly reactive and toxic metabolites with deleterious consequences to the body. This process is referred to frequently as “metabolic activation” or “bioactivation.” Although the chemicals that undergo activation are structurally diverse, the basic mechanism of activation appears to be quite similar. Activation involves primarily oxygenation, although reduction is also important with some chemicals (Fig. 5). The reactive intermediates that are formed are electrophiles, having electron-deficient atoms, and so are chemically very highly reactive. Since these reactive species are generated intracellularly, they can interact readily and irreversibly with vital cellular macromolecules, such as DNA, RNA, and proteins, to provoke various types of toxicity; thus, in this case, metabolism confers to the chemical adverse biologic activity. Alternatively, these reactive intermediates may interact with tissue oxygen, giving rise to toxicity indirectly through redox cycling, by acting as radical generators. These free radicals are capable of inducing cellular damage similar to that resulting from the covalent binding of electrophiles to cellular constituents. Simultaneously, a chemical will be subject to metabolism through pathways that lead to deactivation so that the extent of toxicity will be dependent on the balance of activation and deactivation. An extensively studied example of such drug bioactivation involves the drug paracetamol (acetaminophen), which is primarily metabolized through conjugation with sulphate and glucuronic acid leading to deactivation. However, to a very small extent, it undergoes cytochrome P450-dependent oxidation to form a reactive quinoneimine that has the potential to cause hepatotoxicity following covalent interaction with proteins (Fig. 2). The low levels of the quinoneimine are, however, effectively neutralized by conjugation with glutathione. As a result, paracetamol is a very safe drug at therapeutic doses, despite the formation of a cytotoxic metabolite, and only becomes unsafe when this fine balance of activation/deactivation is disturbed. Some groups of people, such as the chronic alcoholics, are vulnerable to the toxicity of paracetamol. Alcohol is the prototype inducer of CYP2E1, one of the cytochrome P450 enzymes that catalyzes the oxidation of paracetamol to the quinoneimine. Consequently, alcoholics, because of the higher CYP2E1 activity, form more of the toxic intermediate of paracetamol and, therefore, are sensitive to the hepatotoxicity of this drug. Thus, in this case, toxicity ensues because of increased activation that leads to the enhanced production of the toxic metabolite.

Most chemical carcinogens also rely on bioactivation to genotoxic metabolites that readily interact with DNA and set into motion the processes that eventually lead to tumorigenesis. The metabolic pathways once again are catalyzed by both
Phase I and Phase II enzymes, and the chemical is concurrently subject to deactivation pathways. Although cytochromes P450 frequently catalyze the first step in the bioactivation of most chemicals, other enzyme systems, such as the sulphotransferases and acetylases, also are essential in the generation of the ultimate toxic species, the entity that interacts with the cellular macromolecules. For example, the heterocyclic amine 2-amino-3-methylimidazo-(4,5-f)quinoline (IQ), a carcinogen formed during the grilling or frying of meat and fish, requires bioactivation to express its carcinogenicity. The activation pathway involves CYP1A2-catalyzed N-hydroxylation, followed by esterification of the hydroxylamine with sulphate and acetate to generate the sulphatoxy and acetoxy esters, respectively, that break down spontaneously to yield the nitrenium ion, the presumed ultimate carcinogen (Fig. 6). Ring hydroxylation at the 5-position and direct conjugation of the parent compound with glucuronide or sulphate are strictly deactivation pathways; the ring-hydroxylated metabolite of IQ is excreted eventually in conjugated form.

**Figure 6** Metabolic activation and deactivation of IQ. IQ, 2-amino-3-methylimidazo-(4,5-f)quinoline.
Conclusions

The human body is equipped with an array of enzyme systems that enable it to transform the myriad of chemicals to which it is inevitably exposed to metabolites that are readily and efficiently eliminated. In this way, the residence time of chemicals in the body is minimized and their accumulation prevented. Any factor that modulates the enzymes involved in the metabolism of a certain chemical will influence also its biologic activity, including toxicity. Obviously, the amount of reactive intermediate produced, and hence incidence but is determined by the nature of the enzymes active in the body at the time of exposure. A chemical is subject to several metabolic pathways, the majority of which will bring about its activation and facilitate its excretion. However, some routes of metabolism will transform the chemical to a metabolite capable of inducing toxicity and carcinogenicity. Obviously, the amount of reactive intermediate produced, and hence incidence of toxicity, will be largely dependent on the competing pathways of activation and deactivation, and whatever metabolic pathways, the majority of which will bring about its activation and facilitate its excretion. However, some routes of metabolism will transform the chemical to a metabolite capable of inducing toxicity and carcinogenicity. Obviously, the amount of reactive intermediate produced, and hence incidence of toxicity, will be largely dependent on the competing pathways of activation and deactivation, and whatever factor influences this delicate balance of activation/deactivation of a chemical will impact also on its biologic activity and safety.

Polymorphisms, Detection of
Cytochrome P450 monooxygenases represent a large superfamily of heme enzymes, which require a dioxygen molecule and two electrons supplied by a NAD(P)H-dependent protein redox partner to form catalytically active high-valent ferryl-oxo intermediate. These heme enzymes are found in most organisms from all biological kingdoms and catalyze various oxidative chemical transformations important for the biosynthesis of steroid hormones, vitamins, signaling molecules, and many other compounds, as well as for the metabolism of xenobiotics.

Cytochromes P450 represent a superfamily of heme enzymes with a common fold and mechanism that requires an atmospheric dioxygen molecule, two electrons from NAD(P)H, and one or two protons available from solvent water to form an active catalytic ferryl-oxo intermediate (1). All cytochromes P450 have one heme b (protoporphyrin IX) buried deeply in the protein globule, with molecular masses in the range 45–60 kDa. In the resting state, heme iron is oxidized (Fe$^{3+}$) and is coordinated with the thiolate sulfur atom of cysteine as the fifth axial ligand with the sixth position vacant or occupied by water. The iron serves as a sole redox center in the catalytic cycle, which accepts two electrons sequentially and channels them to coordinated dioxygen to form a (hydro)peroxo-ferric intermediate. Second protonation of the distal oxygen atom and transient formation of the iron coordinated oxo-water, Fe–OOH$_2$, results in the heterolytic scission of O–O bond and formation of the ferryl oxo porphyrin-cation radical, which is termed Compound I, by analogy to the same active intermediate first documented in peroxidases and catalases (2).

Reactions Catalyzed By Cytochromes P450

Although they are termed "monooxygenases," cytochromes P450 catalyze multiple chemical transformations that include hydroxylation, demethylation, epoxidation, C–C bond cleavage, deamination, and many others (3, 4). Most reactions performed by cytochromes P450 can be catalyzed effectively by Compound I, which is formally the same high-valent intermediate in all isozymes (5, 6). Substrate binding at the distal site of the heme brings the target chemical group into the close proximity of the reactive iron-oxygen catalytic intermediate, often in the regiospecific and stereospecific mode, to provide the selectivity of the chemical transformation. Thus, the broad range of metabolized substrates and the unprecedented variability of the chemical reactions catalyzed by cytochromes P450 can be attributed largely to the differences in substrate binding properties of different isozymes.

With respect to their functional roles in living organisms, cytochromes P450 can be separated tentatively into the enzymes essential for biosynthetic pathways and the xenobiotic metabolizing enzymes (1). The former group includes cytochromes P450 involved into the biosynthesis of steroid hormones, antibiotics, and the transformation of vitamins and cofactors such as retinoids, carotenoids, eicosanoids, and fatty acid derivatives as well as those involved in endogenous intracellular and extracellular signaling. Most reactions are catalyzed with narrow substrate specificity, and they afford products with high regioslectivity and stereoselectivity. As a result, some cytochromes P450 from this group are critical for normal life cycle, and deficiencies can lead to serious diseases (7). In contrast, most cytochromes P450 that belong to the latter group can metabolize a variety of substrates of different sizes through multiple chemical mechanisms and even can form several different products from one substrate. Some enzymes may also bind simultaneously two or three substrate molecules, same or different, and various cases of the resulting activation or inhibition of the product turnover were documented both in vivo and in vitro (4, 7). Cytochromes P450 from both groups are represented in all biological kingdoms; although in many cases, the information about their biological functions and underlying chemical mechanisms is incomplete and fragmented at best.

Despite the unprecedented variability of chemical reactions catalyzed by cytochromes P450, all the important features of their mechanism can be attributed to the oxidative transformations driven by the main catalytic intermediate, which is a...
Cytochrome P450 Mono-oxygenases. Chemistry of ferryl-oxo heme complex with the porphyrin pi-cation radical, or Compound I (3, 4, 8). Some important exceptions involve the hydroperoxoferric complex, Compound 0, and perhaps the one-electron reduced Cpd I, ferryl oxo heme complex Compound II (1, 3, 4, 9). Nonclassic reactions catalyzed by some cytochromes P450, which do not use oxygen, and thus deviate from the main P450 mechanism, include direct reductive processes driven by the heme iron (conversion of nitric oxide to nitrous oxide by CYP55, reductive dehalogenation, reduction of azo compounds and quinines, etc.). Another important role of cytochrome P450 activity is that they can react with peroxides with no consumption of external redox equivalents and perform peroxidase-type chemistry with the O–O bond scission, or afford rearrangements of fatty acid hydroperoxides.

Hydroxylation of hydrocarbons

Oxygen atom from Cpd I is inserted into the C–H bond of saturated hydrocarbons (Scheme 1a) by means of hydrogen atom abstraction followed by recombination of the transient hydroxyl with the carbon radical [the so-called “oxygen rebound” mechanism proposed by Groves in 1976 (8, 10)]. Another possibility can be the concerted oxygen insertion into the C–H bond. Both pathways are rationalized by the two-state mechanism developed by Shaik et al. (6, 9), which describes different reactivities of Cpd I in the high-spin and low-spin states. The possibility of involvement of Cpd 0, which is the ferric-hydroperoxo intermediate, into the carbon hydroxylation is also debated in the literature, but this species is much weaker oxidant and may participate in catalysis only in rare cases when the barrier for hydroxylation by Cpd 0 is lower than the barrier for the Cpd I formation. Carbon hydroxylation is one of the most common reactions for all cytochromes P450, with substrates that include steroid hormones, fatty acids, vitamins, and antibiotics (5, 11).

Oxidation and dealkylation of heteroatoms

Oxidative transformation of the heteroatom attached to the carbon (Scheme 1b) may result in direct electron abstraction from the former and formation of oxide (-NO, -SO, -PO, etc.) or may proceed through the hydrogen abstraction from the latter with subsequent hydroxylation as in the previous section. The second pathway is often followed by the heteroatom elimination and formation of carbonyl group. Substrates that contain nitrogen (i.e., amines and amides) are easier to oxidize and give more various products in P450 catalyzed reactions than compounds that contain oxygen. An example is the reaction of N-demethylation of caffeine catalyzed by the human CYP1A2.

Olefin oxidation (epoxidation)

Insertion of oxygen atom from Cpd I into the carbon-carbon double bond with formation of epoxide (Scheme 1c) reveals features characteristic for a concerted process, although formation of radical intermediates is possible in many cases. A unified description of this alternative is also provided by the two-state mechanism of catalysis by Cpd I (see the section on Hydroxylation of hydrocarbons). Essentially, the concerted oxygen insertion represents a low-spin reaction surface, whereas the distinct radical intermediate is formed on the high-spin reaction pathway. In the latter case, the carbon radical may attack the nearby heme nitrogen and modify the heme covalently. This reaction is also an important inactivation pathway of cytochromes P450 during oxidative transformations of terminal double and triple bonds.

Aromatic oxidation and hydroxylation

Aromatic compounds may be oxidized either through epoxidation or via addition of oxygen atom from Cpd I (Scheme 1d). Usually, both pathways afford more stable phenols or quinones as the end product through rearrangements and/or addition of another nucleophile. Direct abstraction of an electron from aromatic moiety is viable in the presence of strong electron-donating substituents. The oxidative metabolism of polycyclic aromatic compounds is represented by CYP1A1 in humans.

Dehydrogenation and desaturation

Desaturation, or formation of double bonds after hydrogen abstraction (Scheme 1e), is an important class of transformations of steroids, flavones, and drugs with heterocyclic compounds. These reactions do not involve insertion of oxygen into the
In the resting state (1) of cytochrome P450, the low potential heme iron (−400 through −250 mV) is mostly in the low-spin state (S = 5/2) with the water coordinated as the sixth ligand trans to the proximal thiolate. When the substrate binds in the vicinity of the heme, water ligation is destabilized, and the heme iron may turn to the tetrapyrrolic, pentacoordinated configuration 2 with the concomitant shift of the spin equilibrium to the high-spin (S = 3/2). As a result of the loss of the sixth ligand by the heme iron, the cytochromes P450 saturated with substrates are reduced much faster than in the substrate-free state because of the positive shifts of the redox potential by ∼100 mV. Such control over the rate of the first electron transfer by the substrate binding represents an important feature of the overall steady-state kinetics of many cytochromes P450; although some isozymes exist in a predominantly high-spin state, even without substrates, and they presumably lack this switch.

Some cytochromes P450 can bind two or three molecules of substrate or inhibitor simultaneously (CYP107, CYP158A1, CYP158A2, CYP2B4, CYP2C8, CYP2C9, CYP3A4, CYP245) and as a result may reveal non-Michaelis turnover kinetics. Functional homotropic and heterotropic cooperativity (i.e., the perturbation of the activity of the enzyme with respect to one substrate molecule by the binding of another molecule of the same or different type, respectively) typically is observed for such cytochromes P450. This allosteric behavior of xenobiotic metabolizing cytochromes P450 constitutes the important aspect of the drug–drug interaction problem in the pharmaceutical and medicinal chemistry and industry.

First electron transfer—reduction of ferric heme

Reduction of the heme iron of cytochromes P450 to the ferrous state is necessary for the binding and subsequent activation of atmospheric dioxygen. Initially, two electrons are derived from NAD(P)H by flavin adenine dinucleotide (FAD)-containing prostaglandin peroxidases (CYP2J and CYP108 families), which usually do not involve NADPH and oxygen consumption.

Reaction Cycle and Intermediates

Substrate binding and spin shift

In the resting state 1 (Fig. 1) with no substrate at the active site of cytochrome P450, the low potential heme iron (−400 through −250 mV) is mostly in the low-spin state (S = 5/2) with the water coordinated as the sixth ligand trans to the proximal thiolate. When the substrate binds in the vicinity of the heme, water ligation is destabilized, and the heme iron may turn to the tetrapyrrolic, pentacoordinated configuration 2 with the concomitant shift of the spin equilibrium to the high-spin (S = 3/2). As a result of the loss of the sixth ligand by the heme iron, the cytochromes P450 saturated with substrates are reduced much faster than in the substrate-free state because of the positive shifts of the redox potential by ∼100 mV. Such control over the rate of the first electron transfer by the substrate binding represents an important feature of the overall steady-state kinetics of many cytochromes P450; although some isozymes exist in a predominantly high-spin state, even without substrates, and they presumably lack this switch.

Some cytochromes P450 can bind two or three molecules of substrate or inhibitor simultaneously (CYP107, CYP158A1, CYP158A2, CYP2B4, CYP2C8, CYP3A4, CYP245) and as a result may reveal non-Michaelis turnover kinetics. Functional homotropic and heterotropic cooperativity (i.e., the perturbation of the activity of the enzyme with respect to one substrate molecule by the binding of another molecule of the same or different type, respectively) typically is observed for such cytochromes P450. This allosteric behavior of xenobiotic metabolizing cytochromes P450 constitutes the important aspect of the drug–drug interaction problem in the pharmaceutical and medicinal chemistry and industry.
bacterial cytochromes P450 and mitochondrial P450 systems. In these systems, the electron transfer from the FAD-containing reductase to the heme enzyme cytochrome P450 is mediated by the soluble iron-sulfur protein ferredoxin. In bacteria, all three proteins are soluble, whereas in mitochondria of eukaryotic cells, cytochromes P450 and reductases are associated with the inner membrane. The systems that belong to the second class include only two proteins, and the cytochrome P450 is reduced directly by the cytochrome P450 reductase (CPR), which contains both FAD and flavin mononucleotide. Variations of these systems include fusion enzymes in which a single polypeptide chain folds into two or three domains that correspond to the heme protein, iron-sulfur protein, and flavinprotein components of cytochrome P450 catalytic system (12). Many CPR flavoproteins strongly favor the usage of either NADH or NADPH, whereas some flavoproteins can use both efficiently.

Electron transfer in Class I systems is studied in detail for CY P101 and its reduct partner putidaredoxin (2Fe-2S), which contains protein with molecular mass 12.6 kDa. Binding of puti- daredoxin at the heme proximal site of CY P101 and formation of the transient electron transfer complex is accompanied by subtle conformational changes of both proteins and concomitant changes in their redox properties that stimulate the reduction of the heme iron to the ferrous state. The complex of CY P101-Pd is not very tight (Kd is in micromolar range), because facile dissociation is necessary to maintain the fast overall turnover. However, this complex is highly specific and can be perturbed significantly by single point mutations at the protein-protein interface. The apparent first-order rate of the first electron transfer in this system measured in kinetic experiments is in the range of 50–100 s⁻¹.

Oxygen binding and autoxidation—first uncoupling

Ferrous cytochromes P450 bind dihydrogen as the sixth ligand to the heme iron, and the resulting diamagnetic oxy-ferrous complex 4 is similar to that in myoglobin and hemoglobin. Quantum chemical studies show that the wave function of this complex predominantly is a mixture of approximately similar fractions of Fe²⁺−Ο₂ (closed shell, Pauling configuration) and Fe⁷⁺−Ο₂⁻ (open shell singlet, Weiss configuration), with the minor contribution of other configurations. Results of vibrational spectroscopy reveal that both 0−0 and Fe–O bonds are slightly weaker in oxyP450 (1128–1139 cm⁻¹ and 539–543 cm⁻¹) than in oxygenated myoglobin and hemoglobin (1148 and 572 cm⁻¹, respectively) (13). This difference is caused by more electron-rich thiolate ligand and the excess de- nuration of electron density to the antibonding orbitals of Fe-0-0 moiety in cytochrome P450. Similar effects were observed in nitric oxide synthase, which has the same thiolate ligand for the heme iron.

A comparison of available X-ray structures of oxy-ferrous complexes in CY P101, CY P107, and CY P158 reveals very similar structural arrangements of the heme iron and axial ligand with major differences concerning the detailed stereochemistry of the amino acid side chains and water molecules in the immediate vicinity of the bound dihydrogen (14, 15). The main difference is caused by the replacement of the mostly conserved alcohol functionality of T252 residue in CY P101 by methyl groups of A245 (CY P107) and A245 in CY P158. The absence of T252 hydroxyl within the hydrogen bond distance to the distal oxygen atom of the coordinated dihydrogen is compensated in the latter two enzymes by the specific positioning of hydroxyl groups on the bound substrates, which in turn stabilize water molecules assumed to be the ultimate source of protons for the oxygen activation (see below).

Usually, oxygen binding is faster than other steps in the enzymatic cycle, and it is not rate limiting in the overall substrate turnover. However, the lifetime of oxy-ferrous complex in cytochromes P450 at physiologic temperatures is in the range of seconds, because it decomposes spontaneously back to the resting ferric state with the formation of superoxide ion in an autoxidation reaction. Usually, the rate of autoxidation is lower by one or two orders of magnitude for the enzymes saturated with substrate. Higher stability of substrate-bound oxy-ferrous cytochromes P450 is explained in part by their higher redox potentials (i.e., by thermodynamic stabilization of the oxygenated heme enzyme in the enzyme-substrate complex). In addition, the presence of substrates in the active site was shown to impose dyna- namic constraints on the superoxide escape and to increase the kinetic stability of oxy-ferrous P450. Inhibition of autoxidation is an essential part of the regulatory role played by substrates in the overall optimization of the P450 cycle via minimization of this uncoupling reaction.

Second electron transfer and protonation, compound 0

Direct observation of the reduction of oxy-ferrous cytochrome P450 and formation of peroxy-ferric (5a) or hydroperoxo-ferric (5b) complex was never accomplished at ambient conditions because this intermediate, termed Compound 0, undergoes additional transformations and disappears faster than it is formed. However, it was isolated and studied by electron paramag- netic resonance (EPR), optical absorption, and resonance Raman spectroscopy at low temperatures using radiolytic reduction of oxy-ferrous cytochromes P450. As expected, the hydroperoxo-anion forms a relatively strong bond with the heme iron, and the resulting complex reveals the typical fea- tures of low-spin heme-thiolate complexes with the narrow span of g-values in EPR spectra and red-shifted Soret band (436–440 nm) (20). Spectroscopic and theoretical studies reveal that the length and strength of the 0–0 bond in Compound 0 are similar to those observed in the low-spin oxygen activating nonheme (hydro)peroxo-ferric complexes. The presence of the distinct hydroperoxo-ferric heme intermediate in the frozen solu- tions and in crystals of cytochromes P450 and several other heme proteins indicates that the spontaneous homolysis or het- erolysis of 0–0 bond is unfavorable. Thus, the efficient for- mation of the main active intermediate Compound I requires catalytic delivery of the second proton to the distal oxygen atom.
Second protonation and O-O- scission.

peroxide dissociation–second uncoupling

The second protonation of Compound 0 at the distal oxygen atom catalyzes fast scission of O–O bond with the leaving water molecule. In cryoradiolytic experiments, Compound 0 is stable below the glass transition temperature, 180–190 K, which means that the second proton delivery requires sufficient mobility as well as possibly relaxation and diffusion of the solvent molecules. Experiments with the native CY P101 and D251N mutant proved that at higher temperatures, Compound 0 disappears with formation of Compound I (6) and concomitant product formation (16). For the T252A mutant CY P101, in which the native proton transfer mechanism is perturbed, the dissociation of peroxide with no product formation is the dominant path of Compound 0 decomposition. The latter reaction is considered as the main source of reactive oxygen species in the poorly coupled P450 systems, in which the redox equivalents from NADPH oxidation are not used efficiently for the product formation. In general, the coupling efficiency measured by the ratio of the product molecules formed per one consumed NADPH molecule can be very different for the same cytochrome P450 with different substrates. The efficient proton delivery requires specific positioning and stabilization of water molecules near dioxygen moiety, which can be perturbed significantly by variations in the structure of substrate.

Compound I—properties and activity

Compound I (6) is the main catalytically active intermediate. A description of the main chemical reactions is given above. Compound I has yet to be characterized on the natural P450 pathway, although the transient formation of the short-lived ferryl-oxo intermediate with porphyrin-cation radical has been documented using reaction with peroxides. The electronic configuration of this intermediate, as evaluated by quantum chemical methods, represents it as a triradicaloid with two possible spin states \( S = \frac{1}{2}, \frac{3}{2} \), with closely spaced energies. In addition to the almost degenerate ground state with doublet and quartet relative stability regulated by the protein matrix, the sextet \( S = \frac{5}{2} \) can also be involved. The presence of high spin and low spin states of Cpd I provides variability in the reaction pathways and product distributions. This concept of two-state and multistate reactivity of Cpd I in cytochromes P450 developed by Shaik et al. (6, 9) provides basis for the unified explanation of the plethora of apparently contradictory experimental results in P450 chemistry.

Structures—Common Fold and Variations

All cytochromes P450, from soluble enzymes in archaea and bacteria to the mammalian integral membrane proteins, have essentially the same fold, which is specific for this superfamily despite their functional diversity (17) (Fig. 2). Only several enzymes with this fold do not follow classic P450 mechanism based on activation of dioxygen (i.e., nitric oxide reductase, CYP55 and CYP152, which uses hydrogen peroxide). Approximately 50% of the residues are located in helical fragments, which are designated by letters A to L with the addition of B', F', G', and J' in some isozymes, and 7–10% are found in small beta-sheets interspersed with flexible loops. As compared with the soluble bacterial enzymes, membrane-bound proteins usually have an extra N-terminal fragment that is thought to be incorporated into the membranes and longer loops with one or two small additional helical fragments.

The heme (protoporphyrin IX, heme b) is buried in the protein matrix between the long I-helix on the distal side and L helix on the proximal side. The loop at the N-terminus of L-helix contains absolutely conserved cysteinate with the deprotonated sulfur atom that serves as the proximal axial ligand of the heme iron. Three hydrogen bonds with this sulfur atom are formed by the amide groups of the highly conserved neighboring residues. These bonds are necessary to raise the redox potential of cytochrome P450 to the range accessible for the ultimate physiologic reductant NAD(P)H. Hydrogen bonds between propionic carboxyls and the side chains of protein amino acids prevent the loss of the heme and stabilize the native conformation.

A rather important and highly conserved feature in all structures of cytochromes P450 with only a few exceptions is the
presence of the acid-alcohol pair (i.e., sequential acid and alcohol side chains at the heme) just next to the dioxygen coordinated to the heme iron. An acidic side chain is provided by an Asp or Glu residue (n), whereas alcohol (n + 1) is from Thr or Ser. The hydroxyl of the latter is very often hydrogen bonded to the peptide carbonyl of the Gly (n − 3) forming a kink, which interrupts the regular α-helical structure and is thought to be essential for the efficient oxygen activation. Structures of the oxo-ferrous complexes resolved for CYPI01, CYPI07, and CYF158 reveal the appearance of specifically positioned water molecules, which are stabilized by the appropriate rearrangement of the side-chains of the acid-alcohol pair described above. These water molecules play an important role in the directed proton delivery provided by protein for the formation of Compound I and Compound II, although the details of the mechanism and specific pathway of this proton delivery are still debated.

Helices B, F, G, and G and connecting loops are involved in substrate binding and in general are much more variable and flexible (upper part of the substrate binding cavity shown in Fig. 2). These parts have different length in different classes of P450, with longer disordered insertions typical for eukaryotic enzymes and shorter and more compact structures characteristic for the proteins from extremophilic organisms. In all classes, however, the protein has to experience a large-scale conformational change to open access to the substrate-binding cavity. Comparison of the X-ray structures of cytochromes P450 with and without substrates and the results of molecular dynamics studies suggest that these conformational changes involve concerted movement of the fragments, which form the substrate-binding cavity that includes helices F and G and fragments between them, as well as B and C helices. Such an “opening” movement was first observed in the X-ray structures of CYPI01 with the “wired” substrates (19). In these structures, the diaminealkane chain traced the tentative substrate-binding cavity. However, in many cases, the conformations of cytochromes P450 with the bound substrates or inhibitors are even more compact than in substrate-free state, in which the flexible fragments rearrange to provide additional interactions with the hydrophobic molecule bound in the active center. In general, the high plasticity of P450 fold provides basis for the flexible fragments rearrangement of the side-chains of the acid-alcohol pair described above. These water molecules play an important role in the directed proton delivery provided by protein for the formation of Compound I and Compound II, although the details of the mechanism and specific pathway of this proton delivery are still debated.

Helices B, F, G, and G and connecting loops are involved in substrate binding and in general are much more variable and flexible (upper part of the substrate binding cavity shown in Fig. 2). These parts have different length in different classes of P450, with longer disordered insertions typical for eukaryotic enzymes and shorter and more compact structures characteristic for the proteins from extremophilic organisms. In all classes, however, the protein has to experience a large-scale conformational change to open access to the substrate-binding cavity. Comparison of the X-ray structures of cytochromes P450 with and without substrates and the results of molecular dynamics studies suggest that these conformational changes involve concerted movement of the fragments, which form the substrate-binding cavity that includes helices F and G and fragments between them, as well as B and C helices. Such an “opening” movement was first observed in the X-ray structures of CYPI01 with the “wired” substrates (19). In these structures, the diaminealkane chain traced the tentative substrate-binding cavity. However, in many cases, the conformations of cytochromes P450 with the bound substrates or inhibitors are even more compact than in substrate-free state, in which the flexible fragments rearrange to provide additional interactions with the hydrophobic molecule bound in the active center. In general, the high plasticity of P450 fold provides basis for the ability to bind multiple organic molecules with different sizes and chemical structures, which is critically important for the efficient metabolism of xenobiotics.

Heme (iron protoporphyrin IX) is a fundamental factor in biology with many physiologic roles. Its biosynthesis and degradation are regulated tightly because heme in excess of that required for incorporation into the available apoproteins is toxic. Heme itself is the dominant form in biology, but it is modified additionally to satisfy specific biochemical requirements. Both the biosynthesis of heme and its distribution into the various compartments of the cell and organism require the intervention of heme transporters. In contrast to the passive transport afforded by proteins like albumin, the transfer of heme across membranes is mediated by energy-dependent transporters. One role of heme is to function as a regulatory molecule whose concentration controls the translational expression of multiple genes directly. As the prosthetic group of receptors that respond to oxygen, nitric oxide (NO), and other iron ligands, it is also involved in signaling. Finally, it is the prosthetic group of diverse families of hemoproteins, including the globins, cytochromes, P450 monooxygenases, NO synthases, dioxygenases, peroxidases, peroxygenases, and catalases.

Iron is an essential element for life because its oxidation-reduction properties are in the biologically accessible range, are readily modulated, and can be used to satisfy a diversity of functions. These functions include electron transfer, ligand binding and sensing, ligand transport, and catalytic functions that involve the activation of molecular oxygen or peroxides. However, iron itself is highly insoluble in the ferric state, and in the ferrous state it supports the formation of deleterious species such as the hydroxyl radical. Therefore, nature has evolved strategies for the chelation and encapsulation of iron that allow the exploitation of its useful features but minimize the associated toxicity. The most effective and ubiquitous of these solutions is to incorporate the iron into a porphyrin, producing heme. Incorporation of the iron into heme not only allows better control of its solubility and spatial localization, but also enables fine-tuning of its redox properties for specific tasks.

The field of hemes in biology is enormous and it is possible only to touch on the salient points in this article, which focuses primarily on the biosynthesis, degradation, transport, and regulatory role of heme. The catalytic functions of heme are diverse and fascinating, but many of the relevant enzymes are summarized only briefly here.

Heme Structures and Nomenclature

Heme (heme B) is a highly conjugated cyclic tetrapyrrole in which an iron is coordinated to the four nitrogen atoms of a protoporphyrin IX framework. In heme, four methyls, two vinyls, and two propionic acid substituents are distributed asymmetrically around the porphyrin periphery (Fig. 1). The four pyrrole rings are labeled A to D, the four meso-carbons are denoted by Greek letters, and the positions of the eight substituents are numbered. Crystallographers sometimes use a different A–D order for the four pyrrole rings. The formal IUPAC nomenclature for heme (Fig. 1) is used by organic chemists but is not often used in biology. The compound is called heme when the iron is in the ferrous state and is called hemin when it is in the ferric state, but chemists do not always adhere strictly to this distinction.

Heme is the most common biologic form, but additional elaborations of the porphyrin skeleton are required for certain purposes. Among these more baroque iron porphyrins are heme A, the structure found in cytochrome c oxidase; heme C, the prosthetic group of cytochrome c in which the covalently bound cysteines are part of the protein structure; and less common structures such as the heme D in the catalase from Escherichia coli (Fig. 2). The 5-methyl group of heme is modified additionally by the formation of an ester link to an active-site carboxyl group in most members of the CYP4 family of cytochrome P450 enzymes (1), and by both the 1-methyl and the 5-methyl groups in the mammalian peroxidases, including myeloperoxidase, lactoperoxidase, eosinophil peroxidase, and thyroid peroxidase. In myeloperoxidase, a third covalent bond is formed in addition to these ester links that links a methionine to the 2-vinyl group. Other modifications are known that tailor the heme for specific biologic functions.

Heme Biosynthesis

Mammalian heme biosynthesis traverses eight enzymatic steps and requires shuttling of the first intermediate, 5-aminolevulinic acid from the mitochondrion into the cytosol, and later transferring coproporphyrinogen III back into the mitochondrion for the three final biosynthetic steps (2).

Pre-porphyrin steps

The first and rate-limiting step in heme biosynthesis is the condensation of glycine and succinyl-CoA to give 5-aminolevulinic acid by aminolevulinic acid synthase (ALAS) (Fig. 3). Two mammalian forms of this enzyme are known: ALAS1, which is ubiquitously expressed, and ALAS2, which is specifically expressed in erythroid precursors (3, 4). Both enzymes are homodimers and use pyridoxal 5-phosphate as a cofactor. Although the crystal structures of mammalian ALAS1 and ALAS2 have not been determined, the structure of a highly homologous enzyme from Rhodobacter capsulatus has been (5). The condensation reaction catalyzed by these enzymes involves the formation of an imine bond between the pyridoxal and glycine followed by deprotonation, the displacement of the CoA from succinyl-CoA, decarboxylation, and the hydrolytic release of 5-aminolevulinic acid from the pyridoxal cofactor. ALAS1 has three putative
heme-binding motifs (HRMs), two in the N-terminus of its mitochondrial targeting domain and one in the N-terminus of the mature protein. Binding of heme to one or more of these HRMs inhibits mitochondrial import of the protein and thus provides end-product feedback regulation of heme biosynthesis (6). This regulation complements the direct heme-dependent downregulation of ALAS expression at the transcriptional level. Mutations in ALAS result in X-linked sideroblastic anemia (5).

In plants and in most bacteria, 5-aminolevulinic acid is produced by an alternative pathway involving tRNA-bound glutamate and two enzymatic steps catalyzed by glutamyl-t-RNA reductase and by glutamate-1-semialdehyde-2,1-aminomutase (7, 8).

The 5-ALA formed in mammalian mitochondria is transferred to the cytosol, where aminolevulinate dehydratase (ALAD) catalyzes the condensation of two monomers to give porphobilinogen (Fig. 3), the monopyrrole building block of the porphyrin skeleton. ALAD is a zinc-dependent tetramer of homodimers with one catalytic site per dimer (9, 10). The condensation reaction requires the formation of an enamine link, tautomerization of the enamine, closure of the five-membered ring by an aldol-like reaction, and dehydration to give the pyrrole ring. Mutations in ALAD are associated with the rare recessive autosomal ALAD porphyrias. Deficiencies in ALAD activity are also involved in hepatorenal tyrosinemia and lead poisoning, the former because the defect produces succinyl acetone that...
inhibits ALAD and the latter because lead displaces essential zinc ions from the protein complex.

The next stage of heme biosynthesis is the formation of the linear tetrapyrrole hydroxymethylbilane by porphobilinogen deaminase (PBGD). The crystal structure of PBGD shows that a dipyrrole cofactor is covalently within the active site of the enzyme (11). This dipyrrole is condensed with four additional porphobilinogen monomers to form a hexameric polymer. Cleavage of the tetrapyrrole unit from the dipyrrole cofactor produces hydroxymethylbilane (Fig. 3). Mutations in the PBGD gene are responsible for the disorder known as acute intermittent porphyria (12). A cute episode of this disorder are treated by the administration of hematin (the Fe–OH complex of heme), which leads to restoration of heme levels, the downregulation of ALAS1, and a decrease in the synthesis of toxic porphyrin precursors.

**Porphyrens and heme**

Hydroxymethylbilane is converted by uroporphyrinogen III synthase into uroporphyrinogen III in a remarkable ring-closing reaction that inverts the orientation of pyrrole ring D of hydroxymethylbilane (Fig. 3). This ring flip exchanges the positions of the propionic and acetic acid side chains and introduces the substituent asymmetric character of heme. The crystal structure has not yet provided a clear understanding of how this transformation is achieved (13). Mutations in uroporphyrinogen III synthase cause a rare disease known as congenital erythropoietic porphyria (14). This disease results in the accumulation of uroporphyrin I, the abnormal porphyrin without the pyrrole ring D. Fig. Uroporphyrin I is formed by an abnormal, nonenzymatic closure of hydroxymethylbilane and cannot be processed further. The accumulated porphyrin acts as a photosensitizer that causes the cutaneous lesions associated with the disease.

Uroporphyrin III is the branching point in the pathway at which heme synthesis diverges from those of chlorophyll and the corrin. In heme biosynthesis, uroporphyrinogen III is next decarboxylated by uroporphyrinogen III decarboxylase to give coproporphyrinogen III (Fig. 3) (15). This enzyme promotes the decarboxylation of the four acetic acid side chains to give the methyl groups at positions 1, 3, 5, and 8 of the heme framework. Mammals use a form of this enzyme that is oxygen-dependent and releases CO2 and H2O2, but an oxygen-independent form is found in bacteria. The crystal structures of the human and the yeast enzymes have led to both acid-base and free radical mechanistic proposals (18, 19).

This decarboxylation reaction occurs in the mitochondria and thus requires the translocation of coproporphyrinogen III from the cytosol into this organelle. Hereditary coproporphyria, the disorder in humans that is caused by mutations in the coproporphyrinogen oxidase gene, is treated by the administration of hematin.

Coproporphyrinogen oxidase converts protoporphyrinogen IX to the fully deuterated porphyrin in a reaction that uses O2 as the terminal electron acceptor (Fig. 3). The crystal structure of the homodimeric enzyme shows it has one FAD per monomer, which presumably mediates the porphyrin oxidation reaction (19). Like the decarboxylation mediated by coproporphyrinogen oxidase, this reaction also occurs in the mitochondrion. Mutations in the protoporphyrinogen oxidase gene are responsible for variegate porphyria (21). A cute attacks of this disease can be effectively treated by intravenous administration of hematin.

The synthesis of heme (Fig. 1) is completed in the mitochondrion by insertion of iron into the protoporphyrin IX framework by ferrochelatase. Ferrochelatases from various organisms have been crystallized and their structures determined. The human enzyme contains one 2Fe-2S cluster in each of the two subunits of the functional dimer (22); possibility as a mechanism to link heme synthesis to iron availability. Erythropoietic protoporphyria, which is characterized by cutaneous photosensitivity, is caused by mutations in the ferrochelatase gene (23).

**Additional elaboration of the heme framework**

The formation of heme C requires the addition of a cysteine thiol to each of the two vinyl groups of heme B (Fig. 2). The thiol links are usually formed with a cysteine in a CXXXCH sequence, but small variations of this motif are known (24).

Three systems catalyze the formation of these bonds and are known imaginatively as systems I, II, and III (25). System I occurs commonly in Gram-negative bacteria and in plant mitochondria, system II in Gram-negative and Gram-positive bacteria as well as in thylakoids, and system III in fungi, invertebrates, and vertebrates. In all three systems, an addition of the cysteine to the vinyl group is mediated enzymatically, with a supporting cast of several proteins required in systems I and II but not in system III. Despite its ubiquitous nature, the catalytic or structural advantage of the heme C covalent linkage remains unclear (26). Interestingly, a Synechocystis hemoglobin is known in which the heme is covalently linked through a vinyl group to a histidine residue (27).

The synthesis of heme A (Fig. 2) involves the initial addition of the farnesyl moiety to the heme 2-vinyl group by heme O synthase, which generates heme O that only has this modification. In a second step, heme A synthase oxidizes the B-methyl of heme O to an aldehyde, which generates heme A. An electron transfer mechanism (rather than double hydroxylation) has been proposed for this final biosynthetic step (28).

In contrast to the biosyntheses of heme A and heme C, which require dedicated protein catalysts, the ester groups that link methyl groups of heme B with protein carboxy groups are generated autocatalytically. As has been clearly shown...
for lactoperoxidase (29) and for several CYP4 cytochrome P450 enzymes (30), the ester links are generated in the initial catalytic turnovers of the proteins in question. Investigation of the reaction details, and mimicry of the reaction in horseradish peroxidase (31), a protein that normally does not form such bonds but does upon introduction of an active site carboxylic acid residue, strongly supports a carboxyl radical/hydrogen abstraction mechanism (Fig. 4).

Heme Catabolism

The only physiologic (as opposed to pathologic) mechanism for the degradation of heme in mammals is catalyzed by heme oxygenase. Analogous heme oxygenases are found in plants, bacteria, and fungi. Two heme oxygenases, known as HO1 and HO2, are present in mammals. HO1 is distributed widely, is induced by a diversity of agents, and is critical for the removal of the heme released by erythrocyte lysis and the degradation of hepatic hemoproteins. The levels of HO1 expression are regulated in a feedback manner at the transcription level by heme. HO2, although widely distributed, is concentrated in tissues such as the testes and the brain, is only induced by hormones, and has been postulated to fulfill physiologic roles beyond the simple removal of excess heme. For example, HO2 has been reported to function as an oxygen sensor that controls a potassium channel in the carotid body (32). The structures of rat and human HO1 (33, 34), and of heme oxygenases from several microorganisms (35), have been determined, but HO2 has not been crystallized. One of the significant differences between the sequences of HO1 and HO2 is the presence in HO2 of two HRMs analogous to those in 5-aminolevulinate synthase. The role of these HRMs in HO2 is unknown.

The oxidation of heme by heme oxygenase requires O2 and seven electrons. The electrons in mammals are provided by cytochrome P450 reductase, but alternative electron donors are employed in the plant and bacterial systems. However, the actual transformation is similar in all cases. The first step is hydroxylation of the meso-carbon at which the porphyrin ring will be cleaved (Fig. 5). In mammals, this position is the α-meso carbon, but alternative meso-positions can be oxidized in bacteria. The resulting α-meso-hydroxyheme is further oxidized by O2 to α-verdoheme and CO. Additional catalytic turnover produces ferric biliverdin that, after reduction of the iron, loses the iron atom and dissociates from the protein. In mammals, the biliverdin is further reduced to bilirubin by biliverdin reductase and is then excreted as a glucuronic acid conjugate. In situations where the relevant glucuronyl transferase activity is low, as in some neonates or in Crigler–Najar syndrome, bilirubin accumulates and causes jaundice or, at higher levels, causes neurological toxicity. Agents such as tin protoporphyrin IX can be used to inhibit heme oxygenase and thus to decrease the formation of biliverdin and bilirubin.

All the products of the oxidation of heme by heme oxygenase are important physiologically. Biliverdin and its reduction product bilirubin are powerful antioxidants and, at nontoxic concentrations, contribute to cellular protection. CO, the second product, also has potent biologic activities, although it is often...
Figure 5 The multistep conversion of heme to α-biliverdin catalyzed by heme oxygenase. The electrons from NADPH are transferred to heme oxygenase by cytochrome P450 reductase or other electron donor proteins.

unclear how these activities are mediated. Finally, the ferrous iron that is released causes upregulation of the iron-binding protein ferritin and can also have an antioxidant effect. These products, singly or in combination, have been shown to confer protection against oxidative injury and cellular stress. Induction of HO1, or administration of CO or bilirubin, inhibits apoptosis, whereas inhibition of HO1 stimulates apoptosis. Therefore, the inhibition of heme oxygenase may be relevant to the treatment of cancer (36). In another context, oxidized low density lipoprotein (LDL) is a key player in the development of atherosclerotic plaques, and LDL oxidation is inhibited by HO1 and its antioxidant products. The manipulation of the HO1 system is therefore of potential interest in cardiovascular disease (37). The heme oxygenases and/or their products are relevant to the amelioration of reperfusion injury, avoidance of transplant rejection, and a variety of inflammation-based disorders (38).

In bacteria, heme oxygenases play a role in iron acquisition. A greater variety is seen in the bacterial heme oxygenases than is seen in man, but the essential catalytic features are preserved and the mechanism of the oxidation is the same (35, 39). The presence of two heme oxygenases in Pseudomonas aeruginosa, one that cleaves the heme at the α-meso-carbon and the other at the δ-position, may reflect the fact that one of the two provides the tetrapyrrole for a bacterial phytochrome response regulator (40, 41). It may be desirable to generate a different regioisomer of biliverdin in the iron acquisition pathway so that it does not interfere with the regulatory system. Under oxidative-stress conditions, heme can also be degraded nonenzymatically to nonporphyrin monopyrrole and dipyrrole products, although the mechanistic details of this degradation remain obscure (42).

**Figure 5**

Heme Transport

Heme (hemin) at physiologic pH is relatively insoluble and is found bound to proteins or membranes except for a low concentration (<10⁻⁷ M) of so-called “labile” heme (43). Unbound heme is potentially cytotoxic and its levels are controlled tightly by feedback regulation of its biosynthesis at the level of 5-aminolevulinic acid synthase, and of its degradation by heme oxygenase, which is a heme-inducible enzyme. As heme is lipophilic, it is able to diffuse into and through cell membranes. Nevertheless, the efficient trafficking of heme involves protein transporters, some of which have been identified. Transporters of heme in the circulatory system, such as albumin, can be classified simply as heme-binding proteins. However, proteins that mediate the energy-dependent transmembrane transport of heme have been identified. Subtractive suppression hybridization has led to the identification of heme-carrier protein 1 (HCP1) in the duodenum of mice (44). This protein also transports Zn protoporphyrin IX, which indicates that the iron is not essential for recognition. Interestingly, homologous proteins are found in man and other mammals. HCP1, which is upregulated in hypoxia, has 459 amino acids and is predicted to have nine
transmembrane domains (44). It has a GxxSxxGxGRR motif that is found in bacterial tetracycline transporters, with which it has significant (22%) similarity, but it does not have the CP motif of the HRMs in proteins such as HO2.

Heme must be exported from the mitochondrion, where the final steps of heme synthesis occur, and a system may exist to import heme into the nucleus, as diverse genes are regulated directly at the transcriptional level by heme. The transporters that mediate this trafficking of heme have not been unambiguously identified. Recent work has shown that the mitochondrial ATP-binding cassette transporter ABCB6, a homodimeric protein that is located on the outer mitochondrial membrane, is required for porphyrin uptake into the mitochondria during heme biosynthesis (45). Heme can be transported by this protein, but it transports coproporphyrinogen III more efficiently, which implicates it as the protein involved in importation of this heme precursor. A 60-kDa protein known as FLVCR, which serves as the feline leukemia virus C receptor (thus the name), has been shown to export cytoplasmic heme from developing erythroid cells and is postulated to do so to protect them from heme toxicity (46). FLVCR has the same GxxSxxGxGRR motif found in HCP1. A second heme efflux protein denoted as ABCG2, also known as breast cancer resistance protein (BCRP), has been reported (47). This 70-kDa protein, a member of the ABC transporter family, has six predicted transmembrane domains and is functional as a homodimer.

Heme that is released into the blood stream by lysis of red cells, catalysis of haptoglobin-hemoglobin complexes, or other mechanisms binds to albumin ($K_d \sim 10^{-10} M$) and hemopexin ($K_d \sim 10^{-8} M$) (48). The hemopexin–heme complex is taken up in the liver by a receptor-mediated process. A candidate for the hemopexin–heme receptor has been identified (49). Other heme-binding proteins are scavenging and degrading heme. Gram-negative bacteria have receptors that interact directly with hemoproteins, such as hemoglobin and hemoglobin–haptoglobin, or that interact with a hemophore excreted by the bacterium that scavenges the heme and delivers it to the cell (50). The receptors use the TonB/ExbB/ExbD complex to transport the heme through the outer membrane. The best understood of these hemophores is Serratia marcescens, for which a crystal structure is partially determined by control of Bach1 nuclear localization. Bach1 has six HRMs that are critical for regulation of its binding to DNA, whereas seven HRMs are involved in its response to heme.

In mammals, Bach 1 is a heme-activated leucine zipper protein that acts as a transcriptional repressor (54). Bach1 associates with members of the Maf-related oncogene family. The resulting heterodimers bind to the Maf recognition element of target genes, including HO1, globin genes, and ALAS2. Bach1 has six HRMs that are critical for regulation of its activity by heme. Heme binding seems to act as a signal for nuclear export of the protein, so that heme regulation is partially determined by control of Bach1 nuclear localization. A concentration of $-1 \mu M$ heme almost completely inhibits the binding of the Bach1-Maf dimer to DNA.

The maturation of reticulocytes to erythrocytes requires a massive synthesis of heme to enable the assembly of hemo
globin. It is important to couple the synthesis of heme to that of the hemoglobin α-chains and β-chains, as both the unassembled apoproteins and excess heme are toxic to the cell. The HRI kinase is responsible for coordinating heme and protein synthesis in reticulocytes. HRI inhibits globin synthesis at the translation initiation level under limited heme conditions. Under these conditions, HRI is activated and phosphorylates Ser51 of the eIF2 α-subunit. The phosphorylated protein binds tightly to eIF3B and ties up this protein, preventing it from catalyzing the replacement of GDP by GTP in eIF2α required for its role in initiating protein synthesis (55). HRI has three HRMs, one of which binds heme reversibly and is thought to couple the activity of the protein to the heme concentration and another that binds heme stably and is thought to be involved in the response of HRI to gases: NO increases HRI activity, whereas CO decreases it. The molecular chaperones Hsp70 and Hsc70 play important roles in this process, as immature HRI has no activity but becomes responsive to heme deprivation when transiently complexed to the chaperones.

Neuronal differentiation has been found in a model system to be heme-dependent (58). Inhibition of heme synthesis at the level of ALAS reduces the number and the length of neurites to and regulates histidine kinases, heme-responsive transcription factors, cyclic nucleotide phosphodiesterases, and factors such as the eIF2α heme-regulated HRI kinase. Through these interactions, heme contributes to cellular functions such as cell growth and differentiation, oxygen and nitric oxide sensing, cell respiration, and globin gene activation. Furthermore, as illustrated by its control of heme synthesis through binding to ALAS1 and inhibition of its migration into the mitochondrion, it can influence protein maturation directly.

5. cerevisiae, a facultative aerobic, responds to changing oxygen levels by altering the expression of a battery of genes. This coordinated response to oxygen levels in S. cerevisiae is mediated by the heme activator protein Hap1 (53). The activation of Hap1 increases in parallel with the concentration of heme and reaches maximum activation at micromolar heme concentrations. The binding of heme allows Hap1 to bind to regulatory motifs in nuclear DNA and, thus, allows it to promote the transcription of genes encoding proteins that are essential for respiration and the control of oxidative damage. A repressor (ROX1) of genes involved in anaerobic growth is also regulated by Hap1. A zinc cluster and a dimerization domain are involved in its binding to DNA, whereas seven HRMs are involved in its response to heme.

Heme as a Regulatory Molecule
Heme is not only a protein prosthetic group but also it controls the activities of diverse regulatory systems directly. Heme binds
induced by nerve growth factor (NGF), and this effect can be overcome by the addition of exogenous heme. These consequences of heme deficiency reflect the associated inactivation of the NGF-dependent Ras-ERK 1/2 signaling pathway.

Heme as an Enzyme Prosthetic Group

Heme is a ubiquitous prosthetic group in proteins with oxidation-reduction functions. The proteins that incorporate heme as an essential component include respiratory proteins, such as cytochrome c and cytochrome c oxidase. The oxygen carriers myoglobin and hemoglobin are members of a second class of hemoproteins that have some relationship to gas sensor hemo-proteins, as represented for NO by guanylate cyclase; for O2 by Hap1, FixL, and HemA T; and for CO by CooA. The largest class of hemoproteins is made up of catalytic enzymes and includes the cytochromes P450, peroxidases, peroxygenases, catalases, NO synthases, prostaglandin synthases, and thromboxane/prostacyclin synthases.

A general scheme of the catalytic manifold of hemoproteins is outlined in Fig. 6. In this abbreviated mechanism, the reaction of the ferric heme with H2O2, or with oxygen and two electrons derived from NAD(P)H, produces a “Compound I” ferryl (FeIV = O) intermediate. This intermediate can catalyze a single two-electron oxidation (monooxygenase or peroxygenase activity) or two one-electron oxidations (peroxidase activity) (57, 58). In addition to the dominant role of the ferryl intermediate in hemoprotein catalysis, oxidations can also be mediated by intermediates that precede the ferryl species. For example, the iron peroxy anion (Fe-OO-), a precursor of the ferryl intermediate, is thought to be involved in the carbon–carbon bond cleaving reactions of cytochrome P450 enzymes and the formation of NO by NO synthases. The function of these and other catalytic hemoproteins, all of which illustrate the virtuoso catalytic power and flexibility of the heme group, are reported in more detail in other chapters of this volume.

Human hemoglobin binds four oxygen molecules with positive cooperativity in a binding cascade of eight partially ligated intermediates whose oxygen ligands are distributed in different combinations between the hemoglobin’s two αβ dimers. Traditionally, it had been assumed that, given their close association in forming the hemoglobin tetramer, the two αβ dimers would always respond to oxygen binding in a synchronous and symmetric manner. Using linkage thermodynamics, the intermediate binding constants are evaluated via dimer–tetramer assembly with ligand configurations within the tetramer fixed through the use of hemesite analogs. It is observed that the free energy contribution of the asymmetrically ligated intermediate composed of one fully oxygenated αβ dimer plus one unoxygenated dimer is not the same as other doubly ligated intermediates, which contain at least one bound oxygen on both dimers. Therefore, the dimers within the tetramer respond to oxygenation differently, and cooperativity is dependent on the distribution of ligands between the two αβ dimers.

Introduction

The structural and functional properties of human hemoglobin (Hb) have been the subject of study for decades, stimulated by the intriguing characteristic of positive cooperativity. How do the four subunits that compose the Hb tetramer communicate with one another? The answer to this question has been sought primarily through the comparison of deoxy with oxy Hb. However, to understand the molecular mechanism of a chemical reaction, it is necessary to characterize the intermediate(s) of the process, and the reaction of Hb with O2 is no exception.

The binding of four O2 ligands by human Hb occurs through a series of 14 partially ligated intermediates, of which eight are unique in their combinatorial arrangement of bound O2 among the two α-subunits and two β-subunits. The well-known sigmoidal binding curve that results (see Fig. 2 for an example) is indicative of a strong positive cooperativity of oxygenation, thus, the binding constants for each Hb intermediate are changing as the O2 binding process continues.

The individual microscopic binding constants cannot, however, be measured from the binding curve: Only four average, macroscopic binding constants can be directly observed. This result is a result of several factors, foremost of which is the high cooperativity of O2 binding itself, which suppresses the concentrations of the intermediates. Thus, the binding curve is dominated by the properties of the two end-states, i.e., the fully deoxygated tetramer and its fully oxygenated counterpart. Other factors that contribute to the low resolution of the binding curve are the lability of the bound O2 and the continuous dissociation of the tetramer to its constituent αβ dimers.

Therefore, in a system that binds O2 close to equilibrium to begin with, the rearrangement of bound O2 among the heme binding sites acts only to mask the individual properties additionally (such as a microscopic binding constant) of a given intermediate. This classic problem of disproportionation can be solved experimentally through the use of hemesite analogs that either block O2 binding or O2 dissociation in specific subunits (α1, β1, α2, β2) within the tetramer. The dissociation of tetramer to free dimer, and the resulting dimer rearrangement among tetramers, cannot be blocked but can be measured. The dimer → tetramer assembly free energy, $\Delta G_{asm}$, can then be applied as a constraint that permits the determination of the Gibbs free energy, $\Delta G_{ij}$, of each intermediate binding reaction by employing thermodynamic linkage analysis.

The microscopic O2 binding constants thus determined reveal a particularly strong energetic coupling between the subunits.
within each αβ dimer of the tetramer (2). This intradimer cooperativity is evident particularly in the intermediate composed of one oxy dimer and one deoxy dimer, or the asymmetric doubly ligated species. Identification of this intermediate provided the first direct experimental evidence of intradimer cooperativity, which challenged the commonly held two-state model of cooperativity, in which the two dimers within the tetramer are assumed to maintain the same structural and energetic properties throughout the binding process. Rather than maintaining dimer–dimer symmetry, the αβ dimers each exhibit a unique O2 affinity and continue to modulate the O2 affinity of each other.

Background
Since the determination of its crystal structure almost five decades ago, the study of cooperativity and allostery in human Hb was focused primarily on the properties of the two end-states, the deoxy and oxy tetramers. The approach to mechanistic questions of subunit–subunit coupling within the tetramer is now shifting to the characterization of the partially ligated intermediates. Although crystal structures are not yet available for the intermediates, their individual O2 binding constants are now determined for one set of solution conditions.

Structural elements of the hemoglobin tetramer
The human hemoglobin tetramer is composed of two types of polypeptide chains, designated α (with 141 amino acid residues) and β (with 146 residues). Both subunit types exhibit a high degree of α-helical content with no β structure, and each contains a noncovalently associated b-type Fe heme to which O2 binds. As a tetramer, the four subunits are organized structurally as two αβ dimers held together by a polar, water-filled dimer–dimer interface (Fig. 1). Although the dimer–dimer interface dissociates readily under physiologic conditions to produce free αβ dimers, the intradimer interface is hydrophobic and only dissociates appreciably in the presence of certain metal ions or under denaturing conditions. Therefore, the αβ dimers are shared constantly and redistributed among the tetramers. When the Hb tetramer binds O2, a large change in quaternary structure is observed in which the two αβ dimers reorient relative to one another. From the deoxy or T structure, this reorientation can occur in either one of two major forms, which yields the R or the R2 structure. The R structure is observed by crystallization of oxyHb under high salt conditions, whereas the R2 structure is observed in low salt crystals. Nuclear magnetic resonance analysis has demonstrated that the R and R2 structures can coexist in solution (3). Additional crystal structure conditions have revealed that multiple oxy or R as well as deoxy or T forms are possible (6–8). All structural forms of the tetramer are ligated symmetrically (or unligated); i.e., the two dimers within the tetramer are always observed as structurally equivalent in available crystal structures. Structural changes that take place in the αβ dimers themselves are referred to in the Hb literature as “tertiary” and include the movement of the heme Fe into the plane of the heme when oxygenation begins; subsequent movement of helices are close to the heme and to the dimer–dimer interface. A significant structural change in the intradimer interface is not observed in crystal structures, which has led to the conclusion that oxygenation-induced tertiary structural changes are not communicated between the subunits within a dimer, i.e., between α1 and β1 or between α2 and β2. Although this belief has spanned the course of several decades, more subtle structural changes in the intradimer interface have not been ruled out. Recently, A one et al. have pointed out that the intradimer structure has not been analyzed thoroughly in modern crystal structures of Hb.

Figure 1. The cascade of O2 binding to the four subunits of the human Hb tetramer. The polar dimer–dimer interface is composed of J1 plus J2 plus J3 contacts. Two intradimer interfaces exist, the a1b1 and the a2b2, both are nonpolar. Each tetramer is assigned a species designation, which begins with deoxy Hb (species 01) and ending with oxy Hb (species 41). The first O2 can bind to any one of four subunits; however, because oxygenation of the α1 subunit is indistinguishable from oxygenation of the α2 subunit, the two isomeric tetramer species that result are designated “11a” and “11b.” This labeling is likewise the case for the β subunits. Similar isomeric oxygenation microstate tetramers are also generated in the second and third binding steps. Crystal structures are from the Arnone laboratory 14, 15.
Very few attempts to crystallize the partially ligated intermediates of Hb have been reported, and structural information is still not available. When O2 binding occurs, the quaternary reorientation of the two dimers forms the primary basis for the popular two-state model of Hb cooperativity. In this model, O2 binding to a heme Fe causes significant structural change only in the dimer-dimer interface. The bonds of the deoxy or T interface, held by the model to be significantly weaker than those of the oxy or R interface, maintain the tetramer in the low-affinity conformation. Oxygenation of deoxy Hb causes bonds in the T dimer-dimer interface to break, which weakens the low-affinity T state relative to the high-affinity R state. Therefore, the O2 affinity of the tetramer is controlled by the strength of the dimer-dimer interface, as modulated by the number of O2 ligands bound to the subunits. The particular configuration of the bound O2 among the four hemepools is not significant in this model. For example, in a tetramer that bears two bound O2, six possible configurations of the bound ligands exist among the four hemepools (see Fig. 1). In the two-state model, all six of the doubly ligated tetramers have the same O2 affinity because differences between the two ligands results in the same number of bonds broken in the dimer-dimer interface, regardless of the exact distribution of the ligands among the four hemepools.

**Relationship of macroscopic to microscopic binding constants**

Oxygen-binding curves can be analyzed directly to yield four macroscopic binding constants: $K_5$, $K_6$, $K_7$, and $K_8$. Usually, the microscopic constants are defined as product constants, i.e., products of the microscopic constant $K_{i,j,k,l}$ (where $i$ is the number of bound O2):

$$K_1 = K_{0,1} = K_{0,1}$$
$$K_2 = K_{0,2} = (K_{0,2})(K_{0,1})$$
$$K_3 = K_{2,0} = (K_{0,2})(K_{0,2})(K_{1,2})$$
$$K_4 = K_{2,0,2} = (K_{0,2})(K_{2,0})(K_{2,2})(K_{2,4})$$

The constant $K_{i,j,k,l}$ is composed of microscopic constants, as each O2 binding step is composed of multiple microscopic reactions, which is illustrated by the reaction arrows in Fig. 1. Thus, $4$ ways exist to bind the first O2, $12$ ways to bind the second O2, $12$ ways to bind the third O2, and $4$ ways to bind the fourth O2. Each microscopic constant is designated by the notation $i,j,k,l$ or the species formed in the binding process (Fig. 1, Table 1). For each binding step $i = 1,2,3$, and $4$, the microscopic constant $K_{i,j,k,l}$ is defined. For example, the reaction arrows in Fig. 1 illustrate the binding process.

**Chemistry**

The dimer-tetramer assembly constant $K_{0,0}$ is very sensitive to O2 binding by human Hb, which ranges over 130,000-fold among the intermediates, in comparison with the 400-fold change in O2 binding constant under conditions of this study (pH 7.4, 21.5°C) (9). The equilibrium between free dimer and assembled tetramer is an integral property of Hb in solution, and has a marked impact on the O2 binding curve observed experimentally.

**The concentration-dependent oxygen isotherm**

The sigmoidal shape of the O2 binding isotherm, i.e., the cooperativity of O2 binding, is dependent on the concentration of the Hb solution (Fig. 2). As the solution is diluted, the relative concentration of free dimer increases, and unlike the tetramer, the free dimer binds O2 noncooperatively with high affinity. Thus, the true tetramer-binding curve is observed only at the highest Hb concentrations. At lower concentrations, the experimental isotherm reports a mixture of tetramer and free dimer (1). The thermodynamic scheme that links the ligation of the free dimer to the ligation of the assembled tetramer (Fig. 2) shows all reaction equilibria that contribute to the concentration-dependent isotherms. Binding to the free dimer is designated by $\Delta G_{exo}$, which denotes the change in intrinsic (noncooperative) free energy. To solve the linkage scheme experimentally, the assembly free energy change for the deoxy tetramer, $\Delta G_{as}$, is determined in an independent kinetic measurement using haptoglobin trapping of the free dimer. In addition, the correspond-
The macroscopic thermodynamic linkage scheme

The concentration dependence of the O₂ binding curve is a result of thermodynamic linkage between O₂ binding and dimer → tetramer assembly. Consider the first binding step as illustrated in the linkage scheme in Fig. 2. Conservation of free energy dictates that the change in free energy during assembly followed by ligand must equal the change in free energy during ligand followed by assembly:

\[ \Delta G_{\text{asm}} + \Delta G_1 = \Delta G_{\text{tet}} + \Delta G_{\text{asm}} \]  (3)

Therefore, the change in the tetramer assembly free energy during O₂ binding is equal to the change in the O₂ binding constant during tetramer assembly:

\[ 1\Delta G_{\text{asm}} - 2\Delta G_{\text{asm}} = \Delta G_1 - \Delta G_{\text{tet}} \]  (4)

Each stepwise microscopic binding reaction follows the same formula, as thermodynamic linkage holds for all binding steps.

Forming hybrid tetramers from parent tetramers

The equilibrium between free dimer and tetramer can be exploited to provide a means of forming partially ligated hybrid tetramers by mixing any two parent tetramers. However, it is necessary to fix the hemestesite ligand to prevent disproportionation caused by ligand rearrangement among the hemestesites. Hemestesite analogs employed for either the deoxy heme (which replaces Fe^II) or the oxy heme (which replaces Fe^III) O₂ are:

</table>

Each hemestesite analog perturbs the Hb tetramer in some manner. The Fe^II/CN and Mn^III analogs are susceptible to electron exchange over very long incubation periods (10). The Co^III analog exerts a specific effect on α-subunit binding constants (11), and the use of Zn^II imparts a light sensitivity to the solution (12). However, the relative relationship between each measured microstate-binding constant is found to be invariant among the analog species (9).

Using the Zn^II/Fe^II/O₂ analog as an example, when deoxy ZnHb (species 01) is mixed with an equimolar amount of native FeHb (species 41), a mixture is formed that contains the asymmetrically doubly ligated species 21 (Fig. 3A). Likewise, species 11 or 12 are formed by mixing species 01 with 23 or 24, respectively (see Fig. 1 for illustrations of each species). Species 22 is formed by mixing species 23 with 24.

Each binding step is composed of multiple microstate binding steps, and each microstate binding step represents an average of isomeric forms of the microstates, yielding the average microstate binding constants. The macrostate binding constant is then the average of the binding constant for each microstate.
species 31 or 32 are formed by mixing species 41 with 24 or 23, respectively. In this way, all possible combinatorial forms of the partially ligated intermediates can be formed. Only the parent tetramers 01, 23, 24, and 41 are present in pure form in solution: All other species are present in equilibrium with their respective parent tetramers. A assembly of tetramers from free dimers occurs very rapidly with a rate constant \( k_{on} \) of \( 1.1 \times 10^7 \text{M}^{-1}\text{s}^{-1} \). This assembly is referred to as the “consensus on constant,” which is not dependent on the number of bound ligands or their configuration, the presence of hemestie analogs, or the presence of mutations. Therefore, it is in the tetramer->free dimer dissociation constant, \( k_{off} \), that the sensitivity of the assembly constant is manifest, because

\[
\Delta G_{asm} = -RT \ln \left( \frac{k_{on}}{k_{off}} \right)
\]

**Key Experiments and Observations**

Two experimental approaches are taken to measure the assembly free energy of partially ligated Hb intermediates: an equilibrium method and a kinetic protocol. In the equilibrium method, symmetrically ligated tetramers are mixed to generate asymmetrically ligated hybrid tetramers. Then, the relative stability of the hybrid to its parents is measured, which permits the hybrid assembly free energy to be calculated from the independently measured \( \Delta G_{asm} \) of the parents. In the kinetic approach, the tetramer->dimer dissociation constant is measured by trapping free dimers kinetically with the plasma protein haptoglobin.

**Assembly free energy of hybrid tetramers**

**Low-temperature isoelectric focusing**

Species 21 represents a unique halfway point in oxygenation of Hb in that one of its dimers is fully ligated and the other is fully deoxygenated. The 21 hybrid is formed in vitro by mixing species 01 and 41, as in the example in Fig 3. One of the two parent Hbs carries an electrophoretic tag to enhance separation based on charge, typically the HbS variant (Hb Glu→Val). At equilibrium, the assembly free energy of species 21 is related to the assembly free energies of each parent by

\[
\Delta G_{asm} = \frac{1}{2} (\Delta G_{asm}^{41} + \Delta G_{asm}^{21}) + b_{21} \tag{6}
\]

where \( b_{21} \) is the free energy deviation from the average of the parent tetramer assembly free energies. The deviation free energy is measured directly from the fraction of each tetramer at equilibrium:

\[
b_{21} = -RT \ln \left( \frac{f_{21}}{f_{41}} \right) \tag{7}
\]

The relative fractions of hybrid and parent tetramers are measured by quenching the dissociation of tetramer to free...
dimer dissociation constant, \( k_{\text{off}} \), to the assembled tetramer. The tetramer dissociation reaction to the right:

\[
\text{Hb} \xrightarrow{k_{\text{off}}} 2\text{a} \beta \text{dimers} + \text{Hp} \xrightarrow{k_{\text{kon}}} \text{Hb}_2 + \text{Hp} \text{(dimers)}_2
\]

Because both \( k_{\text{kon}} \) and \( k_{\text{off}} \) are very rapid (essentially diffusion-controlled) processes, the overall rate-limiting step in Equation 8 is \( k_{\text{kon}} \).

The \( k_{\text{off}} \) for the asymmetrical ligated species 21 was measured first by forming the unligated version of the hybrid by mixing native Fe-heme deoxy Hb with 2\(n\) Hp (Fig. 4). Because both parents and hybrid (the unligated species 21 or 21L) have the same assembly free energy, \( \Delta G_{\text{asm}} \), mixing the parent tetramers in a 1:1 ratio generates an equilibrium hybrid mixture that contains approximately 50% hybrid 21L. Because of the slow \( k_{\text{off}} \) for both parents and hybrid (7.5 hours), equilibrium is attained after 3 days of incubation. In practice, the amount of hybrid present after 24 hours is sufficient for detection in the reaction with Hp.

The anaerobic hybrid mixture is mixed with an oxygenated solution of Hp in a stopped-flow instrument. The absorbance is monitored for 20 seconds, and the resulting observed rate constant is measured at 0.20 ± 0.02 s⁻¹. This results in an assembly free energy, \( \Delta G_{\text{asm}} \), of –0.3 ± 0.1 kcal/mol when combined with the consensus on constant in Equation 6 (9).

This value is in excellent agreement with the results of the equilibrium low-temperature isoelectric focusing experiment.

Model-independent distribution of \( \Delta G_c \) among the hemoglobin intermediates

The measurements described here show that binding \( O_2 \) ligands to only one \( \alpha \beta \) dimer within the Hb tetramer occurs with a
An extensive kinetic analysis of ligand binding in normal Hb carried out by Goldbeck et al. has demonstrated agreement with the unique binding constant for the asymmetric doubly ligated Hb (14). Thermodynamic experiments from the Ackers laboratory that employs asymmetrical modified human Hbs have confirmed the asymmetric character of Hb cooperativity (15). This discovery generates critical energetic and structural questions, particularly with respect to the relationship of interdimer to cross-dimer cooperativity, in a classic system that was once thought to be well understood.

Transition metals are a key component of biological systems. Because of their special properties, they are incorporated into proteins functioning in dioxygen transport, electron transfer, redox transformations, and regulatory control. The metals used in biological systems have been selected throughout evolution based on their availability in the environment and their kinetic lability, resulting in preferential use of first-row transition metals in biology. These essential metals must be obtained from the environment and concentrated within the cell for use in biochemical pathways. Once appropriated, metals must be directed to metalloenzymes or metal storage proteins within the cell. In addition, organisms must be able to distinguish between essential and toxic metals and must have mechanisms for minimizing the toxicity of both essential and toxic metals that are present in excess. Metal homeostasis is broadly defined as the metal uptake, trafficking, efflux, and sensing pathways that allow organisms to maintain an appropriate (often narrow) intracellular concentration range of essential transition metals. This review will introduce several unifying concepts of metal homeostasis with brief illustrative examples for each concept.

Transition metals are key nutrients for nearly all organisms because of their role in critical biochemical pathways such as respiration, photosynthesis, and nitrogen fixation. However, metals cannot be synthesized like other biomolecules and must be obtained from the environment. Once acquired by organisms, metals must be routed to the correct intracellular destination while preventing deleterious side reactions or nonspecific chelation by other cellular components. Metals that are difficult to obtain may be stored for future use by the organism. As intracellular metal concentrations increase, organisms must have the ability to remove (efflux), sequester, or detoxify the excess metal. Finally, organisms must have some ability to distinguish between essential and nonessential metals, despite their similarities, in order to prevent poisoning by nonessential metals. The genetic and biochemical pathways that are used by organisms to acquire, traffic, store, and detoxify metals are collectively known as metal homeostasis systems. Maintenance of intracellular transition metal concentrations within an optimal range has posed a major challenge for biological systems throughout evolution. The study of metal homeostasis has been a key part of the field of bioinorganic chemistry since its inception, providing numerous insights into how transition metals are integrated into biological systems.

Concepts in Metal Homeostasis

There are many functions for transition metals within biological systems (Table 1). The choice of metal used for each function is determined by the chemical characteristics of that metal, including its size as well as its thermodynamic stability and kinetic lability when complexed with biological ligands. Biological systems have mostly incorporated the first-row transition metals. The divalent forms of these metals are particularly common in biology because they have higher ligand exchange rates than their M³⁺ counterparts. Kinetically labile transition metals are required to allow assembly and disassembly of metal centers and for rapid binding and release of substrates in metal-catalyzed reactions. The relative abundance and availability of the transition metals in the environment has also dictated their use in biology because they have higher ligand exchange rates than their M³⁺ counterparts. Kinetically labile transition metals are required to allow assembly and disassembly of metal centers and for rapid binding and release of substrates in metal-catalyzed reactions. The relative abundance and availability of the transition metals in the environment has also dictated their use in biology. An excellent discussion of these issues in the context of metal selection for metalloenzyme use is presented in the technical article "Chemistry of Metalloenzymes" by R.J.P. Williams.

To ensure an ample supply of transition metals for incorporation into biomolecules, organisms have been selected to contain metal homeostasis systems.

Note: Although zinc is not considered a transition metal based on the IUPAC definition, zinc has often been included with the transition metals as distinct from the alkali and alkaline earth metals. For the purposes of this review, we will consider zinc as part of the transition metal group with the caveat that it does not strictly meet the IUPAC definition.

**The metal quota**

A key concept in metal homeostasis is the "metal quota." This quota is simply the amount of a given metal required for normal cellular function under a specific growth condition. In theory the metal quota can vary considerably. For example, metal requirements may change in response to growth stage (quiescence or active growth), oxygen availability, carbon source, and a variety of other environmental factors. Similarly, different organisms or different cell types within an organism may have different metal quotas (1). For example, photosynthetic cyanobacteria have been reported to have higher Mn and Fe quotas than other nonphotosynthetic prokaryotes (2). In this case, the higher metal quotas stem directly from increased amounts of specific metalloproteins (Photosystem I and Photosystem II). At the other extreme, the obligate parasite that causes Lyme disease, Borrelia burgdorferi, seems to have no requirement for Fe and lacks many metalloproteins found in other microbes (3). These unusual adaptations may allow B. burgdorferi to survive in the iron-limited environment within the host. In general, however, direct measurement of cellular metal concentrations has shown remarkably small differences between widely divergent organisms, often less than an order of magnitude (Table 1). Thus there does seem to be a well-conserved optimum range of intracellular metal concentrations for most essential metals. The quota of a specific metal is largely dictated by the concentration of cellular proteins that require the metal for their function and by the importance of the metalloproteins (i.e., does the metalloprotein play a critical role or can another protein functionally substitute?). However, metal bioavailability and metal toxicity also strongly influence the metal quota and the nature of each metal-specific homeostasis system.

**Metal bioavailability**

A critical factor in metal homeostasis is the bioavailability of the specific metal. The "bioavailability" of a metal can be distinct from the overall abundance of the metal in the environment. For example, iron is the fourth-most abundant element in the Earth’s crust. However, in the current-day oxygen-rich atmosphere of Earth, iron is largely present in the ferric (Fe<sup>3+</sup>) form. In aqueous, aerobic environments at neutral or basic pH, ferric iron forms nearly insoluble iron hydroxides. Because of the insolubility of Fe<sup>3+</sup>, iron is one of the least bioavailable of the essential transition metals. The concentration of iron in seawater (3 × 10<sup>-5</sup> ppm) is nine orders of magnitude lower than the crustal concentration (5.10<sup>10</sup> ppm). In contrast, zinc (Zn<sup>2+</sup>) is present at only 70 ppm in the crust but is found at 1 × 10<sup>-3</sup> ppm in seawater (4, 5). The increased solubility of zinc means that it is actually more bioavailable than iron, despite its overall lower abundance. As discussed, iron homeostasis requires strategies for mobilizing iron in the environment, whereas homeostasis of metals such as zinc largely begins with cellular uptake.

The bioavailability of a given metal is influenced by its chemical speciation in the ambient environment. Although some metals occur predominantly in their "free" or "aquo" form (that is, the inner coordination sphere of the metal ion is occupied solely by water molecules), most bioactive metals occur as complexes in the natural environment. Hydroxide, carbonate, and chloride anions can all bind transition metals to a significant extent. For example, Fe<sup>2+</sup> forms hydroxide complexes.
complexes [e.g., Fe(OH)$_3^+$ or Fe(OH)$_2$] in natural waters at pH > 7 and Cu tends to form carbonate complexes (CuCO$_3^-$) under similar conditions. Metals may also bind to organic molecules, which may be expressly produced by resident biota to influence metal availability (such as siderophores for iron) or result from the degradation of cells. It has been shown that most iron, copper, cobalt, and zinc ions in the marine environment are bound to unidentified organic molecules (6-9). Metals in terrestrial, freshwater, and near-shore environments are often bound to humic and fulvic acids produced via decomposition of terrestrial organic matter (10). As a general rule, only the free metal ion can react with uptake or transport proteins (11). However, the ligand exchange kinetics of most inorganic complexes are fast enough that these forms are often considered bioavailable as well. Organic complexes are often not immediately available (except in some cases such as lipophilic complexes); however, some cells have evolved specific biochemical mechanisms for obtaining required metals from organic ligands. For example, iron-siderophore complexes may be directly transported into the cell, and iron bound to nonspecific ligands may be obtained with ferric chelate reductases that reduce Fe$^{3+}$ to Fe$^{2+}$ for subsequent transport across the cell membrane (12).

In environments where metal bioavailability is limited by biological or geochemical factors, normal cellular growth and functioning may be impaired. For example, nearly 40% of the limited availability of iron is a fascinating and fully developed field. Readers are referred to the following sections for more information on this topic.

The "labile metal pool"

It is currently routine to quantify the total metal content of cultured cells or organisms using sensitive analytical techniques. For example, inductively coupled plasma mass spectrometry (ICP-MS) enables simultaneous detection of most transition metals in bulk cell culture samples at parts per trillion concentrations, and high-resolution magnetic sector instruments are capable of separating all transition metals from common matrix plasma interferences. These approaches have been used to establish the metal quota under various conditions in various organisms (17, 18). Most of any given metal within the cell will be stably incorporated into metalloenzymes and storage proteins. However, a small but physiologically critical pool of the metal has to be available for incorporation into newly synthesized metalloproteins. This "labile pool" of metal is not "free" in the chemical sense as the metal is likely bound to metallochaperones or other carrier proteins or to small molecules like citrate or glutathione. The labile metal pool is an important aspect of homeostasis because intracellular metal sensors that regulate
Metal Homeostasis

Metal homeostasis likely respond to changes in this subpopulation of metal. Also, the labile metal pool is more likely to undergo spurious side reactions under adverse conditions than metal safely incorporated into metalloenzymes or storage proteins. Thus it is critical to define the concentration of the labile metal pool and to understand how it is maintained as part of overall metal homeostasis. As is evident in the “Chemical Tools and Techniques” section, it is not trivial to establish a value for the labile metal pool.

Cellular Mechanisms to Maintain Metal Homeostasis

**Figure 1** shows a generic scheme for a typical metal homeostasis system. We now will consider each component in detail.

**Acquisition of metals from the environment**

Some metals may need to be mobilized from the environment to make them bioavailable. Iron in particular must be rendered more soluble to be accessible for uptake. Microorganisms and some plants have evolved with secreted ligands known as siderophores (or phyto-iron transport proteins). These ligands bind Fe³⁺ with extraordinary affinity. For example, a complex of the siderophore enterobactin with ferric iron has a formal stability constant of 10⁴⁹ (19). Once siderophores compete with other environmental ligands for iron, the ferric iron–siderophore complex then binds to specific transport proteins at the microbial cell surface and is taken into the cell. Most microorganisms can synthesize or use multiple siderophores as a source of iron. A similar strategy is used to move iron through the blood of multicellular organisms like mammals. Transferrin is an iron-binding plasma protein that preferentially binds ferric iron. Circulating Fe³⁺–transferrin complex is recognized by cell-surface receptors for uptake via receptor-mediated endocytosis (20). Because of tight regulation of iron transport throughout the body, pathogenic microbes are faced with the same problem of limited iron availability as their microbial counterparts in other environments. In response to this pressure, many microbial pathogens contain transporters and enzymes that allow them to obtain iron from host sources, such as hemoglobin and transferrin (21). Some plants use an alternative strategy for iron acquisition from the environment. Plant cells in the roots (where most iron is obtained) excrete protons in order to acidify the soil. Lowering the pH in the microenvironment around the roots increases the solubility of iron and allows it to be acquired by transporters (16). A similar pH-dependent process allows mammals to render dietary iron more soluble during digestion. In addition, some organisms contain ferric reductases that reduce ferric iron to the more soluble ferrous form. Reduction of ferric iron can occur at the cell surface or within the cytoplasm to release iron from ferric chelates like siderophores (22).

**Concentrating metals within cells**

Once the metal has been removed from the environment, it must be transported into the cell for use. In most cases, environmental metal levels are significantly lower than the cellular metal quota (Table 1). This dichotomy requires organisms to concentrate...
metals inside cells via energy-dependent processes. Transport of metals across the lipid bilayer by transport proteins is often linked to ATP hydrolysis or to the proton motive force (PMF) in order to provide the energy for concentrating metals. In some cases, the soluble metal is directly transported into the cell. In other cases (such as iron), metals complexed with acquisition molecules are transported. Once inside the cell, these complexes are disrupted to release the metal. In addition to transmembrane transporters, uptake of some metals requires other accessory proteins. For example, ferrous iron must be oxidized by a multi-copper oxidase enzyme at the cell surface in order to be transported by some eukaryotic transporters (23).

Intracellular metal trafficking

Once concentrated within the cell, specific metals must be routed to the proper metalloprotein. This problem is not trivial since many biological ligands are capable of binding essential metals. Nonspecific interaction of metals with inappropriate ligands could prevent the metal from reaching the necessary target metalloprotein. Spurious side reaction of metals with other molecules in the cell may also generate free radicals. For instance, the Fenton reaction between Fe^{2+} with H_2O_2, which is a normal byproduct of aerobic respiration, can generate highly dangerous hydroxyl radicals leading to cell damage. The routing of a metal to its correct target protein may occur as a result of the affinity of the metalloprotein for its specific metal. However, this mechanism seems inadequate as the intracellular concentration of a specific metalloprotein may be quite low compared with the concentration of competing, nonspecific ligands such as glutathione, citrate, or nucleic acids. In addition, the presence of multiple transition metals within the cell would make it difficult for a metalloprotein to partition a specific metal in a single step. It has become clear that several metalloproteins require a metallochaperone carrier protein to donate the correct metal to their active sites. For example, the Cu-Zn superoxide dismutase (SOD1) enzyme requires a copper metallochaperone, known as CCS, to donate copper for assembly of its active site (24).

Metal efflux and detoxification

If metals accumulate to high intracellular concentrations (for example, because of environmental excess), organisms must have homeostasis mechanisms for removing, sequestering, or detoxifying the metals. In the case of toxic metals such as silver, removal of the metal via efflux transporters may be sufficient. Increased expression of metal storage proteins or novel metal sequestration proteins can also protect the cell from excess metal. This strategy seems to predominate for essential metals under most conditions. For example, the model organism Escherichia coli contains multiple ferritin homologues that are differentially regulated to provide excess storage capacity for iron under adverse conditions (28). In eukaryotes and some prokaryotes, the cysteine-rich metallothionein protein family functions to store or buffer excess copper and zinc (27).

Regulation of metal homeostasis

Expression of the systems mentioned must be carefully coordinated within the cell in order to maintain metal homeostasis. Consequently most organisms contain metalloregulatory proteins to regulate metal homeostasis. Metalloregulatory proteins are transcription factors that sense cellular metal levels and either activate or repress transcription of metal homeostasis genes in response to changes in metal levels. Typically the metal in question binds directly to the cognate metalloregulatory protein and acts as an allosteric switch for activating or inhibiting the transcription factor. In addition to regulation at the transcriptional level, some metal homeostasis systems are also regulated post-transcriptionally. For example, bacteria and mammals regulate iron homeostasis at the mRNA level. In bacteria, a small regulatory RNA, RyhB, binds target mRNAs involved in iron homeostasis and metabolism and regulates their stability or their translation. The ryhB gene itself is under the control of a metalloregulatory protein, Fur, that senses cellular iron (29).
helped to identify new genes that encode metal homeostasis to characterize metal responsive gene transcription and have been used to isolate novel antioxidant factors. In addition, gene resulting phenotypes. For example, the Atx1 copper metallochaperone was originally identified in yeast as part of a genetic screen to isolate novel antioxidant factors. In addition, gene reporter constructs and DNA microarray analysis have been used to characterize metal responsive gene transcription and have helped to identify new genes that encode metal homeostasis proteins. Global transcriptional analysis has also led to a deeper understanding of how perturbations in metal homeostasis impact other cellular pathways. For example, DNA microarray analysis in E. coli has revealed that extensive remodeling of iron metalloproteins occurs when cells shift from an iron-rich environment to an iron-poor environment. Overall iron metalloprotein content is reduced in order to conserve available iron. However, this remodeling has profound effects on cellular metabolism since many metabolic proteins contain iron in the form of Fe-S clusters or heme. Similar processes have also been observed in eukaryotic organisms. Thus, genetic techniques are allowing investigators to determine how metal homeostasis is integrated with overall cellular metabolism and physiology.

Chemical Tools and Techniques

Genetics

Genetic approaches have been used with considerable success to study metal homeostasis in genetically tractable model organisms like E. coli and S. cerevisiae. These approaches involve deleting genes that encode metal homeostasis proteins (such as metal transporters or metallochaperones) and analyzing the resulting phenotypes. For example, the A31 copper metallochaperone is a small, representative sample from a large body of literature). Herein are only a small, representative sample from a large body of literature). Herein are only a small, representative sample from a large body of literature).

Biochemical characterization of metal homeostasis components

Purification and in vitro characterization of metal homeostasis proteins has provided a wealth of information about protein function. Specific metal binding sites have been characterized in metal transporters, metallochaperones, and metalloregulatory proteins using physical inorganic techniques such as extended x-ray absorption fine structure (EXAFS) spectroscopy, Mossbauer spectroscopy, nuclear magnetic resonance (NMR) spectroscopy, and electroparamagnetic resonance (EPR) spectroscopy. For example, spectroscopic analysis of the C001–A31 complex revealed the coordination chemistry of the copper binding site and led to a chemical exchange model for step-by-step copper donation from A31 to the target metalloprotein C002. Three-dimensional crystal structures of metal homeostasis components have also given researchers insight into the mechanisms of homeostasis. Proteins involved in metal transport and storage proteins by directly binding to 5’ or 3’ untranslated regions within the mRNA and altering translation initiation or mRNA stability. IRP directly senses cellular iron levels by virtue of an Fe-S cluster present in the protein. A detailed discussion of these metalloregulatory proteins is presented in the technical article “Metalloregulatory Proteins” by Deborah Zamble.

Measurement of the “labile metal pool”

As mentioned, accurate determination of the “labile metal pool” is a key goal of metal homeostasis research. Most recent efforts have focused on measuring the labile metal pool in yeast without disrupting the cell. This trend toward nondisruptive approaches stemmed from the realization that metal localization and speciation could be greatly perturbed by diluting cellular reductants, exposing the intracellular milieu to oxygen, disrupting subcellular organellae, and other adverse consequences of cell breakage. The general approach to define the labile metal pool relies on chelation of the labile metal pool in situ followed by detection and measurement of the chelator-metal complex. For example, to measure labile iron in E. coli, the ferric iron chelator desferrioxamine can be added to cells resulting in stabilization of all labile iron in the ferric form. The ferric iron can then be measured using EPR spectroscopy. Similarly, metal-specific fluorescent probes can be added to cells and the concentration of “available” metal measured by changes in fluorescent signal. Probes such as calcein and zinquin have been used to quantify the labile pools of iron and zinc, respectively. However, interpreting the results from these approaches can be difficult. If the metal binding affinity of the chelator or probe is sufficiently higher than the metal binding affinities of cellular metalloproteins, the probe may strip metal ions from metalloproteins and artificially increase the amount of “labile” metal (for a thorough discussion of troubleshooting the measurement of labile iron, see Reference 40). In addition, the cell membrane permeability, intracellular localization, and toxicity of the probe must be considered when evaluating its use.

To avoid these sorts of problems, some investigators have relied on the metal binding affinities of metalloproteins to estimate the labile metal concentration. For example, two zinc metalloregulatory proteins, Zur and ZntR, control expression of zinc homeostasis genes in E. coli by directly binding Zn to sense cellular zinc levels. Zn-Zur represses zinc uptake systems when cellular zinc levels are adequate, whereas Zn-ZntR activates zinc efflux systems when zinc levels rise too high. Thus, the two regulators are thought to sense zinc at the lower and upper concentration limits of the labile zinc pool in E. coli. Measuring zinc-dependent DNA binding by Zur and ZntR allowed the investigators to establish the threshold zinc concentrations for activation of each regulator. These values were then reported as the upper and lower concentration limits of the labile zinc pool in E. coli (18). This approach assumes that both metalloregulatory proteins are in equilibrium with the labile zinc pool. It is not clear if this assumption applies in vivo since regulation of homeostasis proteins at all levels (from gene transcription to protein degradation) necessarily requires a lag between metal sensing and the desired change in the activity of the target homeostasis components, such as transporters and storage proteins. This lag may prevent a true equilibrium from forming under typical conditions where metal availability is not constant. Intermediate
proteins may also act as carriers to load Zn into Zur or ZntR in vivo, which further complicates the labile zinc measurement since the additional protein–protein interactions required in vivo could significantly alter the zinc concentrations at which the regulators respond.

Measurements of labile iron range from about 0.9 to 12.3 \( \times 10^{-6} \) M in the cytoplasm of a range of organisms from bacteria to mammals (40, 41). In contrast, some approaches have estimated cytoplasmic pools of labile zinc and copper to be 10\(^{-15}\) and 10\(^{-18}\) M, respectively (18, 45), whereas other studies have measured labile zinc at around 5 \( \times 10^{-12} \) M (43). Although the absolute measurements vary somewhat, these studies clearly demonstrate that labile pools of copper and zinc are tightly controlled in vivo to avoid accumulation of these metals. The identity of the biological ligands that maintain such small labile pools of zinc and copper remains a topic of some controversy. As we can see, measurement of the labile metal pool is strongly influenced by the technique used and final determination of labile metal pools will likely require a convergence of approaches.

**In vivo localization of cellular metals**

The specific localization of transition metals within subcellular compartments has been characterized by a variety of methods. Subcellular organelles, such as mitochondria, purified by traditional centrifugation methods have been directly analyzed to identify subcellular populations of metals like copper (46, 47). Use of fluorescent probes coupled with microscopy allows investigators to visualize the subcellular location of metals, especially in eukaryotic cells because of their larger size. Studies of metal homeostasis in vivo have also benefited greatly from recent advances in analytical instrumentation. Subcellular mapping and quantification of transition metals within cells is possible using electron, proton, and X-ray microbeam techniques. Electron microprobes are capable of a spatial resolution of several nanometers (48) but require that cells be sectioned before analysis. Although widely available, electron microprobes also lack sensitivity to transition metals. Much higher sensitivity is possible when X rays are used to excite characteristic fluorescence, and impressive advances have been made with synchrotron X-ray fluorescence (SXRF) microprobes (49) (Fig. 2). Through the use of Fresnel zone plate optics at third-generation synchrotron facilities, spatial resolutions approaching 50 nm are now possible, and detection limits on the order of 10\(^{-18}\) mol per cell are routinely achieved for the transition metals (50). SXRF has been used to determine subcellular localization of transition metals in cardiomyocytes (52), human leukemia cells (52), and plant seeds (53). SXRF can also be combined with immunofluorescence probes (54) or metal-specific fluorescent sensors. For example, Yang et al. (55) visualized the localization of intracellular “labile” copper in the mitochondria and Golgi apparatus of...
mouse fibroblast cells using both fluorescent probes and X-ray analysis.

Future Research Directions

The metallome and metallome homeostasis

Initial study of metal homeostasis tended to focus on a single metal. However, proper functioning of most organisms requires careful balancing of multiple essential transition metals. The sum of all essential metals used by an organism for cellular function is known as the "metallome." The metallome consists of the total metal content of a cell but also includes all specific metal–biomolecule complexes that are present in a given cell. Characterizing this global entity is one of the most exciting future research directions in the field of metal homeostasis. Measuring the metal quota for each essential metal is still a key requirement for defining the metallome. Recently it has become possible to simultaneously measure all essential transition metals in an organism. For example, ICP-MS has been used to measure metal quotas in a diverse range of prokaryotic and eukaryotic organisms under controlled growth conditions. If the number of cells in the sample and the cell volume are known, ICP-MS measurements can be converted into total cellular concentrations to facilitate the comparison of metal quotas in organisms with a wide range of cell sizes. The power of approaches like ICP-MS is that they allow investigators to simultaneously measure cellular concentrations of essential transition metals in different organisms, under different environmental conditions, and in different genetic backgrounds to more fully define the metal quota. A further dimension of the metallome concept is the specific location of transition metals within the cell (as opposed to their total concentrations in the entire cell). In this context, localization can refer to the protein or biomolecule component where the metal is bound as well as the subcellular localization of the metal in various organelles. One approach to define metal localization will be to combine metal analysis techniques with proteomics in order to identify all metalloproteins, including their specific transition metal content, within an organism (56, 57). Global analysis of the metalloprotein portion of the metallome will also lead to the identification of previously unknown metalloproteins, including their specific transition metal content, within an organism (56, 57). Metalloregulatory proteins are proteins that bind metals and modulate gene expression through direct interactions with DNA or RNA. The genes under this metal-dependent control encode a variety of proteins involved in the cellular homeostasis of both essential and toxic metals. Metalloregulators are present in all types of organisms, and extensive information exists about their mechanisms, although many unanswered questions remain. The global activities of these metal-responsive factors require overcoming complex challenges, such as the manner in which the proteins regulate gene expression, the mechanisms of the metal-dependent protein conformation transformations, and the ability of the proteins to recognize the designated metal(s). An understanding of these key biomolecules draws from disciplines such as cell biology, protein chemistry, and inorganic chemistry and provides molecular insight into one fundamental aspect of life.

Although a variety of biologic processes are regulated by metals, for the purposes of this review metalloregulators are defined as proteins that act as metal-responsive genetic switches (1). These proteins are sensors that monitor the cellular levels of one or more metal ions and then respond to changes in availability by modulating the expression of a variety of metal pathways. A few examples of metalloregulatory pathways exist in which the two responsibilities, sensing and regulating, are divided up between separate protein components. Learning how metalloregulators function entails defining the cell biology of what they do and the bioinorganic and bioorganic chemistry of how they do it. This article considers some of these aspects in general and then addresses them more specifically in the context of examples. The focus is on how these proteins bind and respond to metal ions. Other properties, such as the details of specific protein contacts with nucleic acids or RNA polymerase, will not be discussed. For more information on that area, the reader is referred to the article entitled “Transcription Factors.” Furthermore, the scope of this article includes protein families that respond to transition metals, both essential and poisonous, as well as the environmental toxins arsenic and lead. The alkali and alkaline earth metals will not be included here. Finally, the examples described are predominantly from prokaryotic organisms because these systems are more clearly defined than the eukaryotic versions. Several reviews on eukaryotic regulators are listed at the end of this article under “Further Reading.” Unfortunately, space limitations prohibit citing many of the primary references of the information discussed below, so the references are limited to a small number of publications. The reader is directed to the comprehensive review articles that are listed at the beginning of each section, which contain all of the appropriate references.

Biology
Many metal ions that can get into cells, such as mercury or lead, are poisonous and must be neutralized and exported as quickly as possible. However, even metals that have an essential cellular role, such as zinc, iron, or copper, can be toxic in excess. An organism must ensure an adequate supply of these nutrients while keeping the concentrations under tight control to prevent accumulation and cellular damage. Furthermore, each essential metal performs distinct cellular functions and seems to be regulated independently. Consequently, the metalloregulators are not only sensitive to changes in metal availability, caused by variations in the external supply or the nutritional needs of the organism, but they must be able to discriminate between the various types of metals present in the biological system. Metalloregulators contribute to the maintenance of this delicate balance by controlling the expression of metal uptake and export pathways, detoxification and storage/sequestration systems, as well as proteins that employ the metals such as metalloenzymes. The activity of the metalloregulators is linked intimately to the operations of these metal-centered pathways. For more information, see the articles on “Metal Complexes, Assembly of,” “Metal Homeostasis, intercellular,” “Metal Homeostasis: An Overview,” “Metal Transport through Membranes,” and “Metalchaperones, Chemistry of.”

The most common genetic control point of the metalloregulators is transcription, with one major exception in iron regulation discussed below. The response elicited by the metal can be repression, derepression, and/or activation of transcription (Fig. 1). Proteins are classified into families based on sequence homology (Table 1), and usually they respond in
the same manner as other family members to metal ions, although they may differ in metal selectivity. In many cases, the mechanism of genetic control is fairly straightforward. Metal binding to members of the ArsR/SmtB, DtxR, Fur, and NikR families of metalloregulators either activates or inhibits DNA binding. The DNA recognition sequences of these proteins are close to or are overlapping the transcription start sites in the promoters of the genes that they regulate, so it is likely that DNA binding by these proteins (either the apo or holo, depending on the system) sterically blocks transcription initiation by the RNA polymerase (2, 3, 4, 5).

However, as described in this section, the regulation by some other metalloregulators is more complicated. Several examples are discussed, each showcasing a possible mechanism of genetic control. A thorough understanding of the cellular biology of how these systems work, the biological chemistry is an integral component of their activities and thus is a part of the discussion.

**Mercury regulator**

One of the first metalloregulatory proteins to be characterized extensively is the prokaryotic MerR transcription factor (1, 6, 7), which acts either as a repressor (apo-protein) or an activator (holo-protein) of the mer operon encoding mercury resistance proteins (Fig. 1c). The −35 and −10 sequence elements of the mer promoter, binding sites for the RNA polymerase initiation complex, are separated by an unusually long distance that results in poor constitutive transcription. A apo-MerR binds to the DNA between these sequences and blocks the DNA, which results in a slight increase in repression on the suboptimal promoter. It also recruits the RNA polymerase to the transcription start site where it waits in a stalled complex. Upon binding of

*This table is not an exhaustive list of metal-dependent members of these families. Furthermore, proteins in these families that respond to factors other than metals that are not listed here.*

**Hg(II).** MerR undergoes a conformational change that causes the DNA to straighten out and to unwind; these distortions place the −10 and −35 sites in optimal positions for productive initiation of transcription. MerR can activate fully the mer promoter over a small range (less than an order of magnitude) of mercuric salt concentrations that range around $10^{-8}$ M in vitro and slightly higher in cell culture experiments. This sensitive and cooperative sensor provides a rapid and robust response that only is turned on when needed and is activated fully before cytoplasmic Hg(II) concentrations reach levels that affect cell growth.

Once the mercury has been eliminated from the cell, it would be wasteful energetically to continue to synthesize the resistance proteins. However, it is unclear how the Hg(II)-MerR complex could disengage from the promoter in a timely manner. It is possible that apo-MerR can displace the metal complex at the promoter because it binds the recognition sequence with slightly higher affinity (7), or that the Hg(II) is released eventually from the MerR-DNA complex. However, a recent study suggests that another protein encoded by the mer operon, MerD, may play a role in switching off the induction (8). MerD, which shares sequence homology with MerR, can form a ternary complex with apo-MerR and the DNA recognition complex. At the addition of mercury, the presence of MerD causes a fraction of the DNA to be released, which allows the expression of the divergently transcribed mer operon.

**Post-transcriptional iron regulation**

In mammals, as well as in certain other species, iron metabolism is regulated at the posttranscriptional level (for reviews see References 9-12). Two homologous iron-regulatory proteins (IRP1 and IRP2) bind with high affinity to specific RNA sequences called iron-responsive elements (IREs), which are present in the untranslated regions of the mRNAs that encode many of the proteins involved in iron metabolism. The IREs are conserved hairpin structures, but subtle differences in the sequences of the IREs and the surrounding mRNA affect IRP binding and fine-tune the strength of the interaction.

The IREs are bound by the IRPs at low iron concentrations (Fig. 1d). Two different effects of IRP binding exist, depending on the location of the IRE in the mRNA. In the case of proteins that would not be useful under limiting iron conditions, such as ferritin (iron storage), ferroportin (iron efflux), and aminolevulinate synthase (heme biosynthesis), the IRE is near the translation start site at the 5′ end of the mRNAs and IRP binding blocks translation initiation and protein production. In contrast, under the same iron-deficient conditions, the mRNA for the transferrin receptor (iron uptake) is protected from degradation by IRP binding to multiple IREs at the 3′ end of the mRNA, which enhances protein production and leads to an increase in iron intake. In an iron-replete situation the IRPs do not bind to the mRNA so the effects are reversed: The genes for iron-using proteins are translated, and the transferrin receptor mRNA is degraded.

The RNA-binding activities of the two IRPs have different mechanisms of inhibition by iron, and not all of the details are defined clearly. The binding of IRP1 to mRNA is blocked by the formation of an [4Fe-4S] cluster, which allows the protein to bind to the mRNA. The binding of IRP2 to mRNA is blocked by the formation of an [4Fe-4S] cluster, which allows the protein to bind to the mRNA.
to function as a cytosolic aconitase enzyme. IRP2 does not have an iron cluster, but it is targeted for proteosomal degradation in an iron-dependent process. The IRPs are regulated by a variety of additional factors such as heme, oxidative stress, nitric oxide, and phosphorylation by intracellular signaling factors, indicating that IRPs provide a bridge between iron metabolism and other cellular pathways.

**Other links to translation**

Another link to posttranscriptional regulation of metal homeostasis is the global iron regulator Fur (4). Fur controls the transcription of a large number of genes (more than 90 in E. coli), most of which encode proteins involved in iron acquisition as well as other essential metabolic pathways. The Fe(II)–Fur complex represses the transcription of these genes when Fe(II) is limiting, the Fur repression is alleviated when iron reaches critical levels, the internal kinase domain of the Fur protein is coupled to a protein conformational change such that it alters the DNA or RNA complex. In several examples, high-resolution structural studies have shed some light on the mechanisms of this allosteric response.

**Chemistry**

**Allosteric regulation**

The binding of the metal ion coregulator to a metalloregulator protein is coupled to a protein conformational change such that it alters the DNA or RNA complex. In several examples, high-resolution structural studies have shed some light on the mechanisms of this allosteric response.

**ArsR/SmtB family**

In the absence of metal, members of the ArsR/SmtB class of transcription factors bind to their respective DNA promoters and inhibit transcription; metal binding to the proteins decreases the affinity for DNA and allows transcription to proceed (derepression, Fig. 1b (2, 7)). All members of this family have a conserved helix-turn-helix (HTH) DNA-binding motif, with the same overall dimeric "winged" helix structure. Phylogenetic analysis suggests that this family evolved from a common evolutionary ancestor to sense specific types of metals (2, 17). However, the mechanisms of metal-induced DNA release do not seem to be the same. Furthermore, substantial variability exists in the metal-binding sites, which roughly can be divided into two distinct types based on their location and the nature of the amino acid ligands. A few family members have both metal sites, although in these cases, the metal bound to one of the sites may act as a structural cofactor, and at least one other member possesses a divergent third site (18).

Several proteins in this family respond to metal binding in a cysteine-rich site with at least some of the ligands from the N-terminal helix (α3) that is a part of the HTH DNA-binding motif. This site, often referred to as α3, α3N, or site 1, controls a response to thiophilic ions such as cadmium, lead, or arsenite. For example, the arsenic-bound by ArsR is coordinated by 2–3 cysteines (cys32, cys34, cys37) from the same α3 helix, so clustering the cysteines around arsenite would cause a large distortion of the helix that is proposed to disrupt DNA binding (19).

SmtB is regulated by the second type of metal-binding site called α5, α5C, or site 2. This site, which bridges the interface between α5 helices of the dimer, is composed of carboxylate and imidazole ligands and regulates the response to harder metal ions such as Cu(II), Ni(II), and Zn(II). The structures of SmtB revealed that when both α5 sites of the dimer are filled with zinc, a significant change occurs in the 3' structure of the protein that compacts the molecule (Fig. 2a (20)). This zinc-dependent conformational switch likely is controlled by a hydrogen-bond

Figure 2

(a) Metal binding to SmtB. (Top) The holo-SmtB structure (dark gray, pdb 1R22) is significantly more compact than the apoprotein (light gray, pdb 1R1T). The zinc ions (spheres) are only observed in the θ5 sites because the ligands of the θ3 sites were mutated to generate a protein that is still functional in vivo but only binds one zinc ion per monomer. The putative DNA-binding helix of the HTH motif is indicated. (Bottom) The hydrogen-bonding network between one of the θ5 zinc ions and the DNA-binding helix (L83) is highlighted. This network is not observed in the structure of the apoprotein. For clarity, the holo-protein is rotated slightly from the above view, and the two monomers are colored with different shades of gray. Putative hydrogens are indicated by thin bonds. (b) Structure of the E. coli nickel-responsive repressor NikR. The apoprotein (top, pdb 1Q5V), holo-protein (middle, pdb 2HZA), and DNA complex (bottom, pdb 2HCV) are shown with each monomer in the tetramer drawn in a different shade of gray. Two ribbon–helix–helix DNA-binding dimers flank the central core of four metal-binding domains. The nickel ions (smaller spheres) are coordinated in a square-planar site by H87, H89, C95, and H76' of the opposing monomer (shown in inset, site rotated for clarity). The larger spheres in the DNA complex are best modeled as potassium ions. The sections of the metal-binding domain that contact the DNA are circled, and these regions are not well ordered in the apo-structure and could only be modeled in one of the four monomers. A recent structure of apo–CadC suggests a different allosteric mechanism (21). CadC has both metal-binding sites, but the second site is probably structural because mutagenesis of the ligands in site 2 does not affect the metal-dependent response. The inducer site is u3N, and only two of the ligands (cys58 and cys60) are in the u3 HTH helix; the other two (cys7 and cys11) are donated by the N-terminal of the opposing subunit. Although the crystal structure does not have metal bound to the

u3N site, the structure suggests that binding of the metal would pull the N-terminal strand toward the DNA-binding motif and block access to the DNA sterically block. However, mutants of the u3N ligands do not release the DNA even though they still bind metals tightly, albeit in altered coordination sites, which indicates that the allosteric response must be more complicated (22). Structures with metals bound to the regulatory site or in a complex with DNA will help to clarify the details of this system.

NikR

NikR is the only known metalloregulator with a ribbon-helix-helix DNA-binding motif (5). This protein is a nickel-responsive repressor (Fig. 2b) that functions as a tetramer (Fig. 2b). It binds four nickel ions in square-planar sites that bridge the protein subunits, with the two flanking DNA-binding dimers linked to the central core of four metal-binding domains by flexible linkers. Several structures of E. coli NikR (apo-
Metalloregulatory Proteins

DtxR/Idr family

The homologous iron-dependent regulators DtxR and IdeR control the expression of virulence factors as well as proteins involved in iron homeostasis in pathogenic and nonpathogenic bacteria (3, 26, 27). The DNA-binding domains are N-terminal HTHs, and the dimeric iron complexes bind to palindromic sequences in the promoters of regulated genes and repress transcription (Fig. 1a and Fig. 3). Two distinct metal-binding sites exist in each monomer. One site is referred to as ancillary because metal-dependent activity is much less sensitive to mutating this site than of the primary-site ligands (See Reference 3 and references therein), although this site does have a role in enhancing the metal sensitivity of the repressor (28). Biochemical studies support a multistep, metal-activated DNA-binding mechanism that includes dimerization (29–32). Multiple X-ray crystal structures of the proteins without metals, in complexes with a variety of divalent metals bound in one or both sites, or bound to DNA, revealed that two dimers bind independently to opposite sides of the DNA (Fig. 3). Also, they suggest how the metal could influence DNA binding in addition to stabilizing the active dimer (for example, see References 33–36). The corepressor causes a shift in the DNA-binding domains in relation to the metal-binding domains, which closes the distance between these motifs and rotates them with respect to the rest of the molecule. One link between these two domains is Met10, which is a ligand of the primary-site metal from an N-terminal helix that contacts the DNA-recognition helix. The conformational change that allows Met10 to serve as a ligand also promotes hydrogen bonding between Glu9 and the imidazole of His106, another metal ligand. A hydrogen bond between His79 and Glu105, ligands of the ancillary and primary sites, respectively, support communication between the two metals. Furthermore, in the DtxR–DNA complexes, it was observed that the N-terminal helix is unwound so that it can be moved out of the way and avoid a steric clash with the DNA (34). This change in secondary structure may be mediated through hydrogen bonding with a metal-bound water.

Metal selectivity

Organisms employ a variety of transition metals, each for distinct functions. Although indirect connections exist between the metal pathways, it seems that the direct cellular control of individual metals, both nutrients and environmental toxins, functions independently. Each metalloregulator is dedicated to one metal or a subset of metal ions, even though it may belong to the same family as other metalloregulators. It is becoming clear that to differentiate between the available metals these proteins can take advantage of the inorganic chemistry of the metals’ ions by a variety of means (18).

Metal selection by protein sites

The high-resolution structures of the metal-binding sites of two MerR homologs, CueR and ZnR, reveal very distinctive coordination environments, in part controlled by the number of cysteine residues (Fig. 4) (37). CueR responds to Cu(I), Ag(I), and Au(I), and it binds all three metals in a linear, two-coordinate site composed of two cysteine residues that are conserved in all members of this family. This low coordination number is preferred by metals in the +1 oxidation state, and the site is shielded to prevent expansion of the coordination

number with external ligands. In addition, the authors suggest that CueR can discriminate against Hg(II), which is one of the few divalent metals that binds favorably to linear dithiolate sites, because it is optimized to provide charge compensation for a +1 metal ion but not +2. ZntR, which responds to Zn(II), Cd(II), and Pb(II), has the same overall dimeric structure as CueR, but it has four cysteines in each metal-binding site that contains a dinuclear zinc cluster. Additional ligands include a histidine and a phosphate ion (or sulfate). One of these cysteines, Cys79, is from the opposite end of the dimerization helix of the opposing subunit, which is linked to the DNA-binding domain of the monomer and suggests a mechanism of communication between the two domains. However, this cysteine is conserved only in the homologs that respond to divalent metals, which prefer higher coordination numbers and require larger charge neutralization than the monovalent metals.

Although the structure of Hg(II)-MerR has not been reported yet, a sequence alignment indicates that only three of the four cysteine ligands of ZntR are conserved in MerR. Furthermore, spectroscopic and mutagenesis analysis demonstrated that the metal is bound to these three cysteines (7). This intermediate number of cysteines suggests how MerR can select against the monovalent ions, which prefer the dithiolate sites and would not provide as much charge neutralization, as well as the divalent metals such as Zn(II) that prefer higher coordination numbers.

Metal selectivity through the metals

Given that the coordination geometry of a metal complex is a determinant of metal selectivity, it is predicted that all metalloregulators would have a metal-binding site preorganized to accept the appropriate metal(s) while excluding all others. However, this clearly is not always the case because many examples of metalloregulators exist in which the metal ligands could accommodate multiple different metals. Furthermore, if this model were correct, the affinity of the different metals would parallel the selectivity for the DNA-binding response, which is not always observed. Instead, in some cases, the metal-binding sites are clearly flexible and the presence of the correct metal is recognized by the distinct coordination geometry imposed on the protein.

For example, NmtR from Mycobacterium tuberculosis is a member of the ArsR/SmtB family that responds in vivo to nickel, and to a lesser extent to cobalt, which binds in an α₅ site. Zinc is a poor allosteric inducer both in vitro and in vivo, even though it binds more tightly to the protein than nickel and cobalt (38). An explanation for these observations was provided by spectroscopic analysis that revealed the Zn(II) ion bound in a tetrahedral 4-coordinate site, whereas N(III) was bound in a 6-coordinate octahedral site (38, 39). In contrast, CzrA from Staphylococcus aureus responds well to zinc, not nickel, but this protein binds the different metal ions in an α₅ site with the same type of geometries as in NmtR (39). Thus, these two proteins accommodate each metal ion in the preferred coordination geometries of the metals, but they have evolved such that only one activates the allosteric response of each protein: 4-coordinate activates CzrA and 6-coordinate activates NmtR.

One question that is raised by these studies is whether a metal ion that binds tightly to the protein but is a poor allosteric effector in vitro will compete with the inducer and act as an inhibitor. This issue is currently under investigation (40), and one factor that clearly must be addressed is whether all of the possible metals are even available in vivo.

Metal availability

When NmtR from M. tuberculosis was transplanted to a cyanobacterial host, a response from the protein was observed when extra cobalt was added to the growth media but not to...
operons that encode proteins that are clearly involved in metal specific metalloregulators can be found through genetic experiments that demonstrate a change in expression when the organism is grown in the presence of extra metal. Then, the expression of genes controlled by a metalloregulator can come from these operons. The first clue that a gene or an operon is controlled by a metalloregulator, i.e., how much metal is necessary to activate the genetic switch? For example, in an in vitro study of a pair of E. coli zinc sensors, ZnRE and Zur, revealed a sensitivity that correlated with physiological function (42). In response to zinc, Zur shuts off transcription of zinc uptake genes and ZnRE turns on transcription of efflux. They have a graded response such that Zur responds to lower zinc concentrations than ZnRE, turning off uptake before efflux is activated, which prevents both uptake and efflux from working against each other concurrently in a futile cycle. It is also interesting to note that the responses of ZnRE and Zur both occur over a very small gradient of zinc concentrations (≈10 orders of magnitude), which reveals the tight window of optimal zinc levels that falls between starvation and toxicity. However, the metal-buffered conditions suggest that this optimum is on the order of femtomolar free zinc, which is far less than one zinc ion per cell. CusR, which activates CusEs export, may be even more sensitive (37). Essentially, such sensitivities imply that no free copper or zinc exists in an E. coli cell under healthy growth conditions and invite questions about the availability of the essential metals for the destination biomolecules that use the metals as cofactors, many of which have much weaker thermodynamic affinities for the metals than the metalloregulators. It has been proposed that in a cellular context, metal delivery is under kinetic control (43), possibly through the activity of intracellular trafficking factors. In addition, many factors exist in a cellular milieu with varying degrees of metal-binding capabilities, such as amino acids, carbohydrate metabolites, thiol-containing molecules, and even weak nonspecific sites on protein surfaces, which would soak up any "free" metal ions and would provide pools of readily accessible ions if needed. The metalloregulators must be tuned to this buffering capacity to respond appropriately and to maintain a healthy balance of metal homeostasis.

Tools and Techniques
To define the complete mechanisms of the metalloregulators requires the use of a broad spectrum of methods, some of which are mentioned below. The first clue that a gene or an operon is controlled by a metalloregulator can come from in vivo experiments that demonstrate a change in expression when the organism is grown in the presence of extra metal. Then, the specific metalloregulators can be found through genetic experiments. A novel approach, facilitated by the many complete genome sequences now available, is to search for a gene that encodes a homolog of a known metalloregulator, or to examine operons that encode proteins that are clearly involved in metal homeostasis. Once a gene is identified as a possible metalloregulator, the assignment must be confirmed by in vitro experiments. A flip recombinant expression and purification of the protein, several different methods are used to examine metal binding and how this affects DNA (or RNA) binding. The protein might be purified with some metal bound, but whether that metal is physiologically relevant or one that was available in the expression host is a tricky question and should be resolved by in vivo experiments. Some metal–protein sites can be observed by electronic absorption spectroscopy (UV/visible spectroscopy), which can be used to determine the stoichiometry if the affinity is tight enough, as well as the dissociation constant, possibly through the use of small-molecule chelators as competitors. Metal binding and stoichiometry can also be examined by treating the protein with excess metal, removal of unbound metal with a method such as dialysis or gel filtration chromatography, and then direct metal analysis with inductively coupled plasma atomic emission spectroscopy ICP-AES, ICP-MS, atomic absorption spectroscopy, or other techniques. If any standard procedures to measure the strength of a protein–ligand interaction can be used to determine the metal affinity; in addition to UV/visible spectroscopy, these procedures include fluorescence spectroscopy, isothermal titration calorimetry, and equilibrium dialysis.

Conserved residues, particularly cysteine, histidine, and aspartate/glutamate, can signal likely metal ligands, which is an assignment that can be tested by mutagenesis. Detailed information on the coordination sphere can also be provided by spectroscopic techniques such as X-ray absorption spectroscopy, as well as UV/visible spectroscopy, or electronic paramagnetic resonance spectroscopy for some metals.

To examine DNA binding, typically a pair of complementary oligonucleotides that contain the DNA recognition sequence is used. If the binding site is not known, a method such as DNA se footprinting on a longer fragment of DNA that contains the whole promoter region will reveal the location of the binding site. The recognition sequence can be confirmed by using in vivo reporter assays. DNAase footprinting, mobility shift assays, and fluorescence anisotropy are some common techniques used to monitor DNA binding in the presence or absence of metal(s). Variations on these methods can provide information on whether the protein binds or unwinds the DNA, in the case of metalloregulators that function as transcription factors, in vitro transcription assays can sometimes be used to examine directly how the protein and metal influence transcription.

Finally, biophysical studies can examine how metal binding influences protein conformation and can serve as the basis for a hypothesis about the connection between the two activities, metal binding and DNA binding. Furthermore, it is clear from the discussion that a high-resolution structure, either from X-ray crystallography or nuclear magnetic resonance spectroscopy, is indispensable. A structure of the apo protein provides information on likely metal sites and the conformation of the DNA–binding domain. Structures of the metal-bound and/or DNA-bound complexes, in comparison with the isolated protein, can illuminate the molecular details of the structure-function relationship and can serve as a key reference point in understanding all of the pieces of information provided by solution studies.

Carbohydrate–Carbohydrate Interactions
Nicole Seah and Amit Basu, Brown University, Providence, Rhode Island
doi: 10.1002/9780470048672.wecb199

Carbohydrate–carbohydrate interactions have been suggested as mediators of cell adhesion and aggregation. Studies of four different interactions—sponge cell aggregation, embryo and myelin compaction, and melanoma cell adhesion—have provided insights into the role of the saccharides in these events. The biological context of these associations as well as the results of experiments using biophysical and chemical model systems are described.

Cell-surface glycans in the form of glycoconjugates, glycoconjugates, and glycolipids play an important role in biological recognition processes. Although most known receptors for cell-surface carbohydrates are proteins (i.e., lectins), several studies over the past few decades have clearly established that carbohydrates can function as binding partners for each other. These investigations of carbohydrate–carbohydrate interactions (CCIs) are broadening our view about the function of cell-surface glycans and may lead to a more thorough understanding of the principles of carbohydrate recognition. Although noncovalent interactions between individual residues of polysaccharides such as glycosaminoglycans and hyaluronic acid have long been recognized (1), the role of CCIs in cell adhesion and signaling is not fully understood. Some types of CCIs, such as those involved in sponge cell adhesion, are thought to have primarily structural roles. In other instances, such as melanoma cell adhesion, the CCI is believed to initiate signal transduction.

Chemical structures of carbohydrate epitopes from four well-studied CCIs are shown in Fig. 1. CCIs can occur via homotopic self-recognition, or they can be heterotopic. A homotopic interaction of the sulfated disaccharide 1 mediates sponge cell adhesion, whereas self-recognition of the Lewis x triaccharide 2 has been identified in embryonic development. Divalent cations are required for these two homotopic CCIs. The interaction between the glycosphingolipid GM3 (3) and the glycolipids LacCer (4) or GalCer (5) mediate the adhesion of melanoma cells to lymphoma or endothelial cells and initiate signal transduction. Carbohydrate epitopes involved in CCIs can also be as small as a monosaccharide, as is the case with the glycolipid GalCer (6) and cerebroside sulfate (CBS, 7) found in the myelin sheath. These heterotopic CCIs also use calcium, but the metal does not seem to be essential for association. Other carbohydrates that engage in CCIs have been reported for the aggregation of human embryonal carcinoma cells and trout sperm fertilization (2, 3).

All structures shown in Fig. 1 are involved in a trans-interaction, which requires that sections of the apposing cell membranes be brought in close proximity so that membrane-bound carbohydrates can interact with each other. This type of cell junction has been referred to as a glycosynapse, an analogy to immunologic and neurological synapses. The existence and characterization of glycosynapses and the elucidation of their mechanisms of action remain important challenges for the field of cell-surface carbohydrate recognition.

Alternatively, preliminary evidence has hinted at the occurrence of CCIs between carbohydrates that are present on the same membrane, i.e., interactions in cis. In these cases, a glycolipid has been shown to perturb the function of an N-glycosylated membrane-bound protein (5–7). Although the perturbation may be a result of a CCI between the glycolipid and the N-glycan, a specific and conclusive demonstration of a CCI in these systems awaits further studies.

The following sections provide a biological context for each of the four well-characterized CCIs shown in Fig. 1 and describe in greater detail the results of studies using a variety of chemical model systems and biophysical tools. It is notable that despite the very different contexts for these interactions (e.g., glycolipid vs. proteoglycan), in each case the minimal carbohydrate residues alone are necessary and sufficient for association, as long as the sugars are presented in a multivalent format. This ability to reproduce CCIs in model systems (e.g., glycosylated polymers, surfaces, proteins, vesicles, etc.) has greatly facilitated studies of this phenomenon. Although biomimetic models necessarily do not capture all components of a CCI present in the cellular context, they provide insights into carbohydrate molecular recognition. Additionally, these model systems offer tools that can subsequently be used to study the biological functions of CCIs in their more complex native environments.
Carbohydrate–Carbohydrate Interactions

Figure 1 Glycan structures that participate in carbohydrate–carbohydrate interactions.

CCI in Sponge Cell Adhesion

Biological Context

One of the first examples of a CCI was identified in various sponge species, where interactions between cell-surface proteoglycans mediate the self-association of sponge cells (8). Sponges that have been dissociated into their component cells are capable of reassociating in a species-specific manner. This phenomenon has been extensively studied using the marine sponge *Microciona prolifera* as a model system. The selective self-association is mediated by a proteoglycan referred to as the *Microciona* aggregation factor (MAF). MAF contains an N-linked sulfated glycan (g200) composed of fucose, glucuronic acid, mannose, galactose, and N-acetyl-glucosamine (9). MAF extracted from sponge cells does not bind to other sponge cells until it is rendered multivalent by glutaraldehyde cross-linking (10). MAF-mediated cell aggregation can be inhibited by several antibodies that bind to specific carbohydrate epitopes within the glycan. The Block 1 antibody reactive epitope is a carbohydrate containing a novel pyruvate ketal (11). A second epitope, reactive with the Block 2 antibody, was identified as GlcNAc(3S03)β1–3Fuc (12). The identity of these oligosaccharide epitopes was determined by degradation of the polysaccharide followed by nuclear magnetic resonance (NMR) and microscopic (MS) analysis. Other oligosaccharide components of proteoglycan aggregation factors from additional sponge species have also been identified (12).

Model Studies

Early studies of sponge cell aggregation demonstrated that CCI s were still observed when the glycans were removed from their native context. A striking visual example of the species specificity of CCI is evident in the aggregation of proteoglycan-attached microbeads, shown in Fig. 2 (13). Figure 2a shows three different sponges, each with a distinct coloration. Adhesion factors from the sponges were removed and covalently attached to beads color-coded pink, yellow, or white for each sponge. When the three beads were mixed together in the presence of calcium, they self-sorted into singly colored clusters based on the origin of the glycans on each bead (Fig. 2b). In contrast, if the pink, yellow, and white beads were all coated with the same glycan, no color sorting was observed (Fig. 2c). These glycan-coated beads are also competent binding partners for whole cells, as well as immobilized glycans 14.

To demonstrate the minimal structural requirements for aggregation, sulfated disaccharide 1 was attached to a gold nanoparticle via a thiol linker (15). Particles coated with α-linked fucose residues rapidly aggregated in the presence of Ca2+. Minor structural modifications to the sugar prevented aggregation, and although the β-linked sugar was capable of forming aggregates, the association was weaker than the α-anomer.
Sponge cell CCI has also been studied using bovine serum albumin (BSA) conjugates of the disaccharide 1 (16). A solution of 3BSA aggregated rapidly in the presence of Ca\(^{2+}\) but not Mg\(^{2+}\), which is consistent with previous results observed with the intact proteoglycans. 3BSA was immobilized on a dextran-coated surface for adhesion studies using surface plasmon resonance (SPR). When a solution of 3BSA was flowed over the chip, formation of glycoconjugate multilayers on the surface was observed. Similar results were obtained from SPR measurements using intact MAF or g200 (17). Analysis of binding isotherms from the adhesion studies with 3BSA provided an association constant of 10\(^{10}\) M\(^{-1}\) for the interaction of the carbohydrate units. The adhesive forces between glycans involved in sponge CCI have been examined using atomic force microscopy (AFM) (14, 17, 18). AFM tips and mica surfaces were modified with intact MAF or the extracted g200 glycan. Pull-off adhesion forces ranging between 100 and 300 pN have been measured for these interactions. Examination of g200 adhesion from different individuals exhibit distinctions between self–self-interactions and self–non-self-interactions, consistent with the allogenicity of sponge cell adhesion (17).

### CCI in Embryo Cell Adhesion

#### Biological Context

Embryonic development is a process in which cell–cell adhesion is crucial for proper growth of the nascent organism. After fertilization of an egg, the embryo begins to divide into a tightly packed cell cluster known as the morula. The Lewis x trisaccharide, also referred to as the stage-specific embryonic antigen 1 (SSEA-1), mediates cell adhesion and compaction of the morula during the 8–16 cell developmental stages. Lactofucopentaose III (LNF-III), a Lewis x-containing oligosaccharide, was identified as a carbohydrate inhibitor of fully compacted 8–16 cell embryos. Multivalent inhibitors were constructed by conjugating LNF-III to a lysyllysine peptide (19). Decompaction of embryo cells was observed only with the multivalent LNF-III conjugate, and not with free LNF-III oligosaccharides or other multivalent oligosaccharides. F9 embryonal carcinoma cells resemble cells undergoing early stages of embryonic development, as they also express surface Lewis x antigens at the undifferentiated stage and express less of the antigen upon differentiation. Aggregation of these cells was inhibited by LNF-III or EDTA, consistent with a calcium-dependent, homotypic Lewis x interaction (20). Furthermore, solid-supported F9 cells interacted preferentially with Lewis x-containing liposomes. Glycolipids bearing the Lewis x trisaccharide specifically interact with F9 cells, Lewis x-containing liposomes, Lewis x-functionalized columns, and other Lewis x-bearing lipids. Finally, latex beads or gold nanoparticles coated with Lewis x glycolipid aggregate in the presence of calcium ions (21, 22). In each case, the divalent cations Ca\(^{2+}\), Mg\(^{2+}\), or Mn\(^{2+}\) are required for the interaction. The Lewis x CCI was used to engineer the adhesion of non-Lewis x producing cells. Additions of Lewis x glycoporphin-gold nanoparticles to a culture of nonaggregating rat basophilic leukemia (RBL) cells resulted in the incorporation of these glycolipids into the plasma membrane and the subsequent clustering of the RBL cells in the presence of calcium (23).

#### Model Studies

Structural studies using NMR, MS, and X-ray crystallography provided molecular details of the Lewis x CCI. Electrospray ionization mass spectrometry of Lewis x in the presence of calcium ions gave rise to ion peaks consistent with two Lewis x moieties bound to a single calcium atom (24). Additionally, this complex was observed by cold spray ionization, which also detected Lewis x aggregates formed in the absence of calcium (25). NMR spectroscopy of Lewis x in the presence of divalent manganese cations identified tentative metal binding sites based on chemical shift perturbations induced by the paramagnetic ion (26). The binding of monomeric Lewis x to liposomes containing Lewis x has been detected using transfer NOESY experiments, although the strength of the association was exceedingly weak due to the monovalency of one of the binding partners (27). While calcium binding to the trisaccharide alone could not be detected by NMR, linking two molecules of Lewis x by a short tether provided a complex for which nuclear Overhauser enhancements (NOEs) were observed (28). The NMR experiments, along with computational analysis, suggested a model for the complex in which the calcium atom is sandwiched between the two linked trisaccharides with an association constant of 55 M\(^{-1}\). In the solid-state structure of Lewis x, rows of trisaccharides are arranged in a head-to-head arrangement with especially strong interactions between fucose and galactose residues (29, 30). Three intermolecular hydrogen bonds between each Lewis x pair are proposed to mediate their association.

The Lewis x CCI was probed using a variety of quantitative biophysical approaches. Lewis x bearing a thiol-terminated lipid tail has been attached to gold surfaces and AFM tips. AFM measurements of the interaction between these tips and surfaces measured an adhesion force of 20 pN (31). The aggregation of Lewis x-coated gold nanoparticles in a calorimeter was found to be highly exothermic (31, 32). SPR measurements of the interaction between Lewis x-coated gold nanoparticles and a self-assembled monolayer on gold functionalized with Lewis x have been carried out, and association constants of 1.9 \times 10^7 M^{-1} have been reported (33). In an alternative approach, two vesicles containing Lewis x were held in tight contact using micropipette manipulation (34). An adhesion energy of approximately 0.6 kJ/mol was obtained from contact angle measurements of the vesicle interface.

CCI in Melanoma Cell Adhesion

Biological Context

Heterotopic CCI involving glycolipids were first identified from studies of the adhesion of murine B16 melanoma cells. These cells, which express high levels of the glycoprophospholipid GM3 (3), adhered to mouse AA12 T-cell lymphomas that express the glycolipid Gg3 (6), but not to the non-Gg3-expressing AA27 variant of the cell line (35). The adhesion of AA12 lymphoma cells to a GM3-coated surface was inhibited either by pretreatment of the AA12 cells with an anti-Gm3 monoclonal antibody or by blocking the GM3-coated surface with an anti-Gm3 antibody. Conversely, adhesion of B16 melanoma cells to Gg3-coated solid surfaces was correlated to levels of an anti-Gm3 antibody. Adhesion of B16 melanoma cells to GM3-coated solid surfaces was correlated to levels of a monoclonal antibody. Avidity of B16 melanoma cells to GM3-coated solid surfaces was correlated to levels of a monoclonal antibody. Avidity of B16 melanoma cells to GM3-coated solid surfaces was correlated to levels of a monoclonal antibody.

The GM3 in B16 cells is localized within glycolipid-enriched microdomains in the lipid membrane (37). The microdomains, often referred to as lipid rafts, also contain a variety of signal-transducing proteins and enzymes. Binding of B16 cells to immobilized Gg3 activates the signaling proteins Ras and Rho, suggesting that CCI does not simply mediate cell adhesion but may also be involved in signal transduction. The structure and function of the glycolipid signaling domains in B16 cells is perturbed by the addition of an unnatural, synthetically prepared glycosphingolipid (38). The synthetic glycolipid reduced GM3 clustering on the cell surface and diminished the activity of the kinase c-Src, identifying another link between CCI and signal transduction. The specific mechanism by which binding to GM3 activates signal transduction is not currently known.

Several studies suggest that interruption of the LacCer-GM3-mediated adhesion prevents metastasis, raising the possibility of targeting this CCI for cancer therapy. The metastatic potential of several variants of the B16 cell line is correlated with their LacCer binding ability (39). Injection of LacCer-containing liposomes to mice that have aggressive melanoma inhibited the development of metastatic lung tumors in the animals (39). Administration of multivalent glycoconjugates such as glycosylated peptides or glycosylated gold nanoparticles also inhibits metastasis in vivo (40, 41). Inhibition of GM3 biosynthesis has also been shown to reduce metastatic melanoma migration in an animal model (42). Further studies with these glycoconjugates are needed to clarify their mechanism of action in vivo.

Model Studies

Langmuir monolayers have been used to model the interactions between GM3 and LacCer or Gg3. Micelles of a lactosyl monolayer injected under a GM3-containing monolayer induces a change in the surface pressure (∆π) at the air-water interface in a concentration-dependent manner (43). These increases in ∆π are a consequence of glycolipid insertion into the membrane, but glycoconjugates that do not insert also increase ∆π. The role of the divalent cation in this interaction is unclear, as it is increased in some conditions but not others (43, 45, 46). In a separate study, the behavior of various polystyrene glycoconjugates with a GM3 monolayer was examined (47). Pressure-area compression isotherms of GM3 monolayers exhibited expanded areas when they were generated over a solution of the GM3 glycopolymer. The amount of Gg3 glycoconjugate adsorbed on the GM3 monolayer was quantified using a quartz crystal microbalance by transferring the glycoconjugate-bound monolayer to a quartz substrate (46, 47). An SPR study of this same system provided an association constant for Gg3 glycopolymer binding to a GM3 monolayer of 2.5 \times 10^7 M^{-1} (48, 49).

CCI in Myelin Compaction

Biological Context

The myelin sheath is a multilayered membrane that wraps around axons in the nervous system and facilitates the transport of action potentials by preventing dissipation of a signal as it travels along the axon. The lipid bilayers of the myelin sheath are extensions of the membranes of oligodendrocytes in the central nervous system and Schwann cells in the peripheral nervous system. The specific mechanism by which this CCI mediates adhesion is not currently known.
nervous system. Unlike many other cell membranes, myelin is highly enriched in glycolipids, primarily GalCer (2) and CBS (3), that are preferentially embedded in the outer bilayer (50, 51). In addition, the multilayers are tightly compacted, a process dependent on divalent cations (52). A CCI between GalCer and CBS is believed to play an important role in maintaining the structural integrity of the myelin sheath.

The cellular function of this CCI was studied by examining the interaction of GalCer/CBS containing liposomes with cultured oligodendrocytes (53). Anti-GalCer antibodies bind to glycolipid containing membranes on oligodendrocytes and this binding decreases when the cells are pre-incubated with the glycolipid liposomes. Antibody binding to myelin binding protein (MBP) was similarly inhibited by the liposomes, indicating a colocalization of the glycolipids and MBP in the oligodendrocyte membrane. Liposome incubation also resulted in loss of microtubule fine structures, suggesting that actin filaments are destroyed upon CCI. Similar results were obtained in subsequent studies using galactose (Gal) and sulfated galactose (sGal) conjugates of BSA (54). BSA conjugates containing both Gal and sGal elicited a stronger response than albumin modified with a single carbohydrate.

Model Studies

The interaction between these two glycolipids has also been examined in various chemical model systems. A ceramide sulfate (CBS) coated surface is adherent to liposomes containing GalCer but not to faciol or galactosyl ceramide (55). The aggregation of glycolipid containing liposomes in the presence of various divalent cations was examined (56). The largest amount of aggregation was observed between liposomes containing GalCer and CBS, and the magnitude of the interaction was inversely correlated with the ionic radius of the cations. The presence of longer or N-hydroxylated N-acyl chains on the glycolipids also increased the association between GalCer and CBS liposomes. Infrared spectroscopy of this interaction revealed that the presence of calcium changed the conformation of the sulfate group in CBS, thereby disrupting several intramolecular hydrogen bonds (57, 58). As membranes in myelin contain both GalCer and CBS, this CCI can occur in a cell membrane in myelin.

Molecular recognition is critical to many fundamental processes in biology, including enzymatic reactions, signal transduction, genetic information processing, as well as molecular and cellular transport. The question of how proteins selectively recognize and correctly associate with their partners is an active research problem. For many proteins, experimental information about the structures of their molecular complexes and the details of their interactions are lacking. Macromolecular, structure-based computational techniques provide a means to predict the interactions of proteins and to investigate their recognition mechanisms. Here, we first discuss the general mechanism of molecular recognition as a multistep process from diffusion of one molecule toward the second to tight complex formation. We then describe the main forces and the physical properties that govern biomolecular interactions and introduce the principles of modeling them. Finally, simulation methods and computational approaches for molecular docking are briefly presented.

An understanding of the mechanisms of molecular recognition provides the essential basis for rational structure-based drug design and bioengineering. However, biomolecular recognition is complex and is determined by a fine balance between different contributing properties such as shape, electrostatics, dynamics, and entropy. This complexity makes the modeling of biomolecular recognition and the prediction of the properties of biomolecular complexes challenging. Here, we first discuss the factors important for biomolecular recognition that should be considered in computational models. Then simulation methods, such as Brownian and Molecular Dynamics, as well as other computational techniques that are widely exploited for studying protein-protein and protein-ligand recognition are presented. Last, we describe the principles, approximations, and limitations of some existing computational molecular docking approaches, which provide a means to predict the structures of bound complexes.

Although molecular recognition is of importance to all biomolecules, the astounding molecular recognition properties of the immune system have been the subject of investigations since the nineteenth century. It is intriguing how a vast number of chemically similar antibodies are serologically indistinguishable but can react with different antigens can be produced in one species (1). Similarly, the major histocompatibility complex can recognize a huge variety of peptides. How the immune system achieves this spectrum of molecular recognition properties is still not fully understood. Nevertheless, studies of this molecular recognition process have been exploited practically, namely in the design of vaccines that exploit the molecular recognition between antibodies and cell surface antigens.

The recognition between proteins and nucleic acids has challenged scientists for a long time. RNAs, for example, are capable of enzymatic activity and make direct contributions to substrate recognition and catalysis in ribonucleoproteins such as the ribosome (2) and the spliceosome (3). Nearly all the functions of RNAs are associated with the binding of proteins. However, the question of how a protein recognizes a specific RNA site, what effects it has on the RNA structure and dynamics, and how it promotes a specific RNA function are still very demanding. It is, for example, of great interest to understand how aminoacyl-RNA synthetases achieve the specificity needed to ensure faithful translation of the genetic code.

**Biological Background**

Molecular recognition is one of the most fundamental and important processes in biology. It occurs between two or more molecules, and it is involved in biochemical processes such as enzymatic reactions, molecular transport in the cell, genetic information processing, and protein assembly.
Mechanisms of Molecular Recognition

The mechanism of molecular recognition can be described schematically as a multistep process. Two molecules first come into proximity from afar. If active transport does not occur, then this process will occur by diffusional association with formation of a diffusional encounter complex, which is a loose complex between the molecules. Depending on the degree of burial of the binding sites, diffusion may occur of a small molecule through its macromolecular receptor to the binding site and this may require conformational changes in the receptor. Finally, and usually after induced fit conformational changes, the molecules will form a fully bound complex (11). The extent to which induced fit exists as opposed to selection of a binding conformation among a conformational ensemble of a protein is the subject of debate (12); but presumably, it varies according to the system, as does the extent of conformational change.

The binding process may be mediated first by long-range electrostatic interactions between the two associating molecules and then complemented by short-range van der Waals interactions and hydrogen bonding. Water molecules can either be displaced on binding or retained to mediate binding of the molecules. The forces involved in the process of molecular recognition are discussed in more detail later.

Kinetics and thermodynamics of molecular recognition

The rate of binding of two molecules A and B and formation of their complex AB can be quantified by the bimolecular association rate constant (on-rate constant), $k_{on}$, whereas their unbinding is characterized by the dissociation rate constant (off-rate constant), $k_{off}$.

$$ A + B \rightarrow_{k_{on}} AB \rightarrow_{k_{off}} [A][B] $$

The binding affinity of two molecules can be quantified by the equilibrium dissociation constant, $K_d$.

$$ K_d = \frac{[A][B]}{[AB]} $$

With the relation between $K_d$ and the binding free energy (Gibb's energy), $\Delta G$, $K_d$ can be expressed as

$$ K_d = \frac{C_0 \exp(-\Delta G/RT)}{C_d} $$

where $R$ is the universal gas constant ($\sim 8.31 \text{ J} \cdot \text{K}^{-1} \cdot \text{mol}^{-1}$), $T$ is the temperature in K, and $C_0$ is the standard concentration. The dissociation constant is usually given in molar units (M).

The binding free energy $\Delta G$ is defined by the interplay between two thermodynamic entities: binding enthalpy, $\Delta H$, and binding entropy, $\Delta S$.

$$ \Delta G = \Delta H - T \Delta S $$

The phenomenon of "enthalpy-entropy compensation," in which one term favors binding and the other term disfavors binding, is observed for many molecular recognition processes. On one hand, the binding benefits from enthalpic contributions that include electrostatic, hydrogen bonding, and van der Waals interactions. On the other hand, the unfavorable loss of translational and rotational entropy occurs mainly due to the reduction in the number of degrees of freedom of the molecules on their complexation. Bimolecular binding is also disfavored by the loss of flexibility of the molecules on binding, although it can benefit from increased flexibility at a distance from the binding sites (allosteric effect). The displacement of water molecules on binding may also be entropically favorable. Different sources of entropic contributions to binding are discussed later (see the section entitled "Entropy").

Conformational changes on binding

The conformational flexibility of the molecules plays a very important part in their binding. When a protein–protein complex is modeled using the structures of the two proteins determined in their unbound states, some key side chains or structural motifs might be positioned to result in steric clashes or unfavorable electrostatic interactions (13, 14). Therefore, on binding, the intermolecular interactions should result in some degree of induced fit. Induced fit can be defined as the collection of conformational changes, which results in optimal interactions, when two molecules come into contact (14).

These conformational changes in biomolecules can vary from small-scale motions, which include bond stretching, bond angle bending, and dihedral angle variations, to larger motions of the main chain, which are the loops or entire domains of proteins. Such changes occur on different timescales, which range from picoseconds to hours, with amplitudes that extend to hundreds of Ångstroms (15). Small changes in molecular conformation can adversely affect molecular docking results when using rigid molecular models. For example, Betts and Sternberg (16) have found that RMS deviations of 0.6 Å for backbone and 1.7 Å for side chain atoms affect protein-protein docking.

The dynamics of protein side chains occurs on the time scale of picoseconds to milliseconds with RMS deviations up to about 3 Å. Such motions include the rotation of side chains between different rotamers. A "flexibility scale" for protein side chains has been determined (17). It is shown that protein-protein interactions are critically dependent on
“hot-spot” residues at the binding interface (18). Molecular dynamic simulations have revealed that the hot-spot residues are found frequently in the unbound proteins in the rotamers observed in the protein-protein complex (19, 20). In contrast, the side chains at the perimeter of the interface are mostly found in nonspecific rotamers in the unbound protein, which suggests that their final conformations are induced on binding.

It was proposed by Kimura et al. (19) that these side chains act more as “latches” that hold the molecules together rather than as “keys” fitting snuggly into the binding pocket. According to the mechanism of induced fit, these latches open before docking and “fasten” to their partners later during the binding process.

The conformational rearrangements of backbone atoms and of protein loops play a significant role in ligand recognition, protein-protein association, DNA-binding, and so on (21–24). For developing the docking methodology, Chen et al. (25) and Vajda et al. (26) classified 59 protein complexes based on their docking difficulty. The cases in which substantial conformational changes of the backbone or loops between the unbound and bound structures were observed were referred to as “difficult.” Such backbone motion may be up to 10 Å or more and can drastically modify the steric and the electrostatic properties of the protein face presented to the partner. In some cases, loop motion may be caused by large changes in as few as two torsion angles (27), but sometimes the deformations are distributed over more torsion angles (28, 29).

Large-scale domain or subunit motions are often classified into hinge and shear motions (30). Short loops or elements of secondary structure can serve as hinge regions. Interactions of ligands with binding domains may cause the protein to undergo certain conformational changes, which sometimes leads to closure of a binding site, see Fig. 1.

The extent and the variation of the conformational changes that can occur on molecular binding show the necessity for these changes to be taken into account when modeling the molecular recognition and the binding of two associating molecules.

Modeling Molecular Recognition

Modeling of the different steps of molecular recognition requires suitable models of the corresponding forces and the energetic contributions. These elements will be considered in the next section.

Shape complementarity and van der Waals interactions

In 1894, Emil Fischer postulated that biomolecular recognition is analogous to the matching of a “key” into its “lock,” in which the “lock” refers to an enzyme and the “key” refers to a substrate. Only the correctly shaped key (substrate) fits into the hole (active site) of the lock (enzyme). Describing molecular recognition in terms of structure and bonding in the mid-1940s, Pauling defined the specificity of biomolecular recognition, which occurs due to the mutually complementary configurations of molecular surfaces. In other words, the surface of one molecule conforms closely to the surface of the other molecule on biomolecular binding.

Molecular shape complementarity is critical to biomolecular recognition and specificity. Even if the molecules change conformation on binding and water molecules are trapped at the interface, bound complexes show high shape complementarity (31). This shape complementarity is dependent on van der Waals interactions between the binding molecules. Electron-electron repulsion prevents atomic overlap and intermolecular penetration. However, induced dipole effects as atoms approach lead to short-range attractive interactions.

The simplest approximation in modeling molecular recognition is to model just van der Waals repulsion by preventing steric overlap (e.g., with an infinite wall potential or a geometric shape description). The short-range attraction is usually accounted for in modeling biomacromolecules with an empirical energy function by means of a Lennard-Jones energy (32, 33):

$$E_{13}[r_{ij}] = -\frac{C_{ij}}{r_{ij}^{12}} + \frac{D_{ij}}{r_{ij}^{6}},$$

where the first term describes the attraction and the second term describes the repulsion between a pair of interacting atoms where $r_{ij}$ is the distance between them. The coefficients $C$ and $D$ depend on the type of the atoms and $D_{ij} = 0.5C_{ij}(r_{ij}^{6}/r_{ij}^{12})$, where...
\( \rho_{ij} \) is the sum of the van der Waals radii of atoms \( i \) and \( j \).\( C_{ij} \) is parameterized according to the Slater–Kirkwood equation based on atomic polarizability and the number of outer-shell electrons of interacting atoms (34, 35). For computational convenience, Lennard-Jones energies and forces are often computed only for pairs of atoms within a defined “cutoff” radius of about 10 Å (35).

**Electrostatic interactions**

Electrostatic interactions are long range, vary with distance as \( 1/r \), and play a significant role in molecular recognition. Therefore, they are particularly important to model when simulating the initial diffusional step of biomolecular recognition. Molecules are characterized not only by their net charges, but also by their charge distributions. For modeling electrostatic interactions, formal or partial charges are assigned to the atoms of the interacting molecules. The simplest model to describe the interactions between charges is Coulomb’s law, in which the electrostatic energy \( E_\text{el} \) of charges \( q_i \) in molecule A and \( q_j \) in molecule B is given by:

\[
E_\text{el} = \sum_{i,j} \frac{q_i q_j}{\epsilon_0 r_{ij}}
\]

where \( r_{ij} \) is the distance between atoms \( i \) and \( j \), and \( \epsilon \) is the relative dielectric constant. The potential of a charge \( q \) at the position of an atom \( i \) at distance \( r_i \) in homogeneous dielectric \( \epsilon \) is \( \Phi = q_i r_i / \epsilon \).

Weaker electrostatic interactions occur in a polar medium such as water rather than in vacuum because of dielectric screening. If the atoms in the system, including the water molecules and ions of the solvent, are modeled explicitly, then a relative dielectric constant \( \epsilon_m \) is usually assigned as 1 (\( \epsilon_m = \epsilon_0 \) or 1, where \( \epsilon_0 \) is the permittivity of free space). However, when the molecules and the medium are treated implicitly, the relative dielectric constant is used as a descriptor of the bulk polarizability of the medium. Proteins tend to have a lower relative dielectric constant than water because many dipolar groups can be considered frozen into a hydrogen-bonded lattice and therefore cannot reorient in an external electrostatic field. Typical assignments of the \( \epsilon_m \) for proteins range from 2 to 20. Water, however, has a high \( \epsilon_m \) around 80 because its dipoles can reorient freely. This dielectric heterogeneity should be accounted for in an electrostatic model of a system with protein molecules in water.

The Poisson equation (or Gauss’ Law) describes the electrostatic potential of a fixed charged density of the solute \( \rho_{\text{tot}}(r) \). The exterior charge density of the ions in the solution, \( \rho_{\text{sol}}(r) \), is modeled by assuming a Boltzmann distribution. The Poisson-Boltzmann (PB) equation is commonly applied to molecules in aqueous solution to compute the electrostatic potential of the system. The general form of the PB equation is:

\[
\nabla \cdot [\epsilon(r) \nabla \phi(r)] = -4\pi \rho_s(r),
\]

where \( \phi(r) \) is the electrostatic potential at position \( r \); \( \epsilon(r) \) is the position-dependent dielectric function; \( \rho_s(r) \) is given by the charge density of the solute, \( \rho_{\text{sol}}(r) \), and of the ions in the solvent, \( \rho_{\text{ion}}(r) \); \( \epsilon \) designates the vector differential operator.

The PB equation may be solved numerically for molecules (for reviews, see References 36–38). The finite difference, finite element, and multigrid methods are used most commonly to solve the PB equation. Usually, this technique is performed by mapping the molecules onto a three-dimensional cubic grid. To solve the PB equation, a suitable interior relative dielectric constant and definition of the dielectric boundary should be assigned (39, 40).

**Hydrogen bonding**

Hydrogen bonds are specific, short-range, nonbonded interactions. They occur between a proton donor of strongly polar groups such as FH, OH, NH, and SH, and a proton acceptor that is strongly electronnegative such as O, F, or N. Weak hydrogen bonds may also be formed by CH groups. The “attraction” of the proton has electrostatic nature. However, quantum-mechanical treatments reveal other contributions to hydrogen bonds. These treatments include the short range repulsion due to the smaller distance between acceptor and hydrogen donor than the sum of their van der Waals radii and the attraction that originates from charge transfer (for review, see Reference 41).

Several empirical analytic forms for the energy of a hydrogen bond have been proposed. A general expression for the energy of a hydrogen bond that describes their directional properties is:

\[
E_{\text{H2O}} = E_x + E_n + E_d = (-C_2 r^{-6} + D_2 r^{-10}) - E_x - E_d
\]

The distance-dependent term may have values of \( m \) and \( n \) of 10 and 12 or 6 and 8, respectively, \( \{E_x, E_n, E_d\} \), the latter are used in the GRAM program (42). The angular terms are functions of the angles made at the donor hydrogen and at the acceptor atom and depend on the chemical types and bonding of the hydrogen bonding atoms.

Hydrogen bonds play an essential role in the stabilization of secondary structures in proteins and in the interactions of macromolecules. In proteins, hydrogen bonds “lock” secondary structure elements such as \( \alpha \)-helices, beta-sheets, and beta-turns. Most hydrogen bonds occur between N-H and O=C groups in the polypeptide chain. Because of the strong hydrogen bonding abilities of water molecules to polar groups in proteins, it is believed that the structural water molecules tighten the protein matrix. However, evidence has been provided for the importance of structural water molecules in increasing protein flexibility (43).

Hydrogen bonds are of great importance for the specificity of molecular recognition at short range. Unspecific hydrogen bonding at the binding interface of two interacting macromolecules will disfavor binding. The charged or polar residues at the binding interface of one macromolecule can form hydrogen bonds to charged groups or to polar groups of another macromolecule. Interfacial water molecules may also mediate molecular recognition, due to their ability to donate and accept hydrogen bonds.
Hydrophobic effect

The hydrophobic effect refers to the favorable interactions between nonpolar surfaces immersed in water. These interactions are considered to provide the driving force for protein folding (44) and to make a major contribution to the stability of protein tertiary structures. The hydrophobic effect also plays an important role in protein interactions (45). The hydrophobicity of protein surfaces has been studied experimentally by affinity partitioning of proteins (44). Theoretical studies have shown that the presence of hydrophobic patches on the surfaces of proteins correlates with protein binding sites (47–49).

In simulations with explicit water molecules, the hydrophobic interactions must result from a complicated interplay of Lennard-Jones and electrostatic interactions between the atoms of the protein and the surrounding water molecules. In the case that the water is represented implicitly, the hydrophobic interactions are usually modeled by an empirical term that depends on the surface area buried on binding:

\[ E_{\text{SASA}} = \sum \alpha \Delta \text{SASA}_i \]

where \( \text{SASA} \) indicates the solvent accessible surface area, and \( \alpha \) is a coefficient that depends on the surface area definition and the atom type (50). The SASA was described first by Lee and Richards in 1971 (51). For computational calculations, the “rolling ball” algorithm of Shackle and Rupley is often used (52). The ball or sphere radius is typically 1.4 Å, which approximates the radius of a water molecule.

The buried surface area between two interacting molecules, A and B, is calculated as the difference between the summated SASA of each molecule separately and SASA of the complex:

\[ \Delta \text{SASA}_{\text{buried}} = \left( \sum_{A} \Delta \text{SASA}_A + \sum_{B} \Delta \text{SASA}_B \right) - \sum \Delta \text{SASA}_i \]

Entropy

Many biological processes such as protein folding, molecular recognition, or more specifically ligand-protein or protein-protein binding, are associated with changes in entropy. Entropy is defined as a measure of “freedom” of the system. Several types of entropy are involved in recognition processes.

On bimolecular binding, an entropic loss develops from the reduction of the translational \( S^{\text{trans}} \) and rotational \( S^{\text{rot}} \) freedom because of the transformation of two unbound molecules into one bound complex. \( S^{\text{trans}} \) and \( S^{\text{rot}} \) for the gas phase may be calculated by the “Sackur-Tetrode” approach (53). Modifications are required to estimate \( S^{\text{trans}} \) and \( S^{\text{rot}} \) in other environments (54).

In addition, the loss in \( S^{\text{trans}} \) and \( S^{\text{rot}} \) has been found to be compensated largely by intermolecular, mostly vibrational, motions \( S^{\text{vib}} \) in the complex. \( S^{\text{vib}} \) is expected to be smaller for high affinity complexes and larger for low affinity complexes (55). \( S^{\text{vib}} \) can be estimated using harmonic or quasiharmonic models of the system (for more details, see Reference 56).

Intuitively, binding is expected to restrict the flexibility of both partners and lead to a significant loss in conformational entropy. To overcome this unfavorable loss of conformational entropy, specific and favorable intramolecular or short-range intermolecular interactions such as hydrogen bonds, salt bridges, hydrophobic interactions and so on are formed. In some cases, the binding of the partners causes increased conformational flexibility of regions distant from the actual binding site, which results in allostERIC EFFECTS (57). The change in conformational entropy due to the protein backbone and side chains is usually estimated by considering the protein as having discrete, isoenergetic, conformational states (e.g., side chain rotamers). Then:

\[ \Delta S = k_B \ln(n_1/n_2) \]

where \( n \) indicates the number of states, and 1 and 2 refer to the initial and final situations. The conformational entropy \( S^{\text{vib}} \) is often subdivided into backbone \( S^{\text{back}} \) and side chain \( S^{\text{side}} \) entropies. \( S^{\text{back}} \) is determined by the probability distribution over the dihedral angle space. The contribution of backbone entropy is generally less significant for binding than for folding. \( S^{\text{side}} \) is usually estimated by rotamer counting, although more detailed probability calculations can be performed (also discussed in Reference 58).

During molecular binding, some water molecules are “released” from the interface of the contacting molecules, which causes a favorable entropic contribution, \( \Delta S^{\text{dielectric}} \). The solvation entropy is commonly computed using methods based on solvent accessible surface areas \( (\text{SASA}) \) (58, 59). However, the binding involves highly charged molecules such as nucleic acids, the SASA approach may not be adequate. Because of the presence of highly charged binding partners in the solvent, additional solvation entropy contributions \( (\Delta S^{\text{dielectric}} + \Delta S^{\text{ionic}}) \) should be taken into consideration. These contributions result from ordering of the water dipoles via long-range electrostatic interactions and the formation of an ionic atmosphere. Sharp et al. (60) calculated \( \Delta S^{\text{dielectric}} \) and \( \Delta S^{\text{ionic}} \) using a Poisson-Boltzmann model in conjunction with van't Hoff analysis and applied it to drug and protein binding to DNA. Water molecules may also be trapped at the interface with an entropic cost, which can be estimated by considering the loss of mobility of the water molecules compared to bulk solvent (61).
simulated process or step. Here, we first discuss the use of Brownian and molecular dynamics simulation methods and then discuss how the level of detail can be altered in constructing models for the simulation of molecular recognition.

**Brownian dynamics simulation**

The Brownian Dynamics (BD) simulation technique can be used to simulate the diffusion and the association of molecules in solution. BD simulations have been widely used to simulate protein–small molecule and protein–protein association (62). This method may be exploited to simulate the first step of molecular recognition when two molecules diffuse from a distance. From such simulations, it is possible to compute the structure and the diffusional encounter complex ensemble and to calculate the bimolecular association rate constant for two diffusing proteins or enzymes and their substrates or inhibitors. In these calculations, the effects of mutations and variations in ionic strength, pH, and viscosity can be investigated (63).

The general principle of BD is based on Brownian motion, which is the random movement of solute molecules in dilute solution that result from repeated collisions of the solute with solvent molecules. In BD, solute molecules diffuse under the influence of systematic intermolecular and intramolecular forces, which are subject to frictional damping by the solvent, and the stochastic effects of the solvent, which is modeled as a continuum. The BD technique allows the generation of trajectories on much longer temporal and spatial scales than is feasible with molecular dynamics simulations, which are currently limited to a time of about 10 ns for medium-sized proteins.

The basic BD algorithm developed by Ermake and McCammon (64) provides an approximate solution to the Langevin equation in the highly damped diffusive limit by using the positions of a solute particle at time t, together with the forces acting on them, to estimate the particle’s new position at time, \( t + \Delta t \). The translational behavior of the particle is described by:

\[
 r(t + \Delta t) = r(t) + D \Delta t + \frac{F}{k_B T} + R
\]

where \( F \) is the force that acts on the particle, \( D \) is the translational diffusion constant of the particle, and \( R \) is a random displacement that mimics the effects of collisions of the particle with solvent molecules. The rotational behavior of the diffusing particle is described by a similar equation to the translational behavior. The translational and rotational diffusion constants of proteins can be estimated by the Stokes-Einstein relationship, which depends on the solvent viscosity and the radius of the protein. Larger proteins diffuse slower.

For simulation of molecular recognition by BD to compute association rate constants and for the generation of the structures of diffusional encounter complexes, the following setup may be used. One solute, which usually is the larger one, is positioned at the center of simulation space. The second molecule diffuses from randomly chosen starting points at a specified distance, and many trajectories are generated. The probability of formation of diffusional encounter complexes is computed from these simulations. The method of Northrup et al. (65) allows computation of the association rate constant by combining an analytical solution to the diffusion equation with the numerical data from the BD simulations.

The programs most widely used for simulation of the diffusional encounter of two biomolecules are UHBD (66, 67), Macromod (68), and SDA (66, 67).

**Molecular dynamics simulation**

Molecular dynamics (MD) trajectories can be used to investigate the structure, dynamics, and thermodynamics of biological molecules and their complexes. The motions of the atoms in the system are simulated according to Newton’s equations of motion. The forces on the atoms are calculated using a molecular mechanics energy function. The force field for a protein is given by the sum of various components including bond stretching and bond angle bending, torsional potential, and nonbonded interactions (Lennard-Jones and Coulombic interactions). Several different algorithms may be used to generate snapshots of the system using a time step of about 1 fs (69, 70).

The motions of proteins are usually simulated in aqueous solvent. The water molecules can be represented either explicitly or implicitly. To include water molecules explicitly implies more time-consuming calculations, because the interactions of each protein atom with the water atoms and the water molecules with each other are computed at each integration time step. The most expensive part of the energy and force calculations is the nonbonded interactions because these scale as \( N^2 \) where \( N \) is the number of atoms in the system. Therefore, it is common to neglect nonbonded interactions between atoms separated by more than a defined cut-off (~10 Å). This cut-off is questionable for electrostatic interactions because of their UV dependence. Therefore, in molecular dynamics simulations, a Particle Mesh Ewald method is usually used to approximate the long-range electrostatic interactions (71, 72).

MD simulations are used mainly to investigate in detail the interactions of two associating macromolecules at relatively short distances, rather than to simulate their coming together from afar. Thus, an encounter complex or an approximate protein–ligand complex can be refined using MD simulations. Indeed, MD is an important tool in macromolecular complex structure determination in which it is used with simulated annealing and experimental constraints. Important applications of MD simulations include the computation of the binding free energies and intermolecular forces.

**Coarse graining of a simulation model**

Most biomolecular binding events occur on timescales orders of magnitude greater than can be attained in standard molecular dynamics simulations in which the motion of all atoms is
Molecular Docking: Prediction of Bound Complexes

Whereas dynamic simulations may be used to study the process of molecular binding and unbinding and to predict the structure of the bound complex, many computations are aimed solely at prediction of the structure of the bound complex. This is the so-called “docking problem.” Although this problem can be addressed by using simulations to mimic the physical binding process (77), many other approaches may be used to sample molecular arrangements and to predict the bound complex. Energy minimization from systematically or randomly distributed starting arrangements may be performed subject to a detailed or simplified force field (e.g., for protein-protein docking, (74)). Simulated annealing and Monte Carlo methods include temperature to permit high-energy configurations to be sampled and thereby energy barriers to be overcome (e.g., AutoDock, (78)). Genetic algorithms and particle swarm optimization methods are biologically inspired procedures for optimizing a function efficiently that have been applied to small molecule docking (e.g., GOLD (79), PLANETS (80)) and to protein-protein docking (81). They may be applied with driving “forces” for binding that range from simple geometric complementarity (82) to detailed molecular mechanics type force fields. Systematic searching is widely used. This can be facilitated by FFT methods, which were applied initially to protein-protein docking by optimization of geometric fit (83). Because the direct calculation of the correlation between two functions results in an order of N^6 computing steps, Katchalski-Katzir et al. (83) used Fourier Transforms to calculate the correlation function more rapidly. With this algorithm, the computing time is proportional to N^3 ln N^3, where N is the number of atoms in the complex. FFT methods have been used to optimize not only geometric fit but also hydrophobicity/complementarity (48) and electrostatic complementarity (DOT) (84).

Optimization may be performed in continuous or discrete space. For example, in optimizing the conformations of side chains in proteins, a discrete rotamer representation is often used. In 2003, Gray et al. (85) presented a docking program RosettaDock that allows the side chain conformational stiffness of the interface residues on both interacting partners to change. The side chain flexibility was modeled using a simulated annealing algorithm that searches through backbone-dependent rotamers from the Dunbrack rotamer library (86). The side chains of the partners are rebuilt from rotamers before docking (prepacking) and only the side chains of the interface are then refined later in docking. Additional improvements of this method, such as implementation of a torsion minimization step to sample off-rotamer space and information on side chain packing from the unbound structures, are described in Reference 87. However, in some cases, which may be binding hot spots, side chains adopt nonideal-rotamer conformations and these should be accounted for (88). In the ATTRACT approach of Zacharias (74), several conformations are considered for each side chain simultaneously. Side chain copy selection is coupled to energy minimization in translational and rotational degrees of freedom of the mobile protein partner in an iterative way. This technique is effective for complexes in which side chain conformational changes occur during complex formation. Similar to side chain mobility, this approach can also be extended to treat the flexibility of protein loops.

Conclusions and Future Directions

Biomolecular recognition can be described as a balanced interplay of different forces and energetic contributions. The long-range electrostatic forces together with the short-range van der Waals interactions, shape complementarity, hydrogen bonding, and hydrophobic effects determine the interactions of associating molecules. The flexibility of the partners on their binding is important for induced fit and makes an entropic contribution to the recognition process. Modeling of the structural, dynamic, and energetic determinants provides a tool to simulate the interactions of the macromolecules on their complexation. Different computational docking programs model the forces and the energetic contributions differently. Some docking programs mimic the diffusional association of the molecules; others base their approach mostly on the shape complementarity of associating partners. The varying degrees of the incorporation of electrostatic and hydrophobic interactions and the structural plasticity of the molecules on binding influence the accuracy.
of the prediction of the structure of the bond complex and the ability to compute kinetic and thermodynamic parameters. Because of the large number of degrees of freedom of biologically active molecules in solution, the problem of sampling and scoring of the docked solutions is very challenging. The computational methods must aim at simple, computationally feasible models that provide reasonable accuracy and help to answer the question of whether a given molecule can recognize and bind with their partners selectively and specifically. Current protein–protein docking algorithms can provide good predictions of the structures of complexes when the conformational changes on binding are very limited, but they usually fail when large conformational changes occur (89, 90); see also the CAciPRi experiment for the comparative evaluation of protein–protein docking for structure prediction (http://caspabi.ebi.ac.uk). Ongoing improvements of the computational models for biomolecular interactions include the treatment of large-scale conformational changes of the macromolecules on binding and the modeling of solvation and polarization effects, among others.

Despite the significant research that has been invested in understanding molecular recognition in biological systems, accurate prediction of macroscopic properties based on microscopic interactions remains elusive, which makes it difficult to identify systematically tight binding inhibitors in computational drug design. In the past, most ligand design efforts have centered on descriptors derived mainly from structure, neglecting entropic effects that develop from receptor flexibility. The lack of explicit incorporation of receptor motion has meant that compensatory effects between enthalpy and entropy, which are essential for the accurate estimation of free energy, have also been neglected. In addition, cooperative effects, which develop from alteration in the motion of the receptor because of ligand binding, are not captured. These effects pose a challenge for the design of small molecules that allosterically modulate protein-protein and protein-small-molecule interactions. Here, we describe macroscopic properties of receptor-ligand interactions, which are followed by a discussion of how these properties are predicted with microscopic interactions. A discussion then ensues on some fundamental aspects of the molecular recognition process that have attracted renewed attention, such as conformational selection versus induced-fit binding, entropy-enthalpy compensation, and allostery.

Introduction

Molecular recognition leads to the association of macromolecules, which enables them to perform functions that are vital to the survival of an organism. Evolutionary forces have exploited interactions between macromolecules for the purpose of performing one of a multitude of tasks, including chemical modification (1), transportation (2), signal transduction (3), or recruitment of other macromolecules (4), among other things. The recognition process is driven by a balance between potential energy that develops from physical interactions at the molecular level (5) and kinetic energy that originates from inherent dynamics contained in molecules (6). The physical interaction between macromolecules is driven by various interactions most prominent among them electrostatics, which develops from the positive and negative charge of nuclei and electrons (6) and the hydrophobic effect (7-11). These charges impart attractive and repulsive characteristics to molecules. But it is often overlooked that the dynamics of molecules also play an important role in the recognition process (6).

In solution, molecules constantly encounter each other through collisions. At close distances, repulsions from the nuclei dominate. The balance between repulsive and attractive forces often lead to an equilibrium state such that two molecules will remain associated in a complex. In this state, dispersion or London forces dominate. The motion experienced by the molecules also plays a crucial role in this process. A molecule contains translational, rotational, as well as internal vibrational motion. When two molecules associate, conservation of energy dictates...
that the energy that is initially contained in translation and rotation must be eventually absorbed internally by the molecules through vibrations (12). The failure to effectively absorb this energy could lead to a disruption of the balance between attractive and repulsive forces and the abrogation of the complex.

A thorough understanding of macromolecular and their ligands is essential to the survival of an organism. It is often the case that these same interactions will contribute to pathological processes. Examples include the binding of a growth factor to its cell surface receptor (3, 13), a matrix-metalloproteinase binding to its ligand (14), the binding of a kinase to its ATP substrate (15). Each of these interactions has been targeted by pharmaceutical companies for the development of drugs. Inhibition of the receptor tyrosine kinases has been particularly successful. Targeting the ab kinase, for example, has led to the discovery of Gleevec (Novartis, East Hanover, NJ), which is one of the most effective anticancer therapeutics to date (16). This drug was rationally designed such that structural information of its target was used during the drug-discovery process. It is likely that early version of the drug underwent a series of chemical modifications to optimize not only affinity to the target but also ADME (adsorption, distribution, metabolism, and excretion), toxicology, and pharmacokinetic properties (17). But high affinity to the drug target remains a key criterion that must be constantly maintained. In addition, with the multitude of targets that are now available, selective or broad-spectrum inhibitors are also desirable. Despite the significant progress that we have made over the past decade toward understanding molecular recognition, the systematic ability to design molecules with high affinity to a target based on its structure remains elusive (18).

The focus of this review article will be on the interaction between macromolecules and small-molecule ligands. The discussion will first center on the thermodynamic and kinetic characteristics that are used to measure the extent of binding. Subsequently, we discuss the interactions at the atomic level that drive complex formation. Then, a discussion follows of some tools available to predict macroscopic properties from microscopic properties. We then briefly discuss molecular motions as well as various aspects of receptor-ligand that have attracted renewed attention, such as conformational selection versus induced-fit, entropy-entropy compensation effect, and protein allosterism.

**Macroscopic Properties**

In solution, the mixing of two entities leads to the formation of a chemical equilibrium that is represented by the following equation:

\[ \text{M (aq)} + \text{L (aq)} \rightleftharpoons \text{ML (aq)} \]

where M is the macromolecular receptor, L is the small molecule ligand, and ML represents the complex between the receptor and ligand. Depending on the strengths of the interactions, the equilibrium can favor the formation of reactants or products. The direction of the equilibrium is measured by a ratio known as the equilibrium constant, which is also known as the dissociation constant \( K_D \). The association constant \( K_A \) defined as follows:

\[ K_A = \frac{[\text{ML}]}{[\text{M}][\text{L}]} \]

A measure of the spontaneity of the chemical event is encapsulated in the Gibbs free energy, which is related to the equilibrium constant following this relation:

\[ \Delta G = -RT \ln K_A \]

\( \Delta G \) is the free-energy change, \( \Delta H \) is standard free-energy change, \( R \) is the gas constant whose value is \( 8.31 \) J mol\(^{-1}\) K\(^{-1}\), and \( T \) is the temperature.

A chemical event that results in a reduction of the free energy is referred to as exergonic, whereas a process that results in an increase in the free energy is known as endergonic. Typical values of dissociation constants \( K_D \) for receptor-ligand interactions occur between \( 10^{-3} \) (millimolar) and \( 10^{-9} \) (nanomolar) (19–21), although reports suggest values that reach the pico- to a change in the free energy \( \Delta G^\circ \) of 1.4 kcal mol\(^{-1}\). Hence, \( \Delta G^\circ \) for a millimolar ligand is \(-4.2\) kcal mol\(^{-1}\), whereas that of a nanomolar ligand is \(-9.8\) kcal mol\(^{-1}\). Another well-known equation relates the free energy to the enthalpy \( \Delta H^\circ \) and entropy \( \Delta S^\circ \):

\[ \Delta G^\circ = \Delta H^\circ - T \Delta S^\circ \]

The enthalpy is defined by the following expression:

\[ \Delta H^\circ = \Delta E + \Delta P \Delta V \]

where \( E \) is the internal energy of the system, \( P \) is the pressure, and \( V \) is the volume. Most chemical events occur at constant volume and pressure, and hence the enthalpy can be conceptualized as a measure in the internal energy change. The formation of favorable interactions, such as hydrogen bonds or van der Waals contacts will result in a negative enthalpy change and hence an exothermic process. The loss of favorable interactions leads to a positive enthalpy or endothermic process.

Although the enthalpy is a measure of order in the system, the entropy is a measure of disorder. The second law of thermodynamics states that a spontaneous event results in an increase in entropy. Hence, a favorable process always results in an increase in disorder. The entropy is defined as:

\[ S = k \ln \Omega \]

where \( k \) is the entropy and \( \Omega \) is the phase space that corresponds to all the possible states that a system may adopt. In Newtonian mechanics, a state can be defined by position and velocity. In macromolecules, position can be translated into internal coordinates, such as bonds and torsions that define the conformation of the macromolecule. In the context of receptor-ligand binding, the change in the entropy is the log of the ratio of phase space of the receptor—ligand complex.
and the phase space of the product of the receptor and ligand. The number of states that are accessible for the free receptor and ligands will be significantly larger than that of the complex. Hence, the association of macromolecules and their ligands typically results in entropy loss (22). In some instances that involve the burial of hydrophobic residues, the rearrangement of water could lead to a favorable contribution from entropy (vide infra).

**Microscopic Interactions**

Molecules can have a net positive defined as negative charge depending on the hybridization state of atoms within them. In solution, the net charge often originates from ionizable groups that act as a Brønsted base or acid following this equation:

\[ \text{A}^+ + \text{H}_2\text{O} \rightleftharpoons \text{HA} + \text{H}_3\text{O}^+ \]

Carboxylate, thiols, or amino moieties are a few examples of ionizable groups at physiological pH. The propensity of an ionizable group to lose a proton is measured by the \( pK_a \), which is defined by the following:

\[ pK_a = \log \left( \frac{[\text{HA}]}{[\text{A}^-]} \right) \]

where \( K_a \) is the acid dissociation constant, \( [\text{A}^-] \) and \( [\text{HA}] \) are the concentrations of acid and its conjugate base. Based on this equation, the \( pK_a \) can also be viewed as the pH at which the concentration of base is equal to that of the acid. For example, at neutral pH, the \( pK_a \) of the amino group of a lysine residue is 10.4, whereas that of a glutamic acid residue is 4.5 (\( pK_a \) values are from Refs. 23 and 24). In the former, the amino group is protonated and positively charged at physiological pH, whereas the glutamic acid is unprotonated and negatively charged. Other examples of amino acids with positively charged side chains include the guanidine side chain of arginine (\( pK_a \) = 12.5). A another example of an amino acid with a negatively charged group include aspartic acid (\( pK_a \) = 4.0).

Within macromolecules, however, the \( pK_a \) of ionizable groups can deviate from their standard values, as the groups are not only surrounded by solvent but also by other residues. For example, a carboxylic acid moiety located in a region of low polarity or hydrophobicity will experience an increase in its \( pK_a \). A positive charge near the carboxyl group will reduce its \( pK_a \), whereas a negative charge will lead to a more basic side chain. Conversely, an amino group in a hydrophilic region will experience a reduction in its \( pK_a \), whereas a salt bridge will increase its \( pK_a \). A prominent example that illustrates these trends occurs in the TEM-1 \( \beta \)-lactamase, which is a resistance enzyme in bacteria that destroys \( \beta \)-lactam antibiotics (25). The active site contains two lysine residues and two serine residues in a cross-like arrangement (Fig. 1). This arrangement is universally conserved not only among the \( \beta \)-lactamases but also among their ancestors, the penicillin-binding proteins (PBPs) (26). A lysine residue that is essential for catalysis is found in a hydrophobic pocket that is shielded from direct contact with solvent (Fig. 1).

A nearby glutamate side chain (Glu-166) forms a salt-bridge interaction with Lys-73. Biochemical analyses had described a \( pK_a \) of 5 to Glu-166, nearly 0.5 units higher than that of standard \( pK_a \) of 4.5. An extensive set of biochemical, nuclear magnetic resonance (NMR), and molecular dynamics-based free-energy calculations led to a \( pK_a \) value of 8 for Lys73, which is nearly 2.8 units lower than its standard \( pK_a \). These \( pK_a \) shifts can be rationalized from the microenvironment around the residues. The reduced \( pK_a \) of Lys73 is promoted by the low dielectric medium that surrounds its amino group along with the positive charge of a nearby lysine (Lys234). The negative charge that emanates from Glu166, on the other hand, stabilizes the positive charge on Lys73 and thus raises its \( pK_a \). Interestingly, in the PBPs, which lack a glutamate in its active site (27), the \( pK_a \) of the catalytic lysine residue is reduced even more to 6, such that the amino group on the lysine side chain is neutral (25). The neutrality of the side chain is essential for this enzyme to carry out its transpeptidase function (27).

Electrostatic interactions, along with hydrophobic effects, form the basis of most intermolecular forces that drive receptor-ligand interactions in biological systems. The simplest form of electrostatic interaction is the salt bridge, which occurs between two oppositely charged functional groups (28). The formation of such an interaction within proteins is usually energetically costly (29). An example is the Lys73 and Glu166 salt bridge that was alluded to above (Fig. 1). Other examples of charge-charge interactions in biological molecules include the coordination of transition metals with negatively charged moieties such as carboxylates from glutamate and aspartate side chains or thiolates from cysteine residues (30, 31). Although opposite charges form strong interactions, their presence alters the charge distribution of surrounding residues as well. A fixed charge creates an electric field that emanates from it (for a positive charge), electrons on surrounding atoms will be polarized depending on the nature of the field. For a positive charge, the electron density on surrounding atoms will move toward the charge, whereas a negative charge will cause electrons to move away. This movement of electron density creates a dipole. The region where the electron density is accumulated will be negatively charged, whereas the region that lost electron density will develop a partial positive site. Some dipoles are permanent (32). A prominent example is that of water, in which the electrons accumulate on the electronegative oxygen atom, leaving a partial positive charge on the hydrogen atoms and a permanent dipole that can be visualized as a vector that is perpendicular to the base of the HOH triangle (33). It is worth mentioning that the interaction energy between a charge and a dipole is inversely proportional to the separation to the fourth power, whereas a dipole–dipole interaction is inversely proportional to the separation to the sixth power. Hence, these interactions dominate at short separations, whereas charge–charge interactions dominate at large separations.

A ubiquitous interaction that is electrostatic in nature and commonly occurs in biological systems is the hydrogen bond (see Fig. 1 for examples). It is defined as the interaction between an electronegative atom (acceptor) and a hydrogen atom that is covalently attached to another electronegative atom (donor) (34, 35). At the fundamental level, a hydrogen bond has been
described as a dipole–dipole interaction, but it is likely more complex mixture of physical effects that include covalent characteristics, polarization, as well as charge transfer (34-37). A common hydrogen bond in proteins occurs between an NH bond and an oxygen atom from a carbonyl carbon with an NO distance that falls between 2.8 and 3.4, and between 1.5 and 2 Å for the OH distance. A recent series of surveys conducted on protein–ligand complexes from the Repository Collaboratory of Structural Bioinformatics find that the strongest hydrogen bonds occur for the NH–O (ligand is donor and backbone is acceptor), NH–O (side chain is donor and ligand is acceptor), OH–O (ligand donor and backbone is acceptor), and OH–O (side chain donor and ligand acceptor) bonds with donor-hydrogen-acceptor angles near linearity (38). The textbook definition of the hydrogen bond mentions only N, O, S as donors, but recent work has suggested that carbon can also act as donor atom in the formation of weaker CH–X hydrogen bonds (39, 40), where X = C, N. A comprehensive database analysis suggested that CH–O hydrogen bonds occurred extensively in alpha helices (41). Solvent tends to weaken the CH–O hydrogen bond (42).

Other atoms, such as halogens, have been suggested to act as a bridge between a hydrogen bond donor and acceptor (43). In addition to promoting more favorable intermolecular interactions between receptor and ligand, electrostatic interactions play an important role in the interaction between water and solutes. Water molecules have the tendency to form ordered structures, although it is worth mentioning that the extent of ordering has been difficult to determine (44). Hydrogen bonds have a tendency to favor water ordering at 25 °C and are hence immiscible in water (45). This effect is also observed around nonpolar surfaces of macromolecules in which water molecules are more ordered that in bulk water, resulting in an entropic penalty (46). This effect is known as the hydrophobic effect and is caused by the special hydrogen bonding properties of water (7-11).

A key signature of the hydrophobic effect is a change in the heat capacity (47). It is widely accepted that this effect plays an essential role in protein folding, as hydrophobic residues tend to aggregate at the core of folded proteins whereas hydrophilic moieties are found on the exterior of proteins, maximizing contact with the water solvent (47). In the context of protein–ligand interactions, the hydrophobic effect is defined as the additional stability that is gained as a result of binding in water, specifically caused by the removal of nonpolar surfaces from exposure to water during complex formation. In the case of a small-molecule ligand, the burial of nonpolar functional groups into a protein cavity will be favorable, especially when the cavity is also hydrophobic in nature; here, the hydrophobic effect can exhibit a favorable enthalpic component (48). The magnitude of the hydrophobic effect is proportional to the amount of surface buried as a result of binding.

### Predicting Macroscopic Properties From Microscopic Interactions

The 1990s experienced a surge in the number of X-ray and NMR structures that were solved for macromolecules and their complexes. This surge coincided with 1) a rapid increase in computer power and 2) an increase in the availability of computational chemistry programs that could perform molecular dynamics simulations as well as quantum chemical calculations on systems of biological relevance (49, 50). These changes emboldened scientists to apply computational techniques to biological systems that were otherwise not previously amenable to accurate calculations. Early attempts were mostly limited at predicting the binding mode of compounds, which is a process known as docking. One of the first computer programs to perform docking was DOCK, written by Erwin Kuntz and coworkers at the University of California San Francisco (51). The process of docking consists of sampling many conformations of the ligand and bound to the receptor until the most energetically favorable complex is found (52). Today programs perform docking with both ligand and receptor flexibility (53), including GOLD (54), AutoDock (55), and FlexX (56). The main impediment with docking, however, has been that the accuracy of scoring function that is used to treat the interaction between ligand and receptor (57). Scoring functions were devised with the purpose of estimating the binding free energy of a molecule to its receptor. Several techniques have been used, which include empirical (58-60), knowledge-based (61-64), or physics-based methods (51, 65-67). But insufficient sampling of configurational space (docking typically is conducted on a single snapshot, with at most local flexibility), as well as the lack of accuracy in the force fields used to represent the interaction between compound and receptor, have hampered efforts at obtaining more accurate approximation of the free energy of binding (68). Scoring functions were devised as an alternative to highly intensive methods for computing the free-energy binding. The compute-intensive methods are typically based on molecular dynamics.
Receptor–Ligand Interactions in Biological Systems

![Figure 2](image)

Stereoview that illustrates the motion that is experienced by a protein–ligand complex during molecular dynamics simulation.

Dynamics simulations (MD), which consist of solving Newton’s equations of motion to determine the position and velocities of atoms with respect to time (69). With these simulations, one can gain detailed insight into the dynamics of the system, which can be used to estimate entropy of binding (Fig. 2) (70). Several packages have facilitated the process of carrying out MD simulations for biological systems; these methods include AMBER (71), CHARMM (72), and GROMACS (54, 73) among others. Two requirements exist for conducting an MD simulation, namely a three-dimensional structure, initial velocities for all atoms in the system, and the potential energy of the system (69). The structure is usually obtained from x-ray or NMR. The velocities can easily be obtained from the temperature. The potential energy is obtained through what is known as a force field, which is a mathematical representation of the energy of the system (68). A typical force field contains terms to represent bonds, bonds, bends, torsions, and intermolecular interactions in a system, and it takes the following form:

\[
E_{\text{AMBER}} = \sum_{\text{bonds}} k_b (r - r_{\text{eq}})^2 + \sum_{\text{angles}} k_\theta (\theta - \theta_{\text{eq}})^2 \\
+ \sum_{\text{strain}} k_\gamma (\gamma - \gamma_{\text{eq}}) + \left(1 + \cos(n \theta - \gamma)\right) \\
+ \sum_{\text{dihedral}} k_\phi R_{\phi}^2 + \frac{\phi}{R_{\phi}^2} + \frac{A_{\phi}}{R_{\phi}^2} \\
\]

here, \(E_{\text{AMBER}}\) is the potential energy, \(r, r_{\text{eq}}\) and \(\theta, \theta_{\text{eq}}\) are equilibrium distance and angles for bonds and bends, respectively, and \(k_b, k_\theta, k_\gamma\) are force constants; \(n\) is multiplicity and \(\gamma\) is the phase angle for the torsional angle parameters. The accuracy of force fields remains the main impediment for the accurate computation of free energies based on molecular dynamics simulations (68).

Several methods based on molecular dynamics simulations have been devised to compute the free energy of binding (22, 74), including free-energy perturbation (FEP) and thermodynamic integration (TI). These methods are most useful for estimating the free-energy change as a result of the substitution of a functional group into another (e.g., the conversion of a hydrogen atom (initial state) to a methyl group (final state) (75)). In practice, these techniques consist of running multiple simulations at different values of a coupling parameter that ranges from 0 to 1. Depending on the substitution that is being made, the coupling parameter is multiplied to the relevant terms in the force field such that the initial state gradually converts to the final state. We have recently applied the thermodynamic integration approach toward estimating the pK\(_a\) of a residue in the class A \(\beta\)-lactamase (25) and the penicillin-binding proteins with remarkable success (76). The deprotonation reaction constitutes the full thermodynamic cycle for free-energy variations in aqueous condition, which forms the basis for Eqs. (1–3), and was used to calculate the pK\(_a\) of the lysine residue.

\[
\begin{align*}
\Delta\Delta G_{\text{aq}}(\text{A} - \text{AH}^+) & = \Delta\Delta G_{\text{aq}}(\text{B} - \text{BH}^+) \\
\Delta\Delta G_{\text{aq}}(\text{BH}^+ - \text{AH}^+) & = \Delta\Delta G_{\text{aq}}(\text{B} - \text{A}) \\
\Delta\Delta G_{\text{aq}}(\text{A} - \text{B}) & = \Delta\Delta G_{\text{aq}}(\text{AH}^+ - \text{BH}^+) + \Delta\Delta G_{\text{aq}}(\text{B} - \text{A}) \\
\end{align*}
\]

where \(\Delta\Delta G_{\text{aq}}(\text{X} - \text{XH}^+)\) is for the protonated Lys73 and \(\text{BH}^+\) is for the protonated Lys306 (see Fig. 3). The pK\(_a\) value of Lys306 is expected to be that of a typical lysine (because it is a surface residue). The following equation was used to compute the pK\(_a\) of \(\text{AH}^+\),

\[
\text{pK}_a(\text{AH}^+) = 0.729 \times \Delta\Delta G + \text{pK}_a(\text{BH}^+) = 10.8
\]

where \(\Delta\Delta G = \Delta\Delta G_{\text{aq}}(\text{A} - \text{AH}^+) - \Delta\Delta G_{\text{aq}}(\text{B} - \text{BH}^+)\) (in kcal mol\(^{-1}\)). The constant 0.729 is the value of 1/(2,303 RT) with gas constant \(R = 1.984 \times 10^{-3}\) kcal K\(^{-1}\) mol\(^{-1}\) and temperature \(T = 300\) K, and \(\text{pK}_a(\text{BH}^+) = 10.8\) for the unperturbed surface lysine in the aqueous milieu. \(\Delta\Delta G_{\text{aq}}(\text{X} - \text{XH}^+)\) was computed using the thermodynamic integration approach, which is the free-energy difference between the unprotonated state \(\text{X}\) and protonated state \(\text{XH}^+\),

\[
\Delta\Delta G_{\text{aq}}(\text{X} - \text{XH}^+) = \Delta\Delta G_{\text{aq}}(\text{X}) - \Delta\Delta G_{\text{aq}}(\text{XH}^+)
\]

With the thermodynamic integration method the difference is evaluated with a 12-point Gaussian quadrature.

\[
\Delta\Delta G(\lambda) = \int_{0}^{1} \left[ f_{\text{Vf}}(\lambda) - f_{\text{Vb}}(\lambda) \right] \ d\lambda = \sum_{i=1}^{12} w_i \left( \frac{f_{\text{Vf}}(\lambda_i) - f_{\text{Vb}}(\lambda_i)}{R(\lambda_i)} \right)
\]

where \(w_i\) and \(\lambda_i\) are known (77).
Receptor–Ligand Interactions in Biological Systems

However, when it comes to computing the free-energy difference between two very different molecules, FEP or TI are not suitable (78). Other techniques have been devised for that purpose, such as the MM-PBSA (79, 80) and LIE (81) methods. The MM-PBSA approach is based on the following thermodynamic cycle:

\[
\Delta G_{\text{binding}} = \Delta G_{\text{gas}} + \Delta G_{\text{sol}} + \Delta G_{\text{bind}}^{\text{th}}
\]

The free-energy change \( \Delta G_{\text{binding}} \) is thus expressed by the following equation:

\[
\Delta G_{\text{binding}} = \Delta G_{\text{gas}} + \Delta G_{\text{sol}} - \Delta G_{\text{bind}}^{\text{th}}
\]

Induced-Fit Versus Conformational Selection

More than 100 years ago, Emil Fischer had proposed the lock-and-key hypothesis to explain how an enzyme associates with its substrate (97). He proposed that the substrate (key) adopts a shape that is highly complementary to the receptor (lock), which suggests that an enzyme was predisposed to bind to its substrate. But crystal structures of macromolecules in their apo and liganded states have shown that significant conformational changes can often occur during complex formation (98–100). An update of the lock-and-key model, which is known as the induced-fit hypothesis, was later put forward by Koshland (101). It assumes that the enzyme or macromolecule does not sample supplementary structures to the ligand, and hence the necessary conformational changes required for complex formation are caused directly by the ligand on binding.

An alternative to the induced-fit model has been proposed in light of a growing body of data suggesting that proteins are inherently highly dynamic and hence sample many conformational states (90, 102–104). This model is often referred to as the pre-existing equilibrium or conformational selection model as an alternative to the induced-fit model. It is closely related to the Monod-Wyman-Changeux (MWC) model, which was introduced more than four decades ago to describe allosteric effects in hemoglobin (105). They proposed that a protein exists in an ensemble of conformational states that co-exist in equilibrium; the ligand will bind to one of these conformations and shift the equilibrium toward complex formation. Several authors have discussed these matters extensively, including Hecht et al. (106) and Miller and Dill (107). A prominent example in support of conformational selection was highlighted more than a decade ago by Foote and Milstein (108). Using stopped-flow fluorescence experiments, they found that antibodies existed at an equilibrium between different conformers, with ligands binding preferentially to one form. More recently, James et al. (109) employed X-ray crystallography and pre-steady-state kinetics to propose that antibodies adopt multiple conformers and thereby bind unrelated antigens. But they also suggest the possibility of induced fit on association of receptor and ligand. The conformational selection model was recently supported with computation using normal mode analyses (110).

We recently studied conformational change caused by ligand binding in the bacterial ribosome acyltransfer site (A site), where antibiotics are known to lead to mistranslation and the eventual demise of the organism (111). The conformational change was discovered after the elucidation of the three-dimensional crystal structure of the 30S ribosome (112). It entails the flipping of two bases A1492 and A1493 from an intrahelical stacked conformation to an extrahelical conformation that is completely solvent exposed. We have recently

The free-energy change \( \Delta G_{\text{binding}} \) is thus expressed by the following equation:

\[
\Delta G_{\text{binding}} = \Delta G_{\text{gas}} + \Delta G_{\text{sol}} - \Delta G_{\text{bind}}^{\text{th}}
\]

In practice, the method consists of running a molecular dynamics simulation of the receptor ligand complex, then collecting a series of snapshots, which is followed by energy calculation, solvation energy calculation, and entropy calculation for complex, receptor, and ligand. We have applied this method to protein–ligand as well as nuclei-acid interactions in the past. The method seems to perform best in calculations of differences in free energy (82), but sometimes it performs well for absolute value calculations of the free energy (83, 84).
find that the binding of vancomycin to the acyl-D-Ala-D-Ala tidyl stem, which terminates in acyl-D-Ala-D-Ala. The study (NAM). The NAM residues are incorporated with a pentapep-

Enthalpy-Entropy Compensation (EEC)

It has been known for several decades that the formation of complexes between molecules through weak interactions results in a change of the enthalpy that is accompanied by an opposite change in the entropy (114-116). This effect, which is known as enthalpy-entropy compensation (EEC) (117), can be a hindrance in drug-design efforts. For example, a recent effort at optimizing a picomolar HIV-1 inhibitor based on the crystal structure of the inhibitor bound to the active site resulted in a compound with similar binding affinity (118). The addition consisted of replacing a thioester group by a sulfonyl group. The original compound had $\Delta H = -8.2 \text{ kcal/mol}$ and $\Delta S = -6.7 \text{ kcal/mol}$. The optimized compound showed a gain in enthalpy by 3.9 kcal/mol, which signifies that more favorable interactions were created. However, an equal and opposite compensation of the entropy resulted, leading to no gain of free energy.

Our recent work on the study of binding of the antibiotic van-
comycin to bacterial cell wall with isothermal titration calorime-
try also illustrated the effect of entropy enthalpy compensation (119). The backbone of the cell wall is made up of alter-
ating N-acetylglucosamine (NAG) and N-acetylmuramic acid (NAM). The NAM residues are incorporated with a pentapep-
tidyl stem, which terminates in acyl-D-Ala-D-Ala. The study found that the binding of vancomycin to the acyl-D-Ala-D-Ala fragment resulted in the same free-energy change as the second vancomycin binding to cell wall fragment with two NAG-NAM units. Despite the similarity in the binding affinity, the entropy and enthalpy contributions for binding to the cell wall fragment were different, and the 5 kJ/mol gain in enthalpy was compensated by a loss of 5 kJ/mol in entropy (119).

It has been argued that EEC is a mere artifact (120). In an attempt to establish the existence of the EEC effect, a collection of thermodynamic data collected for the binding of 136 drugs to their receptors revealed strong correlation between enthalpy and entropy (116). Some have attributed these results to inaccuracies of the van’t Hoff analysis that is used for the measurement of thermodynamic parameters (121). But isothermal titration calorimetry data (ITC) does not suffer from the same inaccuracies that plague the van’t Hoff analysis. We have recently created a dataset that contains more than 400 entries containing structural and isothermal titration data (122).

A plot of the enthalpy and entropy results in the following linear relationship:

$$\Delta H (\text{kcal mol}^{-1}) = -8.2154 + 282.89 \Delta S (\text{kJ mol}^{-1})$$

Aalysis of the data from our dataset has firmly established the existence of the EEC effect (122).

Nearly a decade ago, Dunitz et al. (114) attempted to ratio-
nalize the EEC effect with the use of statistical thermodynamic concepts. Using a model for two covalently attached atoms whose bond is described with a Morse potential, he showed that the vibrational entropy decreased exponentially with the frequency of vibration of the bond. In the context of macro-
molecules, this signifies that the high frequency motions such as bond stretching and bending that occur with frequency greater than 1000 cm$^{-1}$ contribute little to the entropy, whereas lower frequency motions, such as those that involve entire domains, make the largest contribution. Using a hypothetical model of a water molecule bound to a macromolecule with a dissocia-
tion enthalpy of 5 kcal/mol, the author estimated an entropic contribution of 4.5 kcal/mol, nearly completely balancing the enthalpy. A plot of the vibrational entropy versus the disso-
ciation enthalpy revealed that for weak interactions (less than 5 kcal/mol), the contributions of enthalpy and entropy compen-
sated each other. These results support earlier plots by Searle et al. (115) that revealed a similar effect from a curve de-
rived based on qualitative thermodynamic considerations. It is of interest to note that the plot of entropy versus enthalpy monoton-
ically increased with respect to enthalpy, which is likely caused by the neglect of the role of solvation in the model.
water molecules generate favorable entropy that should dampen the steep enthalpy increase. These early theoretical treatments of EEC have been followed by more recent work by Ford (123) who argues that in the gas phase, EEC is not a general feature of association. He bases this argument on the observation that both compensation and anticompensation (negative correlation between $\Delta H$ and $\Delta S$) develop from this model. Other investigators have derived a theoretical treatment (117) that supports the EEC effect, but only within a 20% range of the experimental temperature $T_c = - \Delta H / \Delta S$. Other notable investigators that have extensively dealt with the issue of enthalpy–entropy compensation, including Sharp (117), Cooper (124), and Jen-Jacobsen et al. (125).

### Allostery

In 1967, it was discovered that the binding of oxygen to one of the monomers of the hemoglobin tetramer led to a change in the affinity of oxygen on the other subunits of hemoglobin, despite the large distances that separate the oxygen binding sites (126). This effect, which is now known as allostery, has been since observed in a multitude of systems (127, 128). In general, a triggering event at one site of a macromolecule or macromolecular complex leads to an effect at a distal site. The triggering event could be caused by binding of a ligand, or a macromolecule. But it could also be caused by a chemical reaction. The resulting effect that occurs at a distal site could range from modulation of the binding affinity of a ligand (103, 129, 130), to alteration of catalysis (131-133), to causing significant conformational change that is usually essential for the function of the protein (134-136). An extensive list of structures of allostery in their initial and final states has been recently compiled (137).

Just as in ligand binding, allostery can be discussed in terms of the conformational selection and induced-fit mechanisms. The difference is that the triggering event would be causing an effect at a distal site. In the context of conformational selection, the ligand will select not only those conformers that facilitate its binding but also those that lead to an effect at the distal site. If the effect is an enhancement of catalysis, then the ligand would be selecting those conformers with residues at the distal site that are positioned such that the transition state free-energy barrier for reaction would be reduced. If, on the other hand, the effect is enhancement of binding, then the ligand would be selecting conformers that are both suitable for its binding as well as suitable for the binding of another ligand at a distal site.

Induced fit in allostery would entail a propagation of conformational changes from the triggering site to the distal site. This idea was initially proposed to explain cooperativity in hemoglobin by Perutz et al. (138, 139) who suggested a set of consecutive conformational changes that lead hemoglobin from its T-state (tense) to its R-state (relaxed). More recently, Pettigrew and co-workers (140, 141) have proposed the existence of a coupling pathway between two distal sites to explain how glyceral kinase from Escherichia coli but not Hemophilus influenzae is inhibited allosterically by phosphohexo-kinase system protein (142). Through specific mutations, they could interconvert these systems, which confirms the existence of allostery and suggests that allostery was an evolutionary effect. Another example where specific pathways are believed to connect distal sites is the RNA synthesis system. Cognate recognition and translation of aa-tRNA and the codon on mRNA signals RNA synthase to perform its function at a catalytic site that is located more than 70 Å away (143). A thorough recent study has invoked structural change as the main conduit between distal sites, evidence has been mounting that in addition to structural changes, molecular motion, both in the short (103) and longer (102, 103, 132, 143) timescales, plays an important role in allostery.

A prominent allostery system in which ligand binding at one site causes a change in the affinity of another ligand at another site is the catalytic activator protein or CAP (Fig. 4). In solution, the 47-kDa dimer exists as a homodimer and exhibits homotropic negative cooperativity, whereby the binding of the first cAMP molecule reduces the affinity of the second cAMP by nearly two orders of magnitude (144-146). The distance between the cAMP binding pockets on the two monomers is 24 Å and precludes any contribution from electrostatic interactions. A recent NMR study has suggested that the anti-cooperative effect could be caused by changes in the dynamics of the system, rather than by structural changes (103). The NMR data show that the binding of the first ligand causes significant increase in the slower motions but a slight tightening of the faster motions, which is evidenced by a slight increase of the order parameter $S_2$. Hydrogen/deuterium (H/D) exchange experiments show no overall change in the conformational change experienced by the system. The binding of the second ligand, however, causes significant tightening of the structure, both in the ps–ns and the μs–ms regime (103). The negative cooperativity is attributed to this loss of motion. In addition, significant stability of the structure is detected from lower H/D exchange rates.

We have conducted a thorough computational study of allostery in CAP to unravel the structural and dynamic changes that occur as a result of cAMP binding (132). Our extensive simulations for the apo, singly liganded, and doubly liganded CAP have confirmed results obtained from NMR (103), namely that cAMP binding to one monomer causes changes both in the shorter and longer timescale motions. The shorter timescale motions were measured by computing the order parameter $S_2$, whereas the longer timescale motions were obtained through a principal component analysis of the dynamics trajectory. Our simulations, however, included the DNA-binding domain that was absent in the NMR studies. We observed a remarkable conformational change that entailed the complete separation of the ligand binding and DNA-binding domains (Fig. 4). The unique aspect of this conformational change was that it only occurred in unoccupied monomers (Fig. 4). Hence it seems that ligand binding causes significant stabilization of the ligand-binding domain. When our calculations were repeated in the presence of DNA, however, we found that a switch in the cooperativity occurred, whereby the binding of the second cAMP was significantly favored by several kcal/mol (132). This finding explained
Receptor–Ligand Interactions in Biological Systems

Figure 4 A stereoview of CAP dimer in (a) doubly liganded, (b) singly liganded, and (c) unliganded forms. The protein is rendered in cartoon representation, colored yellow for the DNA binding domain, and green for the ligand-binding domain. The cAMP ligands are depicted as red spheres.

the seemingly contradictory fact that CAP has evolved to disfavor the binding of another cAMP, but that doubly liganded CAP was necessary for transcription activation (147).

The transglutaminase type 2 (TG2) enzyme is one example where a triggering event at a GTP-binding site causes alteration of catalysis at a distal site (133). TG2 is a multifunctional protein with roles in receptor signaling, extracellular matrix assembly, and apoptosis (Fig. 5) (133). The catalytic function of the enzyme, which consists of posttranslational amine modification of proteins or cross-linking of interchain glutamine and lysine residues (148), is allosterically controlled by calcium and GTP (149). But the three-dimensional structure of TG2 (Fig. 5) reveals that the binding site of GTP is located more than 20 Å away from the catalytic center, which precludes any direct electrostatic or bonding interaction. It has been shown that transglutaminases exist in an active and inactive conformation, and that GTP binding promotes the formation of the active conformer (150). Recently, a study from Begg et al. (133) has suggested that an arginine residue (Arg-579) is critical for TG2 transition to a compact and inactive form. They suggest that the GTP-mediated conformational transition into inactive form is caused by the formation of a hydrogen bond with the catalytic residues of the active site Cys-277 and a tyrosine residue. They argue that GTP masks the charge of a nearby Arg-579, which promotes the Cys-277 and Tyr-516 hydrogen bond.

In other systems, the triggering event causes significant conformational change. The elongation factor Tu (EF-Tu) is one example in which the hydrolysis of a phosphoester bond from GTP causes interdomain separation within the protein (Fig. 6). EF-Tu is a member of the GTPase superfamily that guides aa-tRNA to the acyltransfer site (A site) of the ribosome, which mediates the accommodation step and initiation of the protein biosynthetic process (see Fig. 6a). Cognate recognition between the anticodon of the nascent tRNA and the codon of the mRNA in the ribosome causes GTP hydrolysis more than 50 Å away in EF-Tu’s active site (Fig. 6b). The allosterically induced conformational change was rationalized as a series of perturbations that start from the GTP binding site that propagate into the nucleotide binding sites (domains II and III, see Fig. 6). It is not unconceivable that alteration in the shorter and longer timescale motions occur as a result of the hydrolysis of GTP. It is likely that the loss of a phosphate moiety will have the effect of increasing local fluctuations in the shorter timescale, which eventually permeates into the longer timescale motion, resulting in the separation of the domains, an entropically highly favorable process.

In many cases, dynamical events as a result of ligand binding involve multiple steps that combine conformational and dynamical changes. An example is a recent study that combined computational and experimental techniques to study the activation of gelatinase-2 (MMP-9), which is a zinc-based endopeptidase whose aberrant control has been implicated in various pathological processes, including cancer (151). The activation process consists of the removal of a ~100-residue peptide through proteolytic cleavage mediated by human kalikrein and involves the dissociation of a bond between a cysteine thiol and the catalytic zinc ion, which is a process known as the “cysteine switch.” A stopped-flow X-ray absorption analysis provided, for the first time, a detailed account of the coordination states of the zinc ion during the activation. The process was found to be triggered by binding of the kalikrein protease. It is interesting to note, however, that the binding site of kalikrein occurs at a distal site from the catalytic zinc ion. This finding suggests that alterations in dynamics and structure mediated by this interaction occur through an allosteric mechanism.

Conclusion

Despite the extensive amount of work that has been done toward understanding the molecular recognition process, the design of small molecules that exhibit potency to biological receptors remains a challenge. Most efforts to date have been driven by
Receptor–Ligand Interactions in Biological Systems

structure, often without the consideration of motion that is experienced by the receptor. Structure-based design often entails the addition of various moieties to improve affinity. The result, however, is that the affinity does not improve because of an effect known as entropy–enthalpy compensation. Incorporating entropic effects is essential for a complete description of the recognition process. The motion that develops because of entropy often leads to effects such as cooperativity and allostery, which add another level of complexity to the ligand design process.

Neuropeptides, Chemical Activity Profiling and Proteomic Approaches for

Vivian Hook, Shin-Rong Hwang, Jill Wegrzyn and Steven Bark, Skaggs School of Pharmacy, Pharmaceutical Sciences, University of California, San Diego, California
doi: 10.1002/9780470048672.wecb381

Peptide neurotransmitters and peptide hormones, collectively known as neuropeptides, are required for cell–cell communication in neurotransmission and for regulation of endocrine functions. Neuropeptides are synthesized from protein precursors (termed proneuropeptides or prohormones) that require proteolytic processing within secretory vesicles that store and secrete active neuropeptides. This article describes the application of chemical biological approaches advantageously used to define protease pathways involved in neuropeptide biosynthesis. Activity profiling of proteases, combined with mass spectrometry, has allowed identification of the novel cathepsin L cysteine protease pathway for neuropeptide biosynthesis, which contributes to neuropeptide production with the subtilisin-like prohormone convertase pathway. Furthermore, proteomic approaches for identifying proteases and protein systems present in secretory vesicles define the protease pathways and the functional protein systems that jointly operate in the secretory vesicle for production and secretion of active neuropeptides. Neuropeptidomic approaches allow defined primary structural analyses of neuropeptides. Future studies that gain understanding of protease mechanisms for generating active neuropeptides will be instrumental for translational research to develop therapeutic strategies for health and disease.

Neuropeptides for Cell–Cell Communication in Nervous and Endocrine Systems

Neuropeptides mediate neurotransmission as peptide neurotransmitters and mediate cell–cell communication as peptide hormones for endocrine regulation of target cellular systems. The term “neuropeptides” refers to this large, diverse class of peptide neurotransmitters and peptide hormones that typically consist of 3–40 residues. More than 100 different neuropeptides exist, and new neuropeptides are yet to be discovered.

The unique primary sequence of each neuropeptide defines its selective and potent biological actions. The same neuropeptides often serve important functions in both the nervous system as neurotransmitters and as peptide hormones in peripheral endocrine systems. For example, enkephalins function as neurotransmitters in the brain and are involved in peripheral actions, including regulation of intestinal motility and immune cell functions (1, 2). ACTH (adrenocorticotropic hormone) is present in the brain where it functions as a neuromodulator; furthermore, ACTH is a prominent peptide hormone released from the pituitary gland for control of glucocorticoid production in the adrenal cortex (3). Neuropeptides such as β-endorphin, NPY (neuropeptide Y), galanin, CRF (corticotropin releasing factor), vasopressin, insulin, and numerous others (Table 1) mediate diverse physiological functions that include analgesia, feeding behavior and blood pressure regulation, cognition, stress, water balance, and glucose metabolism, respectively (4–8).

Proteolytic processing for neuropeptide biosynthesis

Proneuropeptide (prohormone) precursors

Neuropeptides are derived from larger protein precursors known as proneuropeptides or prohormones. Proneuropeptides refer to protein precursors of neurotransmitters as well as peptide hormones, whereas prohormones refers primarily to
Neuropeptides, Chemical Activity Profiling and Proteomic Approaches for

Peptide neurotransmitters in the brain. Neuropeptides in the brain function as peptide neurotransmitters to mediate chemical communications among neurons. Neuropeptides are synthesized within secretory vesicles that are transported from the neuronal cell body via the axon to nerve terminals. The proneuropeptide (or prohormone) is packaged with the newly formed secretory vesicle in the cell body, and proteolytic processing of the precursor protein occurs during axonal transport and maturation of the secretory vesicle. Mature processed neuropeptides are contained within secretory vesicles at the synapse, where activity-dependent, regulated secretion of neuropeptides occurs to mediate neurotransmission via neuropeptide activation of peptidergic receptors.

Peptide neurotransmitters and hormones are collectively termed neuropeptides. Neuropeptides typically consist of small peptides of approximately 3–40 residues. Several neuropeptides and several of their regulatory functions are listed; these neuropeptides and others function in multiple roles as physiological regulators (too numerous to list in this short table). Abbreviations are adrenocorticotropin hormone (ACTH), α-melanocyte stimulating hormone (α-MSH), neuropeptide Y (NPY), and pituitary adenylate cyclase-activating peptide (PACAP).

Although each proneuropeptide precursor possesses a distinct primary sequence, proteolytic processing occurs at dibasic endocrine peptide hormone precursors. To encompass peptide functions in both the nervous and endocrine systems, the terminology of “neuropeptide” and the respective “proneuropeptides” will be used in this article to refer to “neuroendocrine” functions of neuropeptides.

Proneuropeptide precursors share distinct and common features. Notably, the small active form of each neuropeptide is a segment present within its full-length precursor protein. A proneuropeptide may contain one copy of the active neuropeptide, as represented by proNPY, proagalanin, and provasopressin (Fig. 2). Alternatively, a precursor may contain multiple related copies of the active neuropeptide. For example, proenkephalin contains four copies of [Met]enkephalin, one copy of the related [Leu]enkephalin, and one copy each of the ME-Ag-Gly-Leu and ME-Ag-Phe (Fig. 2). Proteolysis of these precursors, especially tissue-specific proteolytic mechanisms, is required for biologically active neuropeptides to be generated.
Neuropeptides, Chemical Activity Profiling and Proteomic Approaches for... 

Figure 2. Proneuropeptides: structural features for proteolytic processing. Neuropeptides are synthesized as proneuropeptide precursors, also known as prohormones, that require proteolytic processing to liberate the active neuropeptide. Proteolytic processing occurs at dibasic and monobasic sites, as well as at multibasic sites. The precursor proteins may contain one copy of the active neuropeptide, such as the proneuropeptides for NPY, galanin, CRF, and vasopressin. Some proneuropeptides such as proenkephalin contain multiple copies of the active neuropeptide; proenkephalin contains four copies of (Met)enkephalin (ME), one copy of (Leu)enkephalin (LE), and the related opioid peptides ME-Arg-Phe (H) and ME-Arg-Gly-Leu (O).

Proteolytic processing of precursors for neuropeptide biosynthesis

Biosynthesis of neuropeptides begins with the translation of the respective mRNAs to generate the preproneuropeptide or preprohormone precursors. Proteolytic processing begins co-translationally at the rough endoplasmic reticulum (RER) where the NH₂-terminal signal peptide of the preproneuropeptide is cleaved by signal peptidase. The resulting proneuropeptide or prohormone is routed through the Golgi apparatus and is packed into newly formed secretory vesicles together with processing proteases. As the secretory vesicle matures, proteolytic processing occurs so that the mature secretory vesicle contains processed, biologically active neuropeptide that awaits cellular stimuli for regulated secretion.

Proteolytic processing at the dibasic or monobasic sites of proneuropeptides occurs primarily within regulated secretory vesicles (12-18). Cleavage at the COOH-terminal side of the paired basic residues results in peptide intermediates with basic residue extensions on their COOH-termini, which must then be removed by Lys/Arg carboxypeptidase to generate the mature neuropeptide (Fig. 3). Alternatively, cleavage of the precursor at the NH₂-terminal side of dibasic residue sites will generate peptide intermediates with basic residue extensions on their NH₂-termini, which then will be removed by aminopeptidase B to generate the active neuropeptide. Processing may also occur between the dibasic residues, which then will require both carboxypeptidase and aminopeptidase exopeptidase activities to generate the final neuropeptides.

Neuropeptides may also undergo post translational modification that modifies the biological activities of peptides. Activities of the neuropeptides may be altered by disulfide bond formation, glycosylation, COOH-terminal α-amidation, phosphorylation, sulfation, and acetylation (6, 7). This article, however, will focus on protease mechanisms for neuropeptide biosynthesis.

Biochemical properties expected of proteases for neuropeptide production

Elucidation of proteases in brain and neuroendocrine tissues is complicated because of the many different cell types and the presence of proteases in many subcellular compartments of these cells. To ensure that authentic proteases are identified for producing an active peptide, the neuropeptide field has used key criteria for successful elucidation of proteases that generate peptide neurotransmitters and hormones. These criteria...
Neuropeptides, Chemical Activity Profiling and Proteomic Approaches for Proneuropeptide Processing

Distinct cysteine protease and subtilisin-like protease pathways have been demonstrated for pro-neuropeptide processing. Recent studies have identified secretory vesicle cathepsin L as an important processing enzyme for the production of the endogenous enkephalin opioid peptide. Preference of cathepsin L to cleave at the NH2-terminal side of dibasic residue processing sites yields peptide intermediates with NH2-terminal residues, which are removed by Arg/Lys aminopeptidase. The well-established subtilisin-like protease pathway involves several prohormone convertases (PC). PC1/3 and PC2 have been characterized as neuroendocrine processing proteases. The PC enzymes preferentially cleave at the COOH-terminal side of dibasic processing sites, which results in peptide intermediates with basic residue extensions at their COOH-termini that are removed by carboxypeptidase E/H.

Application of these criteria has led to elucidation of the recently identified cysteine protease pathway and serine protease pathways, mediated by cathepsin L and proprotein convertases, respectively, for neuropeptide production (Fig. 3).

Chromaffin granules: model neurosecretory vesicles for proneuropeptide processing proteases

Elucidation of protease pathways for neuropeptide biosynthesis has been facilitated in the field with the use of isolated chromaffin secretory vesicles, a well-established model neurosecretory vesicle system used for investigation of proteases that synthesize neuropeptides and small-molecule neurotransmitters (19). Chromaffin secretory vesicles contain proneuropeptide precursors that undergo proteolytic processing to generate enkephalin, NPY, galanin, somatostatin, VIP, and other neuropeptides. These vesicles were used to identify the cathepsin L as a novel proneuropeptide processing enzyme using chemical biological approaches and have identified prohormone convertase processing enzymes (20–23).

Chemical biology for activity-based profiling and identification of proteases

Recent achievements in the development of active-site directed affinity probes for proteases and other enzyme classes provide direct chemical labeling of proteases of interest in the biological system (24–27). These specific activity probes allow joint evaluation of selective protease inhibition concomitant with labeling of relevant protease enzymes for more analyses. Moreover, activity-based probes that selectively label the main protease subclasses—cysteine, serine, metallo, aspartic, and threonine—can provide advantageous chemical approaches for functional protease identification. Activity probe labeling of proteases allows direct identification of enzyme proteins by tandem mass spectrometry. Such chemical probes directed to cysteine proteases have been instrumental for identification of the new cathepsin L cysteine protease pathway for neuropeptide biosynthesis, as summarized in this article.

Activity-based chemical profiling identifies the cathepsin L cysteine protease pathway in secretory vesicles that contributes to neuropeptide biosynthesis

A cysteine protease identified active site-directed affinity labeling of the 27 kDa enzyme of the "prohormone thiol protease" (PTP) complex (18, 22), which represents...
Neuropeptides, Chemical Activity Profiling and Proteomic Approaches for the major proenkephalin (PE) processing activity in chromaffin secretory vesicles (20, 21). The high molecular weight of the PTP complex of approximately 180–200 kDa (21) suggested the presence of several protein subunits because proteases typically possess lower molecular masses than that of native PTP. Studies then were targeted to identify the catalytic subunit of PTP responsible for PE-cleaving activity.

The activity probe DCG-04, combined with differential labeling in the presence of CA074, allowed identification of the 27 kDa protein as the active protease subunit of the PTP complex (18, 22). Two-dimensional gels resolved DCG-04-labeled proteins of 27–29 kDa (Fig. 4), which was identified as cathepsin L by mass spectrometry of tryptic peptides. Confirmation of the localization of cathepsin L in secretory vesicles was demonstrated by immunofluorescence confocal microscopy and immunoelectron microscopy, which illustrated the presence of cathepsin L in enkephalin and neuropeptide-containing secretory vesicles. The secretory vesicle function of cathepsin L contrasts with its well-known lysosomal function for degradation of proteins. These findings suggested a new biological function for cathepsin L in secretory vesicles for producing the enkephalin and related neuropeptides.

Gene analyses of Cathepsin L in neuropeptide biosynthesis by protease gene knockout and gene expression approaches

Cathepsin L knockout mice
Cathepsin L-deficient mice show decreased levels of enkephalin in the brain, with reduction by approximately one half (22). In addition, enkephalin brain levels are also reduced by about one half in PC2-deficient mice (28). These results support dual roles for both cathepsin L and PC2 in enkephalin production. Ongoing studies indicate multiple neuropeptides that are substantially decreased by more than 50% in the brain and endocrine tissues of cathepsin L knockout mice (Funkelstein et al., submitted for publication). With the observed alterations in brain neuropeptides, it will be of interest in future studies to assess the behavioral effects of the loss of neuropeptides in cathepsin L knockout mice. Cathepsin L knockout mice are viable and show phenotypes of hair loss and cardiac myopathy (29, 30). The mechanism for these functional effects of cathepsin L deficiency could possibly involve neuropeptides. New and continued investigations of neuropeptides in cathepsin L knockout mice will provide knowledge of the relative roles of cathepsin L in the production of particular neuropeptides.

Cellular gene expression of cathepsin L for enkephalin neuropeptide production in the regulated secretory pathway
Cellular routing and trafficking of cathepsin L to secretory vesicles for proneuropeptide processing was demonstrated by the coinjection of cathepsin L with proenkephalin in neuroendocrine PC12 cells (derived from rat adrenal medulla) (31). Expression of cathepsin L resulted in its trafficking to secretory vesicles with subsequent processing to enkephalin and related neuropeptides.

Figure 4 Activity-based profiling for identification of proenkephalin cleaving activity as cathepsin L. Activity-based profiling (APB) uses the strategy of labeling the active site of active proteases, often with an inhibitor-related probe, to identify proteolytic activity. Inhibition of proenkephalin cleaving activity by the cysteine protease inhibitor E64c in isolated chromaffin secretory vesicles (also known as chromaffin granules) allowed affinity labeling of the 27 kDa active protease enzyme proteins by a biotinylated form of E64 known as DCG-04 (Panel a). The inhibitor-labeled proteins were separated by two-dimensional gels (Panel b) and subjected to peptide sequencing by mass spectrometry, which revealed the identity of the proneuropeptide processing activity as cathepsin L.
vesicles that contain enkephalin and chromogranin A. Furthermore, cathepsin L expression resulted in cellular processing of proenkephalin into (Met)enkephalin that undergoes regulated secretion from PC12 cells. Cathepsin L generated high-molar-weight PE-derived intermediates (of about 23, 18–19, 8–9, and 4.5 kDa) that represented PE-derived products in vivo (20). Such results demonstrated a cellular role for cathepsin L in the production of (Met)enkephalin in secretory vesicles for its regulated secretion.

**Cathepsin L cleavage specificity indicates the subsequent aminopeptidase B exopeptidase step for neuropeptide production**

Studies of the cleavage specificity of cathepsin L demonstrated that it prefers to cleave on the NH₂-terminal side of dibasic residue processing sites of enkephalin-containing peptide substrates B.A.M-22P and Peptide F (22) and to cleave at the N-terminal sides of dibasic residues within peptide-MCA substrates (32). The cleavage specificity of cathepsin L results in enkephalin intermediate peptides with NH₂-terminal basic residue extensions, which are then removed by Arg/Lys aminopeptidase. Secretory vesicles from adrenal medullary chromaffin cells (33) and from pituitary (34) contain Arg/Lys aminopeptidase activity for neuropeptide production.

Recent molecular cloning studies have identified aminopeptidase B as an appropriate Arg/Lys aminopeptidase (35). Molecular cloning of the bovine aminopeptidase B (AP-B) cDNA defined its primary sequence that provided production of specific antisera to demonstrate localization of AP-B in secretory vesicles that contain cathepsin L with the neuropeptides enkephalin and NPY. AP-B was also found in several neuroendocrine tissues by western blots. Recombinant bovine AP-B (35) and rat AP-B were compared. Recombinant bovine AP-B showed preference for Arg-MCA substrate compared with Lys-MCA. AP-B was inhibited by arphamenine, an inhibitor of aminopeptidases. Bovine AP-B showed similar activities for Arg-(Met)enkephalin and Lys-(Met)enkephalin neuropeptide substrates to generate (Met)enkephalin, whereas rat AP-B preferred Arg-(Met)enkephalin. Furthermore, AP-B possesses an acidic pH optimum of 5.5–6.5 that is similar to the internal pH of secretory vesicles. The significant finding of the secretory vesicle localization of AP-B with neuropeptides and cathepsin L suggests a role for this exopeptidase in the biosynthesis of neuropeptides.

These findings indicate differences in the cleavage specificity of cathepsin L for the N-terminal side of dibasic residues within propeptides, compared with cleavage at the C-terminal side of dibasic residue processing sites by the prohormone convertases 1 and 2 (PC1/3 and PC2) (15–17, 23). These differences result in the requirement for different exopeptidases following endopeptidolytic processing by cathepsin L compared with PC1/3 or PC2. Although cathepsin L cleavage of neuropeptide precursors results in peptide intermediates extended with basic residues at their N-terminal that can be removed by aminopeptidase B, PC1/3 and PC2 cleavage at the C-terminal side of dibasic residues of propeptides results in peptide products containing C-terminal basic residue extensions that are removed by carboxypeptidase E. These dual protease pathways provide alternative routes for cellular processing of propeptides into active peptide neurotransmitters and hormones.

**Chemical biology defines the novel cathepsin L cysteine protease pathway combined with the prohormone convertase subtilisin-like pathway for neuropeptide production**

Significantly, the approach of activity profiling for cysteine propeptides has established cathepsin L as a new protease pathway for neuropeptide biosynthesis. Together with current knowledge in the field, these data demonstrate the existence of two distinct protease pathways for converting propeptides into active peptide neurotransmitters and hormones. These dual pathways consist of the newly discovered cysteine protease pathway for propeptide processing, which consists of cathepsin L followed by Arg/Lys aminopeptidase (aminopeptidase B), and the previously known proprotein convertase (PC) family of subtilisin-like proteases (15–17) that process propeptides with carboxypeptidase E (Fig. 3). Elucidation of these two protease pathways resulted from the application of the biochemical criteria required for processing propeptides.

**Cathepsin L: member of clan CA and the C1A papain subfamily**

Properties of cathepsin L may be compared among papain-like cysteine cathepsins (36–39) for understanding its role in producing neuropeptides. Cathepsin L belongs to the C1A subfamily of Clan CA (36). Clan CA was formed based on recognition of the first cysteine protease papain. The crystal structure of papain shows two structural domains separated by an active-site cleft. The N-terminal domain is comprised of α-helices and the C-terminal domain contains a β-barrel.

Clan CA is composed of twenty families. Family C1 within clan CA is divided into two subfamilies that consist of C1A (papain subfamily) and C1B (blysozyme hydrolase subfamily) groups. The larger subfamily C1A consists of secreted and lysosomal proteases that include the animal cysteine cathepsin proteases cathepsins B, H, and L as well as the plant proteases papain, chymopapain, and actinidain.

A division within the C1A subfamily exists between the papain-like proteases and the cathepsin B-like proteases. Included among the papain-like proteases are cathepsins O, H, L, X, and S. Cathepsin O is divergent, whereas the others are more closely related. Among the cathepsin B-like proteases are dipeptidyl-peptidase I and the endopeptidases from *Giardia*.

The distinction between exopeptidases and endopeptidases is merged for some members of the subfamily C1A. Dipeptidyl-peptidase I acts principally as an exopeptidase, removing N-terminal dipeptides, but may have some endopeptidase activity. Cathepsin B and H both possess endopeptidase activity but also possess exopeptidase activities. Cathepsin B acts as a dipeptidyl-peptidase, releasing C-terminal dipeptides. Cathepsin X is a carboxypeptidase.
Neuropeptides, Chemical Activity Profiling and Proteomic Approaches for

The proteases that enter the secretory or lysosomal pathways are synthesized as precursors, with N-terminal propeptide and signal peptides (36-39). Most members of family C1 have propeptides similar to that of papain. The propeptides act by blocking the active site. Papain-like propeptides are indicated by the ERFNNH motif. Propeptide inserts relative to papain occur within the catalytic domain in other family members. Cathespin B contains the "occluding loop" that carries the histidine residues important for peptidyl-dipeptidase activity. Most members of subfamily C1A are monomeric. In the case of cathespin L, it exists as a single-chain form (≈28 kDa on SDS-PAGE) and as a heavy-chain and light-chain form (≈24 and ≈4 kDa, respectively, on SDS-PAGE).

The specificity subsite that is dominant in most proteases of subfamily C1A is S2, which commonly displays a preference for occupation by a bulky hydrophobic side chain. Cathespin L possesses such S2 subsite preference for aromatic residues in the P2 position.

These properties contribute to the function of secretory vesicle cathespin L as a processing enzyme that produces neuropeptides.

Neuropeptides in mice deficient in PC2, PC1/3, and CPE: evidence for other processing enzymes

PC2 and PC1/3 prohormone convertases

A review of neuropeptide data from PC2 and PC1/3 knockout mice shows that the majority of neuropeptides studied are partially reduced in the knockout compared with wild-type controls. These results indicate roles for PC2 and PC1/3 in neuropeptide production. Importantly, the partial reduction of neuropeptides examined in PC2- and PC1/3-deficient mice also indicates possible roles for other proteases for processing proneuropeptides, such as cathepsin L, in secretory vesicles for neuropeptide production that has been discussed in this article. Thus, the chemical biology approach has identified the novel cathespin L cysteine protease pathway as a candidate route for neuropeptide production.

More specifically, to integrate data from PC2- and PC1/3-deficient mouse studies with recent data that demonstrate a candidate role for cathepsin L in neuropeptide production, results of neuropeptides studied in PC2- and PC1/3-deficient mice are summarized here. In PC2 knockout mice, many neuropeptides were partially reduced, with the exception of α-MSH that was nearly obliterated. PC2-deficient mice show increases in the POMC-derived peptide hormones ACTH and β-endorphin (1-31), which identifies them as substrates for PC2 (40). A mou

Carboxypeptidase E

After the actions of PC1/3 and PC2 for cleavage at the C-terminal side of paired basic residues (Fig. 3), the resulting peptide products contain basic residues at the C-termini that are then removed by carboxypeptidase E (CPE). Studies of CPE<sup>−/−</sup> mice that contain mutant, inactive CPE, showed that these animals show altered neuropeptide production (49-55). Studies of CPE peptide substrates in the fat/fast mice have been facilitated with specific isolation of peptides with C-terminal basic residues by the anhydrotrypsin affinity column for enrichment of CPE substrates (49-53). Analyses of such CPE substrates have demonstrated that numerous neuropeptides use CPE for their biosynthesis (49-55).

Analogously, it will be important to evaluate cathespin L-generated peptide products that serve as substrates for the subsequent anhydrotrypsin B (A-P-B) step. Significantly, the A-P-B substrates contain basic residues at their N-termini; these substrates do not contain basic residues at their C-terminal as CPE substrates do. Therefore, although the anhydrotrypsin affinity column can be used to isolate CPE substrates, selective analyses of A-P-B peptide substrates will require other approaches for isolation and analyses. It will be of interest in future studies to characterize A-P-B neuropeptide substrates generated by secretory vesicle cathepsin L.

Neuropeptidomics: LC-MS/MS tandem mass spectrometry analyses of neuropeptides

Primary structure analyses of neuropeptides are essential for understanding the structure-function features of neuropeptides. The development of mass spectrometry (MS) tools and approaches for identifying neurological peptides has become essential for defining neuropeptide structures that correspond to...
Neuropeptides, Chemical Activity Profiling and Proteomic Approaches for Neuropeptide Biosynthesis

Proteomics of Secretory Vesicles for Defining Proteases and Related Systems for Neuropeptide Biosynthesis

Direct proteomic approaches can be used to identify protease enzyme proteins, as well as protein categories in the biological system, that are present in secretory vesicles for neuropeptide production and secretion. Knowledge of the secretory vesicle proteome can advance our understanding of neuropeptide biosynthetic mechanisms that operate within this organelle. Recent examination of proteins in model chromaffin secretory vesicles revealed several functional protein categories that together support secretory vesicle production of neuropeptides and bioactive catecholamines for cell–cell communication (Fig. 5) (71). Protein systems involved in vesicular neuropeptide biosynthesis were examined in proteomic studies of soluble and membrane fractions of dense core secretory vesicles purified from neuroendocrine chromaffin cells. Proteins were separated by SDS-PAGE, and proteins from systematically sectioned gel lanes were identified by micropreparative LC-MS/MS (uLC-MS/MS) of tryptic peptides (71). Proteomic results revealed functional categories of prohormones, proteases, catecholamine neurotransmitter metabolism, protein folding, redox regulation, ATPases, calcium regulation, signaling components, exocytotic mechanisms, and related functions.

Several proteases of different mechanistic classes were identified by proteomics of secretory vesicles. These proteases included the subtilisin-like prohormone convertases 1 and 2 along with the metalloprotease carboxypeptidase E (CPE), which participates in prohormone processing (15–17). CPE has also been proposed to function as a prohormone sorting receptor (72). Regulators of PC1 and PC2 were found to consist of proSAAS and 7B2 (73, 74), respectively. Interestingly, cathepsin B (cysteine protease) (75) and cathepsin D (aspartic protease) (76) were identified, which indicates a novel location for these previously only known lysosomal proteases. The localization of cathepsin B in these secretory vesicles has been confirmed by immunoelectron microscopy (77). Cystatin C was identified in the membrane and soluble components, which may participate in the regulation of cathepsins L and S; cystatin C is a member of the cystatin superfamily of protease inhibitors (78, 79). Ubiquitin, a highly conserved 76 amino acid protein that is covalently linked to proteins targeted for degradation by the ubiquitin-proteasome system (80, 81), was identified; furthermore, ubiquitin-binding protein 52A was also identified. These findings may possibly be interpreted to suggest that ubiquitin-targeted protein degradation by proteosomes may occur in secretory vesicles. TIMP, tissue inhibitor of metalloproteinase, was also present (82). These identified protease system components were mostly present in both soluble and membrane fractions.

Furthermore, membrane-selective functions were implicated by proteomic data of these secretory vesicles. The membrane fraction exclusively contained an extensive number of GTP nucleotide-binding proteins related to Rab, Rho, and Ras signaling molecules (83, 84), together with SNARE-related proteins and annexins that are involved in trafficking and exocytosis of secretory vesicle components (85, 86). Membranes also preferentially contained ATPases that regulate proton translocation.
vesicles (also known as chromaffin granules) were isolated and subjected to proteomic analyses of proteins in the soluble and membrane components of the vesicles. Protein systems in secretory vesicle function consisted of those for 1) production of hormones, neurotransmitters, and neuromodulatory factors, 2) generating selected internal vesicular conditions for reducing condition, acidic pH conditions maintained by ATPases, and chaperones for the vesicles. Protein systems in secretory vesicle function consisted of those for 1) production of hormones, neurotransmitters, and neuromodulatory nucleotide-binding, calcium regulation, and vesicle exocytosis. These protein systems are coordinated to allow the secretory vesicle to synthesize and protein folding, and 3) vesicular trafficking mechanisms to allow the mobilization of secretory vesicles for exocytosis, which uses proteins for release neuropeptides for cell–cell communication in the control of neuroendocrine functions.

These results implicate membrane-specific functions for signaling and exocytosis that allow secretory vesicles to produce, store, and secrete active neuropeptides for the control of physiological functions. The protein systems used in these chromaffin vesicles, which represent dense core secretory vesicles (73), resemble those of brain synaptic vesicles (88) and secretory vesicles in the liver (89). Proteomic studies provide inference for secretory vesicle protein systems used for functions of these vesicles, including their biogenesis, that are required for production of enkephalin and related neuropeptides in brain and endocrine tissues. Secretory vesicles at synaptic nerve terminals in the brain are essential for chemical neurotransmission among neurons. Proteomic studies of synaptic proteins have revealed their regulation by brain injury (90), brain-derived neurotrophic factor (BDNF) (91), and drug regulation by morphine (92). The protein systems that support secretory vesicle exocytosis of peptide neurotransmitters and receptor activation at synaptic junctions of neurons function in concert to achieve neuropeptide-mediated communication in neural circuits.

Future Perspectives—Chemical Approaches for Elucidating Neuropeptide Mechanisms for Translation into Therapeutic Applications

It is extremely important to apply knowledge of protease mechanisms for neuropeptide biosynthesis to small-molecule strategies for the development of therapeutic agents that can modulate the production of specific peptide neurotransmitters or hormones. Current and future research using new approaches and tools, as discussed in this article, can provide insight into selective pharmacological approaches for exogenous therapeutic regulation of neuropeptide actions. Numerous health and disease conditions are regulated by neuropeptides. Proteases are essential for the conversion of inactive proprotein precursors into the active neuropeptides. Two main protease pathways have been elucidated for processing proenkephalins and hormones: the recently discovered cysteine protease cathepsin L with aminopeptidase B and the well-established subtilisin-like serine proteases that consist of prohormone convertases 1 and 2 followed by carboxypeptidase E/H. Endogenous regulators modulate these two protease pathways as endogenous peptide inhibitors, activators, and in vivo secretory vesicle proteins. Neuropeptides in CSF (cerebrospinal fluid) in neurological diseases can monitor brain nervous activity because neuropeptides represent active neurotransmission (93, 94).

Knowledge of specific regulators for particular neuropeptides can lead to future translational research for small-molecule regulation of prohormone convertases and cathepsin L pathways in the control of physiological functions. For example, regulation of opioid peptide production—enkephalin, β-endorphin, and dynorphin—may lead to new drugs for analgesia and pain relief. Specific small-molecule control of hypothalamic NPY in the control of feeding behavior may lead to improvement in obese conditions. Regulation of hypothalamic CRF and pituitary ACTH production is important for the control of steroid biosynthesis in the adrenal cortex for metabolic regulation. PC-related proteases have been implicated in steroid and lipid metabolism, tumor progression, atherosclerosis, and other physiological and disease conditions (5–8).

Application of chemical biology and proteomic approaches for understanding protease mechanisms in the biosynthesis of neuropeptides, Chemical Activity Profiling and Proteomic Approaches for NEUROPEPTIDES, SECRETION

Figure 5 Proteomics reveals functional secretory vesicle protein systems for neuropeptide biosynthesis, storage, and secretion. Chromaffin secretory vesicles (also known as chromaffin granules) were isolated and subjected to proteomic analysis of proteins in the soluble and membrane components of the vesicles. Protein systems in secretory vesicle function consisted of those for 1) production of hormones, neurotransmitters, and neuromodulatory factors, 2) generating selected internal vesicular conditions for reducing condition, acidic pH conditions maintained by ATPases, and chaperones for protein folding, and 3) vesicular trafficking mechanisms to allow the mobilization of secretory vesicles for exocytosis, which uses proteins for release neuropeptides for cell–cell communication in the control of neuroendocrine functions.
neuropeptides in health and disease is an exciting area of research for neuropeptide regulation of neuroendocrine systems.

Measuring chemical events in neurotransmission is challenging because fast measurements of small amounts of neurotransmitters and neuromodulators are needed to track the dynamics of chemical changes accurately. In this article, we outline the basics of three popular methods for measuring neurochemical changes: electrophysiology, microdialysis, and electrochemistry. Electrophysiological techniques measure changes in membrane potentials associated with neurotransmission. These methods are often used to measure receptor-gated ion channel currents and are popular for neuropharmacology studies. Microdialysis is a sampling technique that can be used to monitor basal levels of neurotransmitters directly. When coupled to a separation technique, microdialysis is advantageous because it can be used to detect virtually any compound in the brain. Electrochemical techniques are popular because microelectrodes allow rapid, direct detection of neurotransmitters with minimal tissue disturbance. Although the analytes must be electroactive, electrochemistry has been used successfully to monitor neurochemical changes in various preparations, from single cells to behaving animals. Future research in monitoring neurochemical events will include improving the temporal resolution, spatial resolution, and selectivity of measurements.

Neurotransmission is the transfer of an informational signal, a chemical messenger, between two neurons. The traditional picture of synaptic transmission is shown in Fig. 1. A terminal from one neuron forms a synapse with a dendrite of another neuron. After the neurotransmitter is synthesized in the perikaryon of the terminal, it is packaged into specialized synaptic vesicles. The vesicles range in size from about 50 nm to 100 nm and can store between 3000 and 30,000 neurotransmitter molecules (1). An action potential propagating to the terminal changes the cell membrane potential and can induce the fusion of vesicles to the synaptic membrane. This fusion results in exocytosis, the coordinated release of transmitter molecules into the synapse (Fig. 1). Transmitters can then bind to postsynaptic receptors and activate signaling pathways through GTP-binding proteins or open gated ion channels, which leads to localized changes in membrane potential (2). Membrane potentials, ionic currents, and action potentials can be measured using electrophysiology techniques.

Released neurotransmitters can have fates other than binding postsynaptic receptors. Transmitters can bind to presynaptic receptors that act as a feedback loop to regulate additional release of the chemical messengers. Transporters take up neurotransmitters back into the neuron and clear them from the extracellular space. Neurotransmission can also be ended by enzymatic degradation of transmitters, although this process is kinetically slower than uptake. Although the traditional picture of neurotransmission is of short-range signaling, neurotransmitters can also diffuse out of the synapse and act at distal targets, which allows longer distance signaling (3). This process is called volume transmission, and extracellular detection methods such as microdialysis and microelectrodes detect these extrasynaptic concentrations.

Postsynaptic Receptors

Figure 1 General concept representation of synaptic transmission. Vesicles that contain neurotransmitter molecules dock to the cell membranes and release their contents into the synapse by exocytosis. Neurotransmitters can diffuse across the synapse and bind to postsynaptic receptors or can diffuse out of the synapse. This extrasynaptic neurotransmitter can bind to presynaptic receptors, diffuse away and activate receptors on distal neurons, or be cleared from the extracellular space by transporters.

Electrophysiology

Electrophysiological techniques measure changes in potentials associated with neurotransmission. The potential of the neuronal membrane is controlled by ionic concentrations, which are regulated by the active transport of ions. As postsynaptic dendrites receive neurotransmitter signals, receptor-gated Na\(^{+}\) and Ca\(^{2+}\) channels are activated, which allows influx down the ionic gradient. Membrane depolarization occurs as cations enter the cell. Once the depolarization reaches a certain threshold, successive Na\(^{+}\) and Ca\(^{2+}\) ion channels open along the axon in a domino fashion to propagate the electrical signal. This propagation of voltage is called an action potential, and it will not occur unless a threshold depolarization is reached. After maximal depolarization, Na\(^{+}\) and Ca\(^{2+}\) ion channels begin to close, and simultaneously, K\(^{+}\) ion channels open and K\(^{+}\) effluxes out of the nerve cell. This process reverses the polarization, and because of the length of time the K\(^{+}\) channels stay open, the abundance of cations outside the cell causes a hyperpolarization of the membrane potential.

Transmembrane movement of ions is controlled by gated ion channels and can be represented by a simple RC circuit, in which the ion channels act as resistors and the cell membrane acts as a capacitor. Hodgkin and Huxley, who won the 1963 Nobel Prize for Physiology or Medicine for their work, quantified these transmembrane voltage changes in the axon of a giant squid and determined the time-dependent behavior of Na\(^{+}\) and K\(^{+}\) channels. Current electrophysiological studies measure neurogenic changes through various intracellular and extracellular techniques. Although these techniques are diverse, common intracellular techniques include the two-electrode voltage clamp, patch clamp, and whole cell methods that measure ion channel currents and common extracellular techniques that measure voltage changes outside cells.

Two-electrode voltage clamp

Voltage clamp methods typically involve two micropipette electrodes that impale the cell; one electrode measures voltage changes, whereas the other applies a stimulating voltage. Transmembrane voltage is clamped at a constant voltage eliminating capacitive current, and allowing conductance to be measured, which is proportional to voltage. The clamped voltage then is varied in a stepwise fashion with each step resulting in a change in ion current, which is measured. For this reason, voltage clamp techniques are useful in studying voltage-gated ion channels. In a typical experiment, voltage steps are applied to an oocyte or insect muscle cell, and the effects of the addition of pharmacological agents on ion channel currents are tested. For example, Fig. 2a shows voltage clamp recordings of inward calcium channel currents in parasitic nematode muscle cells after a series of depolarizing steps (4). The current versus voltage graph shows the maximal current was induced by a step to 0V. The study showed that bathing a voltage-clamped cell in the nematode neuropeptide, AF2, increased the inward calcium currents, which suggests that the neuromuscular function of the parasitic nematode was modulated by AF2. Such studies can be useful for identifying possible target sites for drugs that act at voltage-gated channels.

Patch clamp

Some of the most popular electrophysiology methods currently used are patch clamp techniques, in which individual ion channels can be studied. Unlike the two-electrode methods described above, these methods use a single electrode to measure voltage changes. A glass pipette electrode with a flat, open tip is placed onto a cell, and piece of membrane that contains an ion channel is “sucked” into the pipette tip. This action allows the direct current of ions moving through channels to be measured. Although the pipette tip has a high resistance, negative pressure...

(Data reprinted from Ref. (5) by permission of Elsevier.) c) Inside-out experiment. A continuous single-channel current is shown from in an inside-out membrane patch of a rat cultured hippocampal neuron before and after addition of diazepam. The top trace shows currents induced by 5 µM GABA. The bottom four traces show currents induced after a 1 µM solution of diazepam is introduced. A gradual increase in single-channel current amplitude occurs. (Data reprinted from Ref. (8) by permission of Macmillan Publishers Ltd.)

is applied to form a seal with a gigahm resistance, which is commonly referred to as a gigaseal. The pipette tip is usually filled with a solution that approximates intracellular fluid. Two types of experiments can be performed once the pipette electrode is in place: voltage clamp or current clamp. Similar to two-electrode voltage clamp methods described above, in voltage clamp mode the membrane potential is held at a constant voltage, and current through the ion channels is measured. In current clamp mode, the current is kept constant, and voltage changes are measured. To identify which types of channels contribute to the signal, electrophysiology techniques are commonly used in conjunction with pharmacology experiments, in which drugs are applied to block specific channels. Several configurations of this method correspond to whole cell, outside-out and inside-out models (Fig. 3).

Whole cell model

In the whole cell model, a gigaseal is formed as the pipette is attached to the cell, and then a more dynamic suction is applied, which causes the interior of the cell to be sucked into the pipette tip (Fig. 3a). This action allows current and conductance of the entire cell to be measured. Therefore, the whole cell model measures changes caused by many ion channels on the entire cell membrane. Additionally, the liquid content of the cell will mix and equilibrate with the solution in the pipette, which allows pharmacological agents to be administered into the cell. Of the patch clamp techniques, the whole cell method is the most common and can be used to determine how pharmacological agents affect the total conductance of neurons.

An example of a whole cell study is shown in Fig. 2b. Excitatory postsynaptic currents (EPSCs), which are caused
Neurotransmission, Measuring Chemical Events in Whole Cell Method

- Outside-out Method
  - In the outside-out model, the pipette is attached to the entire cell as in the whole cell model, followed by a sharp pull that causes the cell membrane to break and reseal with the pipette tip (Fig. 3b). With the extracellular region exposed, channel activity as a response to different external stimuli can be probed. This configuration is less common than the inside-out method. Using an outside-out method, single-channel opening activity has been recorded while various neurotransmitters were released. For example, this patch clamp method was used as a detector for capillary electrophoresis separations of GABA, glutamate, and NMDA (7).

- Inside-out Model
  - In the inside-out model, gigaseal formation is followed by a sharp pull, which detaches the cell membrane and exposes the inner membrane of the cell to the bathing solution. The portion of the membrane that was on the inside of the cell is then on the outside of the pipette, whereas the outer portion is in equilibrium with the fluid inside the pipette (Fig. 3c). This configuration is useful for studying the effects of intracellular molecules or drugs on individual ion channels and has been used in pharmacology experiments to study ligand-gated ion channel activity. For example, benzodiazepines, which are used to treat anxiety, are thought to augment synaptic inhibition in the central nervous system. Inside-out patch clamp was used to study the effect of the benzodiazepine, diazepam, on single-channel conductance (8). Diazepam caused a seven-fold increase in the conductance of GABA\(_A\) chloride channels from rat cultured hippocampal neurons (Fig. 2c). This study demonstrates that the inside-out method can provide information about the effect of drugs on the current of a particular ion channel. Inside-out patch clamp has also been used to study pain sensory transduction in rat ganglion neurons through capsaicin-activated ion channels (9). Capsaicin is known to activate certain cation channels and cause severe pain. One study used patch clamp to determine that 12-(S)-hydroxyeicosatetraenoic acid (HPETE), a lipoxygenase product, was an endogenous activator of capsaicin channels. The inside-out technique is widely used to study various channels, both inhibitory and excitatory, and various preparations from retinal neurons to central neurons. For example, inside-out patch clamp has been used to study the photosensitivity of rat intrinsically photosensitive retinal ganglion cells (ipRGCs), which are photoreceptors that control pupil response (10). In this study, inside-out recordings showed that ipRGCs are photosensitive. This study gives insight into the complex cascade of events that lead to vision.

Extracellular Methods

With intracellular methods, the change in voltage caused by the movement of positive ions into the postsynaptic cell through glutamate-mediated channels, were monitored. This study examined whether adenosine receptor activation could modulate EPSCs. Whole cell patch clamp was performed on neurons in striatal rat brain slices. Figure 2b shows an EPSC evoked by electrical stimulation before and after application of an A\(_2\)A adenosine receptor agonist. The decreased amplitude of the EPSC after the adenosine receptor agonist is applied suggests that adenosine receptor activation inhibits glutamate channel-mediated EPSCs (5). Many researchers also study inhibitory postsynaptic currents (IPSCs) mediated by gamma-aminobutyric acid (GABA\(_A\))-gated chloride channels. For example, whole cell patch clamp was used to differentiate two different types of IPSCs in substantia gelatinosa neurons of the mouse spinal cord (6). IPSCs with a fast decay had a different pharmacological profile than those with a slow decay.

Whole cell methods continue to be popular for neuropharmacology studies because they allow researchers to understand the complex actions and regulation of receptors gating ion channels.
an electric field in the extracellular space, and these changes in electrical activity can be measured by extracellular recordings.

Both invasive and noninvasive techniques are routinely used. Extracellular techniques can be used in many preparations, including awake, behaving animals.

In a typical invasive setup, a wire electrode or an array of wires is implanted into the brain, and changes in potential are measured. Electrodes that are directly next to a neuron will record voltage changes when that neuron fires. This setup has been used to measure neuronal firing patterns in animals performing complex behaviors, such as drug self-administration (11). These studies have shown that dopamine neurons fire as predictive signals of reward and will fire in response to cues that have been previously associated with rewards (12).

Multielectrode arrays have also been used to map the response of different neurons to external stimulations. For example, Nicolelis et al. have used multichannel electrodes to map tactile responses of an anesthetized rat (13). Figure 4 demonstrates the neuronal response to stimulation of the infraorbital nerve, which carries information from the whisker’s mechanoreceptors to the brain. Typical data is shown, in which firing patterns before and after the stimulus (dashed line, time 0) are given for multiple trials (top of figure) and then binned to get average firing rates (histograms). The results show that the hippocampal neurons have a longer latency to fire but are activated for longer than the neurons in the somatosensory cortex and thalamic ventral posteromedial nucleus. Such studies help identify and interpret the neuronal pathways that process tactile stimulation.

In a noninvasive setup, surface electrodes are placed on the surface of the skin and can be used to study individual or multiple neurons. Additionally, many studies look at motor units, which are a motor neuron and all muscle fibers that the neuron innervates. For example, stable recordings of single motor unit potentials can be made using electromyography (14). Surface electrodes are of interest in electroencephalography (EEG) measurements, in which electrodes are placed on the scalp. Noninvasive EEG measurements are particularly useful in human studies. For example, EEG recordings have been used to study adenosinergic neurotransmission in homeostatic sleep-wake regulation in humans (15). These studies found that adenosinergic neurotransmission plays a role in non-rapid eye-movement sleep homeostasis.

Summary and future directions

Intracellular patch clamp methods provide a sensitive, high-resolution approach to studying ion channels. Patch clamp studies are particularly useful in pharmacological studies, such as identifying receptor agonists and antagonists. Studies can be performed in brain slices or in vivo. However, several pervasive problems with patch clamping exist. Patch clamping is inherently an invasive technique, and morphological changes in the cell can occur during the clamping process that interfere with the overall function of the ion channel investigated (16).

Although patch clamp methods are robust and have provided information about the function of ion channels, they are labor-intensive, require a high degree of technical skill, and are low-throughput. Therefore, a research topic of current interest is developing automated, high-throughput patch clamp methods. For example, a planar patch clamp electrode, which uses a planar substrate rather than a pipette to determine current for whole cells, has been developed. Planar patch clamp requires less skill and allows higher throughput measurements to be made (17). Interest in developing methods to screen ion channels as drug targets has led to the commercial availability of automated planar patch clamp systems (18). Additional development of these high-throughput methods is expected to lead to widespread adoption of these techniques.

With extracellular measurements, action potential firing adjacent to an electrode gives information about neuron output and synaptic input. These methods are good for measuring neuronal activity of awake, behaving animals. The use of implantable electrodes provides high resolution of single neurons, whereas nonimplantable electrodes sample a larger surface area, which causes them to have a lower resolution. However, noninvasive measurements are the most useful for higher order animals and humans. Signals from extracellular recordings are much smaller and harder to detect than with intracellular methods. For example, the number or type of neurons that are firing at a given time can be difficult to determine (19). Additionally, action potentials are often obscured or unsynchronized, and extracellular recordings can be a summation of multiple neuronal signals. However, with the development of better computer programs and bioinformatics capabilities for data analysis, these problems can be overcome (20). Additional integration of both intracellular and extracellular methods will provide a more holistic picture of neurotransmission.

Figure 4 Electrically evoked single-unit tactile responses recorded with microdrive multielectrode arrays in rat hippocampus CA1, primary somatosensory cortex, and ventral posteromedial nucleus brain regions. (Upper) raster plot of single-unit spikes before and after electrical current stimulation to whiskers. Each row is a separate trial. (Lower) Summed activity for all trials in 1-ms bins that demonstrate a response to electrical stimulation. The graphs show different latencies in firing for the three different regions. In a noninvasive setup, surface electrodes are placed on the scalp. Noninvasive EEG measurements are particularly useful for higher order animals and humans. Signals from extracellular recordings can be a summation of multiple neuronal signals. However, with the development of better computer programs and bioinformatics capabilities for data analysis, these problems can be overcome (20). Additional integration of both intracellular and extracellular methods will provide a more holistic picture of neurotransmission.
Microdialysis

Microdialysis has served as a powerful tool in the direct measurement of cerebral neurotransmitters. It can be used as a qualitative technique to monitor changes in neurotransmitters or as a quantitative technique to determine actual neurotransmitter concentrations such as basal levels. Measurements are made using a probe sheathed with a semipermeable membrane, which allows extracellular molecules of a low molecular weight, such as neurotransmitters, to pass but excludes larger molecules such as proteins. The probe is perfused with artificial cerebral spinal fluid, and molecules diffuse across the membrane according to their concentration gradients. Fluid fractions are collected at the probe outlet. Fractions are typically analyzed using separation techniques, such as high-performance liquid chromatography (HPLC) or capillary electrophoresis (CE). Microdialysis can provide both highly selective and sensitive analysis of neurochemical changes, but the temporal resolution has been limited traditionally to 5–20 minutes (21, 22). Continuous sampling of chemical events allows processes such as drug metabolism and neurotransmitter release to be studied. Microdialysis also is useful for studying neurotransmission in various preparations, including in behaving animals.

Microdialysis Theory

In microdialysis, a solution isotonic to that being sampled is perfused through an inlet tube of the probe (Fig. 5). A concentration gradient is established on each side of the membrane between the perfusate and the sampling region. This gradient causes neurochemicals from the sampling region to diffuse through the membrane, and the compounds are collected for analysis at the outlet of the probe. Analyte removal from the sampling region keeps the concentration gradient intact and allows continual sampling of the extracellular space. This process is highly dependent on flow rate of perfusion.

At typical flow rates, the concentration in the dialysate, Cext, is less than the actual concentration in the extracellular fluid, Cin (23). The ratio of Cin/Cext is defined as relative recovery, R, and must be considered for probe calibration and sampling optimization. In vitro, R is easily calculated because the dialysate and the extracellular fluid are homogeneous; therefore, probe calibration is easily obtained. However, in in vivo studies, calculation of R is difficult because of the active removal of neurotransmitters by uptake and transporters. Movement of analytes is impeded by tissue that surrounds the probe, and this movement cannot be easily accounted for with in vitro calibrations. Therefore, the most common method to determine concentrations in vivo is the zero-net flux method, in which known analytic concentrations are added to the perfusate (Cin), and then the analytic concentration is measured at the probe outlet (Cout). The difference between analytic concentration at the inlet and outlet is used to establish the actual analytic concentration in the tissue, and the relative recovery rate can be calculated. This calibration method can be used to estimate basal levels of neurotransmitters. For example, the zero-net flux method has been used to determine that basal concentrations of dopamine are approximately 1–3.5 nM (24, 25). Although basal level concentrations of neurotransmitters can be determined with this method, the contribution of tissue damage to the microdialysis signal cannot be neglected. Because microdialysis is an invasive technique, a traumatized layer of tissue will be next to the probe, which influences the rate of neurotransmitter release and uptake. Bungay et al. have suggested in the case of dopamine that trauma leads to underestimation of extracellular dopamine concentration and have proposed a quantitative model to correct for that (23).

Microdialysis coupled to high-performance liquid chromatography

Detection of neurotransmitters in microdialysate samples has been achieved traditionally by coupling microdialysis sampling to highly sensitive analysis methods such as high-performance liquid chromatography (HPLC). HPLC is a type of column chromatography, which separates the collected mixture of analytes and resolves them into individual components. Therefore, multiple chemical species can be identified in a given sample. Monitoring changes in concentrations over time gives insight into a wide range of processes such as transporter function, effects of pharmacological agents, and behaviorally evoked neurotransmitter changes.

Glutamate is the most abundant excitatory neurotransmitter in the nervous system. Under normal conditions, glutamate transporters remove extracellular glutamate into glial cells. However, during disease or ischemia, a lack of oxygen delivery to cells, excess glutamate can accumulate and result in excitotoxicity.
Microdialysis studies have played an important role in understanding the relationship between glutamate levels and ischemic events. Glutamate has been shown to increase during a stroke, which contributes directly to neuron damage and additional vulnerability to ischemia (26, 27). Subsequently, methods to reduce glutamate release during an ischemic event have been of interest. Recent microdialysis studies indicate that spinal cord necrosis can be reduced by administering magnesium sulfate to the area experiencing ischemia (28).

Figure 6  Effects of intrathecal magnesium sulfate on ischemia-induced release of glutamate in the dialysate collected from the spinal cord of rabbits. Data are expressed as percentage of the mean baseline levels in each group. Aortic artery occlusion to cause ischemia results in an increase in glutamate in the placebo group (open circles), but administration of MgSO4 before ischemia is induced prevents the increase (triangles). A sham group in which ischemia is not induced is also shown (squares). (Data reprinted from Ref. (28) by permission of Lippincott, Williams, and Wilkins.)

Microdialysis coupled to capillary electrophoresis

Recently, several groups have used capillary electrophoresis (CE) instead of HPLC as an analysis method for microdialysis samples. The chief advantage of CE is that high-speed separations of very small sample volumes can be achieved. The improved temporal resolution allows samples to be analyzed every 10 seconds, which facilitates better understanding of the dynamics of neurotransmitter changes during behavior. This method has enabled the online analysis of microdialysis samples using capillary electrophoresis and eliminated the need to store fractions. The disadvantage is that samples must be derivatized to make them fluorescent so that highly sensitive laser-induced fluorescence can be used for detection.

Microdialysis coupled to CE was used to detect changes in amino acids, such as glutamate, during exposure of rats to a predator fox odor (31). Figure 7 shows that large changes in glutamate were observed after presenting the fox odor, particularly in a subset of rats that were high responders. These changes lasted only a few minutes. The data are compared with a similar experiment that measured glutamate changes in response to the presentation of the fox odor with typical microdialysis–HPLC with only 10-minute temporal resolution (32). The magnitude and duration of the glutamate change are more accurately tracked with the higher temporal resolution CE method. Microdialysis–CE has been used to study amino acid neurotransmitters during learning (33) and catecholamines such as dopamine and norepinephrine during the sleep–wake cycle (34). Future research in this field includes miniaturizing the CE detection on a chip (35) to make the technique more amenable to wide-scale implementation.
Microdialysis may also see more use in the future as a diagnostic tool to improve temporal resolution. Microdialysis coupled to CE provided information not previously found with HPLC because of increased time resolution. (Data adapted from Ref. (31) by permission from Blackwell Publishing.)

Summary and future directions

Although microdialysis is sensitive and selective, it is an invasive technique that causes trauma and tissue damage, such as edema and alteration of the blood-brain barrier and glucose metabolism in areas near probe insertion. Consequently, interpretation of results garnered from microdialysis has been controversial. Several studies indicate cerebral blood flow and glucose metabolism recovery within 24 hours (27), and many studies delay measurements after probe implantation to allow tissue recovery. However, recent studies that compare dopamine levels at the insertion point and 1 mm adjacent to this area indicate permanent changes in tissue because of trauma (36). Furthermore, neuronal loss and tissue disruption have been observed through light and electron microscopic analysis (37).

Nevertheless, microdialysis measurements agree well with other methods used to measure neurochemical changes such as microelectrode techniques (38). For example, pulse voltammetric methods have determined basal concentrations of dopamine to be approximately 1.5 ± 0.5 nM (39), compared with 1–3.5 nM estimated with microdialysis measurements (24, 25). Undoubtedly, efforts to minimize tissue damage should be made to ensure accurate results. However, microdialysis has seen widespread use because the data on chemical changes has consistently provided insight into brain functions and pathologies. The efforts to improve temporal resolution for microdialysis will allow it to be used to track chemical changes specific to certain behaviors. Microdialysis may also see more use in the future as a diagnostic tool in human neurosurgery for monitoring neurotrauma (40).

Electrochemical Techniques

Electrochemical detection is one of the most common methods for neurotransmitter monitoring. Many neurotransmitters are electroactive, including dopamine, norepinephrine, epinephrine, and serotonin, and can be detected directly using microelectrodes. The small size of typical microelectrodes, from 7 to 30 μm in diameter, results in less tissue damage than the implantation of larger probes, such as microdialysis probes or conventional electrodes. Three of the most common methods of voltammetric detection for neurotransmitters are amperometry, high-speed chronoamperometry, and fast-scan cyclic voltammetry. In each of these methods, a voltage waveform is applied to the electrode. When the potential is sufficient, electroactive neurochemicals can be oxidized or reduced, and a current is measured that is proportional to the concentration of analyte at the electrode surface. The range of voltages that can be used is finite because of the possible oxidation or reduction of physiologic solutions and oxygen, which limit detection to the range of about −1 V to 1.5 V. The shape of the potential waveform applied in each technique is unique, and the resulting chemical information is different for each method (41).

Constant potential amperometry

Amperometry applies a constant potential to the microelectrode that will oxidize the analyte at the electrode surface (Fig. 8a). The current is limited solely by the mass transport rate to the electrode. Measurements can be made with extremely high temporal resolution, typically 500 Hz, because time resolution is not limited by the electrochemistry at the electrode. However, little analyte selectivity occurs with amperometry because a change in the concentration of any moleule electroactive at the applied potential will alter the measured signal.

One major use of amperometry is to measure the efflux of neurotransmitters from individual cells (42). Because the cell type and the molecule being released is known, selectivity is not an issue for these experiments. This technique, developed by R. Mark Wightman, is now widely adopted and involves placing a microelectrode directly above a cell (42). A secretagogue known to stimulate release is applied, and vesicular release is monitored with high temporal resolution. Recently, amperometry has been used to show that ionic secretagogues can influence the exocytotic release of specific neurotransmitters. An example experiment is shown in Fig. 8d, in which dopamine release is monitored after application of K+ to isolated dopaminergic retinal neurons (43). Typical data consists of multiple peaks, each of which is representative of neurotransmitter release from a single vesicle (Fig. 8d). The area under the peak is proportional to the total number of molecules in that vesicle and can be calculated. The amount of dopamine released from retinal cells was calculated to be about 32,000 molecules per vesicle (43). Recent studies have shown that small features detected with amperometry are caused by incomplete vesicular release associated with vesicle fusion (1, 44). Amperometry is a good method for studying basic mechanisms of neurotransmission or the effects of drugs on neurotransmitter release from single cells.

Chronoamperometry

For high-speed chronoamperometry, a recurrent square waveform is applied to the electrode, with potentials sufficient...
enough to oxidize the analyte of interest and subsequently reduce the analyte to the initial form. Rapidly changing the potential causes an inherent charging current at the electrode surface, but this current is dissipated quickly because of the micron size of the electrode. Therefore, the current measured at the end of the step, after the charging current has decayed, is proportional to the analyte concentration (Fig. 8b). The ratio of the peak reduction current to the peak oxidation current is a measure of the reversibility of the electrochemical reaction and can be used to differentiate between some molecules. However, this selectivity is limited, and positively identifying the analyte solely by this technique is difficult. The chronocoulometry waveform is typically repeated at 5-25 Hz.

Greg Gerhardt pioneered a chronocoulometry method that has been used to observe diffusion and uptake parameters in the rat brain (45). In this technique an exogenous neurotransmitter, such as dopamine, is introduced into the brain by pressure ejection. Gerhardt’s group could compare dopamine uptake rates of wild-type rats and rats that had been treated with nomifensine, a dopamine uptake inhibitor (46, 47). They found that nomifensine slowed dopamine uptake rates, as seen by the slower return to baseline after injection. (Data from Ref. (47) used by permission from Elsevier.) Cyclic voltammetry data of dopamine concentrations from uptake inhibitor nomifensine was administered. Uptake rate is reduced by nomifensine as seen by the increased concentration and the slower return to baseline after injection. (Data taken from Ref. (43) by permission from the American Chemical Society.)

Figure 8 Electrochemical techniques. Applied potential versus time and resulting current versus time graphs for a) amperometry, b) high-speed chronocoulometry, and c) fast-scan cyclic voltammetry. The dotted circle in b) shows where currents are measured after the charging current has decayed. Panels d-f show real data from experiments using each of the techniques. Amperometry data (d) show a current increase that corresponds to detection of electroactive species. Each peak is representative of dopamine release from a single vesicle in retinal neurons, and the area under each peak was used to quantitate the number of molecules released. (Data taken from Ref. (43) by permission from the American Chemical Society.) d) Dopamine concentrations measured by chronocoulometry. Upward-facing arrows indicate time of dopamine injection; downward-facing arrows indicate time of nomifensine injection. Curve A is dopamine detected after injection of 30 pmol of DA in normal tissue, whereas traces B and C are after the dopamine uptake inhibitor nomifensine was administrated. Uptake rate is reduced by nomifensine as seen by the increased concentration and the slower return to baseline after injection. (Data from Ref. (47) used by permission from Elsevier.)
the charging current is relatively stable at carbon electrodes, the current before analyte introduction can be subtracted from the current after analyte introduction. This method is known as background-subtracted FSCV, and it is best used for measuring concentration changes. The data collected is a plot of current versus voltage, called a cyclic voltammogram, which gives a chemical signature of the molecules detected. The peak locations and shapes help differentiate between different molecules, which gives this method the most selectivity of any of the electrochemical techniques discussed here. Some molecules, such as dopamine and norepinephrine, however, have similar CVs and are difficult to resolve.

R. Mark Wightman’s lab used carbon-fiber microelectrodes to pioneer the use of FSCV in measuring dopamine concentration changes with high temporal resolution. Early experiments focused on measuring dopamine concentration changes after electrical stimulation of the dopamine cell bodies (50). In more recent studies, behaviorally evoked dopamine concentrations have been measured. One example is the detection of dopamine in rats when cocaine was self-administered (Fig. 8f) (51). The subsecond temporal resolution allowed the observation that extracellular dopamine increased continuously for about 4 seconds before the lever press for cocaine administration and after the lever press. This observation shows that one role of dopamine is as an anticipatory signal (51). FSCV has also been used to measure other neurotransmitters, such as serotonin (52) and norepinephrine (53), in vivo and in brain slices. Our lab has recently extended the use of FSCV to detect the neuromodulator adenosine successfully. In vivo detection of adenosine and dopamine simultaneously was achieved, and the temporal resolution allowed us to demonstrate that adenosine accumulation was slower than dopamine (34). Fast-scan cyclic voltammetry is the best choice for detecting neurotransmitters that undergo volume transmission in vivo because the cyclic voltammogram provides a means to identify the species detected and the high temporal resolution allows correlation with behavior.

Summary and future directions

The main advantages of electrochemical methods for neurotransmitter detection are the high temporal resolution, the high sensitivity, and the small size of the microelectrode. The different electrochemical techniques have varying levels of selectivity; however, these methods are not as selective as separation methods coupled to microdialysis. The majority of studies have used a combination of anatomical knowledge, pharmacology, and electrophysiology to identify the analyte being detected. Most electrochemical methods are best for measuring fast changes and do not give information about basal levels. A major disadvantage of the electrochemical techniques is that the method is limited to the direct detection of electroactive molecules. New innovations are constantly being made to minimize these limitations. For example, enzyme electrodes are being developed for the indirect detection of non electroactive species. Enzymes are immobilized in a polymer coating, and the microelectrode detects an electroactive by-product, such as peroxide, from enzymatic activity (55, 56). Research continues into reducing the size of electrodes and increasing the number of molecules that can be detected simultaneously.

Conclusions and future of the field

Measuring neurochemicals is challenging because the brain is a complex matrix. Most studies have concentrated thus far on determining the effects of a single neurotransmitter. However, future research in this field inevitably will begin to examine interactions between various neurotransmitter systems, and techniques will be needed to measure multiple compounds. Separations-based methods, such as microdialysis, are particularly suited for this challenge. In addition, many researchers are starting to use multiple techniques for a single experiment. An example of this use is the combination of electrochemistry and electrophysiology techniques that can be now employed simultaneously at the same electrode (57). Another challenge is to reduce the amount of damage done to tissue from invasive techniques. Methods to microfabricate microdialysis probes or reduce the size of microelectrodes would be useful for maintaining tissue integrity. Noninvasive techniques, such as imaging, are becoming more prominent, especially for human studies. Many of the most popular methods, such as functional magnetic resonance imaging, measure changes in oxygen levels and blood flow but do not directly measure neurotransmitters (58). Positron emission tomography measures changes in receptor occupancy, a more direct measure of neurotransmission (59), but advances are needed to synthesize more positron-emitting ligands for different receptors. Imaging methods for cellular activity are also becoming more popular. For example, fluorescence resonance energy transfer (FRET) can be used to detect binding at receptors (60). However, these studies remain fairly complicated and often require genetic engineering of FRET-based pairs into a system. Optical probes, such as quantum dots or fluorescence-based dyes, may also soon see widespread use in detecting chemical changes in cell culture or brain slices.

The biggest advances for in vivo experiments will be in the area of designing better techniques for behaving animals. For electrochemistry, several groups have explored a wireless system of data collection in which the controls for electrochemistry and data are collected in instrumentation that can be placed in a backpack on the rat (61). The data then is sent wirelessly to a computer, so that the animal is not tethered to the computer. Similarly, telemetric electrophysiological systems are being developed that will enable wireless collection of unit recordings (62). These systems can be used to record spikes of neuronal activity in small behaving animals, such as birds. Integrated systems that measure both behavioral activity and neurochemical changes will also continue to be developed. Making measurements of neurotransmitters will continue to be challenging, but new techniques will lead to better insight into the basic neurobiology and regulation of neurotransmission.

Further Reading

The nervous system is composed of networks of cells that engage in coordinated circuits to permit neural function. Within these precise neural circuits, communication between individual cells is primarily chemical in nature. Neurotransmitter release via exocytosis of neurotransmitter-filled synaptic vesicles is a fundamental step in this process. Here we overview the biochemical processes that regulate exocytic neurotransmitter release by focusing on three key stages: 1) loading of neurotransmitter into synaptic vesicles, 2) synaptic vesicle docking and priming reactions, and 3) calcium triggering of the vesicle fusion reaction. We also introduce the controversial topic of fusion-pore modulation as it pertains to the release of neurotransmitter. Lastly, we discuss current methods for detecting and quantifying neurotransmitter release.

Biological Relevance of Neurotransmitter Release

The process of information flow between neurons is termed synaptic transmission, and in its most basic form it is characterized by unidirectional communication from the presynaptic to postsynaptic neuron. The process begins with the initiation of an electrical impulse in the axon of the presynaptic neuron. This electrical signal—the action potential—propagates to the axon terminal, which thereby stimulates the fusion of a transmitter-filled synaptic vesicle with the presynaptic terminal membrane. The process of synaptic vesicle fusion is highly regulated and involves numerous biochemical reactions; it culminates in the release of chemical neurotransmitter into the synaptic cleft. The released neurotransmitter diffuses across the cleft and binds to and activates receptors on the postsynaptic site, which thereby completes the process of synaptic transmission.

Neurotransmitter release is not assured in response to synaptic stimulation. Rather, the process of vesicle fusion for individual release-competent vesicles is probabilistic. This process confers a discrete probability (between 0 and 1) that a given synapse will release neurotransmitter after an action potential (the synaptic release probability). For the majority of synapses in the central nervous system, the release probability at a defined synaptic contact is below 0.3, which leads to the often-quoted statement that the release process is “reliably unreliable” (1). Despite this fact, it has been demonstrated that some central nervous system synapses (in a variety of brain regions) do exhibit release probabilities as high as 0.9 (2–4). This higher synaptic release probability could be explained by more release-competent vesicles and/or because the vesicular release probability of the individual release-competent vesicles is higher. Moreover, release probability is highly dynamic; it incorporates several forms of short-term plasticity (5).

Although this article focuses almost exclusively on the essential aspects of release of classic small-molecule neurotransmitters from neurons of the central nervous system, it is appropriate to mention that the neurotransmitter release process encompasses several additional, salient facets. Release of neurotransmitters from neurons can occur at various locations on the neuron (e.g., axo-dendritic, axo-somatic, axo-axonal, dendro-dendritic, and, in the case of the neuromuscular junction, from axon to muscle). In addition, neurotransmitter release can occur from various different cell types (e.g., neuroendocrine cells and glial cells), in which case it can be debated whether the use of the term neurotransmission is truly appropriate. Release of neuropeptides is typically from dense-core vesicles rather than small synaptic vesicles, but many mechanisms parallel those for classic neurotransmitters. A group of diffusible messengers that includes nitric oxides, endocannabinoids, and hydrogen peroxide is often classified as retrograde neurotransmitters. However, these messengers are synthesized de novo rather than stored in vesicles and released, and thus they will not be considered here. Finally, even in the case of release of classic neurotransmitters from neurons of the central nervous system, highly specialized synapses have been described and investigated in great detail (e.g., ribbon-type synapses of the retina and Calyx-type synapses in the auditory pathway). These collective special considerations, although not adequately discussed herein, serve as excellent examples of the wide diversity...
of signaling mechanisms employed by the nervous system to achieve information transfer.

**Biological Chemistry of Neurotransmitter Release**

Within the presynaptic terminal, neurotransmitter-filled vesicles are clustered tightly in high numbers. The first electron micrograph images of synapses in which clusters of synaptic vesicles could be seen clearly were obtained in the mid-1950s (6, 7). This work coincided with the classic experiments of Bernard Katz and colleagues on the quantal nature of neurotransmission at the frog neuromuscular junction and thus greatly strengthened the foundation for the quantal hypothesis of neurotransmitter release (8-10). Together, these findings led to the vesicle hypothesis, for example, that a single synaptic vesicle is the morphological correlate of a quantum of neurotransmitter (10).

**Synaptic vesicle morphology and organization into functional pools**

As judged by electron micrograph images, small synaptic vesicles have a clear core and are approximately 35–50 nm in diameter (11–13). By contrast, dense core vesicles, which are found in neuroendocrine cells and for the storage of neuropeptide transmitters in the nervous system, can be as large as 300–400 nm in diameter. Within the presynaptic terminal, synaptic vesicles seem to be morphologically identical at near nanometer resolution. However, three distinct functional pools can be identified based on the differential ability of synaptic vesicles to be recruited for fusion. The vesicles that are docked at the membrane surface in a region called the active zone and that have undergone a series of priming reactions to achieve fusion competence represent the readily releasable pool (RRP) (14). It is believed that release of neurotransmitter will occur predominantly (if not exclusively) from this vesicle pool. Because the synaptic vesicle priming reactions may be reversible, a small subset of the morphologically docked vesicles may exist in the unprimed state and therefore would be unavailable for release (15).

After the fusion of a synaptic vesicle, the RRP is refilled from the recycling pool of synaptic vesicles. For central nervous system synapses (e.g., synapses of hippocampal neurons), the recycling pool of synaptic vesicles consists of approximately 30 vesicles, approximately three to five times the number of RRP vesicles (15, 16). During repetitive synaptic stimulation, the rapid refilling of the RRP from the recycling pool sustains continuous neurotransmitter release. An overview of the synaptic vesicle cycle is shown in **Fig. 1**.

The third and largest synaptic vesicle pool is termed the reserve pool and does not contribute to neurotransmitter release under normal physiological conditions. It is proposed that reserve pool vesicles are only recruited with extremely intense extended bouts of synaptic stimulation, conditions under which the recycling pool of vesicles is depleted (17). When vesicle pool sizes are expressed as percentages of the total synaptic vesicle cluster, these percentages hold well across many synaptic types and species. The RRP typically represents 1–2%, the recycling pool 10–20%, and the reserve pool 80–90% of the total vesicle cluster (18).

The synaptic vesicle as an organelle for neurotransmitter storage and release

Glutamate, gamma amino butyric acid (GABA) and glycine, acetylcholine (Ach), and monoamines are examples of major small-molecule neurotransmitters in the nervous system. Although each neurotransmitter has a distinct structure and biological activity, all share the common feature of being concentrated into synaptic vesicles before release from the presynaptic bouton of the neuron. In this respect, the synaptic vesicle is an organelle specialized for storage and release of neurotransmitter. Furthermore, the synaptic vesicle contains numerous proteins (both transmembrane and vesicle-associated) that are key players in the biochemical reactions that lead to release of neurotransmitter. The very recent detailed molecular characterization of the synaptic vesicle as a model trafficking organelle, including some of the first available estimates of key synaptic vesicle protein copy numbers (13), reemphasizes the fact that the synaptic vesicle is center stage in the consideration of the neurotransmitter release process (**Table 1**).

Although the synaptic vesicle landscape is dominated by an array of proteins, it is of note that synaptic vesicles that contain different neurotransmitters are thought to have largely similar overall protein composition. For example, all synaptic vesicles
require proteins that are essential for membrane trafficking and fusion. The best-studied synaptic vesicle proteins include the transmembrane proteins synaptobrevin, synaptophysin, synaptotubulin (also referred to as vesicle associated membrane protein or VAMP), and synaptic vesicle protein 2 (SV2), as well as the peripherally associated synapsins and the Ras that are attached through lipid modifications. The proton pump is also a key synaptic vesicle component and is critical for establishing the electrochemical gradient across the synaptic vesicle membrane (low pH in the lumen) to power neurotransmitter uptake into the synaptic vesicle lumen. The synaptic vesicle proton pump is unique in that only one copy per vesicle of this multi-protein complex exists, and this proton pump complex is by far the largest component of the synaptic vesicle [13, 18].

The neurotransmitter phenotype, i.e., what type of neurotransmitter is stored and ultimately will be released from the synaptic bouton, is determined by the identity of the neurotransmitter transporter that resides on the synaptic vesicle membrane. Although some exceptions to the rule may exist; all synaptic vesicles of a given neuron normally will express only one transport phenotype (this concept is enveloped in what is known as Dale's principle; see also Reference 19). To date, four major vesicular transporter systems have been characterized that support synaptic vesicle uptake of glutamate (VGLUT 1-3), GABA and glycine (VGA T), acetylcholine (VAChT), and monoamines such as dopamine, norepinephrine, and serotonin (VMA T 1 and 2). Vesicles that store and release neuropeptides do not have specific transporters to load and concentrate the peptides but, instead, are formed with the peptides already contained within.

**Synaptic vesicle docking and priming reactions**

Synaptic vesicle attachment or "docking" occurs in the active-zone region of the presynaptic terminal. This specificity for synaptic vesicle attachment implies a recognition mechanism between the synaptic vesicle and the active zone. In this context, some or perhaps all molecules responsible for synaptic vesicle docking might be expected to exhibit preferential enrichment or exclusive localization to the active-zone region. Despite intense efforts and numerous candidate molecules, the precise molecular mechanisms of synaptic vesicle docking remain poorly characterized at this time. The cytosolic protein Munc18 (which represents the major mammalian version of the sec1/munc18-like or SM family of proteins) is gaining acceptance as an important docking molecule [20], although no clear model for Munc18 function has emerged. Munc18 is proposed to provide the molecular link between the active-zone region and synaptic vesicles. It almost certainly links to the presynaptic membrane via a direct interaction with the N-terminal region of syntaxin [21]; however, the interaction by which Munc18 can also link with synaptic vesicles has proven highly elusive. No additional putative interacting partners have been validated as essential for synaptic vesicle docking. This fact may indicate redundancy in synaptic vesicle docking mechanisms. Alternatively, very recent evidence that demonstrates that syntaxin is required for synaptic vesicle docking [22], despite prior evidence to the contrary [23, 24], may largely explain the notable lack of progress in unraveling synaptic vesicle docking mechanisms to date, although this controversial finding demands additional validation. Notably, neither syntaxin nor Munc18 are preferentially enriched in the active zone; therefore, it is likely that some other protein participates to impart the regional specificity. Such a role has been ascribed to the Munc13 protein, which is reported to be concentrated at active zones [25] and to function upstream of syntaxin in the docking of synaptic vesicles [22].

**Prime** can be defined as the transition of synaptic vesicles from the docked state into the state of release competence. The available evidence supports a critical role for soluble N-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) proteins in the biochemical interactions that underlie synaptic vesicle priming. Our current understanding of intracellular membrane trafficking—including synaptic vesicle fusion—has developed from a general model known as the SNARE hypothesis [26]. In this model, the formation of parallel-aligned α-helices between vesicle SNAREs and target-membrane SNAREs results in the formation of a remarkably stable SNARE complex [27]. In the case of synaptic vesicle fusion, the synaptic vesicle protein synaptobrevin serves as the vesicle SNARE, whereas SNAP-25 (synaptosomal-associated protein of 25 kDa) and syntaxin on the presynaptic plasma membrane serve as the target-membrane SNAREs. These three

SNARE proteins assemble into a heterotrimeric SNARE complex (or core complex). The crystal structure of the core complex revealed a bundle of four $\alpha$-helices, one each contributed by synaptobrevin and syntaxin and two contributed by SNAP-25 (38). The process of SNARE complex assembly proceeds from N-terminal to C-terminal direction in what is commonly referred to as a “zippering” action, which brings the C-terminal membrane anchors of the transSNAREs together (29). This action is proposed to force the closely apposed membranes together to initiate fusion. The transition from unstructured monomeric SNAREs to the assembled SNARE complex likely proceeds by multiple sequential steps rather than at once, and zippering can only occur when all SNAREs are aligned in parallel. One model proposes that initially an acceptor complex forms between SNAP-25 and syntaxin on the plasma membrane (30–32). Only then would the acceptor complex interact with the vesicular SNARE synaptobrevin, aligning the N-terminal ends in parallel, first in a loose conformation, and then undergoing N-terminal to C-terminal zippering. The partially zipped SNARE complex is arrested in a partial fusion or prefusion state and awaits the influx of calcium to activate the neuronal calcium sensor and stimulate the completion of the fusion reaction. These processes are summarized in Fig 2. One important open question is how SNARE zippering might become arrested before completion. Recent evidence supports a role for complexins at this step. Complexins are enriched in the presynaptic compartment, are crucial for highly synchronous evoked neurotransmitter release, and exhibit direct binding to the SNARE complex (33, 34). Although much evidence on complexin function is conflicting or controversial, most available evidence is consistent with a model in which complexins help to stabilize the partially zipped SNARE complex by direct binding but prevent full SNARE assembly and/or completion of fusion before the arrival of the calcium trigger (34–37). However, complexins do not merely function as inhibitory fusion clamps; it has been demonstrated that complexins are capable of both inhibitory and facilitating functions and thus are well suited to impart exquisite control to the final stages of calcium-dependent neurotransmitter release (34).

Although little doubt remains that the formation of the SNARE complex is the critical step in synaptic vesicle priming, several other proteins have been implicated as important regulators of the priming reactions. Two prominent examples are Munc18 and Munc13; these crucial proteins apparently function in both synaptic vesicle docking and priming. The available evidence is largely compatible with an essential role for both Munc18 and Munc13 in facilitating priming by regulating the proper assembly of the SNARE complex, which may be accomplished by the stabilization of the putative SNAP-25-syntaxin acceptor complex mentioned previously. It is unclear whether there is convergence exists between Munc18 and Munc13 in their respective modes of action in this context. To add another layer of complexity, Munc13 also has been shown to antagonize the action of a soluble protein called Tomosyn (38). Tomosyn contains a C-terminal SNARE motif through which it can form a tight complex with SNAP-25 and syntaxin and effectively deter the formation of the prototypical neuronal SNARE complex (39). Thus, Tomosyn serves as a negative regulator of vesicle fusion. Munc13 either prevents the formation of the Tomosyn-containing SNARE complexes or disrupts Tomosyn-containing SNARE complexes to liberate SNAP-25/syntaxin heterodimers, which then would become available to bind to synaptotubulin on the synaptic vesicle. Either model is again consistent with a positive regulatory role...
for Munc 13 in synaptic vesicle priming. Other putative regulators of synaptic vesicle priming include RIM, Rab3, and SV2, although the exact mechanisms for how these proteins regulate priming are much less defined at this time.

**Triggering of the synaptic vesicle fusion reaction**

Once synaptic vesicle docking and priming is completed, the final triggering of vesicle fusion with the presynaptic terminal membrane occurs rapidly in response to action potential invasion of the terminal. This step is highly dependent on calcium ions, which enter the terminal through voltage-gated calcium channels (40–42). The idea that calcium entry into the terminal is a key step in the neurotransmitter release process formed the basis of what is known as the “calcium hypothesis” (43). Although the identity of the molecular calcium sensor for neurotransmission was not known at the introduction of the calcium hypothesis 40 years ago, it is now widely accepted that the calcium-dependent triggering of synaptic vesicle fusion is imparted by the synaptic vesicle protein synaptotagmin (44–46).

The work of Dodge and Rahamimoff (47) initially detailed the quantitative dependence of neurotransmitter release on external calcium concentration at the neuromuscular junction. The relationship was reported to be highly nonlinear with an approximately fourth-order cooperativity. Remarkably, these findings are in near perfect agreement with a more modern study of the relationship between neurotransmitter release and intracellular calcium concentration at a central nervous system synapse (48). Although the basis for the cooperativity of release is not yet clear, multiple calcium coordination sites exist with the tandem C2 domains of synaptotagmin, which suggests that this cooperativity of release may originate with the intrinsic calcium-binding ability of the synaptotagmin protein itself. This suggestion is supported by studies that show that mutations in the synaptotagmin C2 domains alter the apparent degree of cooperativity (45, 49).

How does synaptotagmin trigger synaptic vesicle fusion in response to calcium influx and binding? Synaptotagmin engages in calcium-stimulated binding of both SNARE complexes and membrane phospholipids (50–52). Although still debated, available evidence supports a model of synaptotagmin action in which calcium binding to the C2 domains causes membrane penetration and induction of positive membrane curvature. This buckling of the active zone membrane locally reduces the energy barrier for fusion, which allows the fusion process to proceed to completion (53). A direct interaction of synaptotagmin to the SNARE complex is important in this model (calcium-dependent and/or-independent) to ensure that the local membrane buckling is targeted appropriately to the membrane beneath the vesicle; thus, the SNARE binding and phospholipid penetration activities of synaptotagmin likely work in concert to liberate neurotransmitter (52–55).

Vesicle fusion and neurotransmitter release in response to action potentials is termed evoked release (the main focus of this article); however, it is important to note that action potentials are not absolutely required for liberation of neurotransmitter. Spontaneous release events (also referred to as spontaneous miniature events or “minis” for short) occur in the absence of an overt stimulus (56–58). Evoked and spontaneous synaptic vesicle fusion likely share many commonalities, including the involvement of the same neuronal SNARE complex. However, perturbations to SNAREs can differentially affect evoked and spontaneous events, which suggests that the fusion reactions mediating evoked and spontaneous release events might differ to some extent (56–58).

**Regulation of neurotransmitter release via modulation of the fusion pore**

Although the molecular components of the neuronal fusion pore remain largely unknown, modulation of the fusion pore has been proposed as a mechanism for regulating release of neurotransmitter. Specifically, two modes of release can be summarized: 1) a classic full-fusion model in which the fusion pore completely dilates and the vesicle fully collapses into the plasma membrane of the active zone (59), which thereby releases a vesicle’s full complement of neurotransmitter, and 2) a kiss-and-run model in which a narrow fusion pore is stabilized transiently but then closed rapidly (60). In the kiss-and-run model, the presence of a narrow fusion pore is hypothesized to restrict neurotransmitter efflux, and it thereby might reduce quantal size (62). The prevalence of kiss-and-run-type fusion events has been debated intensely; particularly, the prevalence of these events in central nervous system neurons (which we focus on here) has been debated, with some studies of hippocampal neurons estimating greater than 80% of all fusion events being of this type at low firing frequencies (62) and others reporting negligible kiss-and-run in the same preparation (63). The most recent and direct study to date reported only a 3% rate of occurrence for kiss-and-run at the specialized Calyx of Held synapse (64). Thus, although its frequency is widely debated, it is generally accepted that a nonclassic mode of fusion that is reasonably well described by the kiss-and-run model does in fact exist.

Does kiss-and-run-type fusion influence neurotransmitter release at central nervous system synapses? This topic is a current topic of research that is yet to be resolved; even the existence of kiss-and-run exocytosis in the central nervous system is still controversial. It is worth noting that most current methods for detecting alterations to fusion pore size and/or conductance at central nervous system synapses have been unable to provide simultaneous direct measurements of neurotransmitter release. Thus, a marked absence of evidence exists to support the idea that fusion pore modulation can modulate the amount of neurotransmitter released during vesicle fusion. Of those that have achieved the technical feat of measuring neurotransmitter release during kiss-and-run-type fusion events, one study using a nonphysiological manipulation found no evidence for modulation of quantal size at glutamatergic central nervous system synapses (65), and another study detected, in a subset of release events, a predominant flickering fusion pore mechanism in which each flicker released only 25–30% of the total neurotransmitter contained within a vesicle at dopaminergic central nervous system synapses (66). It is likely that much of the controversy surrounding kiss-and-run can be resolved through...
advancements in technical approaches for measuring neurotransmitter release.

Methods for Quantification of Neurotransmitter Release

To quantitate neurotransmitter release, we ideally would use approaches that can make noninvasive, selective, analytical measurements in situ with millisecond temporal resolution and micron or better spatial resolution. Each of these criteria has been fulfilled by one or more currently available methodologies. However, to date, no single technique is universally suited to all contexts of neurotransmitter-release quantification. Thus, compromises are made in the criteria that are less important to maximize the criteria that are most important to the biological question at hand. In choosing a technique, perhaps the first question is, what type of biological preparation is most appropriate for the study? Advantages of in vitro preparations make these preparations better suited for some lines of work, but advantages of in vivo preparations are better for others. Importantly, some techniques are better suited for some biological preparations than others. Table 2 lists the preparations in which each of the techniques discussed below have been most commonly employed.

- **Radiolabeled neurotransmitters**
  One approach that has been used quite widely to quantitate neurotransmitter release employs radiolabeled (tritiated) neurotransmitter analogs (e.g., Reference 67). First, tissue is incubated in a buffer solution that contains tritiated neurotransmitter. During this time, the radiolabeled transmitter is taken up into cells by endogenous plasma-membrane transporters and packaged into vesicles by vesicular transporters. The tissue preparation then is rinsed in buffer to remove extracellular radiolabeled transmitter leaving only that which was taken up into cells. This stored transmitter is then released over time by exocytosis. To quantitate its release, the tissue is continuously perfused with buffer, and time-dependent aliquots are collected. Radioactivity is measured in the aliquots with a scintillation counter and is used as an index of endogenous neurotransmitter release. Rather than estimate absolute neurotransmitter release, this method is typically used to compare the relative release between two or more conditions.

- **Electrophysiological methods**
  Electrophysiological techniques have high temporal (millisecond) and spatial (micron) resolution. They are carried out at discrete electrodes and so obtain information from a single spatial location or from a finite number of locations if a multiple-electrode system is used. These recording techniques...
use fairly standard electrophysiology recording resources and capabilities to measure neurotransmitter release, and so they are widely used.

Postsynaptic electrophysiological recordings detect the neurophysiological response of a target cell following release of neurotransmitter and represent the least deviation from a standard electrophysiological recording experiment. These recordings are usually carried out at a patch-clamp electrode using a voltage clamp to measure postsynaptic currents (68), but the current clamp can be used if measurement of postsynaptic potentials is preferred. Selectivity of the responses for the neurotransmitter of interest can be achieved with appropriate pharmacological isolation by using a cocktail of antagonists for other neurotransmitters and/or with electrophysiological isolation (by manipulating the holding potential). Postsynaptic signals can be detected for both spontaneous and evoked neurotransmitter release events. The frequency of spontaneous postsynaptic events is often used as an index of neurotransmitter release. Information can also be obtained from the amplitude of postsynaptic responses; however, this metric encompasses both changes in neurotransmitter release (presynaptic effects) and changes in synaptic strength (postsynaptic effects). Presynaptic effects are usually inferred from experiments where postsynaptic responses are evoked by paired pulses of extracellular electrical stimulation separated by tens of milliseconds. The paired-pulse ratio (PPR), that is the amplitude of the response to the second pulse divided by that of the first, is believed to be a reflection of release probability, with low PPR signifying high release probability (argued to be because of depletion of readily releasable vesicles on the first pulse; see Reference 5). Thus, changes in PPR are taken to indicate changes in the amount of neurotransmitter release that can be evoked by an electrical impulse.

During neurotransmitter release events from a cell, the surface area of its plasma membrane changes; it increases during fusion and decreases during subsequent exocytosis. Because the plasma membrane acts as an electrical capacitor, these dynamics can be detected as changes in the total membrane capacitance. Thus, membrane capacitance measurements with whole-cell or cell-attached patch clamp can be used to quantitate exocytosis (69). Using voltage clamp, a sine wave command signal is applied, and the current is measured with a lock-in amplifier to derive the instantaneous capacitance. With these recordings, individual exocytotic events can be detected. In cell-attached preparations, conductance of fusion pores that form within the patch can be measured simultaneously.

The electrophysiological biosensor or “sniffer patch” (70) uses an outside-out patch excised from a donor cell, which has high-density expression of ionotropic receptors for the neurotransmitter of interest. Ideal donor cells are those in which the receptor has been stably overexpressed and low expression of other potential interfering receptors is detected. The electrode, incorporating the patch, is placed close to a putative release site, and channel conductance within the patch is measured in voltage-clamp mode. The neurotransmitter detection range of this technique is quite narrow, around the EC50 of the receptor, but it can be broadened somewhat by increasing the density of receptor expression in the patch. Nonetheless, the detection limit is, by definition, in the physiological range.

The sensor response is nonlinear with analyte concentration, but it can give quantitative information with appropriate calibration.

Electrochemical methods

Electrochemical detection involves the induction of a change in redox state (electrolysis) by application of an electrical potential to an electrode (71). Compounds that can be readily detected by this means are termed electroactive. Under physiological conditions, these compounds tend to be in their reduced state in the nervous system because of the rich level of antioxidants (e.g., ascorbic acid) and, thus, can be oxidized by application of a positive potential to the electrode. The evolved electrons are detected at the electrode in the form of electrical current. This current is proportional to the number of electroactive molecules at the surface of the electrode, and therefore it is proportional to their concentration in the bulk solution. By implanting an electrode in the extracellular space close to the release site and detecting changes in the local (extracellular) concentration of the neurotransmitter, neurotransmitter release can be monitored. The key advantage of this approach is the high temporal resolution that can be in the millisecond domain. Neurotransmitters that can be detected this way include dopamine, norepinephrine, epinephrine, serotonin, and melatonin.

Several variants of this technology differ by the voltage command waveform applied to the electrode to induce electrolysis. The simplest waveform is a constant direct-current potential. This form is known as constant-potential amperometry. This technique yields a constant readout of neurotransmitter fluctuations in real time and provides the fastest available chemical monitoring. For example, using constant-potential amperometry, data has been acquired in the high microsecond range that is sufficient to resolve release during multiple partial fusion events (flickering) (66). However, the disadvantage of this type of electrochemical detection is that it lacks chemical selectivity. Thus, its use is limited to environments where the identity of the analyte is predictable (see Reference 71).

Another commonly used waveform is a square wave where the electrode is held at a nonoxidizing potential and transiently pulsed to an oxidizing potential. An example of this form is high-speed chronopotentiometry, which uses oxidizing pulses that typically last for around 100 ms and are repeated each second. This method provides information (current) both on the oxidation of compounds at the surface of the electrode and on the reduction of the oxidized material. This additional information that is obtained during each measurement aids in the identification of the analyte.

To improve chemical selectivity, a triangular input waveform can be used that separates compounds into resolvable peaks. This form—cyclic voltammetry—can be carried out with high temporal resolution using high scan rates to allow the waveform to be completed in a short time. In fast-scan cyclic voltammetry (also known as fast cyclic voltammetry), waveforms last around 10 ms, and measurements are typically made every 10–200 ms. The newest generation of electrochemical-based biological detection devices is the biosensors. These devices combine the high spatial and temporal resolution of an electrochemical microsensor with a biologically selective recognition element.
current devices, this element is most often an enzyme that is selective for the neurotransmitter of interest. The enzyme exists in a polymer layer that is embedded on an electrochemical probe. When the analyte binds to the enzyme, a chemical coreaction is initiated that generates an electroactive reporter molecule. The reporter molecule is detected by the electrochemical probe using constant-potential amperometry and thus transduces the biological signal to an electrochemical signal. This approach has three main advantages over other electrochemical sensors. First, the range of possible analytes is not limited to those that are electroactive. In fact, it is advantageous for the analyte not to be electroactive so that its direct detection at the electrochemical sensor does not interfere with detection of the reporter molecule. Second, the selectivity of the probe is conferred by a recognition element that can be highly specific. Third, this technology lends itself to upgradeability; new recognition elements can be incorporated into probes as they are developed.

Optical methods

Optical methods offer the benefit of extremely high spatial resolution, in the nanometer range. Moreover, unlike electrode-based techniques (e.g., electrophysiological and electrochemical methods), these measurements can be made over a wide area; that is, rather than obtaining a single time-dependent measurement, multiple parallel processes can be monitored simultaneously at discrete spatial loci (e.g., Reference 72). Currently, optical methods for quantification of neurotransmitter release are not widely used in vivo because of insufficient deep-brain optical access. However, a rapidly growing movement is working to develop these tools for use in systems neuroscience (e.g., using techniques that can penetrate deep enough to measure from superficial cortical layers or fiber optics to access deeper regions). Fluorescent styryl dyes such as FM 1-43 have been used to approximate neurotransmitter release by measuring rates of exocytosis (16, 72, 73). These dyes reversibly label endosomal membranes and can be taken up into intracellular synaptic vesicles during endocytosis in systems in which vesicle recycling is not used, if desired.

Exocytosis. The primary advantage is that this methodology is not constrained to a single analytical tool, and detection schemes can be tailored to the needs of the particular experiment and to measure multiple analytes simultaneously. In fact, any tools of analytical chemistry can be used, including those that cannot easily be miniaturized into an in situ device, for example, gas chromatography or mass spectroscopy. Sampled material is often analyzed offline, but online analysis can be achieved by coupling a detector to the sampling-device outlet if desired.
Microdialysis sampling (78) is conducted using a probe that has an inlet and outlet tube (joined via a semipermeable membrane often a concentric design with the inlet inside the outlet tube). The probe has a molecular weight cutoff high enough that it is permeable to small-molecule and peptide neurotransmitters. Buffer (usually artificial cerebrospinal fluid) is perfused through the inlet tube past the membrane. When the probe is implanted in the brain, neurotransmitters in the extracellular space diffuse across the membrane into the probe down their concentration gradient. An equilibrium between the extracellular and intraprobe neurotransmitter concentration is accomplished, which is dependent on the flow rate, membrane size, and other factors. The ratio between the analytic concentration inside the probe and that on the outside at equilibrium is the relative recovery. Under most experimental conditions, the relative recovery is below 100%, and thus the neurotransmitter concentration in the dialysate is an underestimate of the absolute extracellular concentration. To better measure the absolute basal transmitter level, the no net flux method can be used in which the analytic of interest is perfused through the probe at different concentrations. When the analytic concentration is higher in the inlet than outside the probe, a net flux moves into the probe, and the concentration will be lower in the outlet than the inlet. Conversely, when the analytic concentration is lower in the inlet than outside the probe, a net flux moves into the probe (and the concentration will be higher in the outlet than the inlet). Therefore, the point of no net flux (which can be interpolated if not measured directly) represents the condition in which the inlet concentration matches the concentration of the analytic outside the probe.

Another means of sampling is push-pull perfusion (79) using a probe with an inlet and outlet tube. With this method, a small amount of cerebrospinal fluid is pulled directly from the brain through the outlet tube and replaced with artificial cerebrospinal fluid. This approach has greater spatial resolution than microdialysis; and because cerebrospinal fluid is collected directly, no concern develops that account for spin–lattice relaxation (T1) and spin–spin relaxation (T2) and depend on tissue molecular interactions. Spin–lattice relaxation is the relaxation of the proton spin axis in the longitudinal axis of the magnetic field (z-axis), and spin–spin relaxation is in the transverse (xy) plane. With the appropriate pulse sequence, a blood–oxygen-level-dependent (BOLD) signal, the hemodynamic response, can be extracted from the T2 signal and is used to infer regional brain activity. These types of measurements are typically made during sensory stimulation, in behavioral or cognitive tasks (functional MRI; fMRI) or after administration of pharmacological agents (pharmacologic MRI; phMRI).

One of the largest drawbacks of these techniques is the time it takes to collect sufficient material for an analytic sample. Typically, this time has been on the order of tens of minutes, and thus these techniques are best suited for measuring steady-state levels of neurotransmitter and slow signal changes. However, in recent years, the temporal resolution has been improved significantly to the level of seconds by using capillary and microfluidic devices for sample collection combined with online separation and detection (79, 80).

**Neuroimaging**

Neuroimaging is the least invasive means to measure neurotransmitter release and can be used in living animals or humans without surgical procedures. These techniques permit monitoring over a large area (e.g., the whole brain) in three dimensions with millimeter spatial resolution and temporal resolution in seconds to minutes (81).

Positron emission tomography (PET) detects and spatially localizes radioactive sources, and it can be used to quantitate neurotransmitter release by measuring displacement of radioiodinated ligands (usually antagonists) from neurotransmitter receptors. The radioligand is administered systemically and is sequestered in tissue by selective binding to its receptor. On radioactive decay, a positron is emitted that collides with an electron (annihilation) and produces two photons (gamma rays) that travel in opposite directions. The scanner has a ring of gamma detectors that senses the arrival time of the photons. From the position in the ring and the difference in time of flight between the photons, the location of the annihilation within the plane of the ring can be calculated. The third dimension can be reconstructed by conducting serial measurements in adjacent “slices.” Thus, PET provides a spatial map of the radioligand throughout the brain, which can be updated every few minutes. When an increase in endogenous neurotransmitter release occurs, the radioligand is displaced from receptors, and the tissue radioactivity level is reduced. Note that because this method relies on competitive displacement of a receptor-bound radioligand, increases but not decreases in endogenous neurotransmitter levels (i.e., increases but not decreases in the rate of ongoing neurotransmitter release) can be detected.

Magnetic resonance imaging (MRI) is included here because it is the least invasive method for gathering information about neurotransmission in living humans. However, it should be noted that the inferences about neurotransmitter release are extremely indirect. This technique is used to measure, on a timescale of seconds, local hemodynamic changes that are assumed to correlate with neurotransmission. The experiment is carried out in a high-field magnetic field (≥1 tesla). Excitation by radio-frequency pulses alters the spin axis of hydrogen nuclei (protons; including those in water), which can be measured as changes in the field strength. The dynamics of relaxation of the proton spin axis back to equilibrium is that account for spin–lattice relaxation (T1) and spin–spin relaxation (T2) and depend on tissue molecular interactions. Spin–lattice relaxation is the relaxation of the proton spin axis in the longitudinal axis of the magnetic field (z-axis), and spin–spin relaxation is in the transverse (xy) plane. With the appropriate pulse sequence, a blood–oxygen-level-dependent (BOLD) signal, the hemodynamic response, can be extracted from the T2 signal and is used to infer regional brain activity. These types of measurements are typically made during sensory stimulation, in behavioral or cognitive tasks (functional MRI; fMRI) or after administration of pharmacological agents (pharmacologic MRI; phMRI).

Iron-Sulfur World, Origin of life in an
Günter Wächtershäuser, Chapel Hill, North Carolina
doi: 10.1002/9780470048672.wecb264

The theory of a chemo-autotrophic origin of life in an Iron-Sulfur World postulates quenched, aqueous flows of volcanic exhalations as sites for the emergence of the pioneer organism of life, which are characterized by a composite structure with an inorganic substructure and an organic superstructure. Iron, nickel, and other transition metal centers in the substructure are catalytic for the reductive formation of low-molecular-weight organic compounds by carbon fixation from volcanically derived carbonyl, cyanide, sulfido, aminido, and other ligands. Some organic products become transition metal ligands in statu nascendi with the effect of ligand-accelerated autocatalysis as a chemical basis of pioneer reproduction, inheritance, and evolution. This unitary structure-function relationship of the pioneer organism constitutes the "Anlage" for two major parallel strands of evolution, genetization, and cellularization, and the "mystery" of an increase of complexity throughout evolution is simply caused by the primal synthetic drive of the autotrophic pioneer organism that may well be persisting to this day.

Conventional theories on the origin of life are characterized by a conjunction of several deep-seated misconceptions. Since the time of Nägeli (1), the oldest and most persistent misconception is based on the fact that the bulk material of all extant organisms consists of polymers. It is, therefore, assumed widely that the first organisms of life were engaged already in the polycodensation of monomers to autocatalytic nucleic acids ("RNA World") or to autocatalytic sets of polypeptides ("Protein World"). The origin of the monomers is relegated typically to an obscure chemical evolution in a "prebiotic broth" over thousands or millions of years. This view has been criticized severely, notably by Shapiro (see Further Reading). It suffers from a stark paradox. Liquid water is postulated as the medium of polycodensation; yet it is precisely this medium that tends to counteract polycodensation or polycodensation agents because of the hydrolytic mass effect of liquid water, notably under hot, non-neutral conditions. In the last 20 years, a new approach has been developed (2–5), which aims to avoid these pitfalls. The new theory is based not on a polymer metabolism with catalytic polymers, polycodensation, and replication, but rather on a small-molecule metabolism with catalytic transition metal precipitates and autocatalytic carbon fixation, which gives rise to small organic ligands. It is not restricted to main group chemistry, but it is critically dependent on transition metal coordination structures, organo-metal chemistry, and redox reactions, for which liquid water is a benefit rather than a detriment. In view of the dominance of iron among transition metals and the ubiquity of sulphur, the term "Iron-Sulfur World" has been coined for the setting of the origin of life (3), which is viewed not as a protracted affair of prebiotic chemistry but as a nearly instantaneous induction of an autocatalytic "pioneer organism." The new theory is recognized in the field as one of the "two main theories on the origin of life" and as having generated a conflict over "hot, volcanic origin" versus "cold, oceanic origin" (6).

General Organization and Operation of the Pioneer Organism

The new theory places the pioneer organism in a locally and temporally coherent volcanic flow setting. Therefore, all its assumptions must be compatible with each other. Such a comprehensive theory cannot be conceived in one stroke. It has to evolve. Indeed, the theory presented here has been evolving over the past 20 years, its progress guided by chemical experiments and by the increase of its relative explanatory power (Popper). The partial aspects of the theory as it now stands shall be addressed one at a time in a manner that makes their coherence within the theory apparent.
Structural organization of the pioneer organism

An origin of life by autocatalytic carbon fixation requires a sufficient degree of localization and physical/compositional coherence for preventing decay of the chemical potentials by diffusion and dilution, while permitting access of the volcanic nutrients. These requirements are satisfied by a minimal structural organization that consists of an inorganic substructure of crustal origin and an organic superstructure of volcanic gas origin. Catalytic transition metal centers (e.g., Fe, Co, Ni, Cu, Mn, Mo, W, and V) in the inorganic substructure are exposed to volcanic gas nutrients (CO, HCN, CH₃SH), which are quenched in the liquid water phase and bonded as ligands to the transition metal centers. The chemical potential of these inorganic ligands in conjunction with the catalytic properties of the transition metal centers leads to synthetic reaction cascades that generate low-molecular-weight organic compounds, which are functionalized sufficiently for bonding in situ as ligands to the transition metal centers (2). Thereby they become constituents of the organic superstructure attached to the transition metal centers in outer or inner surfaces of the inorganic substructure. The organic superstructure and the proximal regions of the inorganic substructure define the “pioneer organism.”

The organic superstructure constitutes a dynamic ligand sphere. Its constituents may undergo lateral transfer along the surfaces. At any given time the composition of the superstructure is a steady state between the rate of formation of organic constituents by carbon fixation and the rate of loss of organic constituents by detachment and diffusion into the vast expanses of the ocean (2).

The inorganic substructure should also be viewed as being dynamic. According to Ostwald’s rule of steps, it will change its constitution mainly by conversions of the structure-forming bridging ligands. It may begin as an extended polynuclear, poly-modal, heteroleptic, and hydrated complex or as amorphous, bridging ligands. It may begin as an extended polynuclear, poly-modal, heteroleptic, and hydrated complex or as amorphous, hydrated hydroxide minerals or hydrogels (e.g., [Fe₃N][OH]₄), which subsequently stabilize by crystallization. The additional development depends on the relative rates of introduction of polymerizing bidentate ligands (cyanidation, dehydrogenation, or sulfidation) versus depolymerizing ligands (carboxylation or ammoniation). Under conditions of high-sulfide activity, the substructure will convert to sulfides, which are at first amorphous or poorly crystalline, and finally to pyrites.

Inorganic starting conditions of the pioneer organism

The discovery that liquid water may well have existed on Earth 4.4 billion years ago has made room for the possibility that life originated deep in the Hadean, i.e., at a time when magma and crust of the Earth were much hotter than today and much more reducing. As a consequence, the water gas equilibrium of the volcanic gases

$$CO + H_2O \rightleftharpoons CO_2 + H_2 \quad (1)$$

favors a high concentration of CO at the magmatic source. For example, under conditions of saturation with graphite, the molar ratio of CO/CO_2 is about 1:1 at 1200 °C and 2 kbar or at 900 °C and 0.1 kbar. If the rate of quenching along the flow path (by cold water or ice) is fast compared with the rate of equilibration, a significant disequilibrium concentration (chemical potential) of CO is the result (5). Quenched volcanic gases also contain H_2, which increases in concentration by water gas equilibration (2), as well as the sulfur compounds H_2S, CH₃SH, and COS; the nitrogen compounds NH_3, HCN, and HCN (5), and the volatile phosphorus compound P_2O_5 (7).

The formation of low-molecular-weight organic compounds by carbon fixation from volcanic nutrients involves primarily electron transfer (redox) reactions. Redox reactions are the most common reactions, catalyzed by metals that can have different oxidation states, with the catalytic activity of a transition metal center dependent on the nature of the ligands bound to the metal center. It is well established that the catalytic activity of a transition metal center is dependent on its ligands and that organic ligands may increase the catalytic activity by a factor of up to 10^4. This ligand feedback is unpredictable theoretically and idiosyncratic (8). Therefore, it is suggested that certain products of the carbon fixation pathways may increase the catalytic activity of transition metal centers as ligands. This result may well be the simplest and earliest form of autocatalytic product feedback. Autocatalytic product feedback (ligand-accelerated autocatalysis) constitutes “metabolic reproduction,” which gives rise to growth and inheritance by lateral spreading.

In broad terms, the proposed origin of life by autocatalytic ligand feedback is characterized by an extreme paucity of chemical possibilities because the starting materials are inorganic and the organic products have a low molecular weight. At the same time, the chemistry is highly selective because of the chemical energy in combination with specific transition metal catalysis. As a consequence, only one possibility may exist for a chemo-autotrophic origin of life.

Flow setting of the pioneer organism

Precious little geological evidence exists concerning the geochemical conditions of the Hadean Earth. Cockell (see Further Reading) has proposed that heavy bombardment caused impact cratering, rock fracturing, and deposition of debris creating a bed with myriads of diverse flow ducts for volcanic, hydrothermal fluids. Such a flow bed would undergo several characteristic transformations. The primal crust beneath the Hadean ocean may well have consisted of ultramafic rocks (e.g., komatiite), with
Ni(OH)₂ generates Ni-hydrogenase: source, which is correlated with the activity of extant Fe, Ni(CN)₂ having a layered crystal structure (9), and organic slowest travelers.

Differential ligand bonding strength would exhibit differential re-

The alkaline (Mg, Ca)(OH)₂ buffers the pH. After exhaustion of the buffer capacity by reaction with CO₂ and with the acidic products of carbon fixation, the flow ducts undergo a pH development from alkaline toward neutral (pH zoning). (Fe, Ni)(OH)₂ undergoes cyanidation, carbonylation, sulfidization, and pyritization. Specifically, cyanidation of Ni(OH)₂ generates Ni(CN)₂, having a layered crystal structure (9), and organic compounds may become trapped in the interspaces between the Ni(CN)₂ layers to form clathrates.

As a consequence of the notions of surface catalysis and volcanic flow (2), the flow ducts would operate like a chromatographic reactor with interacting reactive and chromatographic processes. Organic constituents of the superstructure with differential ligand bonding strength would exhibit differential retention or residence times, with the best surface bonders being slowest travelers.

**Toward the (Bio)Chemistry of the Pioneer Organism**

We now turn to the (bio)chemistry of the pioneer organism and begin with reactions that provide reducing power and nutrients for the pioneer metabolism. The (bio)chemistry of the pioneer organism is testable experimentally with the aim of correlating extant metal/o-enzymes with inorganic transition metal catalysts and with the ultimate goal of establishing a reproducing and evolving pioneer organism.

**Sources of reducing power for the pioneer organism**

CO is a source for reducing equivalents by reaction with H₂O but also with H₂S:

\[
\begin{align*}
(Mg, Ca)\text{SiO}_4 + H_2O &\rightarrow (Mg, Ca)(OH)_2 + (Mg, Ca)\text{SiO}_3 \\
(Fe, Ni)\text{SiO}_4 + H_2O &\rightarrow (Fe, Ni)(OH)_2 + (Mg, Ca)\text{SiO}_3
\end{align*}
\]

Inorganic nutrient interconversions in the surfaces of the inorganic substructure

Ammonia formation by nitrogen fixation under moderate temperature and pressure has been demonstrated unequivocally with ¹⁵N₂ in conjunction with reaction (7) as an electron source (10). It has been suggested as a precursor of extant nitrogenase activity:

\[
N_2 + 3 FeS + 3 H_2 \rightarrow 3 FeS_2 + 2 NH_3
\]

Hydrogen cyanide (HCN), the nitrogen analog of CO, forms by catalytic conversion of CO with NH₃:

\[
CO + NH_3 \rightarrow HCN + H_2O
\]

and it may be trapped as ligand by transition metals under conditions of moderate temperature and pressure (5). In the presence of catalytic NiS or FeS, COS, produced by reaction (5) (11), or from CO₂ by equilibration with H₂S (12), respectively, is reduced via Ni-CH₃ to methanethiol, which also becomes a ligand:

\[
COS + 6H^+ + 6(e^-) \rightarrow CH_3SH + H_2O
\]

α-Hydroxy acids and α-amino acids

Amino acids are among the most important products of extant intermediary metabolism. Therefore, it is of importance that volcanic conditions have been found to generate a suite of α-amino acids and a corresponding suite of α-hydroxy acids at 1 bar CO and around 100°C with (Mg, Ca)(OH)₂ as pH buffer and with an Ni-precipitate with CN-ligands. The CN-ligands serve as C-source and N-source. CO serves as reducing agent. The products satisfy the formula R–CHA–COOH, whereby A

...

The above experimental results suggest that among the most prominent pioneer amino acids of life were glycine \((R=H)\), alanine \((R=CH_3)\), serine \((R=HO-CH_2)\), and valine \((R=CH_2-CH)\). Moreover, the facile formation of serine suggests that cysteine originated early on by sulfidization of serine.

\(\alpha\)-keto acids and \(\alpha\)-imino acids

In the above reactions under modest conditions, traces of pyruvate have been found (13), which indicates that \(\alpha\)-keto or \(\alpha\)-imino acids are intermediates in the pathways to \(\alpha\)-hydroxy or \(\alpha\)-amino acids. The reductive amination of \(\alpha\)-keto acids has been demonstrated experimentally under alkaline conditions with \(\text{FeS/H}_2\text{S}\) or \(\text{Fe(OH)}_2\) as catalyst and reducing agent (14). The formation of significant amounts of pyruvate from \(\text{CO}\) and \(\text{FeS/nonylmercaptan} \at 2000\text{ bar}\) has been reported (15). Remarkably, pyruvate is stable under these conditions and apparently not reduced to lactate.

Sugar alcohols and sugars

In the above reactions, significant amounts of ethylene glycol have been detected (13), which is the simplest sugar alcohol and may form by reduction of glycolaldehyde, the simplest sugar. It is well established that sugars and sugar alcohols are excellent ligands for transition metals, which suggests that we may trace the biosynthetic roots of nucleic acids down to the pioneer metabolism.

Acetyl-thioester

Experiments provide evidence that in the presence of \(\text{Ni(OH)}_2\), \(\text{FeNiS}\), \(\text{NiS}\), or \(\text{CoS}\), the volcanic reactants \(\text{CO}\) and \(\text{H}_2\text{S}\) (or \(\text{CO}\) and \(\text{CH}_3\text{SH}\)) are converted to activated forms of acetic acid \((\text{CH}_3\text{CO-Ni}, \text{CH}_3\text{CO-SNi}, \text{CH}_3\text{CO-SH}, \text{CH}_3\text{CO-S-CH}_3)\) as evolutionary precursor of acetyl-CoA (16):

\[
\begin{align*}
\text{CH}_3\text{Ni} + \text{CO} & \rightarrow \text{CH}_3\text{CO-Ni} \quad (13) \\
\text{CH}_3\text{CO-Ni} + \text{H}_2\text{S} & \rightarrow \text{CH}_3\text{CO-SNi} + (\text{H-Ni}) \quad (14) \\
\text{CH}_3\text{CO-Ni} + \text{CH}_3\text{SH} & \rightarrow \text{CH}_3\text{CO-S-CH}_3 + (\text{H-Ni}) \quad (15)
\end{align*}
\]

Activated amino acids and peptides

The condensation of \(\alpha\)-amino acids to peptides in dilute aqueous systems is endergonic and requires energy coupling. Under alkaline, volcanic conditions \(\text{CO}\) in the presence of \(\text{H}_2\text{S}\) (or \(\text{CH}_3\text{SH}\)) and \((\text{NiFeS})\) is an efficient energy source for the formation of peptides, notably \(\text{CO}\) and \(\text{CH}_3\text{SH}\). The latter operates as a short-lived coupling intermediate, and therefore, the hydrolysis problem associated with theories that require accumulation and/or transport of \(\text{CO}\) is obviated. Interestingly, the addition of \(\text{Na}_2\text{MgPO}_4\) to the system \((\text{FeNiS})/\text{CH}_3\text{SH}\) broadens the \(\text{pH}\)-range of efficient peptide synthesis (16), which indicates nucleophilic catalysis with a phosphorylated intermediate.

As a mechanism of peptide formation, it is suggested that a \(\text{CO}\)-derived activated intermediate \((\text{e.g., COS})\) is formed, which subsequently suffers a nucleophilic attack by the free amino group of an amino acid \((\text{aa})\) followed by ring closure to activate the carboxyl group of the amino acid in a five-membered cyclic intermediate, notably an amino acid \(N\)-carboxyanhydride \((\text{aa}*)\) (16):

\[
\begin{align*}
\text{CO} + \text{H}_2\text{N-CHR-CO-H} & \rightarrow \text{H}_2\text{O} + \text{H}_2\text{N-CHR-CO-NH-CHR-COOH} \\
\text{H}_2\text{N-CHR-CO-NH-CHR-COOH} & \rightarrow \text{CO}_2 + \text{H}_2\text{N-CHR-CO-H}
\end{align*}
\]

Subsequently the free amino group of another amino acid molecule \((\text{aa})\) reacts nucleophilically with the activated amino acid to generate a dipeptide \((\text{aa}-\text{aa})\):

\[
\begin{align*}
\text{R} - \text{H} & \rightarrow \text{R} - \text{H} + \text{H}_2\text{N-CHR-CO-H} \\
\text{H}_2\text{N-CHR-CO-H} & \rightarrow \text{R} - \text{H} + \text{H}_2\text{N-CHR-CO-NH-CHR-COOH}
\end{align*}
\]

Alternatively the free amino group of a peptide may react with the activated amino acid \((\text{aa}*)\), with the result that the peptide is extended by one amino acid unit at its N-terminal end. The reduct energy of \(\text{CO}\) is converted into group activation energy, which then drives the endergonic peptide synthesis pathway. The synthetic pathway is controlled kinetically, and it runs as long as the energy source lasts (16).

Peptide cycle

Surprisingly, it was found that peptide-forming conditions actually support a peptide cycle (18), whereby the peptides react with \(\text{CO}\) to acquire an N-terminal hydantoin ring, which hydrolyzes to an N-terminal urea group. Finally, the urea group is hydrolyzed. The net result is a removal of the N-terminal amino acid unit. The following scheme shows the simplest case of a dipeptide cycle for glycine \((\text{Gly})\) through activated glycine \((\text{Gly}*)\), glycyl-glycine \((\text{Gly-Gly})\), its hydantoin derivative \((\text{H-Gly})\), and its urea derivative \((\text{U-Gly})\):

\[
\begin{align*}
\text{R} - \text{H} & \rightarrow \text{R} - \text{H} + \text{H}_2\text{N-CHR-CO-H} \\
\text{H}_2\text{N-CHR-CO-H} & \rightarrow \text{R} - \text{H} + \text{H}_2\text{N-CHR-CO-NH-CHR-COOH}
\end{align*}
\]

Similar cycles pass through the tripeptide, tetrapeptide, and so on, which results in a concatenation of peptide cycles. The
segment of the cycle up to the urea derivative is anabolic. The hydrolysis of the urea group constitutes a catabolic segment. Because of this anabolic-catabolic character, the peptide cycle generates a dynamic library of peptides, their hydantoin derivatives, and their urea derivatives (“peptide library”). The members of the peptide library come and go, and all transient members of this library are candidates for transition metal ligands. With an increase of the number of amino acids, the peptide library increases exponentially, and so does the likelihood of autocatalytic feedback. It has been discovered that homochiral amino acids undergo slow racemization under the conditions of the peptide cycle, which may be attributed to the hydantoin stage. Racemic amino acids are actually an advantage from the point of view of ligand feedback, because racemic amino acids generate a greater variety of peptides than homochiral amino acids. Remarkably, the dynamic peptide library is also self-selecting because differential bonding of its members as ligands to transition metal centers causes differential stabilization against hydrolysis. It means a self-selection of stable metallo-peptide structures.

The peptide cycle is driven by energy coupling from the redox energy of CO to group activation. The peptide cycle as a whole may be viewed as a catalytic cycle for the conversion of CO to CO$_2$. It may therefore be viewed as a functional evolutionary precursor of extant carbon monoxide dehydrogenase. The Ni-catalyzed hydrolysis of the urea group is the functional evolutionary precursor of the extant Ni-enzyme urease. It is also related to the imidazol ring of the purine bases, which suggests a synthetic as well as an evolutionary precursor relationship.

In the course of evolution of the metabolism by peptide feedback, the system will sooner or later become homochiral because of symmetry breaking by autocatalytic feedback. At this level it has been shown that α-amino acids undergo a facile enantioselective conversion to thermostable β-p-sheets (19).

Energy metabolism of the pioneer organism

In extant metabolism, it is expedient to distinguish an “energy metabolism” that generates a pool of energetic products, like ATP, for energy coupling with endergonic reactions. The initial chemical energy of a volcanic setting is redox energy, and it is surprising that the pioneer metabolism is engaged from the start in various forms of energy conversion and energy coupling. A pool of redox energy originates, if the reducing equivalents of the oxidative half reactions (4) and (6)-(9) are transferred to the transition metal centers in the inorganic substructure, and subsequently, they may undergo lateral transfer through suitably spaced transition metal centers in the substructure. Such a redox pool would form the basis for redox-to-redox energy coupling between exergonic redox reactions and endergonic redox reactions, notably as the beginning of chemiosmotic energy coupling.

Turning finally to redox-to-condensation energy coupling, the simplest case is shown in reaction (8). COS in turn will be the substrate for various forms of condensation-to-condensation energy couplings. For example, C–C-bond formation by carboxylation with COS will generate thioamides (3). Similarly, carboxylation of α-amino acids by COS generate thioamides en route to aminocarbonyl N-carboxyhydrazides:

$$\text{H}_2\text{N}-\text{CHR}-\text{COOH} + \text{COS} \rightarrow \text{H}_5\text{S}-\text{NH}-\text{CHR}-\text{COOH} \quad (16)$$

Cascades of condensation-to-condensation energy coupling are among the hallmarks of extant metabolism. They proceed through compounds of decreasing hydrolytic energy and usually increasing reaction selectivity and constitute a form of chemical energy conservation. Arguably the most important forms of energy coupling and energy conservation involve phosphorylation energy. Volatile phosphoric anhydride P$_4$O$_{10}$ in volcanic exhalations reacts hydrolytically on contact with liquid water through a cascade of oligophosphates (7). Pyrophosphate and other oligophosphates may have provided the group activation for the formation of phosphorylated organic compounds in early evolution (20). It has been proposed by de Duve (see Further Reading) that primordial acetate phosphate originates by reaction of carbon dioxide with phosphate ions. According to the Iron-Sulfur World theory, phosphorylation energy may also result from a transfer of the redox energy of CO/H$_2$S in the presence of amino acids (5), which received its first support by phosphate catalysis of peptide formation (16). Subsequently, it was supported by the discovery of a formation of aminocarbonyl phosphate in reaction of phosphate with aminocarbonyl N-carboxyhydrazide (22):

$$R_2\text{N} + \text{H}_2\text{PO}_4^- \rightarrow \text{H}_2\text{N}-\text{CHR}-\text{COOH} + \text{PO}_4^{3-}$$

and by the discovery of a transfer of the condensation energy of COS to aminocarbonyl phosphate or aminocarbonyl adenylate and further to pyrophosphate (22). The above-reported chemical reactions proceed under conditions that are compatible with an origin of life under the locally and temporally coherent conditions of a volcanic flow system. Therefore, the discovered reactions may well be components of the metabolic system of the pioneer organism. As additional components come into experimental view, the theory is expected to evolve. So far we have addressed the notions of growth and reproduction as aspects of one unitary chemical system. We now show that this unitary system is also the physical basis for the earliest mechanism of evolution and that it constitutes in fact the evolutionary “Anlage” for the emergence of the cellular and genetic features of extant forms of life.
Evolution from the Vantage Point of the Pioneer Organism

In extant forms of life, we distinguish a (fast) process of development over the lifetime of an organism from a (slow) process of evolution over many generations of reproduction. Going back in time we see these two processes fuse into one unitary process, which constitutes at the same time growth by the accumulation of carbon fixation products, reproduction by positive ligand feedback of some products, inheritance by rapid multiplication and lateral spreading of ligands with positive feedback, and metabolic evolution by variation of the set of ligands and by pathway extension. We now treat metabolic evolution in greater detail.

Ligand evolution

Let us assume that a member of the set of products of the pioneer metabolism binds as a ligand to a catalytic metal center and thereby increases the catalytic activity for a rate-determining step in the pioneer metabolism, which in turn increases the steady-state activities of all products downstream from said rate-determining step. This process induces additional ligand feedback effects and so forth, whereby a cascade of ligand feedback effects comes into play. It has the important consequence that the pioneer metabolism is self-expanding because of an avalanche of ligand feedback effects.

Under chromatographic flow conditions, strong bonding ligands have a long retention time and travel slowly in flow direction. Therefore, the strongest ligands (and the best candidates for ligand feedback) tend to become concentrated in upstream flow zones. These ligand zones are areas of ligand feedback concentration and thus constitute the spatial precondition for a local metabolic evolution. This catalyst evolution by ligand feedback is the most basic mechanism of evolution and the source mechanism for the emergence of a mechanism of pathway evolution to which we turn next.

Metabolic self-expansion

The evolutionary increase of catalytic activities and the concomitant widening of the spectrum of catalytic abilities elicit ever more complex expansions of the metabolism. These expansions may be from terminal extension or lateral branching of preexistent pathways. They lead to new synthetic products of the metabolism, which increase the set of potential ligands for the catalysts. Therefore, the catalysts evolve from strictly inorganic catalytic transition metal centers with inorganic ligands to hybrid inorganic–organic catalyst centers with a combination of inorganic and organic ligands. Within the latter category of catalysts, metallo-peptides become more and more dominant. Finally, with the emergence of the genetic machinery, primitive noncoded metallo-peptides are replaced by coded metallo-peptides and ultimately by folded metallo-proteins.

So far we have considered an evolving pioneer metabolism based on the full complement of primordial inorganic constituents of volcanic flow localities. With the expansion of the metabolism, new pathways come into play, which are independent of one or the other inorganic compound. This process allows the descendents of the pioneer organism to venture into spaces that are devoid of such inorganic compounds. For example, the coexistence of amino acid synthesis from CN-ligands and from CO/NH2-ligands allows the gradual colonization of spaces devoid of cy-anide sources. Here the amino acid synthesis becomes restricted to CN-ligands as carbon source and indispensable CN-ligands (in hydrogenases) come to be biosynthesized. In subsequently conquered realms, the CO-ligands become replaced by carbon dioxide as carbon source and by FeS/H2S or H2 as reductant. In new chemical spaces, the catalysts that are dependent on unavailable or extremely depleted inorganic starting materials will be opportunistically lost. Therefore, newly conquered spaces turn from optional habitats into obligatory habitats and metabolic evolution leads by necessity to a biosphere with diverse variants in a diversity of habitats.

In the course of early evolution, the metabolism becomes more and more integrated and centralized, so much so that a chemical conversion of highly integrated constituents tends to weaken the metabolism. The more central the constituent, the more severe is this effect of metabolic decay by chemical conversions, which leads us to yet another strategy of metabolic evolution: the strategy of dual feedback.

Metabolic evolution by dual feedback

So far we have looked at early evolution from the point of view of ligand function for catalyst promotion. Now, we look at it from the point of view of ligand synthesis. Let us assume that a fluctuation in the chemical environment expands the metabolism by the synthesis of a new ligand with new positive feedback into the metabolism from a preexistent ligand. However, if the chemical environment returns to the original state, the new ligand will disappear again, unless it exhibits also a positive feedback into its own synthesis. More generally speaking, duality of feedback of new metabolic products (atrociously into the metabolism and egotistically into their own branch pathways) seems to be essential for metabolic evolution. Extant cellular organisms are replete with dual feedback catalysts. Ribosomes produce all proteins, including ribosomal proteins. Coenzymes catalyze many synthetic pathways, including coenzyme biosynthesis. Protein translocases transport many proteins, including translocase proteins. DNA codes for all genes, including DNA polymerase genes.

Autocatalytic metabolic cycles

According to a general rule of organic chemistry, reactions involving the smallest molecules are catalytically the most restrictive. This rule holds notably for the build-up of carbon skeletons with the arithmetic C1 + C1 = C2 (e.g., C2 = gly-cine or acetyl thio-ester). Therefore, it may not come as a surprise that in the course of metabolic evolution, these most "simple" carbon fixation reactions may fail by the wayside. Under these conditions, an autocatalytic carbon fixation metabolism can only be maintained by a "metabolic cycle," which multiplies the C2 unit autocatalytically in the absence of its de novo synthesis. A prominent example is the reductive citric acid cycle (C2 + C1 =
for a tremendous expansion of the spaces inhabitable by life.}

**Thermal evolution of life**

By a reasoning that goes back to Thomas Brock, evolution can proceed only thermally downward from extremely thermophilic organisms to mesophiles by opportunistic losses of individual thermal stabilities. Such a view of evolution is compatible with an origin of metallo-peptide-protein folding structures with extremely thermostable covalent transition metal-sulfur cross-links, many of which were later replaced opportunistically and irreversibly by the cooperation of a multitude of weak, noncovalent group interactions in concert with an increase of fidelity of the emergent genetic machinery (4, 5).

**Genetization and enzymatization**

According to the RNA World theory, life begins with RNA replication, but the replicated RNA has no function other than its replication. According to the Iron-Sulfur World theory, the early novelties in the pioneer metabolism develop with the catalyst-promoting function of transition metal ligands. Therefore, early on, sugars, nucleosides, and (oligo)nucleotides must have evolved as ligands. Later oligonucleotides folded and were associated by base pairing, which ushered in a new type of catalysis: base pair-assisted positioning of RNA-bonded amino acids for the formation of peptides. This catalysis was of immediate benefit because the function of peptides as ligands was preordained in the universal laws of physics and chemistry. Remarkably, up to the level of the origin of speciation, the iron-sulfur cluster was the only noncovalent group interaction between molecules that is chemically restricted, preordained pathway possibilities. It is this association of chemical necessity and genetic chance that preordained the universal laws of physics and chemistry.

**Cellularization**

The emergence of any multicomponent genetic machinery depends on the existence of compartments. It has been suggested that the chemo-autotrophic origin of life occurred in primordial compartments that were bounded by FeS-membranes. The proposal was based on experimental FeS-precipitations (22). However, the detected cell structures are likely an artifact of sample preparation by freeze-drying of an FeS-hydrogel. Freeze-drying usually produces a porous product, in which the rate of freezing determines the size of the ice crystals, which in turn determines the size of the pores (5, 6). Instead of such chemically unsupported FeS-cells, it is proposed that a cellularization of life occurred step by step with autoformaly generated lipids (2). The first lipids may have been long-chain ω-hydroxy and ω-amino acids (6) to be replaced later by products of Classen condensation of acetyl thioesters fatty and isoprenoid acids (4). The first lipid function must have been lipophilization of the substructure by lipid accumulation. This process had the effect of lowering the H₂O and H₃O⁺ activities near the surface, thereby disfavoring hydrolytic reactions and favoring all kinds of condensation reactions. Because lipid syntheses from acetyl thioesters are condensation reactions, surface lipophilization is seen as collectively autocatalytic. The accumulating lipid molecules will inevitably organize into mineral-supported bilayer membrane patches, which ultimately will coalesce into an extended membrane that covers the mineral surface or surrounds a mineral particle (2).

Semicellular structures, which are bounded partly by a mineral surface and partly by a lipid membrane, form automatically for energetic reasons, when a lipid membrane spans over a small cavity in the mineral surface. The volcanic nutrients can pass freely through the membrane, whereas detached organic constituents are retained under the membrane. Now multicomponent systems can emerge within the incipient cytosol underneath the membrane along with the step-by-step enzymatization of the metabolism. Finally, self-supporting membrane envelopes appear as a result of the wedgeshaped transition metal-sulfur-phospho-glycerol lipids. These lipids are chiral, but they must have appeared first as a racemate. The self-supporting lipid membrane formed the basis for chemiosmosis by harnessing all kinds of environmental redox energy. Ultimately, the lipid racemate underwent chiral symmetry breaking by giving rise to the divergence of the domain Bacteria with one lipid enantiomer and the domain Archaea with the other lipid enantiomer (5, 6). Remarkably, up to the level of the origin of speciation, decisive events in the early evolution of life seem to have been preordained in the universal laws of physics and chemistry.

**Concluding remarks**

From the vantage point of a chemo-autotrophic origin of life, the overall mechanism of evolution is seen as a composite affair. It comprises a primal, direct, chemically deterministic, directional mechanism of evolution and a later, indirect, genetically stochastic mechanism of evolution. The latter is a derivative of and complementary to the primal mechanism of evolution. With the indirect mechanism of evolution appears the need for Darwinian selection, which gives rise to adaptations to the outer conditions of the environment and to the inner conditions of chemically restricted, preordained pathway possibilities. It is this association of chemical necessity and genetic chance that generates biochemical continuity between the origin of life and the extant biosphere. In fact the Iron-Sulfur World theory is not just a theory on the origin of life. It is also an explanatory theory of biochemistry.

Amino acids can be synthesized from inanimate matter through processes independent of living organisms. An overview of these processes occurring in various environments, including interstellar media, is given with a special emphasis on Strecker synthesis and related processes compatible with primitive earth conditions. When analyzing their relevance to the origin of life, chemical pathways leading to α-amino acids from activated precursors may be considered independent from further polymerization into peptides promoted by activating agents. Alternatively, both processes may also be connected to each other so that the emergence of amino acids and the prebiotic formation of peptide may have been closely associated. The last possibility is that prebiotic chemistries of amino acids and nucleotides may have been cooperating with each other in a way that led to the emergence of the genetic code and to a rudimentary translation apparatus.

The emergence of life has become a scientific field of interest since Darwinian theory was introduced, presuming the evolution of living organisms. Strong evidence exists that all living beings on Earth have a common ancestor. However, this Last Common Ancestor (LCA) (1) was most probably a living entity involving nucleic acid-based information storage (RNA and probably DNA) and ribosomal translation machinery. It lived probably several hundred millions years, and possibly more than one billion years, after life originated. We have no clues to the evolution pathway that led from the emergence of life to this LCA and on the preceding chemical evolution. These processes are the field of investigation of researchers in prebiotic chemistry and in early evolution; they try to build self-consistent hypotheses for the development of life. Some information can be gained from the analysis of biochemical pathways, keeping in mind that new pathways may have evolved replacing extinct ones. Other indications can be obtained by reproducing the conditions assumed to have occurred on the early Earth (the panspermia hypothesis will not be considered here). Indeed, the first scientists who analyzed the origin of life process (2, 3) proposed that early life forms were dependent on abiotically formed organic molecules as carbon and energy sources for their growth (the heterotrophic hypothesis). The formation of amino acids by electric discharges in reducing mixtures of gases (CH₄, NH₃, H₂O) through the Miller experiment (4) has given experimental support to this hypothesis by demonstrating that some essential building blocks of life can be efficiently formed abiotically. The presence of amino acids in several extraterrestrial samples of matter delivered to the Earth as meteorites is also clearly established. Amino acids, and more generally organic matter, must not be considered rare in the universe, which is also independently supported by the spectroscopic analysis of interstellar molecular clouds. In the following sections, we will describe different processes leading to α-amino acids under potentially prebiotic conditions, as well as analyze their relevance to the origin of life and their connection with the role of amino acids at the early stages of life evolution.

α-Amino Acids and the Origin of Life Process

Proteins are one of the main classes of biopolymers found in living organisms. They can adopt a large variety of structural patterns, which makes them essential cell constituents mostly involved in recognition processes. Their molecular recognition ability is remarkable in catalysis because enzymes have evolved to accommodate transition states in their active site to lower the kinetic barriers of most biochemical reactions. This ability is connected to appropriate primary sequences, and it allows the proteins to fold into well-defined tertiary structures. However, the accuracy of the primary sequence, which is ensured by the translation of genomic sequences in
current-day living organisms, seems out of reach of prebiotic systems. Therefore, the actual role of amino acids at that time is not clearly known. Nevertheless, if we still assume that their prebiotic role was the catalytic activity of polypeptides, another unresolved question lies in the prebiotic pathway of synthesis of these polymers. It is believed that prebiotic peptides have been formed from monomeric $\alpha$-amino acid through physico- or chemically induced processes. This assumption is not supported by strong evidence and alternative processes may have taken place. From a more general point of view, the biochemical route to biopolymers represents one kind of disconnection among the various possible retrosynthetic pathways that can be conceived starting from highly activated simple organic compounds (5). In this view, the stepwise formation of biopolymers by adding monomeric building blocks using condensing (dehydrating) agents in (most probably) diluted aqueous solution seems unlikely compared with a self-assembly that could take place directly from activated simple organic precursors with no need of further activation. As a result, the current discussion of the emergence of $\alpha$-amino acids also includes the possibility that peptides may have been formed directly from activated precursors through processes bypassing monomeric $\alpha$-amino acids.

**An amino acid and peptide world?**

In biology, the catalytic role is mostly played by enzymes. It is tempting to speculate that life may have emerged in a peptide world (6). Short peptides and even isolated $\alpha$-amino acids are capable of catalyzing prebiotic processes (7). Various physical or chemical pathways are available for the formation of peptides from inactivated or activated monomers. However, with respect to the sequence of peptides derived from common $\alpha$-amino acids, this kind of chemistry still fails to provide an efficient replication system. For instance, peptide segments (activated as thioesters) can be self-replicated by ligation if selected residues (cysteine) are present at the N-terminus (8, 9), but the replication of a complete peptide sequence from monomers seems unattainable. The only remaining possibility is an early system of information storage based on unnatural amino acids that is capable of base pairing or related molecules such as peptide nucleic acids (PNA). Although a transfer of information from PNA to RNA is materially feasible (10), it is unclear why this system could have been replaced by nucleic acids rather than being improved by evolution. Moreover, no remnant of this system has been preserved in current-day living organisms.

**The role of $\alpha$-amino acids in the RNA world scenario**

The RNA-related nature of most coenzymes and cofactors, the role of RNA in the translation process, and the catalytic abilities of RNA show that RNAs have played a crucial role in early biochemistry and have supported the hypothesis of an RNA world (11). In this scenario, living organisms primarily used RNA for both catalysis and information storage before the advent of coded peptides and of the translation apparatus. But most supporters of this scenario believe that amino acids and peptides may have played a part in catalytic activity, for instance as ribozyme cofactors (12). This provides a rationale for the evolution of the genetic code. In any case, covalent interactions of RNA with amino acids and peptides were probably required early to initiate the development of translation, so that hypotheses considering that polypeptides cooperated with RNAs since the early beginning of the RNA world have been presented (13, 14).

**A coevolution process toward the genetic code**

Because the translation apparatus is among the oldest components of living beings, it is tempting to consider the emergence of life and of translation to be closely related. In other words, we can make the hypothesis that nucleic acids and translated peptides may not be considered as two independent subsystems but as one subsystem, the RNA-coded peptides (5). Experimentally, reactions starting from $\alpha$-amino acids activated as N-carboxyamides, and nucleotides have recently demonstrated the possibility of obtaining covalent conjugates (15) under prebiotically relevant conditions. Similarly, reactions of N-phosphoryl $\alpha$-amino acids can result in both oligopeptides and oligonucleotides (16). The chemistry involved in such systems may have served as a starting point for the evolution toward the translation apparatus. Subsequently we must determine how the current-day set of coded residues has been selected among many possible structures and how they have been allocated a triplet codon to allow the translation of the genetic information into protein sequences. The coevolution theory of the genetic code (17, 18) that may also be independent of the coevolution process mentioned above) states that codons have initially been selected for a subset of prebiotically synthesized $\alpha$-amino acids. Then codon allocation was guided by potential biochemical conversions between the amino acids.

**Abiotic and Prebiotic Chemistry of Amino Acids**

Amino acids have probably formed in different places of the Solar system through processes independent of living organisms as shown by their occurrence in carbonaceous chondrites, a particular class of meteorites. Among these processes, only a particular subset of them can be considered to be truly prebiotic. It is the processes that make amino acids available in environments capable of developing a complex chemistry compatible, or at least presumed to be compatible, with the emergence of life.

**Formation on the early earth**

Several processes may have been responsible for the local formation of amino acids. In fact, energy release (electrical discharges, ultraviolet light, or impact shocks) into gas mixtures containing elementary carbon sources (CO$_2$, CO, CH$_4$), water and nitrogen produces organic molecules, including amino acids, but significant yields require a reduced overall redox state.
Figure 1: Strecker and related systems: complex network of equilibrated reactions from aqueous solutions of cyanide, ammonia, and aldehyde. Pathways for exiting the equilibrated network correspond to (a) cyanohydrin hydrolysis, (b) aminonitrile hydrolysis, and (c) Bucherer–Bergs reaction. Adducts 6 and 7 and other hydrolysis products can be formed at high concentrations of reactants.

This requirement is fulfilled for electric discharges in a reduced atmosphere containing methane, ammonia, and water, as in the original Miller experiment. It has also been observed for atmospheres based on N₂ and CO or CO₂ on the condition that H₂ or methane is also present in sufficient amounts (19). A neutral atmosphere (based on N₂, CO₂, and water) would produce much lower yields of organics (by several orders of magnitude). In the absence of other species to be oxidized, the reduction of CO₂ requires the concomitant thermodynamically unfavorable conversion of water into O₂ (as in photosynthesis). However, even if the atmosphere was neutral when life arose, as usually believed, the Earth was not uniform with respect to redox state simply because the reduced state of the mantle and the high volcanic activity favored the occurrence of locally reduced environments (for instance, in hydrothermal vents in the oceans). Then, a preservation of the hydrogen content of the early atmosphere or the diversity of environments on the early Earth is likely to have made amino acid formation possible, at least at specific places.

The strecker synthesis and related processes

The formation of α-aminonitriles: a set of equilibrated reactions

A strong argument in favor of the involvement of Strecker synthesis is that aldehydes and HCN are among the initial species formed in electric discharge experiments leading to α-amino acid formation. Mechanistic and thermodynamic studies (20) of systems derived from aqueous mixtures containing an aldehyde, ammonia, and hydrogen cyanide have disclosed the network of equilibrated reactions involved in these systems (Fig. 1). In the first stage, cyanide is rapidly added to the carbonyl compound and cyanohydrin 2 is produced. Then, the α-aminonitrile 5 is formed more slowly through cyanide attack on an iminium ion intermediate 4. The composition of the equilibrium mixture formed from equimolecular concentrations of aldehyde and cyanide is strongly dependent on the pH and of the initial concentration of ammonia. Then, under conditions simulating a presumed prebiotic aqueous environment (with low concentrations of organic precursors and ammonia and in a 5–7 pH range brought about by a CO₂-rich early Earth atmosphere), α-aminonitriles are formed in very low equilibrium yield (21). However, since hydrolysis pathways (Fig. 1) are likely to proceed at different rates, there is no reason for the final hydroxy acid/amino acid ratio to match the large predominance of cyanohydrin over α-aminonitrile at equilibrium. Actually, an important, often overlooked, feature of the Strecker synthesis is that, under neutral or mild alkaline conditions, α-aminonitrile hydrolysis (or conversion into stable derivatives) proceeds through efficient pathways involving the specific participation of the neighboring amino group, which offsets their low thermodynamic stability.

Catalytic conversion of α-aminonitriles: the determining process

It turned out that α-aminonitrile hydration is subject to efficient catalysis by aldehydes (22), which are already reactants of the Strecker reaction (Fig. 2). This catalytic pathway is still prevailing at 20-μM formaldehyde concentrations (21) and...
half-lives shorter than a year are expected in the presence of 10-mM formaldehyde at pH 7 and 25°C. It proceeds through the addition of the aldehyde at the amino group and the subsequent intramolecular reaction of carbinolamine adduct 13.

**Bücherer-Bergs reaction**

This reaction (Fig. 2) is closely related to the above described catalytic pathway for α-aminonitrile hydration, but it involves CO₂ instead of an aldehyde (23). The main difference lies in the fate of isocyanate 19 (formed instead of imine 15), which easily undergoes the cyclization into hydantoin derivative 12 (instead of hydrolysis to α-aminamide 18). Considering the kinetic stability of 12, CO₂ is a reactant instead of a catalyst for the Bücherer-Bergs reaction; nevertheless, this pathway is an additional, very efficient process for selecting α-amino acid derivatives rather than those of α-hydroxy acids. Moreover, despite the very sluggish reactions of its products, the Bücherer-Bergs reaction must not be considered as a dead-end since the N-carbamoylamino acid 20 can be converted into the α-amino acid N-carboxyanhydride 21 (Fig. 3), readily under the effect of nitrogen oxides (24), but also slowly through a spontaneous pathway (25, 26).

**Hydrothermal formation**

The synthesis of amino acids in aqueous media is energetically feasible in reducing fluids and temperatures found in hydrothermal systems (27). Amino acids have indeed been produced, although in micromolar concentrations, by heating a mixture of methane and nitrogen in simulated hydrothermal fluids (28). A likely process for their production could be a Strecker reaction. Plausible chemical pathways have been thermodynamically analyzed (29), and a process involving reductive amination of keto acids (30) has also been proposed. On the other hand, high temperatures are also likely to damage organic molecules.
Origins of Life: Emergence of Amino Acids

**Formation in interstellar media**

Another potential source of organic compounds on early Earth is extraterrestrial bodies (31–33). This possibility is attested by the presence of α-amino acids in meteorites. The synthesis of organic compounds occurred in the presolar molecular cloud or in the protoplanetary disk that preceded the formation of planets (34). It is likely to have resulted from UV-irradiation of interstellar ices (35) with the formation of radicals and/or other highly activated species, which then randomly combined into more complex organic compounds at the low temperature of the molecular cloud. Then these ice particles were involved in the accretion of meteorite parent bodies, where organic matter could be preserved from the heat released by the process in small accreting bodies. Subsequently, reactions like those involved in Miller’s experiment may have occurred on meteorite parent bodies early in the history of the solar system. Then, these organic molecules could have been delivered to the Earth through impacts of meteorites, micrometeorites, and comets.

**Peptide formation**

Many processes have been proposed for the formation of prebiotic peptides. Peptide bond formation from free amino acids can become thermodynamically favorable using physical or chemical means for dehydration (6, 36). Alternatively, activated amino acid derivatives are capable of polymerizing into oligopeptides in aqueous solution. A pathway for the formation of α-amino acid thioesters starting from sugar precursors has been discussed (37). α-Amino acid N-carboxyanhydrides (NCAs) correspond to the most activated form of amino acids reachable in a prebiotic environment with a high content in CO$_2$ or bicarbonate (38), since carboxyl-activated derivatives are easily converted into NCAs through a very efficient CO$_2$-promoted process (39) (Fig. 3). The length of peptide chains formed by polymerization of NCAs is often limited by precipitation, but longer peptides (up to 55-mers) have been obtained in the presence of illite and hydroxylapatite (40). NCAs can also be formed through prebiotically relevant pathways starting from N-carbamoylamino acids (24–26) or through the activation of amino acids with carbonyl sulfide (41).

**Amino acids and the emergence of homochirality**

The configuration of natural amino acids has led to studies on the possibility that homochirality emerged at a prebiotic stage, which may be supported by the presence of amino acids as non-racemic mixtures in meteorites (32). This enantiomeric excess may have resulted from the exposition of extraterrestrial matter to circularly polarized light (42). Whatever the origin of this enantiomeric excess, it may have initiated stereo-selective processes through different catalytic pathways (7). Symmetry breaking may also have resulted from reactivity in connection with other processes such as crystallization or interfacial chemistry (43, 44) and polymerization of amino acids (45).
Relevance of Abiotic Processes to the Emergence of Life

The presence of amino acids in meteorites (chondrites) and their delivery on the surface of the Earth may have triggered prebiotic pathways starting from these building blocks. On the other hand, their occurrence of meteorite parent bodies may simply be considered as a manifestation of their easy synthesis through various abiotic pathways, and of their abundance in the universe and consequently on the early Earth. The answer to this alternative idea mainly depends on the rate of evolution of the atmosphere and on the development of conditions favorable to life on the planet. Most scientists consider that the atmosphere of the Earth was initially based on a mixture of N₂ and CO₂ with a significant content in H₂ and CH₄ (favorable to the production of organic molecules). Then, it evolved from this reduced state to a more neutral state (N₂, CO₂) as hydrogen escaped to outer space (46). The rate of this evolution depends on both the input of H₂ from the volcanic activity and its loss to outer space (47). Another problem is the presence of conditions that allow the growth of living beings. Studies on the origin of life processes are strongly dependent on the knowledge gained by other fields of science such as astrophysics, geology, and other planetary sciences. Since liquid water was already present on the Earth a few hundred million years after its accretion leading to the early formation of oceans, a major problem encountered by early forms of life would have been that of impact of asteroids or comets capable of vaporizing the oceans (at least in part) and thus of sterilizing the planet. Both issues are still debated, and many hypotheses are acceptable. Life may have emerged early on Earth in a globally reduced environment and may have survived impacts by asteroids or comets. A debatedly, synthetic processes occurring on early Earth with a reduced atmosphere may have no connection with a later emergence of the ancestors of all living beings that we currently know. Instead, it may have resulted from the delivery of organics or their synthesis in locally reduced environments. It is still possible to speculate that life emerged several times and then was annihilated by impacts.

Future Research Directions

More than 175 years after urea was synthesized from mineral precursors, abiotic processes seem to be capable of having made α-amino acids and various organic molecules available in many places of the solar system. The easy abiotic synthesis of α-amino acids may also be the consequence of their composition based on the most abundant reactive elements in the universe (H, C, N, O). Determining the actual pathway through which life emerged is currently unsolved considering the absence of remnants, and we have no indication that this situation may change. However, the study of nonlinear processes of complexification, involving biomolecules (including amino acids) and other prebiotic organic or inorganic derivatives, remains an important field of interest for chemical biology. The discovery of processes working under kinetic control and capable of connecting replication, adaptation and self-maintenance, which is one of the biggest problems in modern science, needs additional analysis of simple and robust pathways. Amino acid prebiotic chemistry, starting from activated species and/or energy sources and potentially capable of delivering energy to such systems, has brought about important pieces of information in this direction and will surely be helpful in the achievement of this goal.

Origins of Life: Emergence of the RNA World

Michael P. Robertson, Center for Molecular Biology of RNA, University of California, Santa Cruz
doi: 10.1002/9780470048672.wecb424

The RNA World hypothesis refers to a period during the evolution of life on Earth, preceding the DNA/RNA/protein-based systems of modern biology, during which RNA alone directed and catalyzed the chemistry of life. The concept is an elegant solution to the problem of devolving our intertwined 3-biopolymer biochemistry toward its origins as the simplest system imaginable. In support of this idea, a scattering of molecular clues within our cells point suggestively toward an RNA-only period leading up to the ribozyme-mediated invention of protein synthesis. Indeed, the RNA World hypothesis is a very sensible scenario when considered from the perspective of trying to simplify life’s complexity. The alternative perspective, however, imagining a sterile, primordial Earth and trying to assemble abiotically produced precursors into the RNA World is an extremely difficult problem. Certain steps along the logical chemical pathway to the RNA World have been demonstrated in the laboratory, but many others remain problematic. The exploration of RNA’s catalytic properties has been encouraging, but complex ribozymes are extremely scarce in RNA populations. If the RNA World did once exist, it came about by a mechanism that has not yet been adequately elucidated, including the possibility that a different, unknown, biopolymer system may have preceded the RNA World.

The mechanism of the emergence of life on Earth is one of the most fundamental mysteries of the biological sciences. Despite centuries of pontification and decades of serious experimental efforts, the details remain poorly understood. The most satisfying attempts to deduce the genesis and earliest evolution of primitive life have focused on what is known of modern biology and attempted to simplify it back to the most fundamental and primitive (1, 2). This simplification exercise quickly leads to a paradox in determining which of the essential biopolymers of life, proteins or nucleic acids, would have come first. Conventional logic indicates that it could not have been DNA either, which, although containing all the coded instructions to make copies of itself and the functional abilities to carry out those instructions that the theory gained wide acceptance. The assumption of a so-called ‘RNA World’ era that preceded the biological assimilation of DNA and protein, during which RNA would have been the primary facilitator of a metabolism of unknown complexity, offers an elegant and appealing solution to the challenge of inventing the system of multiple, interrelated biopolymers that exists today. Clues pointing to this bygone RNA World era are scattered throughout our biochemistry. Considered individually, they are not overwhelmingly convincing, but taken together, they make a compelling case that an RNA-based biology might have preceded what we have today. Despite the deserved enthusiasm that the RNA World hypothesis generates, there remain many puzzling difficulties and unanswered questions. An RNA World is quite appealing from the perspective of modern biology looking backwards in time, but is extremely difficult to envision from a perspective at the formation of the Earth looking forward in time. Bits and pieces of the components of RNA can be synthesized, sometimes efficiently, in prebiotic soup-type conditions, but there is not yet a plausible scenario to assemble them into a monomer or dimer of RNA, let alone a polymer of sufficient complexity and functionality to kick-start a living system.
series of mechanisms, including the possibility of a preRNA World, led to the formation of long RNA polymers and eventually ribozymes, the creation of a self-replicating system based solely on RNA, the simplest possible RNA World scenario, is still a daunting challenge that well over a decade of focused experimental attempts have so far failed to solve. Even so, the prospects remain optimistic. Each year brings new insight into the complex characteristics and abilities of RNA, as the boundaries of its capabilities are explored further.

Life, Dogma, and the RNA World

The term ‘RNA World’ (8) refers to a hypothesized period of the early evolution of life, during which RNA, in the absence of DNA or proteins, served as the sole biopolymer of life. Such a life form would likely be unfamiliar to what we are accustomed to, and so a thoughtful, general definition for what constitutes “life” becomes important in order to identify the boundary that separates non-living from what can be considered alive. However, drafting a fundamental, general, succinct definition of the processes and characteristics that represent life has been difficult, controversial, and often unsatisfying (9). The formulation that seems to enjoy the most widespread support is the “chemical Darwinian” definition, which states, simply, that “life is a self-sustained chemical system capable of undergoing Darwinian evolution” (10). The power of this statement is that the primary natural force that has shaped the diversification and evolution of all the organismal life that we know of, namely Darwinian evolution, is also applicable at the simplest, sub-organismal, molecular stages of life. Implicit in the chemical Darwinian model is a system that can sustain itself and create progeny copies. The copies were slightly less than perfect, such that natural selection could encourage a lineage of generations, improving and diversifying, evolving eventually into the entire biosphere. The “central dogma of molecular biology” (11, 12) describes the flow and directionality of information exchange among the three primary information-rich biopolymers of contemporary biology, namely, DNA, RNA, and proteins (Fig. 1). The biochemistry of life today is intertwined between these major, discrete components, each one dependent upon the others for its existence. However, a scenario in which two, let alone three, of these individual systems arose simultaneously and were able to function synergistically is very difficult to imagine. In theory, a system comprised only of RNA could direct and execute the replication of its own genetic information, producing progeny via a self-templated RNA polymerization mechanism catalyzed by the RNA itself, thus satisfying the minimal definition for life with a single biopolymer.

The central component of this RNA World scenario is a replication system that can make copies of the genetic material to grow and produce progeny. The most basic scenario is a simple templated ligation of small oligomers in a cyclical replication scheme (13-16), but ultimately a catalytic entity responsible for this crucial function of replication would be necessary. The simplest example is a single self-replicating ribozyme that can copy itself. More elaborate scenarios for a mature RNA World might also involve ancillary functions such as producing the nucleotides, or building blocks, for the replicase to work with. A case can be made for numerous other functions as well, but one that seems very probable is the invention of protein synthesis. The observation that a nearly protein-free preparation of ribosomal RNA can catalyze the crucial chemical peptidyl transferase step of ribosomal protein synthesis (17), and subsequent X-ray crystal structures of the ribosome showing the arrangement of RNA around the catalytic center (18), together indicate that the cellular machine for making protein is, at its core, a ribozyme. The invention of protein synthesis marks a boundary between the RNA World and the era that persists to this day, in which proteins have become the dominant agents of catalysis across all forms of life.

Prebiotic Synthesis of RNA Components

Nucleotides are the primary building blocks necessary to assemble an RNA world. Each nucleotide is comprised of a base attached to a sugar through an N-glycosylic bond, with a different site on the sugar phosphorylated (Fig. 2). The information content of a nucleic acid polymer is encoded in the identity and order of the bases—adenine, cytosine, guanine, and uracil in RNA, or thymine in place of uracil in DNA. D-ribose, the sugar moiety in RNA, bridges the backbone with 5′-phosphodiester linkages to adjacent nucleotides in addition to attaching to the base via the C1′ position.

Bases

The bases are nitrogenous aromatic heterocycles, bicyclic in the case of the purines, and pyrimidines with only a single ring. Both systems are decorated with complementary arrays of base-pairing interactions, usually between a purine and a pyrimidine, e.g. adenosine (A) pairs with uridine (U), and guanosine (G) with cytidine (C) (19) (Fig. 3). These canonical Watson-Crick pairings form the basis for the storage and copying of double-stranded DNA and the genetic transfer from DNA to RNA, although non-canonical pairings are common in nucleic acids that adopt structures more complex than a simple double helix.

Purines

Demonstrations of the abiotic synthesis of the nucleic acid bases has been a relative success among the steps necessary to understand the synthesis of RNA nucleotides. Beginning in 1953, when the Miller-Urey spark discharge experiments (20) triggered a shift towards experimental testing in origins of life research, the simplest subunits of life have been favorable targets for investigation. In 1960, O’o demonstrated the synthesis of adenine in yields of less than 1% from simple aqueous solutions of ammonium cyanide (21, 22). Stoichiometrically, adenine is a pentamer of HCN, and although

RNA replication

Figure 1: The central dogma of molecular biology. The central dogma describes the flow of information between the principle biopolymers of the cell. The primary exchange is shown horizontally, left to right, namely, DNA directs the synthesis of RNA, which in turn directs the synthesis of protein. Alternate observed exchanges are depicted off the horizontal with less prominent lines. The letters ‘P’ and ‘R’ indicate that protein or RNA, respectively, are required for particular exchanges.

(b) A purine nucleoside (adenosine) and a pyrimidine nucleoside (uridine). (c) The nucleotide adenosine 5’-triphosphate. (d) An RNA strand with the sequence AGCU.

Some uncertainty about the precise reaction pathway exists, the detection of 4-aminoimidazole-5-carboxamidine (AICA) and 4-aminoimidazole-5-carbonitrile (AICN) in the complex reaction mixture, suggests a role for either or both of these molecules as intermediates in alternate pathways to the synthesis of adenine from HCN (Fig. 4) (23, 24). Diaminomaleonitrile (DAMN), a tetramer of HCN and an abundant component of HCN polymerizations, can be converted to AICN through a photochemical rearrangement and may be an important precursor to adenine under certain conditions (25, 26). Alternatively, Ferris and coworkers have suggested that very little or no free adenine is formed in these discreet scenarios, but rather adenine is released only during the hydrolysis of the complex and insoluble cyanide polymers (27). The synthesis of guanine has also been detected under identical conditions at levels 10 to 40-fold less than adenine.
similar to the original Oró synthesis. Purine syntheses proceed through HCN-mediated mechanisms known to form under these conditions (32). It is likely that these were formed in methane/ammonia mixtures (29–31). Since HCN is in low yields in several discharge/irradiation experiments perpetrator. intermediate.

Figure 4 Prebiotic synthesis of adenine. This schematic shows potential pathways and intermediates in the synthesis of adenine from ammonium cyanide.

Pyrimidines A variety of routes for the synthesis of pyrimidines have also been demonstrated. Uracil is formed in high yields by heating malic acid and urea in sulfuric (33) or polyphosphoric acid (34). Although the simple starting materials are prebiotically attractive, the extreme conditions and anhydrous requirement of this reaction make it of questionable relevance for the prebiotic Earth in anything other than highly specialized local environments. A number of other more plausible pyrimidine syntheses have also been explored, but these tend to be much less efficient. Oró reported low levels of uracil synthesis by heating aqueous acrylonitrile with urea and ammonium chloride (35). A variety of pyrimidines, including oxonic acid, 5-hydroxypyrimidine, and 4,5-dihydroxypyrimidine have been detected at low levels in HCN polymerizations (27, 36), as has uracil (37). Schwartz and Chittenden demonstrated the synthesis of 5,6-dihydropyrimidinol (DHU), a constituent of transfer RNA, by condensation of β-alanine and urea through a β-ureidopropionic acid intermediate, which can then cyclize to form DHU (38, 39). Subsequent photolytic dehydration of DHU produces uracil in a reaction promoted by hydrated clay minerals, particularly montmorillonite. Orgel and coworkers produced reasonable amounts of cytosine and its hydrolysis product, uracil, from solutions of cyanocetylene and cyanoate or urea (40). Cyanocetylene is an attractive prebiotic molecule in the sense that it is a reactive compound formed abundantly in spark discharge experiments (41). However, its reactivity makes cyanocetylene short-lived in the environment, the chief byproduct being the hydrolysis product cyanacetaldehyde. Ferris combined cyanacetaldehyde with guanidine to form 2,4-diaminopyrimidine, which can in turn hydrolyze to make cytosine, and then uracil (42). Nearly 30 years after Orgel’s experiments with cyanocetylene and cyanate, Miller, starting directly with cyanacetaldehyde and exploiting the extreme solubility of urea, was able to produce cytosine and uracil in combined yields greater than 50% (43).

Concentration mechanisms The investigation of prebiotic chemistry often involves a compromise between extreme conditions that favor efficient product formation on a timescale amenable to laboratory investigation and milder conditions that are more plausible on the early Earth. The most optimistic estimates for the production of reactive biological precursor molecules, while substantial in their global amounts, when diluted throughout the volume of the Earth’s hydrosphere would result in only meager concentrations (44). In some cases low reactant concentrations simply result in slower reaction rates, which may not present serious difficulties when considered in the context of a geologic timescale. In other instances, however, reaction pathways at low concentrations may differ significantly from those at higher concentrations. HCN polymerizations, for example, produce biologically interesting materials only at HCN concentrations of about 0.01 M or higher. At HCN concentrations lower than 0.01 M, hydrolysis out-competes oligomerization, resulting in the accumulation of formamide and formic acid instead of HCN oligomers (45). Concentration mechanisms are often invoked to address these
difficulties and boost efficiencies, and, indeed, certain concentra-
tion processes seem likely to have played a role in nature.
Miller’s rationale for using such high concentrations of urea in
his synthesis of cytosine was the “drying lagoon” model of
prebiotic synthesis in which periodic evaporation of bodies
of water to near dryness, such as beaches, lagoons, and tide
pools, concentrate the most soluble compounds to extremely
high concentrations, even if they were initially very dilute (46).
In the case of HCN, its volatility precludes evaporative con-
centration mechanisms, but freezing can be an effective means
of concentration, as the HCN-water eutectic is 74.5% HCN at
−23.4°C (47). HCN polymerizations proceed effectively under
these conditions, the extremely high concentrations compensat-
ing kinetically for the low temperatures (47).

Extraterrestrial synthesis of bases

Aspects of every putative prebiotic synthesis are vulnerable
to critical analysis, and experiments are often open to questions
of interpretation and relevance. This is especially true in ori-
gin of life research where virtually everything is unknown and
will remain so, as no direct evidence survives from that time.
Uncertainties about specific conditions, sources, and reaction
pathways, however, in the context of the discussion of nucleic
acid bases, are secondary to the likelihood that these particular
fundamental building blocks of life were produced in ubiquitous
abiotic processes throughout our solar system and presumably
beyond. Analyses of carbonaceous meteorites have detected
amino acids (48, 49) and nucleic acid bases (50–52) that are ex-
ternal to Earth. However, the distribution of compounds and
their relative abundances are reminiscent of those observed
in known prebiotic simulation experiments. These findings sug-
gest that conditions favoring the synthesis of these fundamental
biological materials, whether they be through the mechanisms
reviewed above or others that have not been considered, were
at work during the formation and early evolution of our solar
system, and, consequently, the nucleic acid bases are very likely
to have been present on the prebiotic Earth.

In addition to invoking the evidence of extraterrestrial syn-
thesis of biomolecules as a means to corroborate that these
reactions could have occurred on the prebiotic Earth, they can
also be invoked directly as potential source material for the
origin of life. The earliest stages of Earth’s history are character-
ized by a steady bombardment of extraterrestrial objects such as
meteorites and comets that could have delivered large amounts
of biologically useful material to the Earth. Less exciting than
meteor or comet impacts, but much more significant in terms of
the amounts of extraterrestrial material delivered to Earth, are
interplanetary dust particles (IDPs). IDPs are small carbona-
ceous particles on the order of tens to hundreds of micrometers
in size that are formed by comet evaporation or asteroid colli-
sions and they “rain down” onto the Earth’s surface in amounts
estimated to be at least several tons per day (153, 54). This sig-
nificant source of extraterrestrially synthesized organic material
is expected to have supplemented, perhaps substantially so, any
endogenously produced biological precursors.

Sugars

A sugar moiety, specifically the pentose D-ribose, is attached to
the base as the other half of a nucleoside. The synthesis of sugars
from formaldehyde, a compound generated in spark discharge
experiments and frequently invoked as a prebiotic reagent, has
long been known (55), and its applicability as a prebiotic pro-
cess has been well investigated. The so-called formose reaction
produces a rich mixture of sugars from a solution of formalde-
hyde, but requires an unrealistically basic pH and improbably
high concentrations of formaldehyde to seem prebiotically fea-
sible (56). The reaction has been modified to proceed under
much milder conditions at neutral pH, and can be catalyzed
by certain common minerals, which is a more attractive pre-
biotic scenario (57, 58). However, a second problem with the
formose reaction exists—its lack of synthetic selectivity. RNA
nucleosides utilize a specific sugar, D-ribose, but the formose
reaction generates a complex mixture of trioses through hex-
oses, including branched molecules, without a preference for
ribose, and without enantiomeric enrichment (59). In contrast,
the base-catalyzed aldolization of glyceraldehyde phosphate in
the presence formaldehyde produces ribose-2,4-diphosphate as
the major product (60). Further refinements to this procedure
using a clay mineral catalyst allow the reaction to proceed ef-
ciently with dilute reactants at neutral pH (61). In addition,
other mechanisms to further enrich for ribose from a mixture
of sugars have been demonstrated, such as selective membrane
permeability (62) or selective reactivity with reagents that form
adducts preferentially with ribose (63). It is also possible that
unknown mechanisms or untested catalysts may exist that can
produce D-ribose more efficiently, but have not yet been dis-
covered. A third problem is the instability of the sugars, which
are very likely to have been present on the prebiotic Earth, but
also, the instability of the sugars make it unlikely that
ribose could persist in solution and accumulate on the prebiotic
Earth on time scales that are typically assumed for the origin of
life (64). However, the clay minerals that have been shown
to catalyze the synthesis of ribose phosphate have also been
demonstrated to provide a protected environment to sequester those
products, resulting in increased stability relative to free solution
(61). An alternative approach involves creating stable adducts of
ribose with other molecules. Recently, Benner and co-workers
have demonstrated that certain borate minerals can substantially
stabilize sugars, such as ribose, that have hydroxyl groups on
adjacent carbons, sequestering the sugar in a stable complex and
thereby prolonging the sugar’s availability for further assembly
(65). Similarly, the product of ribose and cyanamide forms an
insoluble adduct that crystallizes out of solution protecting the
ribose from solution-mediated degradation.
Nucleosides

A nucleoside is the combination of a base and ribose. Their formation, in theory, is most directly achieved by a reaction involving pre-formed bases and ribose, but this approach, so far, has shown little promise. The best attempts have been the demonstrations that the dry-phase heating of purine bases and ribose leads to the formation of purine nucleosides (66, 67). Further, the yields are enhanced several-fold in the presence of certain salts, including evaporated seawater. However, the same investigators were unable to substantiate an earlier report claiming the formation of adenosine from dilute solutions of adenine and ribose exposed to ultraviolet light, and were also unable to detect any nucleoside formation in aqueous solution under a wide variety of conditions. This dry-phase synthesis, while producing nucleosides in yields of several percent, is complicated by a side reaction in which bases bearing exocyclic amines (adenine, guanine) are preferentially ribosylated on the amine group in yields of up to 74% (66). Similar reactions with hypoxanthine, which does not have an exocyclic amine group, were not affected by this side reaction, and produced inosine in yields comparable to the adenine and guanine reactions. As was the case with a lack of selectivity between synthesis of D and L enantiomers, a similar lack of selectivity exists in the formation of α and β anomers.

The problem of pyrimidine nucleoside synthesis has been even more challenging than purines. In dry-phase heating experiments, the pyrimidines do not form detectable amounts of nucleoside (66). Alternative strategies include using prebiotic reagents to build a base on a pre-formed ribose (68-70), or the converse, building a sugar on a pre-formed base. Both tactics have had degrees of success, but neither seem to be the simple and robust processes that might be expected of a convincing prebiotic synthesis, especially of such a crucial class of biomolecules. Still, all of the above approaches use other pyrimidines (not C, U, or T) (71) or pyrimidine-like bases (72) that more readily form nucleosides with ribose. In a subsequent step, these non-nucleoside pyrimidines are then either chemically converted to a standard pyrimidine or else invoked as a precursor to conventional RNA.

Nucleotides

The last step to make an RNA monomer is to add phosphate. This step can be coupled with chemical activation of the nucleoside in order to make the polymerization of monomers energetically favorable. A phosphate links each nucleoside monomer together in an RNA polymer through phosphodiester bonds between the 5′ and 3′ hydroxyls on the riboses of adjacent nucleotides. The activated form of the nucleoside used by all RNA polymerases in contemporary biology is the nucleoside 5′-triphosphate (NTP). The energy that drives polymerization is accessed by breaking the bond linking the α and β phosphate groups, with pyrophosphate released as a byproduct. Attempts to create nucleotides by phosphorylating nucleosides under prebiotic conditions have had mixed success. The most successful approach involves the dry-phase phosphorylation of nucleosides with phosphate salts by heating a dried solution of nucleoside and inorganic phosphate. This reaction produces an assortment of different mono-phosphorylated nucleotides (NMPs) (73). The addition of urea to the reaction increases the yields substantially, but still produces a mixture of products, including 3′- and 2′-phosphates and 2′-3′-cyclic phosphates (NMPs), which, in many cases, are the major product (74). The relative yields of products are sensitive to reaction conditions, which can be fine-tuned to favor the accumulation of 5′-NMP (75). For instance, the temperature of the reaction affects the distribution of products, particularly the formation of NMP. The earliest experiments were carried out at temperatures of 100°C and resulted in the greatest proportion of NMP phosphorylated products. Simply lowering the temperature to 65°C greatly reduces the amount of NMP relative to the 5′-NMP product. However, lowering the temperature below 60°C inhibits all phosphorylation (75).

An alternative to the dry-phase phosphorylation schemes involves the use of a condensing agent in aqueous solution. Small yields of NMPs are produced from heated solutions of nucleoside, phosphate, and certain prebiotically feasible condensing agents such as cyanogen, cyanate, and cyanoacetylene (76, 77). The yields are low because none of the tested condensing agents provide any selectivity for the nucleoside over water. Consequently, water is able to out-compete nucleoside for phosphorylation due to its substantial concentration advantage. With what little phosphorylation of the nucleoside that does occur, as with the dry-phase reactions, NMP is found as a major product of these reactions. The observation that the unimolecular cyclization of 3′-NMP to NMP proceeds efficiently under these conditions is consistent with this model (78).

Other possibilities include adding or building a base onto a pre-formed sugar phosphate as mentioned in the previous section (69, 70) or utilizing phosphate derived from minerals or extraterrestrial sources. For example, the phosphorous-containing mineral schreibersite, found in many meteorites, decomposes in aqueous solution generating compounds containing phosphate, pyrophosphate, and phosphate (79). The proposed degradation pathway proceeds through a phosphate radical intermediate, which could potentially be used to form polyphosphates. In this regard, phosphate has been suggested as an attractive prebiotic alternative to phosphate due to advantages in solubility and reactivity (80).

The mono-phosphorylation discussed above completes the nucleotide unit, but does not create the high energy activated phosphate that drives polymerization, so an additional step must be invoked to complete the activated nucleotide. This could occur either by using a nucleoside with an activated phosphate group or in the form of using an external activating agent to effect the polymerization process. Polyphosphates can be made under similar conditions (81, 82), but generally require higher temperatures to achieve, and their utilization in a prebiotic setting has been questioned (83).

Cyclic phosphates

The emphasis in the area of nucleotide synthesis is almost always focused on 5′-activated phosphates, based in large measure, on nature’s (current) preference for NTPs. Alternatives to this model include 2′,3′-cyclic phosphates, which have a strong case for consideration. First, they are often the major products,
rillonite to otherwise similar reactions has a favorable effect. The distribution of products is highly sensitive to reaction conditions, and the behavior of non-enzymatic RNA polymerization is often bypassed in these types of non-enzymatic template-directed polymerization experiments.

Nonenzymatic Assembly of Oligonucleotides

The prebiotic utility of nucleotides lies in their ability to form long, polymeric chains that store genetic information and form complex and functional macromolecular shapes. Any initial assembly of oligonucleotides presumably would have been non-nucleotide-templated and occurred either in solution or perhaps on a clay or mineral surface. The energy to drive polymerization could come either in the form of a pre-activated nucleotide or by utilizing an external activating agent during polymerization (discussed above). The latter approach, which bypasses the pre-activation of the nucleoside phosphate, would balance that advantage in the inefficiency of polymerization. Typical experiments yield small amounts of mostly dimers and trimers, and among these are a mixture of the "natural" 3'5' internucleotide linkages with unnatural 2'5' linkages, as well as other complex products including 5'5'-pyrophosphate linkages (85). The alternative strategy of pre-activating the nucleoside has produced the most robust laboratory results. The choice of activating group is dictated primarily by practical considerations. Nucleoside triphosphates, nature's chosen activating group, react too slowly to be practical for the laboratory. Other activating groups have been explored, and among these, the most studied have been the phosphorylazidials. The prevalent use of phosphorimidazolides in these types of non-enzymatic polymerization studies is based on the simplicity of their synthesis and utilization, as well as their successful results. The steps and components of their synthesis can be considered plausibly prebiotic, but unlikely to persist and accumulate to reasonable levels. Their popularity as a polymerization substrate is less an endorsement of their prebiotic relevance and more the adoption of a well-behaved model system with which to address general and, hopefully, fundamental questions about the behavior of non-enzymatic RNA polymerization.

Polymerizations of this type in solution produce predominantly shorter than 5-mer oligonucleotides with a mixed and variable composition of 2'5' and 3'5' linkages (86). The distribution of products is highly sensitive to reaction conditions, including the presence of metal ions, modification of the leaving group, and sequence context. The addition of the clay montmorillonite to otherwise similar reactions has a favorable effect on polymerization (87). The effect is likely due to the concentration of monomers within the clay's cationic layers. These clay-catalyzed experiments have produced polynucleotides up to 55 nucleotides long with approximately 80 percent 3'5'-linked composition (88).

Template-directed synthesis

The appeal of RNA or any nucleic acid as a genetic material is due to its ability to base-pair and consequently serve as a template for the synthesis of complementary copies of itself. Eventually, random, non-templated RNA assembly would have had to give way to template-directed systems able to propagate beneficial genetic information from one generation to the next. When a template is added to prebiotic polymerization simulations, the effects can vary dramatically depending on the nucleotide composition of the template. In basic experiments with homopolymeric templates, the complementary strand is polymerized from monomers that base-pair with the template. The incorporation of purines, particularly guanosine, into the complementary strand is much more efficient than pyrimidine incorporation (89). These trends hold true for mixed sequence systems: good templates are generally those with a high percentage of cytidine, directing the incorporation of guanosine. Such a system might be a good template from which to make a reverse-complementary copy, but that copy would be an extremely poor template from which to regenerate the oligonucleotide. The complementary nature of nucleic acid replication cannot succeed with such an extreme templating bias unless another, currently unknown, rescue mechanism is postulated.

The increased efficiency of oligomerizing dimers, trimers, or longer oligomers instead of monomers is an attempt to address some of these difficulties. The energetics of base-pairing longer stretches of nucleotides increases binding efficiency, but unless the pieces are sufficiently long, the templating peculiarities just discussed can still apply to oligomerizations and severely restrict the number of replicable sequences. The feasibility of this kind of system has been characterized using a carefully chosen patroductom system with trimers ligating on a hexamer template (14). A modified system using a manual denaturation step to separate the product strands from the template strands during each generation of copies has demonstrated exponential replication of nucleic acids (15).

Enantiomeric cross-inhibition

A previously mentioned difficulty in prebiotic synthesis, now re-surfacing for this discussion of prebiotic template-directed oligonucleotide synthesis, is the problem of sugar handedness. Unless a reasonable mechanism or process is found that leads to the accumulation of one sugar enantiomer over another, the prebiotic synthesis of sugars must be assumed to produce an equal mixture of D and L ribose, and, consequently, also in the absence of a reasonable selectivity mechanism, lead to a mixture of D and L nucleotides. Studies of uncatalyzed templated polymerizations using a mixture of nucleoside enantiomers indicate that the non-biological "L" enantiomer acts as a chain terminator when incorporated against a D enantiomer template, blocking further templated extension of the oligonucleotide (90). This is another serious difficulty without a satisfactory
resolution with regard to the uncatalyzed template-directed polymerization of RNA nucleotides.

Ribozyme to Replicase

Ignoring, for the moment, the challenges associated with the abiotic synthesis of RNA polymers, the emergence of the RNA World still depends on the ability of RNA to catalyze its own replication in some fashion. An RNA-dependent RNA polymerase is the class of enzyme that modern biology would use for this purpose, and a ribozyme with this functionality is thought to be central to the beginnings and propagation of the RNA World. No such ribozyme has yet been discovered in nature, but a laboratory re-creation of a ribozyme with that functionality, though not proof of its historical existence, would show that it could once have existed, and validate a fundamental pillar of the RNA World hypothesis. The isolation of RNA ligase ribozymes from a population of random sequence RNA molecules was the start of an experimental progression that has come closest to realizing the goal of an RNA polymerase ribozyme (91). RNA ligase ribozymes catalyze the identical chemical reaction as an RNA polymerase, but instead of the triphosphate-bearing half of the reaction being an NTP, it is instead present as the 5' triphosphate of the 5′ terminus of the ribozyme itself (Fig. 5). In terms of in vitro selection targets, ligase activity appears to be relatively prevalent in RNA populations after having been isolated under different reaction conditions by several teams using different starting populations of RNA. The phrase “relatively prevalent”, in this case, means on the order of one ligase ribozyme in every 1011-1014 RNA molecules (91), only about an order of magnitude lower frequency than experiments isolating self-cleaving ribozymes from random sequence populations (92, 93). While these probabilities may seem relatively low, they correspond to finding a ~100 nucleotide ligase ribozyme in approximately every microgram of random RNA, a trivial amount of material assuming that mechanisms for the prebiotic synthesis of RNA oligomers existed at all.

A strategy to convert RNA ligase ribozyme into a general RNA polymerase involves separating the template and substrate from the ribozyme, optimizing the enzyme to “ligate” single nucleotides as substrates, and translocating along the template to the next position. Following a symbiotic regime of rational design and in vitro evolution, Bartel and his coworkers created a polymerase ribozyme able to polymerize along a template up to 14 nucleotides, the equivalent of a full turn of RNA helix (94). Technological advances in in vitro selection methodologies have led to a modest improvement of more than 20 polymerized nucleotides, which represents the current state of the art in polymerase ribozymes (95). This lineage of experiments has generated the most sophisticated artificial ribozyme known to science, but still falls well short of the presumed efficiency that would be needed in the RNA World.

Nucleoside-2′,3′-cyclic phosphates have been mentioned as candidates for activated monomers in the context of non-enzymatic polymerizations, and also deserve mention in the context of ribozyme-catalyzed polymerizations. The initial experimental verification of the possibility of a cyclic phosphate polymerase was the isolation of cyclic phosphate RNA ligase deoxyribozymes (96). Once again, in vitro selection was used to explore large populations of both DNA (97) and RNA (M.P. Robertson, J.E. Blaustein, and W.G. Scott, unpublished results) and isolate new ligases. Attempts to convert these ligases into polymerases have not been reported. RNA has proven to be a remarkably malleable tool in the hands of biochemists, and a satisfactory RNA-dependent RNA polymerase ribozyme will probably be developed in the laboratory eventually. When that happens, it will be the culmination of at least a decade’s worth of directed efforts, using complex combinations of rational design and in vitro evolution. It will be an important demonstration that further strengthens the case that an RNA World could have existed, but it will also show that RNA polymerase ribozymes do not appear to be a simple functionality that is likely to appear de novo from a naïve population of RNA molecules. The possibility of a self-replicating RNA system less sophisticated than a general RNA-dependent RNA polymerase ribozyme cannot be eliminated.

Ribozymic Metabolism

The minimal theoretical requirement to initiate the RNA World is a self-replicating RNA polymerase ribozyme. Realistically, supporting functionalities would soon be necessary to sustain an emerging RNA World. For example, a reliable supply of activated nucleotides would have been essential as the polymerases depleted the presumably scarce supply of abiotically produced material. To demonstrate that ribozymes are capable of catalyzing such complex chemistries, a nucleotide synthetase ribozyme was created in the laboratory (98). The ribozyme appends a base to an activated ribose to form a nucleoside. This is just one step in what can be imagined as an ever more complex network of metabolic pathways supporting the propagation of the RNA organism. But while the boundaries of the RNA World begin with an RNA polymerase, and begin to end with the invention of protein synthesis, less can be inferred about what happened in between and what level of complexity was achieved before the RNA World began to wane. Based on the defined starting and end points of the RNA World, a polymerase with a supporting metabolism to produce its activated nucleotide substrates would be necessary. Closer to the end, a ribosomal-type translation system with a supporting metabolism to produce its necessary substrates is believed to have been in place. Beyond these examples, modern biology may hold clues of extant molecular relics of RNA World functionalities. In fact, the case in favor of an RNA World is built, in part, on the ubiquity of nucleotide-based cofactors throughout biochemistry and the suggestion that they are remnants of an extensive RNA-catalyzed metabolism (99). While the range of chemical reactions that natural ribozymes are known to catalyze is very limited, in vitro selection has generated a rich collection of ribozymes with diverse functionalities indicating that, under the right conditions, RNA is capable of catalyzing a large subset of the reactions normally catalyzed by protein enzymes, though not as efficiently.
A key characteristic of living systems that is thought to have been utilized very early in the evolution of life, if not concurrently or even preceding RNA replication, is compartmentalization. All modern cells are enclosed by membranes that act as a barrier to regulate the intake and escape of molecules from the system. This functionality is necessary to contain the byproducts of metabolism and as a mechanism to link genotypes with phenotypes, which would be just as important for the earliest forms of life. For instance, an RNA replicase operating free in solution without boundaries might be able to replicate RNA molecules that it encounters, but the most efficient replicases would not benefit from an evolutionary advantage unless their systems and progeny were segregated from less efficient competitors. In simple systems involving vesicle-encapsulated RNA, the synthesis of additional RNA resulted in spontaneous vesicle growth at the expense of empty vesicles. Preliminary studies with these types of protocell systems have shown that basic properties like growth, encapsulation, and division occur as a consequence of purely physical functionalities in order to be operational.

**preRNA**

In most discussions, the RNA World is synonymous with the origin of life, but this need not necessarily be the case. The difficulties associated with the prebiotic synthesis of long RNA polymers have led many to speculate that an alternative, simpler biopolymer—that can somehow eliminate the problems associated with RNA—preceded the RNA World. Most of these “preRNA” candidates retain the familiar Watson-Crick base pairing between strands, but a number of different types of alternative backbone systems have been proposed, including a non-cyclic carbohydrate (102), peptide (103), and a variety of non-ribose sugars (104, 105). But unlike RNA, no recognizable molecular artifacts have yet been found in support of any of them. In the absence of direct evidence, for any particular candidate can only be judged against a number of practical factors, including the ease and likelihood of its prebiotic synthesis pathway and the ability to ultimately transfer its sequence information to an RNA polymer. With examples of the genetic transfer of sequence information from a non-RNA polymer to a strand of RNA having been demonstrated (106), the main hurdle, like RNA, is in the ease and likelihood of its prebiotic synthesis. Most preRNA candidates have one or more attributes that address a shortcoming of RNA, but none of the candidates are without flaws themselves. In this respect, no current preRNA candidate has distinguished itself as clearly superior to the others.

**Summary**

The mysteries of how life originated on this planet and came to achieve its current complexity hold a special fascination in the imagination of humankind. The earliest era of life’s evolution are very poorly understood, but fragments of evidence exist. The RNA World hypothesis outlines a description of how the earliest molecular forms of life may have arisen. The fragmented evidence that points most convincingly toward an RNA World relies almost entirely on what is known of modern biochemistry and the plausibility of reverse engineering a pathway from now to then. The converse, however, the period of time leading up to the emergence of RNA-based life, is more challenging to imagine. Difficulties and uncertainties exist at every step leading up to the emergence of the RNA World, from the inefficiencies of abiotic organic syntheses to the probability of inventing a ribosome more complex than any that has been seen today. Because of the difficulties of creating an RNA World from scratch, many believe that a preRNA World based on a simpler, nucleic acid-like polymer, preceded the RNA World as the first living system.

Catalytic Modes in Natural Ribozymes
S-adenosyl-l-methionine is a high energy compound and is the major source of methyl groups for a myriad of biologic transmethylation reactions. These highly specific single-carbon transfers onto diverse nucleophilic centers in biomolecules are catalyzed by methyltransferase enzymes and play important regulatory and structural roles in the cell. Here we discuss the chemical mechanism of the methylation reactions, including structural features of the methylsulfonium center in the cofactor molecule, enzyme-assisted activation of diverse nucleophilic targets by deprotonation or covalent catalysis, and spatial constraints of the reaction.

The first literature source describing biologic methylation refers to the methyl donor S-adenosyl-l-methionine (AdoMet) as “ATP-activated form of methionine” (1). The formation of AdoMet from methionine and ATP is catalyzed by AdoMet synthetase (MAT, methionine adenosyltransferase, EC 2.5.1.6) and occurs in a two-step reaction in which PPi and Pi are released along with the product (AdoMet) (2). Although almost any part of AdoMet molecule can be used by the living organisms (3), the most ubiquitous and important role of AdoMet is the participation in biologic transmethylation reactions (Fig. 1). Other methyl group donors such as tetrahydrofolic acid, betaine, and vitamin B12 are used in certain cases, but AdoMet is by far the most often used source of methyl groups and the second-most ubiquitous cofactor after ATP. The methyl transfer reactions from AdoMet are associated with very favorable enthalpies (∼−70 kJ/mol) compared with other methyl donors, which permits efficient and selective methylation of a large variety of biologic substrates in all living organisms from bacteriophage to humans (4).

### Methyl Group as a Biologic Mark

Methyl group transfer to particular targets is directed by enzymes called methyltransferases (MTases, EC 2.1.1.-). These enzymes catalyze more than 150 different reactions (according to SWISS-PROT database). AdoMet-dependent methyltransferases according to their substrates can be classified into four major groups: enzymes acting on small molecules, proteins, nucleic acids, and glycans. The atomic targets in these molecules can be carbon, oxygen, nitrogen, sulfur, or halides (4). Because of this enormous variety of substrates, methyltransferases play vital roles in many cellular processes, including cellular metabolism, signal transduction, storage, and processing of (epi)genetic information.

In a certain sense, the methyl group plays a comparable role with the phosphoryl group in biologic systems. From the chemical standpoint, the methyl group is a small (volume ∼20 Å³) and uncharged apolar group, which is usually added to replace a hydrogen atom (volume ∼5 Å³) in a target molecule. Therefore, depending on the role and the chemical context of its predecessor hydrogen, the structural content of the methylation signal will be different. If minimal chemical alterations in the target molecule are brought about, the methylation can be regarded as a “steric” signal. Such subtle additions of a small chemical group can lead to a highly specific recognition by cellular components and dramatic biologic consequences. Alternatively, when methylation leads to altered chemical-physical properties, such as tautomeric forms, H-bonding patterns, and new chiral centers, its role could be assigned as “chemical.” As an extreme example of a “chemical” role, the methyl group can serve as a chemical “activator” for a subsequent chemical conversion of a target molecule.

### Small-molecule methyltransferases

Out of more than 150 different reactions catalyzed by the methyltransferases more than 90 are carried on small molecules. The methyl groups serve here as important “chemical” building blocks required for the construction of essential cellular components and metabolites. N-methylation of the smallest amino acid glycine is responsible for regulating AdoMet/AdoHcy ratio in the eukaryotic cells (5). Catechol O-methyltransferase (COMT) is responsible for dopamine and other catecholamine
Chemistry of AdoMet-Dependent Methyltransferases

Figure 1
Action of AdoMet-dependent methyltransferases. (Top) Methyltransferases catalyze the transfer of the methyl group from the cofactor AdoMet onto defined nucleophilic targets (Nu = N, O, C, S) in various biomolecules (shown as gray balls). Activation of nucleophiles is often achieved by abstracting a proton (if present) from the target atom by a general base (B:). (Bottom) The methylation reactions proceed via a direct SN2 transfer, in which the attacking nucleophile and the substrate are involved in a single transition state structure. These reactions require a transient hybridization change from $sp^3$ to $sp^2$ and back to $sp^3$ with inversion of configuration at the reacting carbon.

neurotransmitters’ methylation hence, it influences nervous signal propagation (6). Another important enzymatic methylation converts norepinephrine to epinephrine (adrenaline) (7). Creatine, which is used by the cells for energy storage, is synthesized by methylation of guanidinoacetate (8). Methylated hydroxycinnamic acid derivatives are precursors of the plant cell wall esterified phenolic compounds, soluble sinapate esters, dimeric lignans, and the extensively cross-linked polymer lignin (9). Biosynthesis of vitamin B12 employs six different methyltransferases that add methyl groups to specific positions of the tetrapyrole ring (10). Finally, histamine N-methyltransferase inactivates inflammatory and allergenic mediator histamine (11). An example of a fatty acid methylating enzyme is cyclopropane-fatty-acyl-phospholipid synthase from M. tuberculosis. Its action is required for the long-term survival of nongrowing cells and is often associated with environmental stresses (12).

DNA methyltransferases

DNA methyltransferases modify nucleobases by depositing methyl groups onto exocyclic amino groups (N6 in adenine and N4 in cytosine) or the intracyclic C5-position of cytosine. Because these methylation reactions occur in the major groove of the DNA helix and without chemical consequences on the DNA structure, they can be viewed as “steric” signals designed for recognition by specialized proteins, enzymes, or large multicomponent complexes. All three types of DNA methylation found in prokaryotes and archaea occur sequence-specifically. A unique DNA methylation pattern (a combination of several methylated sequences) serves as a discriminatory species “self” code. In higher eukaryotes, the cytosine-5 methylation is solely known, which occurs in both a sequence-specific and a locus-specific manner. DNA methylation generally leads to a strong and heritable repression of gene expression and plays numerous essential regulatory roles in cellular differentiation and development, parental imprinting, X-chromosome inactivation, and silencing of endogenous retroviruses (13).

RNA methyltransferases

Methylation of RNA is even more diverse and abundant than that of DNA. RNA methyltransferases target nearly all chemically accessible sites on nucleobases and the ribose: N1, N2, and N7 in guanine, N1 and N6 in adenine, C5 in cytosine or uracil, and 2′O in ribose. Most of the known biologic methylation reactions seem to serve as a means for “chemical” tuning of RNA transcripts into biologically active species. For example, guanine-N1 methylation of tRNA prevents frame shifts during protein translation (14) in bacteria. 2′O-ribose methylations at specific positions are essential for stability of tRNA in both eukaryotes and prokaryotes (15). The same modifications guided by small, nucleolar RNAs to specific loci on rRNA is required for ribosome assembly (16). All mRNAs in eukaryotes are capped at their 5’ end, and at least two RNA MTases are required for the maturation of the cap structure; these modifications are required for the stabilization and efficient translation of the transcripts (17). Resistance to clinically important antibiotics (macrolide, lincosamide, and streptogramin B) is conferred by adenine-N6 methylation in 23S rRNA (18).

Protein methyltransferases

In proteins, a large variety of methylation targets has been identified: the carboxylate of aspartate and glutamate, the sulfur of cysteine and methionine, the imidazole of histidine, the amide of glutamine and asparagine, the guanidinium of arginine, the ε-amino group of lysine, and the terminal amino and carboxylate groups (19). Arginine and lysine can accept more than...
one methyl group producing symmetrical and unsymmetrical dimethylarginine, dimethyllysine, and trimethyllysine.

In the focus of a renewed interest are histone M-Tases. They produce monoarginine, symmetrical and unsymmetrical dimethylarginine, and all possible lysine ω-amino group methylation states. Such post-translational modifications of the histones determines whether chromatin adopts a compacted structure and is associated with silenced DNA–heterochromatin, or if it seems to be an extended structure and is associated with transcriptionally active DNA– euchromatin (20). Arginine M-Tases seem to methylate even more substrates, but the modifications effects are not well understood (21). As in DNA, the above-described examples of methylated residues can be viewed as “steric” marks designed for recognition by highly specific proteins.

In contrast, 3-isopropylamine T-MTase methylates the carboxyl group of 3-isopropylamine residues, which are spontaneously accumulated in proteins via inadvertent isomerisation of asparagines and asparagines. The resulting methylisoxa carbonyl group is reactive in the reverse intramolecular trans-esterification reaction, which regenerates an isopropylamine residue. Therefore, the methylation is the activating step on a chemical repair pathway of aged proteins and plays an important role in extending the life span of organisms from all domains of life (22).

The Methyl Donor: S-Adenosyl-L-Methionine

As discussed, AdoMet is a high energy compound. The methyl group is activated by the neighboring sulfonium center, and AdoMet serves as a co-factor during the M-Tase-catalyzed reactions. The sulfonium center induces a partial positive charge on all three adjacent carbon atoms (methyl group, ribose 5'-carbon, and methionine γ-carbon). This charge is clearly observed from a nearly 1 ppm high field shift of proton chemical shifts in AdoMet as compared with those in methionine and AdoHcy (23). Under physiologic conditions, both adjacent methylene groups can be attacked leading to slow decomposition to reactive species. AdoMet is particularly labile under alkaline conditions, forming adenine and S-ribosylmethionine readily. This reaction is initiated by the deprotonation at C-5′ (24). A competing pathway for AdoMet degradation, which is prominent at even lower pH values, involves an intramolecular attack on the methyl group with 2H0 r 13C result in slight positive and negative isotope kinetic effects, respectively, in the case of COMT enzyme. Based on these observations a “symmetrical” and “asymmetric” transition state has been proposed (28). It is now generally accepted that enzymatic methylation reactions proceed via a direct S2′ transfer, in which the attacking nucleophile and the substrate are involved in a single transition state structure (see Fig. 3). The catalytic power of many methyltransferases thus largely derives from their ability to bring the two substrates together in correct orientation.

Substitutions in the sulfonium center

AdoMet analogs, in which sulfur of the sulfonium center is replaced with selenium or tellurium, have been synthesized and used to study the reaction mechanism (Fig. 2a–c). Electronegativities of S, Se, and Te (2.58, 2.55, and 2.30 on the Pauling scale, respectively) suggest that carbons adjacent to telluronium groups are poorer electrophiles as compared with carbons adjacent to selenium or sulfur groups atom because of the reduced ability of the tellurium atom to induce a positive dipole at the adjacent carbon. On the other hand, the increase in atomic radii results in weaker heteroatomic bonds in the series S–CH3 > Se–CH3 > Te–CH3, thus making the higher analogs better leaving groups. These two opposing effects result in a slight chemical activation of the S-analog and substantial inactivation of the Te analog, as observed in the two enzymatic systems examined (29, 30). The same reasoning seems to be valid for explaining the relative effects on the heteroatoms on the two modes of decay of the analogs in water: deprotonation at C-5′ and intramolecular nucleophilic attack at C-γ. The deprotonation reaction is decreased, whereas decomposition via the C-γ attack is enhanced in the selenium analog as compared with AdoMet. This is understood taking into account that the first pathway involves the activation of the carbon atom, whereas the second requires both electrophilic activation of the carbon and a good leaving group.

AdoMet analogs with nitrogen replacements of the sulfur atom (N-adenosyl-L-azamethionine or azo-AdoMet; see Fig. 2d (31) seem even less reactive. These compounds are not susceptible to the decomposition reactions peculiar to AdoMet. They can act as charge-switchable mimics of AdoMet because the tertiary amino group (pKa = 7.1) can be protonated by adjusting the pH slightly below the physiologic values (32). However, because diakylamines are not nearly as good leaving groups as are dialkylsulfides, these compounds are not expected to be efficient methyl group donors in methyltransferase-catalyzed reactions. A further problem may derive from a low inversion barrier at nitrogen as compared with sulfur, leading to lower abundance of the correct epimeric form and thus poor overall positioning of the reactants in the enzyme pocket. Although initial testing suggested that NAM could serve as a substrate (31), this compound functioned as a substrate but not as a methyl group donor in the case of t-RNA uracil-5′-methyltransferase (33) and many other systems. Notably, a significantly improved reactivity is achieved in analogs carrying a sterically tense aziridine cycle (see Fig. 2e). Upon protonation of the ring nitrogen, enzyme-assisted nucleophilic attack on the ring carbon leads to the opening of the ring, which couples the whole cofactor to the target (Fig. 3a (34)). Alternatively, the aziridine ring can be generated in situ in
Nitrogen is a relatively good nucleophile but also a good base. In biologic substrates, nitrogen occurs in the form of alkylamines (glycine, lysine, or phenylethanolamine), aromatic amines (cytosine-N4, adenine-N6, or guanine-N2), heterocyclic systems (guanine-N1 or -N7, adenosine-N7, or histidine), or conjugated amines (glutamine or guanidine). Generally, an enzyme needs only to orient a lone pair of the nitrogen for \( \text{S}_{\text{N}}2 \) in line attack onto the methyl group of the AdoMet. If the nitrogen is protonated (alkylammonium), the proton needs to be removed before, in concert with, or after the methyl transfer; this step usually requires the presence of a general base in the active site.

### N-methylation

A well-studied example of aliphatic primary amino group methylation is provided by histone lysine MTases. The critical step in methylation of this amino group is its deprotonation, because a protonated lysine is a very bad nucleophile. The rate-determining step is the nucleophilic attack by the substrate on the electrophilic methyl group of the AdoMet. The reaction can be rescued by placing a double bond (allylic system) or a triple bond (propargylic system) next to the reactive carbon in the extended side chain (see Fig. 2k and 2l). The unsaturated bonds seem to stabilize the \( \text{sp}^2 \) transition state via conjugation of their \( \pi \) orbitals with the transient \( \rho \) orbital in the penta-coordinated transition state (37). These new synthetic cofactors are thus termed double-activated AdoMet analogs because the reactive carbon located between the sulfur and nitrogen is stabilised by resonance involving double bonds (sp2 orbitals) next to the sulfur atom. Consequently, the whole cofactor is covalently attached to the target molecule and irreversibly inhibits the enzyme (39).

### Substitutions in the transferable methyl group

AdoMet analogs with larger moieties replacing the methyl group (see Fig. 2k) have been obtained previously enzymatically (36) and later via regiospecific chemical S-alkylation of AdoMet. Such “reverse” chemistry additionally enhances the chemical stability of cofactor. Because of the positive charge of the protonated amine and correct chirality at the carbon center, sinefungin has an extremely high inhibitory potential for AdoMet-dependent methyltransferases.
Chemistry of AdoMet-Dependent Methyltransferases

Figure 3  Methyltransferase-directed coupling of extended groups to biomolecules using analogs of AdoMet. (a) Covalent coupling of N-aziridine and N-mustard cofactor mimics; (b) transfer of an extended aliphatic chain from a double-activated cofactor, S-adenosyl-L-propenthionine; (c) covalent coupling of an S-vinyl-analog of AdoMet.

are two possible ways to achieve this, as follows: “passive” catching of deprotonated species or “active” deprotonation of the lysine by a base in the active site of the enzyme. It turns out that both mechanisms are in use. In SET domain lysine MTases, the absence of an apparent general base in the active site and a very high and sharp pH optimum (∼9–10) (40) suggest a passive mechanism. In contrast, classic fold lysine MTases, Dot1p, are active in a broader pH interval (6–9.5). These enzymes contain a conserved essential Asn residue in the active site, which may facilitate the deprotonation of the target lysine (41, 42).

The methylation of exocyclic (aromatic) nitrogens proceeds in a different fashion, because pKa values of such nitrogens are usually low enough to stay unprotonated under physiologic conditions. The best representatives of this kind of N-methylation are cytosine-N4 and adenine-N6 MTases. These enzymes make hydrogen bonds to the target amino group directing its hydrogens to positions corresponding to sp3 hybridization. Such a “forced” hybridization change is thought to enhance the nucleophilicity of the nitrogen lone pair and to accelerate the reaction (43). A similar mechanism may also be used in nonaromatic conjugated amines, for example, in arginine MTases. Because of a very high pKa value of the guanidinium group (∼12), arginine methyltransferases are unlikely to achieve its complete deprotonation. Instead, they could polarize the guanidinium group and redistribute the positive charge away from the target nitrogen such that the nucleophilic attack on the methyl group of AdoMet et is accelerated (44).

O-methylation

Oxygen is less nucleophilic as compared with nitrogen. However, its nucleophilicity can be enhanced by generating a (partial) negative charge on it. In biologic substrates, modifiable oxygens are often found in three types of groups: phenolic, ribose hydroxyl, and carbonyl groups.

No general base catalysis is needed in the case of a carboxyl group, because it is usually deprotonated (pKa ∼4.5) under physiologic conditions. Indeed, a well-characterized example of such an enzyme, protein-isoaspartate O-MTase, contains no acidic or basic residues in the substrate-binding cleft (22). Phenolic hydroxyl groups have a markedly high pKa (∼10.5), and thus, they remain largely protonated under physiologic conditions. Enzymes can enhance the methylation reaction rate by abstracting a proton. For example, in the catechol MTase, the target hydroxyl group is coordinated with essential Mg2+, which apparently replaces the proton to generate a nucleophilic phenolate (6). Interestingly, electron-withdrawing groups in the phenol ring, such as nitro groups, lead to strong inactivation of the substrates converting them to potent inhibitors of the enzyme. Alternatively, caffeate, isoflavone, and chalcone O-methyltransferases use a well-positioned His residue for proton abstraction (45).

As in aromatic alcohols, ribose 2′-hydroxyls are unprotonated under physiologic conditions (pKa ∼14.5). However, it seems less likely that enzymes can catalyze the methylation reaction by abstracting directly the proton from the hydroxyl group.
Alternately, rotation freezing and steering an oxygen lone pair toward the methyl group could sufficiently enhance the reaction. Such a mechanism is exemplified in the VP39 cap-2 mRNA (nucleoside-2′-O-)methyltransferase. The enzyme is thought to form a nondeprotonating hydrogen bond between a Lys side chain and the 2′-OH proton. That would be possible if the lysine was unprotonated beforehand; i.e., its pKa value was much lower than usual. An 15N-labeled steric mimic of the lysine was employed to confirm that the pKa is indeed perturbed (~8.5) by adjacent Arg and Asp residues (46). The ultimate removal of the proton from the ribose oxygen onto the lysine occurs synchronously with or right after the methyl transfer. A similar mechanism may be valid in the case of tRNA guanosine-2′-O-methyltransferase, which uses an Arg residue to scavenge the proton (47).

C-methylation

Because of the low intrinsic nucleophilicity of carbon and a high energetic cost of generating an intermediate carbocation or its equivalent, the formation of a C–C bond in aqueous milieu seems a challenging task. However, single carbon transfers to carbon centers are a common event in biologic systems. Among the best studied examples are the methylation of the CS-position in pyrimidine nucleobases, cytosine and uracil, the methylation of tetrapyrrole system during synthesis of vitamin B12, and in pyrimidine nucleobases, cytosine and uracil, the methylation seems a challenging task. However, single carbon transfers to carbon centers are a common event in biologic systems. Among the best studied examples are the methylation of the CS-position in pyrimidine nucleobases, cytosine and uracil, the methylation of tetrapyrrole system during synthesis of vitamin B12, and in pyrimidine nucleobases, cytosine and uracil, the methylation.

The catalytic mechanism of the pyrimidine-5 methylation in nucleic acids is more complex as it involves covalent catalysis. The mechanism is common for numerous DNA/RNA cytosine MTases as well as for thymidylate synthase (although the latter uses tetrahydrofolate as the methyl donor) and has been studied in detail in several systems (50). Here, the cytosine-5 methylation in DNA is presented as an example (see Fig. 4a). The CS-position of cytosine, which is part of an aromatic ring, does not carry sufficient nucleophilicity for a direct methyl group transfer. The continuity of the aromatic system is disrupted by a nucleophilic attack of thiolate from a conserved cysteine residue in the enzyme on the carbon-6 (51), which is accompanied by protonation of N3 (by a conserved glutamate). The resulting 4-5 exomethylene structure provides sufficient electron density at CS (52) for a direct attack on the methyl group of AdoMet. The methyl transfer step is irreversible. The methylated intermediate 5,6-dihydrocytidine is resolved into 5-methylcytosine and free enzyme via deprotonation at CS and β-elimination of the cytosine residue. The nature of the base responsible for the CS-deprotonation in DNA cytosine MTases remains elusive, whereas an RNA uracil-5 MTase was shown to employ a second conserved Cys residue for that purpose (53). In the absence of cofactor, a proton from bulk water can reversibly bind to the CS of the target cytosine resulting in MTase-dependent exchange of the CS-hydrogen into solvent (54).

A series of mechanism-based analogs of cytosine was used to elucidate the mechanistic details of covalent activation. The significance of these analyses extends into the realm of MTase inhibitor design for anticancer therapies (54). Among the best known inhibitors of DNA cytosine-5 MTases are 5-aza-2′-deoxycytidine (5-aza-dC or decitabine), 5-fluoro-2′-deoxycytidine (5-F-dC), and 2-pyrimidinone-5,β-π(2′-deoxyriboside) (zebularine) (53). In 5-aza-dC, the nucleophilic attack of the thiolate on the ring system is strongly facilitated, because a higher electron negative character of nitrogen at position 5 increases the electrophilicity at C6. In the presence of AdoMet, the covalent complex can still accept the methyl group from the cofactor, but it cannot be resolved additionally because no proton is present at N5, which is required to regenerate the double bond and free the enzyme. A similar mechanism is proposed for zebularine. 5-fluoro-2′-deoxycytidine exerts its catalytic activity through formation of a covalent intermediate with bound AdoMet, which irreversibly traps the enzyme in a stable covalent complex (55). Such covalent complexes were purified and crystallized to reveal first the structural details of the reaction intermediates (56).

Spatial Control in Enzymatic Transmethylation

The catalytic power of AdoMet-dependent MTases to a large extent derives from their ability to bring the two substrates, the cofactor AdoMet and a target molecule, together in the right orientation. As most other biocatalytic enzymes, MTases accommodate their substrates next to each other in a concave catalytic pocket. Five different protein folds are known to date that are used to bind AdoMet; however, one of them, similar to the NAD(P)-binding Rossmann fold, is highly prevalent (4). Many of these enzymes contain flexible loops that close during catalysis to cover the bound substrates from bulk solvent and, in certain cases, bring in important catalytic residues. This unique arrangement serves to create a proper milieu for the reaction. However, binding a target molecule in a concave pocket is not always easily achieved, because access to a specific locus that
Chemistry of AdoMet-Dependent Methyltransferases

Figure 4  Catalytic activation of cytosine for C5-methylation by nucleophilic addition of a thiolate at the C6 position. (a) The chemical mechanism of enzymatic DNA cytosine-5 methylation. Mechanism-based inhibition of DNA MTases by cytidine analogs 5-fluoro-2′-deoxycytidine (b), 5-aza-2′-deoxycytidine (c), and 2-pyrimidinone-1-β-D-(2′-deoxyriboside) (d).

is deeply buried within a large macromolecule is a challenging task. The most extreme and elegant examples are found in DNA MTases, which methylate nucleobases in double-stranded DNA. The target positions for methylation are exocyclic amino groups or the intracyclic C5 position of cytosine, which are located in the major groove of the DNA helix. In the latter case, a covalent catalysis is required for the methylation, meaning that access to both faces of the ring and an edge of the cytosine base is critical (see Fig. 4). It is hard to imagine how that could be achieved in the framework of the DNA helix with nucleobases tightly stacked on each other. Remarkably, this problem is solved by completely rotating the target nucleoside out of the DNA helix and into the active site of a MTase, with minimal distortions to the rest of the DNA (56). Similar mechanisms are operative for many other enzymes acting on nucleic acids, including many RNA MTases.

Another catalytic challenge relates to product control in cases when several methyl groups can in principle be transferred onto the same residue or atom. As mentioned, lysine methylation can lead to monomethylated, dimethylated, or trimethylated products. Because, for example, secondary amines are better nucleophiles than primary amines, it is tricky to stop a chemical alklylation reaction at the monosubstituted product. This problem is solved by building in an appropriate number of bulky residues (tyrosines) in the active site such that only a defined number of methyl groups is accepted (57, 58). But this alone does not ensure processivity. The production of dimethylated or trimethylated lysine requires several cycles of AdoMet binding, methyl transfer, and AdoHcy release. The protein architecture with two substrates bound in a single active site bears the risk of releasing incompletely methylated products upon reloading the cofactor. If that is to be avoided for biologic reasons, different protein architecture should be used. Examples of such enzymes are SET domain lysine MTases, in which AdoMet and the substrate peptide are bound in two separate grooves located on different sides of the protein (57, 58). The successive cycles of methyl transfer are carried out in the cofactor pocket, whereas independent processing of the substrate and release of a properly methylated product occurs in the other.

Practical Implications

Because many MTases play important roles in biologic processes, these are potentially good target candidates for drug design. Inhibitors for numerous enzymes have been produced.
and studied. Among important examples are inhibitors of COMT (see above), which are used as therapeutic agents in Parkinson’s disease (53). 5-aza-2′-deoxycytidine (5-aza-dC) and related analogs of cytidine are metabolically incorporated into DNA leading to mechanisms-based irreversible inhibition of DNA M Tases (54). Despite their high toxicity, these DNA-demethylating drugs can be applied in combination therapies with conventional chemotherapies.

Another interesting application for M Tases is the transfer of larger chemical entities from engineered cofactors. Such enlarged AdoMet mimics, in combination with a myriad of AdoMet-dependent M Tases available in nature, would provide useful molecular tools for targeted functionalization of biomolecules (38). So far, two chemistries have shown a good promise. First, derivatives of N-azidinoadenosyl-adenosine (60) and mechanistically related nitrogen mustards (61) (Fig. 2e) are covalently coupled to their natural targets in the presence of DNA M Tases (Fig. 3a). By attaching chemical groups to these cofactors, they were shown to work as delivery systems for various functional or reporter groups. An inherent feature of this system is potent product inhibition (single-turnovers) by the covalent cofactor-substrate conjugate. A second class of AdoMet analogs circumvents the problem of catalytic product release. In these analogs, the methyl group is replaced with an extended carbon chain that contains an activating double or triple bond (allylic and propargylic systems; Fig. 3b) (37). These cofactors were shown to confer catalytic M Tase-directed transfer of their activated side chains (Fig. 3b), permitting sequence-specific functionalization and labeling of plasmid DNA (62).

The mid-chain dehydrogenation of saturated fatty acyl derivatives is carried out by a large family of O2-dependent, nonheme diiron-containing enzymes known as desaturases. Both soluble and membrane-bound desaturases have been characterized. The mechanism of desaturation is thought to involve the stepwise synthesis of vicinal hydrogen atoms via a short-lived carbon-centered radical intermediate. The most common desaturase inserts a (Z)-double bond between the C–9,10 carbons of a stearoyl thioester; however, many variations of this prototypical reaction have been discovered. Accounting for this diversity in terms of subtle alterations in active-site architecture constitutes a new frontier for research in this area.

The regioselective and stereoselective introduction of an olefinic link into fatty acyl side chains is catalyzed by a unique set of enzymes known as desaturases (1). The overall biochemical equation for this transformation can be depicted as follows:

\[
H^+ + NAD(P)H + O_2 + R-\text{CH}_2-\text{CH}_2R' \rightarrow NAD(P)^{+} + 2H_2O + R-\text{CH} = \text{CH-R}'
\]

Unlike other dehydrogenases, desaturases attack unactivated C–H bonds with the concomitant reduction of molecular oxygen; two reducing equivalents are derived from NADH, and two are derived from the substrate. Most fatty acid desaturases are integral, membrane-bound proteins found in the endoplasmic reticulum and accept substrates bearing phospholipid or Coenzyme A headgroups. In plants, a soluble, plastidial desaturase operates exclusively on acyl carrier protein ACP substrates. Common to all of these enzymes is a nonheme diiron-containing catalytic core (vide infra) that is used to generate the active oxidant in situ. Considerable insight into the detailed chemical mechanism of desaturation has been gained in the last 15 years (2). This knowledge has lead to a more sophisticated understanding of lipid biochemistry in various contexts, including chemical ecology, plant biotechnology, and medical lipidology.

Biologic Context

Fatty acid desaturation is a ubiquitous lipid modification that is critically important to aerobic life forms in two major ways:

1) adjustment of lipidic biophysical properties and 2) biosynthesis of chemical messengers. Saturated fatty acids produced by the fatty acid synthase assembly line, typically are dehydrogenated first at C–9,10 to give an oleate derivative that is additionally desaturated to generate the ω-6 and ω-3 group of the so-called “essential fatty acids” (Fig. 1a). Various highly bioactive signaling molecules (Fig. 1b) containing unsaturated sites are biosynthesized from this collection of primary fatty acids. In addition, desaturase-derived natural products with antifeedant properties have been discovered (Fig. 1c). It should be noted that the introduction of double bonds into biomolecules also dramatically enhances their susceptibility to free radical autoxidation with all attendant deleterious effects (3).

Unsaturated lipids and membrane fluidity

To function properly, cell membranes must exist primarily in the liquid-crystalline state. Model studies using synthetic lipids have demonstrated that the presence of a (9Z)-olefinic fatty acyl side chain in a diacylphospholipid lowers its gel-liquid phase temperature \(T_c\) by some 50°C relative to its fully saturated analog (4). The presence of the \(\Delta^9,12\) fatty acyl side chain lowers the \(T_c\) even more and constitutes an important adaptation to chilling for plants. The regulation of the response to chilling temperatures has been studied in some detail in various organisms (4).
Figure 1: Role of fatty acid desaturases in the biosynthesis of unsaturated fatty acids. Typical fatty acids found as components of cell membranes and storage lipids (a); signalling agents (b); and plant-derived antifeedants (c).

pheromone biosynthesis (5). Species-specific signals are generated by using a chemical language dictated by the number, position, and stereocchemistry of internal double bonds located in a hydrocarbon backbone of varying lengths. Increased differentiation is achieved through additional functionalization and the use of multiple components in specific ratios. The blend of (Z)- and (E)-11-tetradecenoes shown in Fig. 1b is a case in point. In the area of sphingolipid biochemistry, it has been discovered that the position and stereocchemistry of the double bond in ceramide is critically important to biologic function (6).

Plant defense

The involvement of desaturase-type enzymes in the biosynthesis of some important lipidic antifeedants now has been firmly established (Fig. 1c) (7). An instructive example of this phenomenon is the production of ricinoleate (a purgative) by a desaturase homolog found in the castor plant. Here, a subtle variation in mechanistic pathway is responsible for the introduction of a C-12 hydroxyl group rather than a 12,13-double bond (7). Another interesting case features the putative dehydrogenation of a cyclopropyl fatty acid to produce sterculate, a potent inhibitor of the mammalian but not the plant \( \Delta^9 \) desaturase (8). Finally, the biosynthesis of polyacetylenes with antifungal properties such as falcarindiol is thought to involve a sequence of unique desaturase-mediated oxidations (9).

Chemistry of Fatty Acid Desaturase

The soluble castor stearoyl-ACP \( \Delta^9 \) desaturase has served as an important enzyme for detailed structural and biochemical studies (10). A crystal structure of this protein confirmed the presence of a nonheme, carboxylate-bridged diiron cluster in close proximity to a narrow, curved hydrophobic channel (11). The latter can accommodate a stearoyl-ACP substrate that adopts a gauche conformation around the 9,10–carbon–carbon single bond. Delivery of electrons from nicotinamide adenine dinucleotide phosphate (NADPH) via ferredoxin as required by Equation 1 is gated by substrate binding—an event that alters the redox properties of the catalytic center and ultimately triggers oxygen binding. Generation of a potent oxidant then can proceed (12). It is assumed that a similar diiron-based cluster exists in membrane-bound desaturases; Detailed comparison of amino acid sequences for this class has revealed the presence of a highly conserved, catalytically essential 8-histidine motif that is capable of binding two iron atoms. In addition, M Gsobauer studies of a closely related alkane \( \omega \)-hydroxylase revealed the presence of two catalytically active iron atoms (13). However, reconstitution of purified membranous desaturases to permit more detailed structural study has been extremely difficult. Initial design and testing of mechanic probes was carried...
The cryptoregiochemistry of fatty acid desaturation

The term “cryptoregiochemistry” was coined to describe which substrate hydrogen is removed first in fatty acid desaturation (19). In the case of membrane-bound desaturases, the site of initial oxidation could be determined by examining the magnitude of the primary deuterium kinetic isotope effect (KIE) on C-H cleavage as a function of isotopic substitution. According to the mechanistic model (Fig. 2), abstraction of the first C-H bond should be energetically more difficult, and hence more sensitive to isotopic substitution, than the subsequent C-H bond cleavage step. Thus, a large KIE was observed at C-9 but not at C-10 in the desaturation of regiospecifically deuterated substrates by a yeast stearoyl CoA \( \Delta^9 \) desaturase (Fig. 3a) (19). Corroborating evidence for initial attack at C-9 by this desaturase was obtained by observing preferential sulfur oxidation of an S-9 substrate analog (Fig. 3b) (20). A additional proof for a C-9-initiated \( \Delta^9 \) desaturation was the observation of low level (1%) regioselective 9-hydroxylation along with the production of the major 9,10-olefinic product (14). The former pathway presumably occurs by hydroxyl trapping of the putative C-9 radical intermediate (Fig. 2).

The cryptoregiochemistry of a large number of membrane-bound desaturating systems with varying positional specificities has been determined (2), which include desaturases found in species of bacteria, blue-green and green algae, fungi, nematode, plants, insects, and mammals. The somewhat surprising trend that has emerged is that the carbon closest to the C-1 (acyl) terminus always is attacked first during these dehydrogenation reactions. This result points to a highly conserved active-site architecture that is used by desaturases from a wide range of life forms. The corresponding hydroxyl by-product (Fig. 2) with the predicted regiochemistry is observed routinely (14). The determination of the cryptoregiochemistry for the soluble castor \( \Delta^8 \) desaturase has been more difficult because the C-H bond cleavage is masked kinetically by other events in the catalytic cycle, which nullifies the use of an approach that relies on the measurement of an intermolecular KIE. Nevertheless, the results of experiments that use sulfur, oxygen, and fluorine-labeled substrates suggest that, in this case, the initial attack on C-H bonds is at C-10 rather than C-9 (10).

Variations on an oxidative theme: the oxygenation/dehydrogenation connection

Perhaps the most important mechanistic question that remains unanswered with respect to desaturases relates to the switch that controls the choice of dehydrogenation/hydroxylation pathways (Fig. 2). The study of the FAD2 subgroup of plant desaturases has been particularly instructive in this context. Pair
Chemistry of Fatty Acid Desaturases

Figure 3 Evidence for a stepwise removal of hydrogen by membranous stearoyl Δ⁹ desaturase (SCD) initiated at C–9: Primary deuterium isotope effect observed at C–9 but not at C–10 (a); Sulfoxidation of S–9 preferred over S–10 thio substrates (b).

Regiochemistry of desaturation

Regioselective remote functionalization of unactivated C–H bonds has long been a goal of synthetic chemists. Indeed, much early work in this area (26) was inspired by the ability of fatty acid desaturases to introduce double bonds in a regioselective manner. Three modes of regiocontrol have been identified (27, 28). The positional specificity of the Δ⁹ class of desaturases is determined by the location (carbons n, n + 1) of the incipient double bond relative to the acyl head group (C–1) independent of the chain length of the substrate. For example, both yeast and rat liver membrane-bound Δ⁹ desaturases dehydrogenate a range of fatty acyl CoA thioesters (C–15 to C–19) at the 9,10-position with no measurable regiochemical "error" and at comparable rates. Similar regioselectivity is observed for the corresponding soluble castor enzyme; but in this case, the C–18 substrate is a highly preferred substrate (10). Both the regioselectivity and the chain-length specificity of the latter enzyme can be altered through protein engineering experiments (1). The ω-n group desaturases inserts a double bond "n" carbons from the methyl terminus of substrate. Yet a third group of enzyme homologs that are tuned to catalyze either dehydrogenation or oxygenation as the major pathway have been identified (7). Thus, oleate Δ¹² desaturase introduces a double bond at C–12,13 by initial hydrogen abstraction at the C–12 position, as determined by a KIE study (21). However, an enzyme homolog, oleate 12-hydroxylase, forms 12-hydroxyoleate (ricinoleate), a major component of castor oil (Fig. 4a). The results of site-directed mutagenesis experiments that use a bifunctional Δ¹² oleate desaturase/12-hydroxylase demonstrated that relatively conservative changes in a few amino acids have a major impact on the hydration/desaturation ratio (7, 14). An even more dramatic example of this mechanistic dichotomy is the discovery of FAD2-type enzyme homologs in the Crepis species that can execute either the dehydrogenation or epoxidation of the C–12,13-olefinic bond (Fig. 4b) (22). Interestingly, the former reaction is initiated also at C–12, as indicated by a large primary deuterium kinetic isotope effect at this position (23). A similar trend in kinetic isotope effects is exhibited by an insect acetylenase (24). It is tempting to account for these observations in terms of "fine control" of substrate position relative to oxidant in the active site. Alternatively, subtle changes in the coordination chemistry at the catalytic centers, similar to that postulated for clavaminate synthase, could be responsible for the observed divergence in reaction outcome (25).
Chemistry of Fatty Acid Desaturases

Figure 4  Variations on an oxidative theme: the dehydrogenation/oxygenation connection. C-12-initiated oxidation catalyzed by oleate \( \Delta^{12} \) desaturase and its homolog oleate 12-hydroxylase (a) and \( \Delta^{12} \) acetylenase and its homolog \( \Delta^{12} \) epoxidase (b).

of desaturases, the \( \nu+n \) class uses an adjacent double bond as the primary reference point and introduces unsaturation "n" carbons from a preexisting double bond.

Chemical Tools and Techniques

The design of probes for the mechanistic study of fatty acid desaturases had to take into account that this class of enzymes cannot tolerate large alterations in substrate structure. Consequently, use of isotopic labeling and the isomorphic replacement of the -CH2- unit by the sulfur atom or CHF moiety have been the most versatile approaches. Additional challenges were the high endogenous lipid content of membrane-bound desaturases and the need to enzymatically prepare substrate ACP thioesters in the study of soluble desaturases (16). To understand the bioinorganic chemistry of desaturases, a new methodology for probing nonheme iron-containing enzymes also was required (29).

Stereospecific and regiospecific isotopic labeling

To determine the stereochemistry of desaturase-mediated hydrogen removal, the synthesis of stereospecifically monodeuterated fatty acid substrates and a suitable gas chromatography–mass spectrometry (GC–MS) or liquid chromatography–mass spectrometry (LC–MS) method of product analysis is needed (2). The most common method of introducing deuterium stereospecifically is through deuteride displacement of suitable activated chiral alcohols. Occasionally, the latter compounds are available from natural sources; however, when they are not available from natural sources, total synthesis of substrate is necessary. In addition, the frequent problem of mass spectral interference because of high endogenous di-product content must be overcome through additional remote mass labeling of substrate using deuterium, sulfur, or fluorine substitution.

An examination of the primary deuterium kinetic isotope effect on each C–H bond cleavage involved in desaturation can reveal the site of initial oxidation, provided other kinetically more important enzymic steps do not mask these effects. This methodology relies on monitoring the loss of deuterium from regiospecifically deuterated fatty acids via GC–MS. General strategies for the synthesis of the required labeled compounds were devised during early work on assignments of 13C nuclear magnetic resonances (NMRs) for various fatty acids (30).

Use of fluorine as a probe and as a tag

Monofluorinated fatty acids function as fatty acyl substrates for desaturases and can be synthesized in enantiomerically enriched form via diethylaminosulfur trifluoride (D.A.S.T.) treatment of the suitable chiral alcohols. An example of the use of fluorine-substituted fatty acids as mechanistic probes was demonstrated by the use of chiral 9-fluorostearoyl substrates to induce latent stereoselective 10-hydroxylation by the castor stearoyl ACP \( \Delta^{9} \) desaturase (16). In addition, the advantages
of $^1$H-decoupled $^19$F-NMR, such as wide chemical shift range, high sensitivity, and lack of interferences, allow one to monitor desaturase-mediated transformations at $\mu$Molar fluoro-substrate concentrations. In this context, $\omega$-fluorine-tagged fatty acid analogs have proven extraordinarily useful in tracking remote functional group transformations (2).

Use of sulfur as a methylene isostere

This fatty acid analogs are synthesized easily by thiolation of the corresponding bromoacids. When the sulfur atom in this substate is remote from the site of desaturation, normal olefinic this products are produced, with the observed chemoselectivity being a consequence of a strict, desaturation-imposed, regiochemical imperative. Thia compounds also can be used to determine the site of initial oxidation in desaturase-mediated reactions because oxo transfer occurs most efficiently when the sulfur atom is located at the site of initial oxidation (20). A as a bonus, the enantiospecificity of the oxidant can be ascertained by determining the absolute configuration of the resultant dialkyl sulfides (20). It was found that the stereochemistry of sulfoxidation matched that of hydrogen removal for the parent substrate. These analyses can be carried out on a microscope by using $\omega$-fluorine-tagged thia derivatives and suitable Pirkle-type NMR shift reagents (31).

Future Directions

Currently, efforts are underway to obtain more structural information on desaturases to address the mechanistic issues that have been raised through substrate-based studies. The need for more detailed 3D active-site information is acute, particularly in the case of membrane-bound desaturase for which only hypothetical models currently are available. Design of mechanism-based inhibitors of medically relevant desaturases such as stearoyl-CoA $\Delta^\text{9}$ desaturase (SCD) (metabolic syndrome) (32), DesA3 (tuberculosis) (33), and dihydroceramide desaturase-mediated transformations at $\mu$Molar fluoro-substrate concentrations. In this context, $\omega$-fluorine-tagged fatty acid analogs have proven extraordinarily useful in tracking remote functional group transformations (2).

Use of sulfur as a methylene isostere

This fatty acid analogs are synthesized easily by thiolation of the corresponding bromoacids. When the sulfur atom in this substate is remote from the site of desaturation, normal olefinic this products are produced, with the observed chemoselectivity being a consequence of a strict, desaturation-imposed, regiochemical imperative. Thia compounds also can be used to determine the site of initial oxidation in desaturase-mediated reactions because oxo transfer occurs most efficiently when the sulfur atom is located at the site of initial oxidation (20). A as a bonus, the enantiospecificity of the oxidant can be ascertained by determining the absolute configuration of the resultant dialkyl sulfides (20). It was found that the stereochemistry of sulfoxidation matched that of hydrogen removal for the parent substrate. These analyses can be carried out on a microscope by using $\omega$-fluorine-tagged thia derivatives and suitable Pirkle-type NMR shift reagents (31).

Membranes, Fluidity of Natural Products: An Overview

Organic Chemistry in Biology
All cells must respond appropriately to external stimuli, including nutrient availability, hormones, and growth factors. A main focus of biologic research is aimed at elucidating the molecular mechanisms of how signals are relayed within cells. Protein phosphorylation is a central mechanism of signal transduction in eukaryotes and is involved in nearly all regulated cellular processes. Two families of enzymes control the phosphorylation state of cellular proteins: protein kinases catalyze phosphorylation of either serine/threonine or tyrosine residues of target proteins using ATP as the phosphodonor, whereas protein phosphatases catalyze removal of the phosphate group from phosphoproteins (1). Thus, phosphorylation of cellular proteins is a reversible switch that controls the enzymatic activity, cellular localization, conformation, or macromolecular binding capacity of the target protein, ultimately culminating in cellular responses to a variety of stimuli. The families of protein kinases and phosphatases are large: the human genome contains ~600 protein kinases and ~150 protein phosphatases. Similarly, the extent of protein phosphorylation is immense; it is estimated that one third of all human proteins are modified by phosphorylation (2, 3). Thus, understanding protein phosphorylation is a major challenge for biologic research and also has implications for developing therapies to treat the many human diseases that originate from misregulated signal transduction. In this article, I will discuss the chemistry and enzymology of the phosphorylation/dephosphorylation reactions catalyzed by protein kinases and phosphatases as well as describe some chemical tools that have been developed to study features of protein phosphorylation that otherwise resist analysis.

### Enzymology of Protein Kinases

**The phosphotransfer reaction mechanism of protein kinases**

Protein kinases catalyze transfer of the \( \gamma \)-phosphate from ATP to hydroxyl side chains of target proteins. This phosphotransfer reaction lies somewhere on a continuum between two limiting mechanistic possibilities (4). The **associative** mechanism is analogous to the \( \text{Sn2} \) reaction, where the hydroxyl group of the phosphoacceptor protein attacks the \( \gamma \)-phosphate of ATP, followed by the formation of a \( -3 \) charged trigonal bipyramidal transition state, which is resolved then into ADP and phosphoprotein (Fig. 1a). This trigonal bipyramidal transition state has two positions around the phosphorous center. \textit{Apical} positions are long, weak bonds \( 180^\circ \) apart from each other where groups enter or depart, and \textit{equatorial} positions are shorter, stronger bonds \( 120^\circ \) apart from each other. A dissociative phosphotransfer reaction can be \textit{in-line}, where the incoming nucleophile approaches from the backside of the scissile bond (as in a classic \( \text{Sn1} \) reaction), or \textit{adjacent}, where the nucleophile approaches the backside of a nonscissile bond. The second limiting mechanism is dissociative phosphotransfer, where the \( \gamma \)-phosphate ionizes (as in an \( \text{Sn1} \) reaction) to form a \( -1 \) charged metaphosphate intermediate that subsequently is captured by the hydroxyl nucleophile (Fig. 1b).

Phosphotransferases are ubiquitous in biology and have varied mechanisms. To determine whether the phosphotransfer
Chemistry of Protein Kinases and Dephosphorylases

(a) The limiting case of purely associative phosphotransfer involves attack of the hydroxyl on the phosphoanhydride followed by release of ADP. (b) The alternative limiting case of purely dissociative phosphotransfer possible in kinase reactions involving ionization of the phosphoanhydride bond followed by capture of the metaphosphate intermediate by the hydroxyl nucleophile. (c) Structure of a transition state mimic of protein kinase A. The phosphoacceptor peptide is yellow with the nucleophilic serine in blue; the AlF₃ mimic of the γ-phosphate is gray. The structure shows that the β-phosphate–aluminum–serine internuclear geometry is in-line, and the internuclear distance suggests the mechanism is closer to the associative end of the mechanistic spectrum.

Catalysis by protein kinases

How protein kinases facilitate phosphotransfer is well understood from structural studies. The overall structure of the catalytic domain of protein kinases is bilobal, consisting of a small, mostly β-sheet subdomain at the N terminus connected by a short linker to a larger, mostly α-helical C terminus. The N-terminal domain binds Mg:ATP, whereas the C terminus binds the phosphoacceptor protein substrate (Fig. 2a). The detailed architecture and catalytic residues of the active site are very highly conserved among the family. Much structural biology analysis has been performed on protein kinase A (PKA), and its catalytic residues are conserved across the family (6, 7). In PKA, lysine 72 and glutamate 91 orient the γ-phosphate toward the protein substrate (Fig. 2b). Aspartate 166 acts as a catalytic base to accept the proton from the hydroxyl nucleophile, and Lys 168 acts as an electrostatic catalyst to stabilize the γ-phosphate during the reaction. Asparagine 171 positions a magnesium ion that coordinates the α/β phosphates (Fig. 2c).
Enzymology of Protein Phosphatases

Phosphatases hydrolyze phosphate groups from phosphoproteins, thereby reverting the action of protein kinases. Two classes of protein phosphatases exist with distinct structures, substrate specificities, and mechanisms: protein serine/threonine phosphatases and protein tyrosine phosphatases. A few dual-specificity phosphatases also are known that are similar in structure to protein tyrosine phosphatases.

Protein tyrosine phosphatases (PTPs) cleave phosphate groups from phosphotyrosine residues. As is the case with protein kinases, these enzymes are well characterized structurally.

Protein tyrosine phosphatases specifically recognize phosphotyrosine because of the presence of a P-loop binding motif, with the general sequence HCPxxxxxxR(S/T) (8). The P-loop arginine and several backbone amide nitrogens are the primary contacts to the phosphate oxygens through hydrogen bonds. The active site pocket is also deep, which disallows proteins phosphorylated on serine to access the P-loop. Hydrophobic side chains also pack the aryl moiety of phosphotyrosine to provide additional selectivity versus phosphoserine.

The mechanism of the PTP hydrolysis reaction has two steps. First, phosphate is transferred from tyrosine to the cysteine residue of the P-loop, which generates a phosphoenzyme intermediate with concomitant release of tyrosine. This process is followed by hydrolysis of the phosphoenzyme to free enzyme and inorganic phosphate. Two active site residues are of primary importance during the catalytic cycle: the nucleophilic cysteine and the general acid/base catalyst. After attack of the cysteine on phosphotyrosine, tyrosine can be expelled as the cysteine thiolate, with concomitant release of tyrosine. The aspartate also has a lowered pKa value, which amplifies its nucleophilicity. Measurement of the pH profile of the rate of alkylation of this cysteine with iodoacetate has determined its pKa to be as low as ~5 (normally 8.3), which makes the residue ionized at physiologic pH (10). The aspartate also has an anomalous pKa value and is believed to be protonated at the beginning of the reaction coordinate, as evidenced by cocrystal structures of multiple protein serine phosphatases.

Resolution of the phosphoenzyme intermediate into free enzyme and inorganic phosphate is accomplished by orientation and deprotonation of water by the aspartate residue and attack at the phosphophosphate. Mutagenesis of the aspartate residue to alanine (as well as the Arg in the P-loop) shows its importance in this second step, as it leads to accumulation of the phosphoenzyme intermediate (12).

As was the case with other phosphotransfer reactions, the hydrolysis reaction catalyzed by PTPs lies along a mechanistic continuum between the limiting cases of associative and dissociative mechanisms. In the case of Yersina PTP, a crystal structure was solved with nitrate, a mimic of the transition state with exogenous thiol, which explains the role of peroxide inactivating several PTPs and is reversible by treatment with exogenous thiol, which explains the role of peroxide use as a rapid diffusable signaling molecule (13).

Protein serine/Threonine phosphatases

Protein phosphatases that are specific for phosphoserine or phosphothreonine have a distinct reaction mechanism from tyrosine phosphatases. Protein serine phosphatases are transition metal-dependent, and the reaction mechanism does not involve a phosphoenzyme intermediate as in the case of PTPs. Crystal structures of multiple protein serine phosphatases have revealed how the enzymes catalyze hydrolysis of phosphoserine (14).

Serine phosphatases are metalloenzymes with two transition metals (Fe3+ and Zn2+–Mn2+) in PP2B and PP1, or 2 Mn2+ in PP1B.
Chemistry of Protein Kinases and Dephosphorylases

(a)

(b)

Figure 3 Structure of protein serine phosphatase PP2C with bound phosphate showing the binuclear metal site (purple spheres) and the nucleophilic water (red sphere). Also shown are residues that ligate the transition metals as well as two key asparagines that coordinate the phosphate group.

Figure 4 Protein kinases with the “gatekeeper” residue mutated to glycine that makes them recognize N6-substituted ATP analogs also programs them to be uniquely sensitive to designed inhibitors, allowing rapid generation of potent selective kinase inhibitors of any protein kinase.

PP2C) coordinated by Asp, Asn, and His residues to form a binuclear metal center in the active site. This metal center is bridged by a well-ordered water molecule. In the proposed hydrolysis mechanism, the metal-bound water acts as the nucleophile to attack the phosphorous center of phosphoserine/threonine. The metal centers contribute by Lewis acid catalysis to lower the pKa of the bound water and to enhance its nucleophilicity. The metal's in some cases (PP1 and PP2B) also coordinate the phosphate of pSer/pThr, which would serve to enhance the electrophilicity of the phosphate. A second metal-bound water has been proposed to perform general acid base catalysis to shuttle protons to the departing serine hydroxyl. The phosphate of the substrate is positioned by hydrogen bonding to Arg33 residue as well as metal bound waters (Fig. 5).
Chemical Tools to Study Protein Phosphorylation

Chemical tools have played a central role in elucidating the function of posttranslational protein phosphorylation. Kinase and phosphatase inhibitors have played a major role in the study of protein phosphorylation because they allow rapid, reversible inactivation of the target in meaningful contexts (cells and organisms) to study its biologic function. Chemical tools have also helped identify the direct substrates of individual kinases and phosphatases, and conversely, they have helped identify which kinase is responsible for phosphorylating a particular phosphoprotein. Here I will focus on chemical tools developed for protein kinases; several reviews discuss chemical tools for protein phosphatases (15, 16).

Engineering protein kinases to label direct protein substrates

A main question regarding protein phosphorylation is what the direct targets of any given protein kinase are, within a signal transduction event. If all phosphotransfers could be mapped, the sequence of events that lead to a host of important biologic functions would be known, which not only would be important for a full understanding of signal transduction but also would enable the rational design of drugs that target signaling systems with predictable outcomes. This information is very difficult to obtain because many kinases work in concert during a signaling event and phosphorylate many different proteins.

A chemical method was devised to address directly the issue of determining the direct substrates of any given protein kinase (17). The idea is centered on generating ATP analogs (A*TPs) that can function as phosphodonor in a kinase reaction only with a protein kinase that has been engineered properly to accept the modified nucleotide. Thus, the addition of radiolabeled A*TP to a cell lysate that contains one such A*TP-sensitive protein kinase would result in selective radiolabeling of its direct substrates (Fig. 6a).

Several requirements of an unnatural A*TP analog and engineered kinase exist to have substrate labeling capabilities. First, the A*TP must not be a substrate for any endogenous kinases. Second, a mutation in the ATP binding site of a kinase must be discovered such that A*TP is now used in the phosphotransfer reaction with good efficiency. Finally, the mutation that expands the nucleotide specificity of the kinase should be functionally silent, so the mutant kinase performs its roles normally, with the single exception of accepting A*TP for substrate labeling purposes.

Toward this goal, several radiolabeled N6-substituted A*TP analogs were synthesized and tested for their ability to label kinase substrates in a cell lysate rich in active kinases. Several bulky N6 substituents rendered the ATPs "orthogonal" to the set of all wild-type kinases, such as N6-cyclopentyl ATP and N6-benzyl ATP. Examination of available ATP:kinase cocrystal structures then allowed design of mutations that would allow these substrates to bind productively to the active site. One residue in the link region between the small N-terminal and larger C-terminal subdomains (M120 in protein kinase
Chemistry of Protein Kinases and Dephosphorylases

Figure 6  Scheme of the method to identify direct protein kinase substrates using the unnatural nucleotide N^6-(benzyl) ATP and kinases engineered to accept them by mutation of the gatekeeper residue (T338G in c-Src). Introduction of either the engineered kinase or γ-32P labeled ATP analog alone results in no substrate labeling, but in combination, the direct substrates of the engineered kinase are radiolabeled. (b) The crystal structure of wt c-Src and ADP shows direct contact between the Thr338 residue (red) and the N^6 position of ATP, precluding catalytic activity with N^6-substituted ATP analogs. (c) The crystal structure Thr338Gly c-Src and N^6-(benzyl) ATP shows the this mutant exposes a hydrophobic pocket that allows recognition of the unnatural nucleotide.

A) directly contacts N^6 of ATP and is conserved large hydrophobic residue. This hydrophobic residue serves as a “gatekeeper” to a larger hydrophobic pocket behind it (Fig. 6b). Point mutation, in which this residue is changed to glycine, allows the bulky N^6 benzyl/cyclopentyl substituent to access the hydrophobic pocket. This action rendered the mutant kinases efficient catalysts with the N^6-substituted ATPs and only modestly changed their catalytic efficiency with ATP, thereby making the mutation functionally silent. Most impressively, the mutation that sensitizes kinase toward ATPs is portable to nearly all kinases in the superfamily and in multiple organisms. Numerous groups have used this system to identify kinase substrates from many different signaling pathways in several organisms.

Specific kinase/phosphatase inhibitors as chemical tools

Perhaps the largest contribution that chemistry has made to the study of kinase-mediated signaling is the development of chemical inhibitors of protein kinases and phosphatases. Kinase inhibitors are under intense investigation as drugs after the spectacular success of the Abl tyrosine kinase inhibitor Gleevec as a treatment for chronic myelogenous leukemia. Because of this interest in drug development, many inhibitors of kinases are known and used as biochemical tools to inactivate rapidly kinases of interest. However, chemical inhibitors are useful to study the biology of kinases and phosphatases only if the compounds are selective for one member of the larger family. If compounds are monospecific, their biologic effects can be assigned unambiguously to the inhibition of a single enzyme. For protein kinases, however, truly selective inhibitors have been difficult to discover, and because the family is so large, it has been very difficult to confirm what the selectivity of commonly used inhibitors actually is. A recent comprehensive survey of the actual specificity of commonly used kinase inhibitors showed that many compounds are not as selective as previously thought and that many have more potent targets than the kinase they are commonly used against (18). This article highlights the need for strategies that preserve the advantages of using small molecule inhibitors to probe kinase function, such as speed, ease, and tunability, with stringent verification of target specificity. The difficulty in generating specific kinase inhibitors stems from the fact that most inhibitors target the kinase ATP binding site. This site is conserved highly among the family, which makes development of specific compounds difficult.

Toward this goal, a chemical-genetic strategy for developing specific kinase inhibitors was developed (19). The “gatekeeper” residue that when mutated to alanine or glycine sensitizes protein kinases toward unnatural ATPs also was exploited to generate kinases that are sensitive to inhibitors with similar bulky substituents oriented toward the gatekeeper residue. In this way, cells carrying the mutant kinase would be uniquely sensitive to inhibitors that require binding the hydrophobic pocket adjacent to the gatekeeper. The relatively nonselective inhibitor scaffold PP1 was synthesized with bulky substituents and ring expansions that were designed to contact the gatekeeper residue (Fig. 3). It has been shown that virtually any kinase can be “programmed” to be sensitive to these bulky inhibitors by mutating

Figure 7  Structure of ATP-peptide substrate linked “bifunctional” kinase inhibitors are a general strategy to generate specific inhibitors of any protein kinase whose peptide substrate specificity is known.
Chemistry of Protein Kinases and Dephosphorylases

a single amino acid. The selectivity of these compounds toward "analog-sensitive" kinase alleles is remarkable (∼1000 fold versus wild type kinases), as is their affinity, with IC50 values in the low nanomolar range. Furthermore, because inhibition requires a specific genetic background, for example, mutation of the gatekeeper residue, off-target effects can be controlled for by comparison with drug-treated cells with an intact gatekeeper. A more recent general strategy to generate specific kinase inhibitors involves generating compounds that probe the phosphoacceptor peptide binding groove between the small and large lobes of the catalytic domain (28). Oftentimes kinases are selective for specific peptide substrates, so exploitation of this selectivity can yield specific kinase inhibitors. Inhibitors were generated by linking the ATP moiety to kinase-specific peptide substrates to yield "bifunctional" inhibitors that capture interactions in the ATP and peptide substrate binding sites (Fig. 7). In one such study, targeted against the insulin receptor tyrosine kinase domain, γ-thio ATP was linked to an optimized IRK peptide substrate, which creates a nucleotide–peptide conjugate that has a submicromolar K_i (370 nM). The bifunctional inhibitor also shows selectivity toward IRK, as the K_i of the conjugate for the tyrosine kinase Csk was 100-fold higher. This strategy is suitable for any kinase whose peptide substrate specificity is known and has been applied for many diverse kinases.

Chemically cross-linking kinases and their substrates

Another chemical biology tool generated to study protein kinase signaling is a method to identify a kinase responsible for phosphorylating a particular phosphoprotein. Two methods have been devised by designing ATP molecules that form covalent bonds to both the kinase and substrate, which allows identification of the unknown partner by mass spectrometry.

Figure 8. Two strategies to cross-link kinases with their substrates, involving either photo-cross-linking groups (a) or a mechanism-based annihilation reaction (b).
In the first case, ATP analogs that have two azido groups attached at the purine and gamma-phosphate were synthesized (21). Such a molecule can bind the ATP binding site of a given kinase and allows its physiologic substrate to bind the bisazo-ATP kinase complex, which brings both kinase and target in close proximity to the azido groups. UV irradiation then uses each azide to form reactive nitrenes, which form a covalent ATP bridge between the kinase and substrate (Fig. 8a).

An alternate strategy to identify the upstream kinase responsible for phosphorylating a particular phosphoserine protein also was reported (22). In this scheme, a bis azide ATP analog was designed to form an imine with the lysine (Lys 72 in PKA) essential for orienting the αβ-phosphates of ATP. The substrate of interest, with its target serine mutated to cysteine, provides a nucleophile to attack the imine, which then cyclizes with a second azide to form a stable isoindole adduct that links kinase and substrate (Fig. 8b).

O-GlcNAcylation is a prevalent posttranslational modification that occurs when a molecule of the monosaccharide N-acetylglucosamine (GlcNAc) is adjoined to a serine or a threonine residue of a cellular protein. This modification can influence a protein in many of the same ways that a serine or threonine phosphorylation can. In addition, much like the kinases and phosphatases involved in phosphorylation/dephosphorylation, unique enzymes are responsible for the addition and removal of O-GlcNAc modifications, with an O-GlcNAc transferase that catalyzes the addition and an O-GlcNAcase that is responsible for the removal. This review will give a summative description of the diverse biochemical roles that this O-GlcNAcylation can play on individual proteins, and on whole animal systems, and will detail the current understanding of the enzymes involved in its maintenance. Finally, we discuss here the recent advances that have been made in the development of tools to study O-GlcNAcylation.

O-GlcNAcylation, which was first described just over 20 years ago, is a ubiquitous posttranslational modification, whereas a sugar molecule, N-acetylglucosamine (GlcNAc), is added to precise serine or threonine residues on cellular proteins. This modification can alter the physical properties of a protein in several ways, and it is highly analogous to posttranslational phosphorylation. The study of, and the understanding of, phosphorylation is well established, and in recent years, it has resulted in many advances in the comprehension of several proteins that are O-GlcNAc modified, as well as how this modification influences individual protein activities. The last five years have also brought about a wealth of biochemical information that concerns the enzymes accountable for the regulation of this modification, the O-GlcNAc transferase and the O-GlcNAcase, which includes their domain structures and the characterization of their catalytic activities. The mapping of O-GlcNAcylation sites has also experienced highly significant progress. Although O-GlcNAcylation still lags behind phosphorylation in popularity, this profusion of information is leading to the firm establishment of the importance of O-GlcNAc in cell and molecular biology.

Biologic Background

When glucose enters a cell, its primary fate is to be phosphorylated and converted to glucose-6-phosphate. The glucose-6-phosphate is then converted to fructose-6-phosphate, whereby it awaits one of several fates. The greater percentage will eventually be converted either to glycogen for storage in skeletal muscle and in liver or broken down for energy in the glycolytic pathway. A approximately 2-5% of the fructose-6-phosphate, however, enters the hexosamine biosynthetic pathway (HBP), where it ultimately will be converted to the high energy compound UDP-N-acetylglucosamine (UDP-GlcNAc). These sugar residues are linked commonly to proteins in two different ways. N-linked glycosylation occurs when the attachment is made to the amide nitrogen of asparagine side chains. N-linked glycosylations contain a minimum of four sugars in addition to the terminal GlcNAc, and this modification typically is implicated in the directing of proteins through the endoplasmic reticulum–Golgi–plasmalemma pathway. The second fate of the UDP-GlcNAc is its O-linkage to proteins (Fig. 1).

O-GlcNAc as a posttranslational modification

First described in 1984, O-linked GlcNAcylation is a form of posttranslational modification where a single sugar, the monosaccharide GlcNAc, is affixed via a beta linkage to the hydroxyl group of specific serine and threonine residues on target proteins (1). In rare cases, O-linked N-acetylglucosamine (O-GlcNAc) linkage can occur on lysine side chains. Although this modification has not been witnessed in bacteria, it is otherwise ubiquitous in all eukaryotic cells that have been studied.
When entry into a cell occurs, glucose is converted to glucose-6-phosphate (Glc-6-P) and then into fructose-6-phosphate (Fruct-6-P). Approximately 5% of the fructose-6-phosphate enters the hexosamine pathway, where the enzyme GFAT converts it to glucosamine-6-phosphate (GlcN-6-P), in a process that requires glutamine’s (Gln) conversion to glutamate (Glu). Eventually, the glucosamine-6-phosphate is converted to UDP-GlcNAc, and this can be added to protein serines or threonines by the enzyme O-GlcNAc transferase (OGT). O-GlcNAcase is the enzyme that removes this modification.

O-GlcNAcylation can occur on both extracellular and intracellular proteins and can be found on both cytosolic and nuclear members of the latter (1). O-GlcNAc additions are reversible, highly dynamic, and occur on proteins involved in most, if not all, processes of fundamental importance to a cell, including transcription, DNA replication, protein-folding, cytoskeletal regulation, translation, metabolic and signaling pathways, nuclear import-export, protein degradation, and vesicular trafficking, among many others. In addition to these downstream roles, the HBP is speculated to act as a global cell nutrient sensor. Given the makeup of the substrate UDP-GlcNAc, its levels are governed by the availability and the metabolism of amino acids (glutamine is used as the amine donor), fatty acids (which supply the eventual acetate), nucleotides (for UDP), and glucose in particular (for the sugar backbone). The global accumulation of O-GlcNAcylated proteins, as a result of an increase in glucose uptake and therefore UDP-GlcNAc availability, may act as a negative feedback, directly or indirectly, to downregulate proteins involved in additional glucose import (2, 3). This may be the case with catabolism and anabolism of the other constituents of UDP-GlcNAc as well.

O-GlcNAcylation in disease states

As a result of all of the above, the deregulation of protein-O-GlcNAc homeostasis has been linked to several disease pathologies, particularly diabetes, cancer, and Alzheimer’s disease. For example, increases in protein-O-GlcNAc—either by increasing the flux through the HBP, by overexpressing the enzyme responsible for its addition to proteins (N-acetylglucosaminyl transferase or OGT), or inhibiting the enzyme responsible for its removal (O-GlcNAcase)—can recapitulate several hallmark features of type II diabetes (OGT and O-GlcNAc case will be discussed). In fat or muscle tissue, increased O-GlcNAc leads to insulin resistance and to the hyperinsulinemia associated with increased fat synthesis and storage (4). In liver cells, an increase in O-GlcNAc results in an upregulation of glycogen storage, impaired glucose tolerance, and whole animal hyperlipidemia and obesity (5). In pancreatic β-cells, inflations in O-GlcNAc produce apoptosis (6), hyperinsulinemia, and insulin resistance (7); this inflation is postulated to be primarily because many proteins involved in the insulin-signaling pathways are O-GlcNAc-ed, including IRS-1, Akt, and PI-3 kinase. Finally, the O-GlcNAcase gene is located in a characterized diabetes susceptibility locus, and a naturally occurring single nucleotide polymorphism discovered within this gene was found to correlate with an increase in diabetic risk (8).

Second, because several proteins have been demonstrated to be O-GlcNAc-ed in a cell-cycle-dependent manner, and because cellular O-GlcNAc levels are highly correlative to the cell cycle (9), as well as in response to mitogens, growth factors, and cell stresses (see review by Zachara and Hart (10)), the disruption of O-GlcNAc pathways can be tumorigenic. Altering flux through the hexosamine pathway, providing more O-GlcNAc substrate for target proteins, has been shown to modify the growth rate of various cell types (11). In addition, overexpression of OGT, which results in more protein-O-GlcNAc, can result in polyplody and defects in cytokinesis. Overexpression of the reverse enzyme, O-GlcNAcase, influences cell cycle, which results in mitotic exit delays, altered cyclin expression, nuclear morphological differences, and delayed mitotic phosphorylation (9). Thus, cancerous phenotypes can result from faulty O-GlcNAcylation.

Finally, much evidence indicates that O-GlcNAc signaling is involved in neurodegenerative diseases. The potential role of...
O-GlcNAc in the pathogenesis of Alzheimer’s disease, in particular, has drawn much attention. The OGT and O-GlcNAcase enzymes are highly enriched in the brain and are particularly high in the Purkinje cells. The pathogenesis of Alzheimer’s disease involves, among other events, the accumulation of β-amyloid and tau aggregates, both of which have been shown to be O-GlcNAc modified and increasingly are modified in Alzheimer’s striken cells (12). Their ability to be degraded and cleared by the proteosomes in hippocampal cells is inhibited by increased O-GlcNAc levels (13, 14). In addition to being a hot spot for diabetes susceptibility genes, the chromosomal locus for the O-GlcNAcase gene is a candidate locus for late-onset Alzheimer’s disease. Interestingly, the locus for the single OGT gene is very near the locus responsible for dystonia-Parkinsonism syndrome.

The Roles of an O-GlcNAc Modification

Although the explanation of O-GlcNAc as a posttranslational modification has taken time (it has been just over 20 years since its discovery), the rate of its appreciation is similar to that of phosphorylation after its discovery. Hundreds of proteins have been demonstrated to be O-GlcNAc modified (Table 1), with a great many more as yet untested that possess potential O-GlcNAcylation sites. The roles that an O-GlcNAc modification can play on a protein have been found to be comparable to those of O-phosphorylation. Although O-GlcNAc is a neutral molecule, and does not possess the strong negative charge of a phosphate, its possession of numerous negatively polar hydroxyl groups allows it to perform many of the same reversible functions.

The addition of O-GlcNAc can alter protein-protein interactions. For example, adding it to the ubiquitous transcription factor Sp1 can inhibit its binding to TATA110 and can prevent gene transcription (15), and its addition to the chaperone HSP60 can obstruct HSP60-Bax interaction, which results in Bax translocation to the mitochondria in initiating steps of the apoptotic response (16). Conversely, O-GlcNAc modification on the signal transducer Stats can enhance the interaction of Stats with the transcriptional coactivator CBP (17). Protein-DNA interactions can also be influenced by an O-GlcNAc addition or loss, as is observed, for example, on the PDX-1 transcription factor, where increased O-GlcNAcylation on PDX-1 increases its DNA binding affinity (18). Within the transcription factor Oct-2, O-GlcNAcylation likewise regulates DNA-binding specificity (19).

O-GlcNAc modifications can also lead to the stabilization of a target molecule. O-GlcNAcylation of piklgothion, which is a component of adherens junctions and desmosomes, increases the stability of the protein and thereby promotes cell-cell adhesion (20). Another example occurs with eff2-p67 complexes, where an O-GlcNAcylation event on p67 leads to an increased half-life of these components, which allows the subsequent activation of the eff2 subunit required for protein translation (21). Furthermore, O-GlcNAc can contribute directly to global protein stability by modifying the ATPase subunit Rpt2 within proteasome caps, which results in the inhibition of proteosomal degradation (14).

Like phosphorylation, O-GlcNAc modification can activate or inactivate a protein through conformational changes. It is suggested that O-GlcNAc modifications on Stats are involved in its transient activation (22), and its addition to p53 is expected to increase the protein’s outside-in signaling necessary for cytoskeletal rearrangements and cell spreading (23). Conversely, O-GlcNAc modification can inhibit the signaling activity of PLC-β1, which is an enzyme involved in the generation of important second messengers that trigger intracellular Ca2+ release (24) or can result in the inactivation of the nitric oxide synthase eNOS (25).

Along with the above phenomena, the addition of O-GlcNAc influences a target protein’s cellular localization. According to several studies, it seems that O-GlcNAc may act as a nuclear localization signal. O-GlcNAcylated proteins seem to be more prominent in nuclear over cytosolic fractions (26), and proteins such as Akt1, mTOR, α4, and Sp1 translocate to the nucleus after O-GlcNAc modification. Exceptions exist, as witnessed with a viral protein Vpr, where O-GlcNAc added near the NLS influences nuclear import (27) negatively. The nuclear pore is considerably O-GlcNAc modified, and this can influence the transport into or out of the nucleus. The direct influence of O-GlcNAc on pore components is still being explored. Finally, because this modification occurs on serine and threonine residues, it can also compete directly with an O-phosphorylation event at an identical or nearby site to provide an additional level of regulation on a specific protein. To date, all described O-GlcNAc-modified proteins have been found to be phosphoproteins (28, 29, 30). Such competition between O-GlcNAc and O-phosphate binding occurs with many examples listed above as well as with others.

The Enzymes that Regulate O-GlcNAcylation

O-GlcNAc transferase

The enzyme that catalyzes the reaction between the target protein and the UDP-GlcNAc, with UDP being the leaving group, is OGT. OGT is a highly conserved, 1036-amino-acid protein found in all metazoa, and it is expressed ubiquitously in all tissues, although mRNA and protein levels can vary. OGT can be found in both the nucleus and the cytosol; however, localization studies have revealed a slight preference for the nucleus (31). The OGT protein is encoded by a single, highly conserved gene mapped to a location on human chromosome Xq13.1. Murine as well as cell knockouts have proven to be lethal, which indicates that the ability to glycosylate proteins is essential to complete embryogenesis and overall individual cell viability (32, 33). Conversely, overexpression of OGT is also toxic to cells, which suggests that, in addition to the necessity of the presence of O-GlcNAc modification, the maintenance of proper protein-O-GlcNAc levels is also essential for cellular function.

**Survival.** O-GlcNAc transfer is mediated by two C-terminal catalytic domains (CD I and CD II) that form a pocket together with both UDP–GlcNAc binding sites and a catalytic center (34, 35). In addition to its catalytic domains, OGT contains 11.5 tetratricopeptide (TPR) motifs in the protein’s N-terminus. TPR motifs are 34-amino-acid structures with several electrostatic surfaces that function primarily in protein–protein interactions, and this allows OGT to interact with a large number of proteins and with itself (36). OGT has at least three known isoforms with different cellular localizations (37). These isoforms all contain the catalytic domains; however, they differ in their number of TPR motifs, which suggests that the variations in cellular localization are in part caused by the targeting of its binding partners (37).

Because OGT has several binding partners, substrates, and varying expression levels and localization, it is not surprising that it is regulated tightly. To date, OGT has been shown to be O-GlcNAc modified as well as tyrosine phosphorylated (35, 38). The roles and sites of these modifications have not yet been elucidated, but studies suggest the tyrosine phosphorylation may have an activating effect on the enzyme’s catalysis (39). OGT substrate specificity and localization are regulated by its binding partners as well as by its own multimerization (35). Finally, OGT activity can also be influenced by feedback mechanisms. OGT is highly responsive to intracellular UDP–GlcNAc levels (35), and free UDP is a potent inhibitor of this substrate recognition (35). OGT catalytic activity has also been demonstrated to be inhibitable by the drug compound alloxan, which is a uracil analog (40). Naturally, neither of these inhibitors is specific for OGT activity within a cell. Currently, the development of OGT-specific inhibitors has only been preliminarily characterized (41).
O-GlcNAcase

β-O-linked N-acetylglucosaminidase, or O-GlcNAcase, is a 917-amino-acid enzyme responsible to remove O-GlcNAc modifications on a protein selectively. Like OGT, O-GlcNAcase can be found in the nucleus and in the cytosol of all tissues and organisms higher than yeast. Also, like OGT, O-GlcNAcase is expressed by a single gene product at a chromosomal locus at 10 q24-1 3 (in humans) that encodes at least three alternative splice variants in addition to the full-length product. The O-GlcNAcase active site, a TIM barrel (42, 43), resides in the protein’s N-terminus (44, 45) and is part of a larger enzyme that contains an acetyltransferase (AT) domain in the protein’s C-terminus. O-GlcNAcase has been shown to have acetyltransferase activity, at least for histone substrates, and therefore, it is sometimes referred to as NCOAT (nucleus-cytoplasmic O-GlcNAc and acetyltransferase) to reflect both activities (46). Two naturally occurring splice variants of this enzyme lack a portion of the O-GlcNAcase active site (exons 8 and 9, encoding amino acids 250-345 and 250-398, respectively), and therefore, they are defunct for O-GlcNAcase activity (46). The third variant lacks the AT domain (47) completely. O-GlcNAcase/NCOAT has been shown to be a substrate of the pro-apoptotic protease caspase-3. The cleavage site flanks the C-terminus of the O-GlcNAcase domain, and because the cleaved products retain their respective activities (46, 48), this may regulate/deregulate these activities as well as disconnect their locality within a cell (48).

Although it is speculated that 0-GlcNAcase activity must be regulated highly, little progress has been made to reveal posttranslational modifications that may occur on the protein. O-GlcNAcase has been shown to be O-GlcNAc modified, although it has not been elucidated as to whether this would have an activating or inhibiting effect on the enzyme (37). Like with OGT, O-GlcNAc modification on O-GlcNAcase may represent a unique feedback mechanism to help regulate cellular protein O-GlcNAc levels by regulating the enzymes responsible for the modification themselves. In addition to the variants and caspase cleavage products mentioned above, it is interesting that O-GlcNAcase exhibits strong direct interaction with OGT. It does so via a domain in the middle of the enzyme and through the N-terminus and first six TPRs of OGT (49). To prevent a futile cycle of glycosylation/deglycosylation that surrounds these complexes, the regulation of these enzymes becomes of paramount importance.

Several O-GlcNAcase inhibitors have been described, the most popular are streptozocin (STZ) and PUGNAc. Both of these compounds are substrate mimetics that inhibit O-GlcNAcase activity by resembling the natural substrate’s oxazoline transition state after its entrance into the active site (50, 51). Unfortunately, the above inhibitors are nonselective and can inhibit other glycosyl hydrolases; therefore, they are a detriment to a multitude of cell pathways. A more potent transition state analog, N-acetylglucosamine-thiazoline (NAG-thiazoline), has been described recently (5). The increased potency likely is because the compound already resembles the oxazoline intermediate before it is exposed to the enzyme. Macauley et al. (52) have begun recently to generate NAG-thiazoline derivatives with augmentations to the thiazoline ring. In particular, the addition of a butyl chain to the ring caused a dramatic increase in potency over the NAG-thiazoline parent compound and exhibited a selectivity toward O-GlcnAc case over lysosomal hexosaminidases. In addition, Stubbs et al. (53) and Kim et al. (54) have begun to characterize PUGNAc derivatives. These analogs involve alkyl extensions, and whereas the extensions are the same and in a position analogous to those of the NAG-thiazoline derivatives, the extensions are somewhat less potent and specific for O-GlcNAcase, although their usefulness may yet be evident in different contexts. The increased potency and selectivity of these compounds over their precursors represent important advances and will make them invaluable tools in the study of O-GlcNAcylation. Furthermore, Kim et al. (55) have exploited this butyl-extension to increase the sensitivity of a fluorogenic O-GlcNAc substrate, giving the field a promising high-throughput imaging tool for the analysis of O-GlcNAc functions.

Emerging approaches for the Study of O-GlcNAcylation

Until the last decade, proficient methods to study O-GlcNAcylation on a target substrate had been slow to develop. In whole-cell systems, the use of OGT or O-GlcNAcase inhibitors—or the overexpression of these proteins—is toxic or affects too many cellular pathways to interpret results directly. In isolatable systems, recombinant OGT or O-GlcNAcase, together with their respective inhibitors, can be used to identify target substrates, either by radiolabeling using UDP-[3H]GlcNAc or by Western blotting using protein-O-GlcNAc specific antibodies such as RL2 or CTD110.6. In several cases, the subsequent effect of the O-GlcNAc modification on the protein’s function could be determined in isolatable in vitro assays. More commonly, the effect of the O-GlcNAc modification on the protein was never fully understood, because the sites of O-GlcNAcylation could not be detected. This limitation prevents mutational analysis, and the direct investigation of the role of the O-GlcNAc in purified assays, in signaling pathways and in whole-cell and animal contexts.

Traditional methods to map posttranslational modification sites, like those of phosphorylation, have been anchored by protein digest and mass spectrometric (MS) approaches (for a review on the classic evaluation and for MS analyses of O-glycans, see Reference 56). Unfortunately, like many posttranslational modifications, O-GlcNAcylation occurs routinely on a protein population with substoichiometric frequency, which results in a very small detectable fraction of the O-GlcNAc-modified product. Also, much like O-phosphorylation, the protein-O-GlcNAc bond is labile and is detached by cell-permeable dissociation (CDD) during MS analysis. Often, the bond is lost before it can be detected on the peptides analyzed (57, 58). Phosphate modifications, however, can overcome this limitation by enriching the peptide mixtures via collision-induced dissociation (CID) during MS analysis.
through chromatographic approaches, for example, by using immobilized metal ion affinity columns. Such methods to enrich O-GlcNAc-modified peptides specifically are beginning to be optimized.

Recent advances have been developed to enrich O-GlcNAcylated peptides by using a lectin weak affinity chromatography (LWAC) approach. In the LWAC approach, a column of wheat germ agglutinin (WGA), which has binding affinity for GlcNAc as well as sialic acid, is used to separate and enrich GlcNAcylated peptides from the non-GlcNAcylated population (57). Although the binding affinity is weak, with dissociation constants in the 10-millimolar range, the interaction is sufficient to retard the rate of flow of GlcNAcylated peptides by HPLC enough to separate them for MS analysis and for sequencing. It has also been shown that such WGA chromatography is sufficient enough to purify proteins for 2-D gel electrophoresis and for subsequent MS proteomic analyses (59). These protocols can be used both on purified protein digests as well as in cellular extracts, and they represent a key advance in identifying O-GlcNAc modification sites.

A second promising method for mapping of O-GlcNAcylation sites involves a β-elimination/Michael addition with the DTT (BEMAD) approach (57, 58). This technique can be used alone, or in conjunction with the above LWAC method. Briefly, the use of a strong base such as sodium hydroxide can result in the β-elimination of the C–CH2–O–GlcNAc to C=CH2, where the first C is within the protein backbone on the digested peptides. This technique is followed by a Michael addition of DTT to the CH2 group (other “tags” can be added through this technique as well). The result is a formerly β-elimination susceptible site modified so that it can be enriched by chromatography (and is less labile), as mentioned above for O-phosphate peptide enrichment. In the case of BEMAD, an activated thiol-Sepharose can purify the DTT-tagged peptides, although a variety of columns can be used depending on the tag chosen. These affinity-tag methods have advanced enough so that they can be used to label O-GlcNAc sites selectively, whereas other β-elimination susceptible sites, like those of O-phosphate, are left undisturbed.

Affinity tags have also been developed to circumvent the β-elimination. The first uses an engineered galactosyltransferase to apply a UDP-ketone analog in the place of O-GlcNAc, which can be biotinylated for purification (60, 61). This strategy has been implemented successfully in both pure protein preparations and whole cell lysates. The second strategy exploits a phenomenon first reported by Vojdani et al., in which N-acidic glucosamine can be used as a substrate for both OGT as well as O-GlcNAcase (62). This method can be applied to cell culture, where a peracetylated GlcNAc azide analog is incubated with the cells (along with an O-GlcNAcase inhibitor to prevent deacetylation). After the incorporation of the analog at O-GlcNAc sites, the mixture can be treated with a biotinylated phosphate reagent to tag the sites of incorporation for streptavidin purification (63).

Oligosaccharides are essential for interactions of cells with their environments. These complex carbohydrates are often found covalently attached to proteins embedded in eukaryotic cell membranes. Protein glycosylation is heterogeneous; this heterogeneity stems from the biosynthesis of these polymers. As proteins destined for secretion or cell-surface presentation travel through the endoplasmic reticulum and the Golgi apparatus, they are modified with sugars in a stepwise fashion by enzymes called glycosyltransferases. The differential expression of these enzymes leads to a multiplicity of specific oligosaccharides both among and within cells because not all cells contain all enzymes and because not all substrate proteins will encounter every enzyme. Although myriad oligosaccharides are found attached to proteins, most of these diverse structures can be grouped into several classes of glycans. In this article, we will discuss some of the most common forms of Golgi protein glycosylation: mucin-type O-linked glycosylation, N-linked glycosylation, and the formation of glycosaminoglycans. In addition, we will briefly consider some less common, but essential, forms of glycosylation.

The Organelles of the Secretory Pathway form an Assembly Line for Glycoprotein Biosynthesis

A large percentage of eukaryotic proteins have oligosaccharides covalently linked to certain amino acid side chains post-translationally. These posttranslational modifications are essential for cell–cell recognition, cell–matrix interactions, and cell–pathogen recognition. The protein-linked oligosaccharides are known as glycans. Biosynthesis of glycans occurs in the secretory pathway of eukaryotic cells.

Cellular glycans are biosynthesized in eukaryotic cells by sugar-transfer enzymes called glycosyltransferases. These enzymes reside in the secretory pathway, which comprises the endoplasmic reticulum (ER) and the Golgi apparatus. Glycosyltransferases transfer sugars from activated nucleotide sugar donors to a protein or nascent oligosaccharide substrate. Most Golgi-resident glycosyltransferases are type II membrane proteins, which are characterized by a short N-terminal cytoplasmic tail and a single-pass transmembrane region, followed by a variable-length stem region and catalytic domain, both of which extend into the Golgi lumen. Glycosyltransferase enzymes are localized to different parts of the Golgi, enzyme localization influences the order in which substrate proteins encounter different glycosyltransferases and thus the order and arrangement of sugar attachment. The cytoplasmic tail, transmembrane domain, and stem region have all been implicated in controlling localization of glycosyltransferases within the Golgi.

Nucleotide sugar donors, such as UDP-GalNAc, UDP-GlcNAc, GDP-fucose, and CMP-sialic acid, serve as substrates for the glycosyltransferases and are the source of the sugars that are added to substrate proteins (Table 1). Nucleotide sugar donors are synthesized in the cytoplasm and imported into the secretory pathway by membrane-resident transporters (1).

Glycan biosynthesis, unlike DNA, RNA, or protein biosynthesis, is not template directed. Rather, the secretory pathway functions as an assembly line that substrate proteins traffic through on their way to the cell surface. Substrate proteins enter the secretory pathway in the ER. As the proteins pass through the ER and the Golgi, they are modified by enzymes residing in these compartments. Glycosyltransferases that add sugars directly to the protein tend to be found earlier in the secretory pathway, particularly in the ER and the cis-Golgi. Other enzymes are responsible for further glycan modification. These elaborating enzymes tend to be localized in later Golgi compartments (medial and trans-Golgi) or in the trans-Golgi network (TGN) (Fig. 1). The exact modifications that occur depend on two factors: the availability of activated sugar donor.

Here, we delineate the biosynthetic pathways of the most common types of protein glycosylation occurring in the secretory pathway: mucin-type O-linked glycosylation, N-linked glycosylation, and the formation of glycosaminoglycans. In addition, we will briefly visit the biosynthesis of some less-common varieties of protein glycosylation.

Secretory Pathway Enzymes Perform the Chemistry of Glycosylation

Mucin-Type O-Linked Glycosylation

Glycans can be attached via a glycosidic bond to the hydroxyl group of serine or threonine in a polypeptide. In these cases, the glycosidic bonds connect a sugar to an oxygen in the polypeptide; therefore, this type of glycosylation is termed O-linked. In mammals, the most common type of O-linked glycosylation is the mucin-type, in which N-acetylgalactosamine (GalNAc) is α-linked to either serine or threonine and is subsequently modified by additional sugars (Fig. 2). The name mucin-type derives from the initial isolation of glycoproteins containing these sugar moieties from mucus. Mucins are secreted by many types of tissues, including the linings of the digestive tract and airways.

Mucin-type O-linked glycans are synthesized in the Golgi apparatus of eukaryotic cells. Synthesis is stepwise, with individual Golgi-resident glycosyltransferases transferring sugars one at a time to the growing glycoprotein. A wide variety of final glycan structures is possible. The heterogeneity depends on the set of glycosyltransferases that are present in a particular cell and the order in which substrate polypeptide encounters its modifying enzymes. The sequence of steps required for biosynthesis of mucin-type glycans can loosely be divided into the following types of sugar transfer events: initiation, core formation, elongation/branching, and termination.

Initiation: The ppGalNAcTs

Polypeptide α-GalNAc transferases (ppGalNAcTs) initiate biosynthesis of mucin-type O-linked glycans by transferring GalNAc from UDP-GalNAc to an acceptor protein. Sequence analysis has revealed approximately 24 mammalian genes with high homology to known ppGalNAcTs. So far, 21 of these genes have been demonstrated to encode proteins that exhibit ppGalNAcT activity. Within the large ppGalNAcT family, individual isoforms display discrete patterns of tissue- and stage-specific expression (4), suggesting that they serve distinct developmental roles. However, there is some functional redundancy among family members as evidenced by the absence of discernable phenotypes in mice harboring targeted disruptions of individual ppGalNAcT genes.

Subcellular localization studies have been completed for some, but not all, of the ppGalNAcTs. Those enzymes that have been examined localize to positions within the Golgi; however, the exact distributions are isoform and cell-type specific. For example, α-GalNAcT3 (5) is localized to the cis-Golgi in...
Core Formation

Addition of a single GlcNAc to serine or threonine constitutes a structure called the Tn-antigen, often observed on tumor cells. However, in most cases, one or more additional monosaccharides are attached to the 3 or 6 positions of the initiating GalNAc, forming the core O-linked structures (Fig. 2). As with the GalNAc in low-molecular-weight polysaccharides, the 3 position of the initiating GalNAc can be modified by the 3- GlcNAc transferase (Fig. 2a), yielding the GlcNAc2,3GalNAc structure. The core 3 structure is not as ubiquitous as core 1 and has been found only in mucin-secreting tissues.

Despite the fact that only certain serine and threonine residues are glycosylated into the Golgi in other types of tissue. Other ppGalNAcT isoforms localize to the trans-Golgi compartments. Examples include human ppGalNAc-T2 and -T3, which localize to the trans-Golgi in HeLa cells (6). The localization of the initiating ppGalNAc-T determines which other enzymes the substrate protein can encounter as it completes its transit through the secretory pathway. Therefore, the localization of the initiating ppGalNAc-T affects the final structure: If the ppGalNAc-T is localized relatively late in the Golgi, fewer additional modifications are possible.

Porcine submaxillary gland, although it is distributed throughout the Golgi in other types of tissue. Other ppGalNAcT isoforms localize to the medial and trans-Golgi compartments. Examples include human ppGalNAc-T2 and -T3, which localize to the trans-Golgi in HeLa cells (6). The localization of the initiating ppGalNAc-T determines which other enzymes the substrate protein can encounter as it completes its transit through the secretory pathway. Therefore, the localization of the initiating ppGalNAc-T affects the final structure: If the ppGalNAc-T is localized relatively late in the Golgi, fewer additional modifications are possible.

A notable example is the porcine submaxillary gland, although it is distributed throughout the Golgi in other types of tissue. Other ppGalNAcT isoforms localize to the medial and trans-Golgi compartments. Examples include human ppGalNAc-T2 and -T3, which localize to the trans-Golgi in HeLa cells (6). The localization of the initiating ppGalNAc-T determines which other enzymes the substrate protein can encounter as it completes its transit through the secretory pathway. Therefore, the localization of the initiating ppGalNAc-T affects the final structure: If the ppGalNAc-T is localized relatively late in the Golgi, fewer additional modifications are possible.

Therefore, the localization of the initiating ppGalNAc-T affects the final structure: If the ppGalNAc-T is localized relatively late in the Golgi, fewer additional modifications are possible.
Glycosylation of Proteins in the Golgi Apparatus

The core 2 and 4 structures are synthesized by the addition of GlcNAc to the 6 position of GalNAc in the core 1 (Fig. 2c) and core 3 structures (Fig. 2e), respectively. These structures are produced by a family of β1-6GlcNAc-transferases that catalyzes the formation of the GlcNAc-α1-6GalNAc linkages. At least three β6GlcNAcT isoforms exist; they vary in their preference for core 1 or core 3 substrates (15). For example, the L-type (leukocyte) core 2 β6GlcNAc-T accepts only the core 1 substrate, producing core 2 antigen. The M-type (mucin) isoform, expressed in mucin-secreting cell types, exhibits broader substrate scope and is capable of synthesizing both core 2 and core 4 structures, as well as the I antigen (discussed below) (16).

Core 2 β6GlcNAcT localizes to the cis- and medial Golgi (17).

The addition of GlcNAc to core 1 by β1-3 GlcNAc-transferase 3 (β3GlcNAcT-3) results in the formation of extended core 1 structures (Fig. 2b). These glycans are frequently modified with additional sugars to form sialyl Lewis x or 6-sulfated sialyl Lewis x; this elaboration is essential to leukocyte rolling and L-selectin binding. Extended core 1 oligosaccharides may be further elaborated by the addition of GlcNAc to the 6 position of GalNAc, forming branched glycans containing core 2 (18). A dition of GlcNAc in a β1-6 linkage to Tn antigen generates the putative core 6 structure (Fig. 2g). Core 6 structures have been reported to occur in human ovarian tissue, but an enzyme responsible for core 6 formation has not been identified (19).

Less common core structures are formed when the initiating GalNAc is modified by the addition of α-linked sugars at either the 3 or 6 positions. Core 5 is formed by the addition of a second GalNAc in an α3-3 linkage to the first (Fig. 2f) (19–21). This enzymatic activity has been detected in biological samples, but the responsible gene has not been identified. The core 7 (GalNAc-β1-3GalNAc-c) (Fig. 2h) (22) and core 8 (Galα1-3GalNAc) (Fig. 2i) structures (23) are produced in restricted tissues and the responsible genes are not yet known.

Branching and Elongation

A common motif found in larger O-linked glycans is poly-N-acetylactosamine (Galβ1-4Galβ1-3), also called poly-LacNAc or the type 2 backbone (Fig. 3a). PolyLacNAc repeats are commonly found on fetal erythrocytes, where they constitute the blood group i antigen. PolyLacNAc chains of varying length are synthesized by the alternate action of two enzymes, a β1-4galactosyltransferase (β4-GalT) and a β1-3GlcNAc-transferase (β1-3GlcNAcT). A family of at least five β4-GalTs has been discovered and at least eight β1-3GlcNAcTs have been identified; these biosynthetic enzymes are widely expressed. The most well-characterized of the β1-3GlcNAcTs is known as iGnT because of its role in synthesis of the i antigen (24).

PolyLacNAc can be extended from sugars attached to either the 3 or 6 position of the initiating GalNAc; however, addition to the 6 (upper) branch is more common (Fig. 3c). A ditional branching can be introduced into the LacNAc backbone by the action of β1-6 GlcNAc-transferases, including the previously

mentioned core 2 β-GlcNAc α-M is a isoform. This type of branched structure, the I antigen, is commonly found on adult erythrocytes. Members of the β-GlcNAc α-transferease family that produce branched structures are known as IGnTs. Synthesis of branched structures is developmentally regulated, and members of IGnT enzyme family have differing substrate specificities. Some IGnTs select for terminal Gal whereas others modify internal Gal residues. The type 1 (Galα(1→3)Galβ(1→3)-β, polymer, also called lacto-N-biose, is a related but less common, backbone motif (Fig. 2b). Lacto-N-biose is synthesized by a β3-galactosyl-

Glycosylation of Proteins in the Golgi Apparatus
Glycosylation of Proteins in the Golgi Apparatus

Figure 4  Biosynthesis and structure of N-linked glycans. (A) The ER-resident Alg glycosyltransferases are responsible for addition of the individual monosaccharides to assemble the dolichol oligosaccharide donor. Initial steps are accomplished by Alg7 (a), Alg13/14 (b), Alg1 (c), Alg2 (d), and Alg11 (e) on the cytosolic face of the ER. The oligosaccharide is “flipped” from the cytoplasm to the ER lumen by Rft1 (f). Inside the ER lumen, additional sugars are added by glycosyltransferases Alg3 (g), Alg9 (h), Alg12 (i), Alg6 (j), and Alg10 (l). The assembled dolichol donor is transferred to the nascent polypeptide by the oligosaccharyltransferase (m). Trimming of the dolichol donor is catalyzed by glucosidase I (n), glucosidase II (o), and α-mannosidase I (p). In the Golgi, additional trimming is performed by Golgi-resident α-mannosidases (q) and GlcNAc is added by GlcNAcT-I (r). In the synthesis of typical complex glycan, two more mannoses are removed by α-mannosidase II (s), followed by the addition of GlcNAc by GlcNAcT-V (t) and GlcNAcT-V (u) and peptide residues by α1-4GalT (v). Extension of polylactosamine chains is performed by α1-3 GalNAcTs (w) and α1-4GalTs (x), whereas terminal sialic acid residues are added by fucosyltransferases (y) and sialyltransferases (z). (B) Subtypes of N-linked glycans include (a) mannan-type glycan; (b and c) monoantennary hybrid glycans; (d) a biantennary complex glycan; (e) a triantennary complex glycan; (f) a tetraantennary complex glycan; and (g) an N-linked glycan with a “bisecting GlcNAc.”

the ER through the translocon (40, 41). The heteromeric OX complex is composed of at least nine different polypeptides, including the STT3 subunit that provides the active site (42–44). The oligosaccharide is transferred to asparagines within the minimal consensus sequence Asn-X-Thr/Ser, where X is any amino acid except proline (45). The amino acids surrounding the consensus sequence also affect whether a particular Asn is a substrate for glycosylation. In addition, Asn-X-Cys sequences are occasionally glycosylated. After the oligosaccharide is transferred to a substrate protein, it is processed by ER- and Golgi-resident glycosidases.

Exit from the ER

The ER-resident glucosidase I removes the terminal α1-2 linked glucose from the oligosaccharide (Fig. 4A, n). Subsequently, glucosidase II removes the α1-3 glucose-linked glucose and then, more slowly, removes the α1-3 mannose-linked glucose (Fig. 4A, o) (46, 47). The presence of this mannose-linked glucose is intimately associated with protein folding. If a protein is folded improperly, the mannose-linked glucose is reinstalled by a glucosyltransferase (UGGT) and the protein remains in the ER to complete its folding (48, 49). Once the protein is properly folded and all three glucoses removed, α-mannosidase I removes the terminal α1-2 linked mannose from the middle chain (50) (Fig. 4A, p). The properly folded protein with its remaining Man0GlcNAc2–Asn glycan is now able to exit the ER and traffic to the cis-Golgi.

Trimming in the Golgi

Proteins destined for the cell surface or secretion are processed by Golgi-resident α-mannosidases, which add additional mannoses to produce Man2GlcNAc2–Asn (Fig. 4A, q).
Biosynthesis and structure of glycosaminoglycans. Synthesis of the core linkage tetrasaccharide is accomplished by XylT, GalT-I, GalT-II, and GlcAT-I. The repeating disaccharides of heparin/HS, CS, and DS are shown.

Chemical tools can be used to interfere with cellular glycosylation. Tools to interfere with mucin-type O-linked glycosylation include (a) α-benzyl GalNAc; (b) Galβ1-4GlcNAcβ-O-naphthalenemethanol; (c) Galβ1-3GlcNAcβ-O-naphthalenemethanol; (d) 1-6A; and (e) 2-6A. Molecules used to disrupt N-linked glycosylation at different steps include (f) 1-deoxymannojirimycin; (g) deoxynojirimycin; (h) tunicamycin; and (i) swainsonine.

\[ \text{Man}_{5}\text{GlcNAc}_{2} \] is also referred to as high-mannose (51) (Fig. 4B, a), and it serves as the starting point for the synthesis of a variety of other N-glycan subtypes, described below.

An alternative processing pathway is used by proteins that will traffic to the lysosome. GlcNAc-phosphotransferase adds phosphate ester-linked GlcNAc residues to two mannoses in the oligosaccharide (52). A GlcNAcase then removes the GlcNAc sugars (53), revealing mannose-6-phosphate, which serves as a signal for the protein to be shuttled to the lysosome.

**N-Glycan Subtypes**

Despite the conservation of the core structure, the ways in which N-linked glycans are elaborated vary among organisms and cell
types. In yeasts, Man\(_{n}\)GlcNAc\(_{2}\) is elaborated by several mannosyltransferases to form large mannan-type structures. In metazoan organisms, there are 3 N-glycan subtypes: high-mannose, hybrid, and complex. Invertebrates produce high-mannose and hybrid-type N-glycans, but not complex structures (54). In vertebrates, Man\(_{n}\)GlcNAc\(_{2}\) can be modified to form hybrid and complex N-glycans. The central \(\alpha\)1,2-linked mannose bears two mannoses, which are \(\alpha\)1,3- and \(\alpha\)1,6-linked. Addition of GlcNAc to the \(\alpha\)1,3-linked mannose yields the hybrid structures (Fig. 4B, b–c), whereas complex structures have GlcNAc added to both the \(\alpha\)1,3- and \(\alpha\)1,6-linked mannoses (Fig. 4B, d–f). Hybrid and complex glycans can be described by the number of GlcNAc-containing branches, or antennae, they possess. Six different GlcNAc-transferases can initiate branch formation, generating various antennary structures (55).

Synthesis of both hybrid and complex N-glycans begins with the addition of GlcNAc \(\alpha\)1,2 to the \(\alpha\)1,3-linked mannose, forming a monosialo hybrid glycan (Fig. 4A, a). GlcNAc addition is catalyzed by the GlcNAcT-I enzyme encoded by the Mga1 gene (56). The resultant glycan is a substrate for the medial Golgi enzyme, a-mannosidase II, which removes two mannoses to generate GlcNAcMan\(_{n}\)GlcNAc\(_{2}\) (Fig. 4A, a, b). This same glycan can be produced by an alternative route: a-mannosidase-II catalyzed removal of two mannoses from the high-mannose glycan and subsequent addition of GlcNAc by GlcNAcT-I. Synthesis of biantennary hybrid glycan is also possible, through the action of GlcNAcT-V, which adds a GlcNAc in a \(\alpha\)1,4 linkage to the \(\alpha\)1,3-linked mannose (57).

Complex glycans (Fig. 4B, d–f) are produced when GlcNAcT-II adds GlcNAc in a \(\alpha\)1,2 linkage to \(\alpha\)1,6-linked mannose (Fig. 4A, c). Once this linkage occurs, an additional antennae can be produced by GlcNAcT-V, which adds GlcNAc in a \(\alpha\)1,4 linkage to the \(\alpha\)1,6-linked mannose (Fig. 4B, e–f) (58). Finally, addition of GlcNAc in an \(\alpha\)1,4 linkage to the \(\alpha\)1,6-linked mannose is a rare modification catalyzed by GlcNAcT-VI.

Glycosaminoglycans and Proteoglycans

Glycosaminoglycans (GAGs) are defined by their composition; they are composed of long chains of repeating disaccharides. Alternating amino sugars (GlcNAc or GalNAc) and uronic acids (glucuronic acid or iduronic acid) comprise their disaccharide building blocks. The exact sugar composition and modifications to the sugars determine the classification of the GAG. Commonly occurring GAGs include heparin, heparan sulfate (HS), chondroitin sulfate (CS), and dermatan sulfate (DS). GAGs contain a common core tetrasaccharide linking them to a protein. Proteins or polypeptides with GAG chains attached are known as proteoglycans.

Biosynthesis of the Linkage Tetrasaccharide

Heparin, HS, CS, and DS share a common serine-linked core tetrasaccharide, GlcA\(\beta\)1,3-Gal\(\beta\)1,4-Gal\(\beta\)1,4-GalNAc Ser. Biosynthesis of this core tetrasaccharide, known as the linkage tetrasaccharide, is initiated in the ER by the transfer of xylose to serine by a xylosyltransferase (63, 64) (Fig. 5). This enzyme prefers to transfer sugars to serines followed by glycine and flanked by one or more acidic residues (65). The xylosylated protein is then transported to the Golgi to undergo further modification by three Golgi resident enzymes. GaT-I adds galactose in a \(\alpha\)1,4 linkage (66, 67). The resulting disaccharide is then elongated by GaT-II (\(\beta\)1,3-GalT6), a \(\beta\)1,3 galactosyltransferase. Finally, GlcAT-I, a GlcA transferase specific for this trisaccharide precursor, adds \(\beta\)1,3 glucuronic acid to complete synthesis of the linkage tetrasaccharide (68–69).

Sugars in the linkage tetrasaccharide can be modified. Common modifications are phosphorylation of xylose at c2 (70, 71) and sulfation of the second galactose at C4 (72). The function of these modifications is not known; not all proteoglycans containing the linkage tetrasaccharide are modified (73, 74).

The Branching Point: Addition of GlcNAc or GalNAc

Once the synthesis of the linkage tetrasaccharide is complete, it can be further modified by one of two Golgi-resident glycosyltransferases. The enzyme α-GlcNAcT-I can add \(\alpha\)1,4-linked GlcNAc, thereby initiating the heparin/HS biosynthetic pathway. In vitro activity assays indicate that α-GlcNAcT-I also appears to be capable of adding an \(\alpha\)1,3-linked GalNAc to cap the linkage tetrasaccharide, resulting in a pentasaccharide that cannot be further elongated (75). However, the biological relevance of this modification is not known. If the protein is not modified by α-GlcNAcT-I, ji-GalNAcT-II can add GalNAc \(\beta\)1,4 to the glucuronic acid, initiating the CS/DS pathway (76). The CS/DS pathway is suggested to be the default pathway for linkage tetrasaccharides not intercepted by α-GlcNAcT-I.
Heparin and HS

After the initiation of heparin/HS biosynthesis by the addition of GlcNAc to the linkage tetrasaccharide, polymerization of the disaccharide β1-4GlcA–1-4GlcNAc begins (Fig. 5). The polymerization reaction is catalyzed by two bifunctional Golgi-resident glycosyltransferases, EXT1 and EXT2. Individual, these enzymes each exhibit GlcNAc- and glucuronic acid-transferase activity, but they are most active when they are physically associated with one another and localized to the Golgi (77).

As the β1-4GlcA–1-4GlcNAc, polymer is produced, it is modified by a number of Golgi-resident enzymes that deacetylate, epimerize, and sulfate the growing GAG. The GlcNAc N-deacetylase/N-sulfotransferases (NDSTs) catalyze both the deacetylation and N-sulfation of GlcNAc in the repeating disaccharide. The four different NDST isozymes display different substrate specificities and vary in their enzymatic activities (78–83). Glucuronic acid (GlcA) residues adjacent to GlcNAc can be epimerized to iduronic acid (IdoA) by GlcA-C5 epimerase. The newly formed IdoA can then be sulfated at the 2 position by the 2-O-sulfotransferase, which prevents reverse epimerization to GlcA. The epimerase and 2-O-sulfotransferase work in close concert and are known to physically associate with one another (84). Further O-sulfation of the GAG chain is accomplished by 6-O-sulfotransferases (6-OSTs) and 3-O-sulfotransferases (3-OSTs). The three 6-OSTs that add sulfate to N-sulfated GlcA (deacetylated GlcNAc) (85) and the six 3-OSTs that sulfate the 3 position of the hexosamine (86) exhibit varying substrate specificities (87, 88).

Heparin and HS are formed from the same disaccharide repeat and differ only in their degrees of modification. Heparin is highly modified, containing more Idas than GlcA and having many sites of N- and O-sulfation; the predominant carbohydrate motif is a repeating trisulfated IdoA (2-O-SO3)–GlcNAc(6-O-SO3)(6-O-SO3) unit. HS is considerably more heterogeneous; modifications are confined to distinct regions of the oligosaccharide chain. HS can be rather large, reaching up to 70 kDa, whereas heparin is generally only 10–12 kDa. Like other glycans, the structures of heparin and HS GAGs are ultimately determined by expression levels of Golgi-resident glycosyltransferases and the availability of activated substrate.

CS and DS

Linkage tetrasaccharides not modified by α1-3GlCNAcT-I in the Golgi will be converted to CS or DS in the TGN. The oligosaccharide chain is elongated by the bifunctional CS synthase, which produces the β1-3GlcA–β1-4GlcNAc–3Cl polymer (89–90) (Fig. 5).

As the oligosaccharide is elongated, it is modified by several sulfotransferases. At any point during these modifications, a CS-epimerase is able to convert GlcA to IdoA (91). The presence of IdoA indicates that the oligosaccharide is DS rather than CS (Fig. 5). Three GalNAc-C5-OSTs are involved in the transfer of sulfate to GlcNAc in GlcA-rich regions of the oligosaccharide (92). The CS-epimerase works in conjunction with a DS-specific GalNAc-C6-O-ST (DSTST1) (93). A 2-O-sulfotransferase known as C5DS2ST catalyzes the addition of sulfate to both IdoA and GlcA (94). In addition, two different 6-O-sulfotransferases can produce chondroitin 6-sulfate. These two sulfotransferases have different substrate specificities, with C6ST-II sulfating GlcNAc(4-O-SO3) and with C6ST producing GlcA(2-O-SO3)–GlcNAc(6-O-SO3). In addition, a DS-specific GalNAc-C6-O-ST (DSTST) sulfates C6 on GalNAc flanked by two IdoAs (95).

Keratan Sulfate

Keratan sulfate (KS) is often grouped with the GAGs even though it does not meet the definition of a GAG. KS consists of polyN-acetylglucosamine sulfated at C6 on both hexoses. Three distinct types of KS exist that are differentiated by the way the sulfate is attached; these types are designated KS1, KSII, and KSIII (96).

KS biosynthesis is initiated in the same way as N-linked glycan biosynthesis, with the addition of an oligosaccharide to Asn from the dolichyl donor in the ER. The oligosaccharide is trimmed to form the KS linkage oligosaccharide, which is is of the complex biantennary type (97). The linkage oligosaccharide can be modified on either the C6 branch or the C3 branch to form KS structures (98–100). The nonreducing terminus is usually very highly sulfated, whereas the sugars nearest the reducing end are not sulfated (101). KS1 chains are frequently terminated with sialic acid and less frequently with GalNAc or Gal (97, 102).

KS1 biosynthesis is initiated by the formation of mucin-type core 2 disaccharide (103). KS1 is usually capped with sialic acid at either C3 or C6 of terminal GlcNAc. Sulfated GlcNAc in KS1 is often modified with α1-3-linked fucose, although not within four sugars of the terminus (104). KSII is the least-characterized member of the KS family. This polyN-acetylglucosamine polymer is extended from a serine-linked mannosyl and has been found in brain tissue (105).

Elongation of KS is not well understood. The activities of β4GalT-I, β3GnT, and IgNt have been suggested to fulfill this role, but none of these enzymes have been directly linked to KS biosynthesis (106–109). Sulfation of KS is catalyzed by at least two sulfotransferases. KSαGal6ST can sulfate terminal and internal galactoses of the elongating oligosaccharide (110); sulfation of terminal galactose is believed to block further KS polymerization (111). In contrast, GlcNAc6-O-sulfation occurs only on nonreducing GlcNAc and must be simultaneous with chain elongation. GlcNAc6ST-5 is the most likely candidate to provide the GlcNAc6-O-sulfation activity (112).

Other Types of Protein Glycosylation in the Golgi

O-fucose is an important modification that mediates cell-cell interactions and leads to intracellular signaling events. Fucose is linked to either serine or threonine found in the consensus sequence CXXGXXGXXFC3. The best-characterized modification sites are in the EGF domain of Notch (113). O-Fuc is added by protein O-fucosyltransferase (O-FucT-I) and may be either a standalone modification or further extended. If extended,
Glycosylation of Proteins in the Golgi Apparatus

Fringe glycosyltransferase, a β-3GlcNAcT, adds GlcNAc to fucose, followed by addition of galactose by β-1,4GalT-I. The single LeaNAc is terminated with α-2 6 sialic acid, although this modification is not essential to notch signaling. Glycans can also be associated with proteins via O-linked mannoside. Mannose is added in the ER and can be further elaborated in the Golgi to form a tetrasaccharide, 1,2-3Gal(1-4)GlcNAc(1-2)Man-Ser/Thr (114). O-mannose glycans are essential to proper brain and muscle function and their absence is associated with muscular dystrophy.

Polyasialic acid (PSA) is a linear homopolymer of α-2-8- or α-2 3-linked sialic acid attached to protein scaffolds including the neural cell adhesion molecule (NCAM). Two Golgi-resident polysialyltransferases, PST and STX, are responsible for its synthesis. Although PSA is widely distributed in embryonic tissues, it is normally found only in regenerating neural and muscle tissues in adults. Neo-expression of PSA is often associated with metastatic cancer (115).

Collagen is an important glycoprotein whose glycosylation does not fit into any of the categories previously described. In collagen, many prolines and lysines are posttranslationally hydroxylated and the hydroxyl-lysine residues further glycosylated. Hydroxyl-lysine may be modified by the presence of either a single galactose or Glc1-2Gal (116).

Chemical Tools to Manipulate Cellular Glycosylation

Protein glycosylation affects a large number of biological interactions, including developmental processes, cancer metastasis, and host-pathogen interactions. Small molecule tools allow researchers to control glycosylation in vivo and determine the roles of oligosaccharides in biological processes. Chemical tools provide advantages over genetic approaches because they offer time-dependent, dose-dependent, and reversible control of glycosylation events.

Small molecules such as brefendin A and nocardazole are molecules that disrupt the architecture of the Golgi apparatus, which results in a perturbation of the spatial organization of Golgi-resident proteins, including glycosyltransferases. Substrate proteins no longer encounter glycosyltransferases in the correct order, leading to gross changes in cellular glycans. Brefendin A reversibly inhibits vesicle trafficking from the ER to the Golgi; nocardazole depolymerizes microtubules and arrests the cell cycle, leading to improper formation of the Golgi.

Competitive primers function as alternative substrates for elaborating glycosyltransferases. These small molecules have provided a facile way to interfere with mucin-type synthesis and lead to truncation of the O-linked glycans found on cellular substrates. The competitive primer α-benzyl-α-galNAc (Fig. 6a) mimics the Tn antigen, whereas Galβ1-3GlcNAcβ1-2D-naphthalenemethanol (Fig. 6c) and Galβ1-4GlcNAcβ1-4N-p-naphthalenemethanol (Fig. 6d) are competitive with type 1 and type 2 backbone polymers. Inhibition of the initiating pgGalNACT is an alternative strategy for obstructing mucin-type biosynthesis. A uridine-based library has yielded several competitive inhibitors of the pgGalNACTs, including 1-6BA (Fig. 6d) and 2-6BA (Fig. 6e) (117). These molecules have been used successfully in cellular and organ culture (118).

Chemical control of the biosynthesis of N-linked glycans has been facilitated by the availability of cell-permeable natural products that interfere with various steps in oligosaccharide processing. Tunicamycin (Fig. 6b) impedes the first step of dolichol oligosaccharide donor synthesis, preventing transfer of GlcNAc from UDP-GlcNAc to Dol-P. Consequently, N-linked glycans are transferred to polypeptides. Once the oligosaccharide is added to the protein, desoxynojirimycin (Fig. 6g), nojirimycin, and related derivatives can be used to prevent further processing. These molecules inhibit trimming by ER-resident glucosidase (119, 120). Another azasugar, 1-desoxymannojirimycin (Fig. 6f), is a mannose analog that is able to inhibit the ER a-mannosidase I, keeping the substrate protein from being transported from the ER to the Golgi (121). Swainsonine (Fig. 6i) functions in the Golgi as a reversible inhibitor of a-mannosidase II. Treatment with swainsonine blocks elaboration of the oligosaccharide, precluding modifications by the GlcNAc-transferases (122). As each of these molecules functions at an early stage in N-linked glycan biosynthesis, they have a global effect on N-linked glycosylation.

Competitive primers can also be used as alternate substrates for GAG biosynthesis. β-D-xylolides containing two fused aromatic rings interrupt the galactosyltransferases involved in linkage tetrasaccharide biosynthesis (123).

Summary

The plethora of oligosaccharide structures synthesized by living organisms provides a tantalizing diversity of structures for chemists to explore. Although methods to analyze glycoconjugates are rapidly improving, we remain unable to predict or program cellular glycosylation events because of the challenges posed by the nontemplated nature of glycan biosynthesis. In the future, systems biology approaches may give a predictive understanding of the glycans produced by a given cell. Further exploration of these pathways will be enhanced by chemical biologists' development of additional chemical tools with targeted, rather than global, effects on cellular glycosylation.

Acknowledgments

We thank Dr. Danielle H. Dubé, Michelle R. Bond, Peter L. Lee, and Ethan J. Greenblatt for discussions and comments on the manuscript.

Glycosyltransferases (GTs) form glycosidic bonds by catalyzing the transfer of saccharides from a donor to a wide variety of acceptors. The donors used by GTs are sugars conjugated to nucleotides, phosphates, or lipid phosphates; whereas acceptors consist of carbohydrates, proteins, lipids, DNA, and numerous small molecules such as antibioticonols, steroids, and so on. Together, the products of these reactions comprise the most diverse and abundant class of natural compounds found in nature. Numerous GTs are needed to synthesize these compounds because the formation of each distinct glycosidic linkage requires a different enzyme. The abundance of these enzymes is emphasized by the fact that GTs constitute 1% of the genes in all genomes sequenced. They are ubiquitous in every kingdom of life and in all compartments of the cell. Currently, over 32,000 GT ORFs have been classified into 90 families on the basis of amino acid sequence similarity. The structures for 64 GTs have been determined to date and generally reveal conserved architectures of a GT-A or GT-B fold, although other folds have been observed and are predicted. These crystal structures, together with biochemical data, have provided insight into the catalytic mechanism. GTs generally exhibit strict regio/stereospecificity and transfer with either retention or inversion of configuration at the anomeric carbon of the donor sugar. The importance of characterizing the precise activity of these enzymes is exemplified by the many genetic disorders that have been linked to aberrant glycosylation.

Glycosyltransferases (GTs) comprise a group of enzymes that catalyze the synthesis of glycosidic linkages by the transfer of a sugar residue, which generally is a monosaccharide, from a donor to an acceptor substrate (1–3). The products of these reactions are oligosaccharides, polysaccharides, and also numerous glycocompounds, which consist of carbohydrates linked to other noncarbohydrate molecules (Fig. 1). Together, these reaction products comprise the most diverse and abundant class of natural compounds found in nature. A different GT is required for each distinct sugar that is transferred and for each unique linkage that is formed. Because thousands of different linkages exist, this class of enzymes is enormous. In fact, GTs encode for 1% of the genes of all genomes sequenced to date. However, compared with well-characterized families of enzymes like the proteases or the protein kinases, considerably less is known about the GT enzyme family. Now the monumental task begins of identifying the precise function for each GT enzyme. This article will give an overview of GT mechanisms and structure/function relationships that have aided our understanding of the numerous biological roles of GTs. Furthermore, classification schemes as well as biotechnological and pharmaceutical aspects of GTs will also be discussed.

Glycosyltransferase Reactions

GTs catalyze the transfer of a monosaccharide or more rarely an oligosaccharide residue from a donor to an acceptor. The most common donors are sugar-nucleotides and GTs that use these donors are termed the Leloir-type GTs. These GTs comprise 90% of GT annotations, with UDP/TDP nucleotides accounting for more than 60% of these. However, dolichol-phospho-sugars, sugar-1-phosphates, and sugar-lipid-phosphates also serve as donors (Fig. 2). Acceptors cover every chemical class of compounds that include saccharides, polysaccharides, lipids, protein, DNA, and other natural products. GTs use these donor and acceptor substrates to form glycosidic linkages either through processive transfers with multiple additions of the same monosaccharide to the nonreducing end of a growing chain, as

![Chemical structures]

Figure 1  The diversity of natural structures produced by GTs. These structures include carbohydrate energy sources such as sucrose, lactose, and amylose, as well as oligosaccharide structural elements such as cellulose, chitin, and peptidoglycan. Secondary metabolites like the flavonoid delphinidin 3,5,3'-tri-O-glucoside are modified by GTs, whereas the steroid estrogen is inactivated by conversion to estrone 3-glucuronide. Glycoconjugates important in therapeutics and disease such as antibiotics (streptomycin and oleandomycin), sialoside receptors for viruses, and blood group antigens are also produced by GTs. The synthesis of glycolipids such as GM1 ganglioside and galactolipid, is also dependent on GTs. Cellulose, chitin, and amylose are synthesized by processive enzymes that repetitively transfer monosaccharides, whereas the remaining structures are synthesized by nonprocessive enzymes each carrying out single addition of a different sugar.
Figure 2 Examples of glycosyl donors. Nucleotide donors are represented by UDP-galactose (UDP-Gal), GDP-fucose (GDP-Fuc), CMP-N-acetylneuraminic acid (CMP-sialic acid, CMP-Neu5Ac), GDP-galactose (GDP-Gal), dTDP-rhamnose (dTDP-Rha), and dTDP-daunosamine; lipid phosphate donors are represented by Lipid II and dolichol-phosphate-glucose (Dol-P-Glc); sugar phosphate donors are represented by glucose-1-phosphate. The saccharides are transferred from these donors by GTs to form oligosaccharides and glycoconjugate products.
Glycosyltransferases, Chemistry of

observed in the production of glycan biopolymers like cellulose and amylose, or through nonprocessive single transfer reactions, as exemplified by the blood group antigens, glycolipid GM1 ganglioside and streptomycin (Fig. 1). Because a different enzyme is required to synthesize each distinct glycosidic linkage, GTs are probably the enzyme class with the greatest chemical diversity of substrates.

Catalysis

With rare exceptions, the transfer of saccharides by GTs is regiospecific, such that the saccharide is transferred to only one of the many hydroxyl groups on acceptor molecules. The transfer reaction is also highly stereospecific. Thus, GT reactions follow two mechanistically distinct pathways that result in either inversion or retention of configuration of the anomeric configuration of the transferred sugar (Fig. 3). It is commonly assumed that the mechanisms of GT enzyme reactions are similar to those of the well-studied glycosidases that hydrolyze glycosides; one difference is that glycosidases transfer to a water molecule whereas GTs transfer to a hydroxyl group of an acceptor molecule. Although GT reactions in general favor the formation of glycosidic bonds biosynthetically, the reversibility of sucrose synthase and some natural-product enzymes has been useful for the production of nucleotide donors and natural product libraries (4).

Inverting mechanism

Inverting GT reactions are believed to follow a single displacement mechanism that involves nucleophilic attack of the OH-group of the acceptor on the anomeric center of the donor sugar (Fig. 3a). In this mechanism, a catalytic amino acid serves as a general base to deprotonate the reactive oxygen of the acceptor. Reaction occurs with formation of an oxocarbenium-ion transition state and is concomitant with departure of the nucleotide leaving-group. X-ray structures of several inverting enzymes (β1,4-galactosyltransferase, α1,3-galactosyltransferase, and the bacterial α2,3-sialyltransferases CstI and CstII) in complex with their donor and acceptor substrates, have revealed an amino acid residue (E317, E317, H202, and H188, respectively) that is in position to deprotonate the acceptor molecule or to stabilize the transition state (5–8). Other residues have also been found that determine the substrate specificity. In the β1,4-galactosyltransferase, a tyrosine residue (Y289) facilitates the use of UDP-Gal as a substrate but not UDP-GalNAc (5). A histidine (H308) plays a similar role in β1,3-glucuronyltransferase I by determining its specificity for UDP-Glca (9).

![Figure 3](image_url)

Figure 3  GT reactions are regiospecific and stereospecific that occur with either inversion (a) or retention (b and c) of configuration at the anomeric center of the donor sugar. Inverting enzymes are thought to follow a nucleophilic displacement mechanism in which a general base deprotonates the acceptor, which renders it nucleophilic so it can attack the donor sugar. In contrast, retaining enzymes are thought to proceed through a double displacement reaction via the formation of a covalent intermediate (b) or by the SN2-like mechanism (c) where the nucleophilic acceptor and departing donor are on the same face of the sugar ring.
Retaining mechanism

The catalytic mechanism for retaining GTs is unclear but is believed to occur via a double-displacement mechanism or a $S_{N}2$-like mechanism. The double-displacement mechanism (Fig. 3b) involves nucleophilic attack by an enzyme active site residue on the anionic center of the donor substrate. This mechanism leads to the formation of a covalent glycosyl-enzyme intermediate with inversion of configuration. In the second displacement, the glycosyl-enzyme intermediate is attacked by a hydroxyl group of the acceptor, after its deprotonation by a catalytic base. The configuration is inverted in the second step, which results in net overall retention of configuration in the product (Fig. 3a). For the $S_{N}2$-like mechanism (Fig. 3c), catalysis involves nucleophilic attack and departure of the leaving group through a concerted, asynchronous manner on the same side of the sugar ring. In early proposals, it was believed that a single catalytic residue on the retaining GT was required to act as the catalytic nucleophile by attacking the anomeric carbon of the donor. This mechanism was supported by the data obtained from structural elucidation of two retaining GTs, $\alpha$-lipo polysaccharide-$\alpha$-1,4-galactosyltransferase C (LgtC) from Neisseria meningitidis (10) and $\alpha$-1,4-N-acetyl glucosaminyltransferase (EXTL2) (11). Amino acids Gin189 and Arg 293 of LgtC and ETLX2, respectively, were the only functional groups positioned to contribute in the mechanistic process. Thus, it seems that (at least for these two enzymes) a single catalytic residue is likely, but more experimental evidence is required to corroborate these findings. Molecular modeling of various reaction processes with LgtC (12) as well as structural complexes of trehalose-6-phosphate synthase with nontransferable acceptors (13) suggested that the catalytic mechanism may actually be reminiscent of that proposed for glycosen phosphorylase (14). In this mechanism, it is thought that the active site constraints of the retaining GTs position the donor and the acceptor substrates in conformations that may not require a catalytic amino acid. When bound to the enzyme, the nucleotide sugar adopts a conformation where the sugar is folded over the pyrophosphate. The anomeric bond is elongated and weakened in this conformation thereby making the C1 position of the donor spatially accessible to direct attack by the OH nucleophile of the acceptor (13).

Glycosyltransferase Structure

Given the vast structural and functional diversity of GT products, together with the divergent evolution of the enzymes, it may be expected that numerous possibilities exist for GT folds. Indeed, GTs display a high level of diversity in their primary sequences, which indicates that multiple solutions may exist to the problem of how a protein can catalyze glycosyl-transfer. Furthermore, a large number of folds have been identified for the glycosyltransferases enzymes (15). Structural data indicate that GTs belong mainly in either the GT-A or the GT-B fold superfamilies or variants thereof (Fig. 4a-e 5, 8, 16, 17), although a lysozyme-like fold has been observed for peptidoglycan glycosyltransferase (18) (Fig. 4f), and a GT-C fold is predicted for integral membrane protein GTs that use lipid donors. Therefore, from an evolutionary standpoint, nature has settled on a limited number of protein folds to facilitate glycosylation events. It is noteworthy that the stereoselective outcome of glycosyl transfer reactions is not determined by fold because both retaining and inverting enzymes can belong to the same fold superfamily.

Glycosyltransferase-A fold

The first member of the GT-A superfamily fold was identified in 1999 when the three-dimensional structure of SpA was reported (19). This enzyme from Bacillus subtilis is involved in the formation of the spore coat and is a member of the Leloir type of GTs given its apparent use of nucleotide-diphosphate donor sugars as a substrate. Enzymes with the GT-A fold have an N-terminal $\alpha/\beta$ sandwich motif that resembles a Rossmann motif and is involved in nucleotide donor binding. Most GT-A fold enzymes also have a characteristic $\alpha$-$sp$-$\alpha$-$xx$-$\alpha$-$sp$ (DXD) or equivalent motif (EKD or TDD) near the center of the protein that coordinates to the phosphates in nucleotide donors via a divalent metal cation (M$^{2+}$) or M$^{4+}$. These motifs are present in the structure of the bovine $\beta$1,4-galactosyltransferase I (5) (Fig. 4a). Binding of the acceptor substrate does not have the same strong consensus character that has been noted for the donor site, but it has been noted that it takes place in the C-terminus. This acceptor-binding region generally contains motifs that consist of two flexible loops that undergo conformational changes after donor binds. In the retaining $\alpha$1,4-galactosyltransferase LgtC, the central flexible loop was shown in crystal structures to interact with both the donor and the acceptor sugar substrates (10, 20). An additional flexible loop involved in acceptor binding is located at the extreme C-terminus of these enzymes (20). Isothermal titration calorimetry studies with $\alpha$1,3-galactosyltransferase demonstrated that the disordered loop of the free enzyme has little affinity for the acceptor substrate (6). In this form, the enzyme possesses a wide-open active site cavity that serves to facilitate initial access of the donor sugar to the active site. Similar results have been noted for the crystal structure of $\alpha$1,4-GalT in complex with donor substrate (5) (Fig. 4a). It seems that residues in the flexible loop are fixed by their interactions with the donor sugar that leads to a semi-closed conformation of the active site that can bind the acceptor. It has been speculated that this semi-closed form is important for excluding solvent from the donor-binding site and thereby for preventing unwanted hydrolysis of the nucleotide-sugar substrates in the absence of acceptor. Once the acceptor binds, the loop adopts a closed conformation where donor and acceptor are positioned properly for catalysis (5, 6, 20).

Figure 4b shows a modular variant of the GT-A fold as reported for poly-epitope GaINAc transferase 10 (21). This enzyme has a C-terminal lectin domain that is thought to bind to GaINAc-containing peptides, which favors its substrate specificity for glycosylated peptides. Another variation of the GT-A fold is observed in the structures of $\alpha$2,3-sialyltransferases, CslI, and CslJ, from Campylobacter jejuni (7, 8). These enzymes use a monophospho-nucleotidyl sugar CMP-Neu5Ac as a donor. Crystal structures of these enzymes with substrate indicate that...
Glycosyltransferases, Chemistry of

this protein has an αβα sandwich motif reminiscent of the GT-A fold (Fig. 4c) and also contains flexible loops that undergo similar conformational changes on substrate binding.

Glycosyltransferase-B fold

The GT-B fold family includes most prokaryotic enzymes that produce secondary metabolites, like the antibiotics streptomycin, oleandomycin (Fig. 1) and vancomycin, and important bacterial cell wall precursors. It is also predicted to contain the vitally important O-GlcNAc transferase that modifies many nuclear and cytoplasmic proteins and influences gene transcription. The first glycosyltransferase structure reported in 1994 was for the GT-B fold enzyme, ji-glucosyltransferase (BGT) from bacteriophage T4 (22). This enzyme attaches glucose to modified cytosine bases on duplex DNA. Its low-sequence homology to other GTs made it difficult to draw comparisons between it and other GT-B enzymes. Only after the structures of two additional enzymes, MurG and GtfB, became available could consensus domains within the GT-B fold be verified (23, 24). MurG is an enzyme from Escherichia coli that catalyzes the transfer of GlcNAc from UDP-GlcNAc to the nonreducing end of a lipid-linked N-acetylmuramic acid acceptor to form the repeating unit of peptidoglycan. GtfB is a UDP-glucosyltransferase involved in the biosynthesis of chloroeremomycin (or vancomycin). More recently, the structure of another GT-B folded enzyme, oleandomycin glucosyltransferase from Streptomyces antibioticus that is involved in antibiotic synthesis was also reported (16) (Fig. 4d). All these enzymes, OleD, MurG, GtfB, and BGT, exhibit almost identical topology despite very little
sequence similarity. These enzymes and other members of the GT-B fold super family adopt a two-domain structure with a Rossmann-like fold in either domain. The predicted active site of the GT-B folded enzymes is located between the two Rossmann folds. Within the C-terminal portion of the cleft between the enzymes, another subdomain consists of an α/β structure that has a consensus glycine-rich pattern. This subdomain compromises the donor-binding domain. A crystal structure of MurG complexed with UDP-GlcNAc revealed that the first α-helix of this subdomain makes contact with the ribose moiety of the nucleotide, whereas the second α-helix interacts with the pyranose residue. Enzymes that use diphospho-containing sugar donors have to contend with the negative charge of the phosphates. The GT-B enzymes, unlike the GT-A enzymes, do not seem to use divalent metal cations for this purpose. Instead, the α/β subdomain of the Rossmann fold may account for this by creating a positively charged helix dipole with the first α-helix that acts to stabilize the α-phosphate of the nucleotidyl donor (2, 25), whereas other enzymes use basic residues to counteract the positive charge of the diphosphate moiety.

In addition to the conserved donor binding domains, the acceptor-binding site for GT-B folded enzymes has also been identified near the N-terminus. Analysis of GtfB-related sequences aided the identification of this site because all these enzymes are highly homologous at the primary sequence level; but functionally, they glycosylate different acceptors (2, 24). Because the acceptors are all from a similar group of peptide antibiotics, the variation in the sequence was presumed to reflect structural adaptations in the binding site to accommodate the slightly different acceptors.

A variant of the GT-B fold is shown in Figure 4d for an α1,6-fucosyltransferase (17). The structure shows an N-terminal coiled-coil domain, a catalytic domain that is similar to GT-B fold enzymes, and a C-terminal SH3 domain whose biological significance is currently uncertain.

Other glycosyltransferase folds

In addition to the variations of the GT-A and GT-B fold described above for sialyltransferases (7, 8) and fucosyltransferases (17), a distinct GT-C fold family has been predicted for GTs that use lipid linked donors. The crystal structures of the GT-domain of the peptidoglycan glycosyltransferase from Staphylococcus aureus (18) and Aquifex aeolicus (26) show structural similarity to the bacteriophage λ-lysozyme. These novel structures demonstrate the possibility of additional folds.
Glycosyltransferases, Chemistry of

Classification of Glycosyltransferases

The classic enzyme commission (EC) classification for GTs is on the basis of their donor and acceptor specificity as well as the product formed. Currently, 295 entries are in this database (http://www.chem.qmul.ac.uk/iubmb/). The distinction between these enzymes is noted by their ability to catalyze the transfer of hexoses (EC 2.4.9, hexosyltransferases), pentoses (EC 2.4.2, pentosyltransferases), or other glycosyl groups (EC 2.4.99, sialyltransferases). This classification is restricted to enzymes that are fully characterized, and it can be problematic for enzymes that act on several distinct acceptors but at different rates. It also does not take into account the origin of the enzyme or its three-dimensional structure.

A powerful, comprehensive classification of GT enzymes has been proposed by Henrissat and coworkers (http://www.cazy.org/). This classification scheme has been termed CAZy for carbohydrate active enzymes and delineates the enzymes into families based solely on amino acid similarity. This scheme has also been applied to the classification of other groups of enzymes, such as the glycosyl hydrolase, polysaccharide lyases, and carbohydrate esterases. These families are updated continually; currently, over 32,000 GT CRFs have been identified and classified into 90 families. Most enzymes in these families remain biochemically uncharacterized ORFs, but it has been demonstrated with both the GT and the glycosyl hydrolase families that this method of classification often leads to the grouping of enzymes with similar three-dimensional structures. However, as outlined in the structural fold section above, these three-dimensional structures do not necessarily translate into a predictable catalytic mechanism, substrate specificity, or the origin of the GT. For example, a few of the larger CAZy families, like GT2 with 8800 members, contain sequences that originate in bacteria, yeast, plant, viral, archaeal and animal species. This family also has at least 12 distinct GT activities, which include cellulose and chitin syntheses, mannosyltransferases, rhamnogalactosyltransferases and galactosyltransferases. Family 63 is mono-functional with a single entry for α-glucosyltransferase from bacteriophage T4. However, these families are not static. An example is the introduction of family GT78 when the three-dimensional structure of α-mannosylglycerate synthase (Mgs), from Rhodothermus marinus was reported (27). Despite the fact that this enzyme has high sequence similarity to members from GT2, a new family was generated because Mgs is a retaining enzyme whereas members of GT2 are typically inverting enzymes.

Glycosyltransferases in Biological Systems

The chemical diversity of glycosyltransferase reaction products is also reflected in their numerous biological roles (28). They serve as sources of energy exemplified by sucrose, lactose, and amylose (Fig. 1). They are also structural elements in cell walls and extracellular matrices. Oligosaccharides found on glycoproteins and glycolipids can be involved directly in the structure and the function of these molecules by affecting their stability, half-life, and activity within the cell. These oligosaccharides can also serve as receptors in biological recognition events such as signaling, development, and cell-cell adhesion or provide receptors for hormones, bacterial toxins and viruses. In bacteria and plants, oligosaccharides are also known to modulate the activity of secondary metabolites. Given these numerous biological roles of glycan products, it is important to understand the structure and the function of the GT enzymes that synthesize them. It is also pertinent to understand their overall function in the context of the biological system to which they belong. An overview of some important biological glycosylation reactions performed by GTs is described below. They are separated by taxonomy, but many occur throughout the kingdoms of life.

Eukaryotic glycosyltransferases

The best characterized eukaryotic glycosyltransferases are those from mammals. These GTs are important for the synthesis of N- and O-linked glycoproteins and glycolipids and are integral to the process of storing energy in the form of glycogen. Mammalian GTs use only nine nucleotide donor sugars, UDP-D-Galactose, UDP-D-Glucose, UDP-D-N-acetylglucosamine, UDP-D-Glucuronic acid, UDP-D-N-acetylgalactosamine, UDP-D-xyllose, GDP-D-mannose, GDP-D-L-Fucose, or CMP-D-N-acetylneuraminic acid. Mammalian GTs also use dolichol-phosphate-GlcNAc2Man9Glc3, dolichol-phosphate-mannose and dolichol-phosphate-glucose (Fig. 2).

In comparison with mammals, plants contain considerably more GTs because, in addition to the reactions carried out by mammalian GTs, they are required to convert the products of photosynthesis into diverse cell carbohydrates. For example, these GTs synthesize cell wall polysaccharides as well as secondary metabolites and xenobiotics. Plant GTs differ from mammalian GTs even more by their diversity of nucleotide donors. They use not only eight of the nine mammalian nucleotide donors, but numerous others such as UDP-L-rhamnose, GDP-L-glucose, GDP-L-galactose, UDP-L-arabinose, UDP-D-galacturonic acid, UDP-D-apiose, and so on. (29).

Despite the differences in roles, nucleotide donors, and number of GTs between eukaryotes, striking similarities exist between the processes by which these organisms synthesize glycan products. For example, the GTs responsible for the synthesis of N- and O-linked glycoproteins and glycolipids may differ in their substrate specificity, but they are all primarily located in the endoplasmic reticulum (ER) and/or Golgi apparatus. Furthermore, they follow similar steps for the assembly of their respective glycans. Although fewer in number, both plants and mammals do possess some important GTs that are not localized to the ER-Golgi synthesis pathways. Examples have been noted in both the cytoplasmic and the nucleoplasmic compartments as well as associated with the plasma membrane. To elaborate on some prominent GT reactions, the following descriptions have been separated based on their cellular location.

The GTs located in the ER-Golgi produce glycolipids and glycoproteins that are found on cell surface, in the extracellular matrix, or in fluids throughout the organism. These enzymes are usually type 2 transmembrane proteins composed of a short N-terminal cytoplasmic tail, a transmembrane domain,
Glycosyltransferases, Chemistry of

A through still associated with the ER-Golgi, the synthesis of O-linked glycoproteins differs greatly from the N-linked processes described above. Typically O-linked glycosylation of proteins occurs on serine and threonine residues, but it has also been identified on hydroxylated lysines (38). Semidineamine glycosylation is initiated in the Golgi by the action of retaining polypeptide GalNAc transferases (ppGalNAcTs, Fig. 42 (21, 39). The ppGalNAcTs represent one of the largest human GT families because they account for over 20 of the 250 known human GTs. Unlike N-linked protein glycosylation, the specificity of O-GalNAcTs does not seem to be determined by a known consensus sequence. This enzyme family is rather unique among GTs, in possessing a C-terminal, ricin-type lectin domain (39). This additional domain is believed to endow certain ppGalNAcTs with an even greater capacity to adapt to and capture glycosylated substrates, which ensures the high density of glycosylation characteristic of mucin domains (39). After ppGalNAcTs initiate glycosylation, other nucleotide GTs produce core 1 and core 2 glycan structures that can in turn be elaborated even more. These glycan structures impart unique physicochemical features to the proteins. For example, heavily glycosylated mucins facilitate the retention of water along environmentally exposed surfaces of the body.

Mammalian proteoglycans represent another class of heavily O-glycosylated proteins; however, they are synthesized by an alternative ER pathway. The protein attachment site for glycan synthesis initiation contains a Ser-Gly motif that is β-pyrosylated by the action of a xylosyltransferase (40). The β-pyrodase is extended by the action of additional galactosyltransferases to produce a core common to proteoglycans. This core is decorated by GTs even more through the sequential addition of alternating sugars of disaccharide repeating units to produce heparin, keratan, dermatan, and chondroitin (41). The biosynthesis of fully glycosylated proteoglycans involves different GT reactions that result in a heterogeneous product. Despite this heterogeneity, the glycans all contain the reproducible structural elements that allow them to fulfill their functions, such as in load-bearing portions of the joint that release water slowly under pressure then reuptake water when pressure is reduced.

Apart from GTs associated with the ER-Golgi, eukaryotes also possess biologically significant GTs that are associated with the plasma membrane. In particular, cellulose synthase is a complex of GTs that are responsible for the synthesis of the most abundant polymer on earth, cellulose. These GTs range in size from 988 to 1088 amino acids and have approximately eight transmembrane domains with large central cytoplasmic domain (42). Research on cellulose synthase has focused on understanding how these enzymes associate and how they coordinate the progressive addition of p-glucose to a growing polymer. This research is complicated by the fact that the formation of cellulose depends on several noncellulosic cell wall polysaccharides as well. Hemicellulose and pectin form the cell wall backbone on which cellulose is assembled, but these polysaccharides are synthesized within the Golgi by the activity of glycan synthases. Taking this into account, the synthesis of the final cell-wall polysaccharide product is astonishingly complex. Not only do they require the coordinated synthesis of a stem region of variable length, and a large catalytic domain that faces the luminal side (30). Proteolysis in the stem regions can generate soluble forms that are found in fluids such as milk and serum. It should also be noted that a crossover exists between the two groups of these GTs, which means that they can act on both lipids and proteins. Protein glycosylation events in the ER-Golgi are divided into two groups that consist of either N- or O-linked glycosylation.

Synthesis of N-linked glycoproteins begins by the precursory glycan first being assembled by GTs on dolichol-phosphatidate. In mammals, successive addition of monosaccharides from UDP-GlcNAc, GDP-Man, dolichol-phosphate-Man, and dolichol-phosphate-Glc results in a 14-sugar chain product [GlcNAc2Man9Glc3] (31). The next step involves the activity of a membrane-associated enzyme complex, which is termed oligosaccharide transferase (GST). This complex catalyzes the en bloc transfer of the assembled sugar chain from the dolichol-phosphatidate donor to an asparagine residue of a nascent protein. GST specifically modifies surface-exposed asparagines within the consensus sequence Asn-Xaa-Ser or Asn-Xaa-Tyr. After the en bloc transfer, the N-glycans are trimmed by ER glucosidases and ER-Golgi mannosidases and then converted to more complex structures by different GTs that use various donor sugars. By this process, it is possible for N-linked glycans to exhibit heterogeneity even on the same polypeptide. These glycans are called glycoforms, and well over 500 different structures have been chemically characterized (32). Among these glycans are the ABO blood group antigens. In the case of the O blood group, the structures terminate in 1,2-Gal. The A and B alleles are characterized (32). Among these glycans are the ABO blood group antigens. In the case of the O blood group, the structures terminate in 1,2-Gal. The A and B alleles are characterized (32).

The synthesis of glycolipids also occurs by successive GT reactions associated with the ER-Golgi. Two common classes of glycolipids synthesized by this method are the glycosphingolipids and the glycoalkyl and glycoalfosphoryls (GPI). Within the glycosphingolipid class, Glc-ceramide synthesis is initiated by the addition of β-Glc from a UDP donor by glucosylceramide synthase (35). For GPIs, the first sugar attached to the lipid is GlcN-ac that is desacylated to GlcN (36). These initial steps occur on the cytoplasmic face of the ER followed by flipping to the luminal face. The GPIs are then conjugated to proteins through N-linkages, whereas glycosphingolipids are modified by the addition of Gal, GalNAc, and NeuAc by Golgi GTs. This method of glycosylation and flipping across a membrane has been noted in plants during galactolipid synthesis on the chloroplast's thylakoid membrane. The GTs that form these galactolipids are particularly interesting because these galactolipids are the most abundant class of lipids in the biosphere (37).
activity of over 50 GTs, but also the action takes place in two different cellular locations.

Given the above processes, it is evident that the synthetic processes of glycans and glycoconjugates are often associated with a membrane in some fashion. Consequently, this process helps to organize or sequester the correct GTs for a particular function. Some important glycosyltransferase reactions have also been noted in other areas of the cell. For example, the energy storage enzyme glycogen synthase and a superfamily of CA2y family 1 glycosyltransferases, which is involved in the biotransformation of drugs and xenobiotics via glucuronosylation in mammals and glucosylation of small molecular weight acceptors in plants (44), are known to be located in the cytoplasm. The protein-modifying O-GlcNAc transferase is particularly interesting in that it uses UDP-GlcNAc to glucosylate serine or threonine residues on specific proteins. Glycosylation of these target proteins is balanced by the action of a soluble N-acetylglucosaminidase and seems to be reciprocal with protein phosphorylation. This dynamic balance in glycosylation levels is predicted to be involved in numerous processes, which include glucose metabolism, chaperone folding, nuclear pore protein translocation, and transcription factor regulation (43). The importance of O-GlcNAc transferase is clearly apparent not only because of its numerous activities in the cell, but also because of its discovery within the nucleus and cytoplasm of all metazoans.

Prokaryotic glycosyltransferases

Glycans in prokaryotic cells are integral to several cellular roles. Peptidoglycan is a determinant of cell shape and helps esubacteria withstand the pressures of the external environment. Lipopolysaccharide (LPS), lipooligosaccharides (LOS), capsules, and slime layers serve as attachment sites/receptors for cellular interactions, provide protection from environmental factors and are involved in immune system modulations/invasion. In addition to these cell wall polysaccharides, the list of other glycosylated natural products, which include antibiotics and other xenobiotics, continues to grow. In fact, the only GTs that prokaryotes were believed to lack were those for the synthesis of glycoproteins. However, this group has recently been re-visited given increasing demonstrations of the structure, function, and biosynthesis of glycoproteins in prokaryotes (45-47). The diversity of prokaryotic carbohydrate structures, and the corresponding GTs that synthesize them, is overwhelming. Moreover, striking similarities seem to exist between the glycosylation events of the prokaryotes and the eukaryotes. For example, both kingdoms use nucleoside-donor sugars to assemble oligosaccharide chains, trimming reactions are present in both, and they both use lipid-bound intermediates. Studies with S-layer glycoproteins have also demonstrated that prokaryotes are O-glycosylated at serine/threonine residues and N-glycosylated at asparagine residues (45).

Despite their similarities, glycosylation events in prokaryotes and eukaryotes have critical differences. The absence of intracellular organelles means that polymerization of prokaryotic oligo/polysaccharides takes place entirely in the cytoplasm or in controlled extracellular reactions. It is important to note that the extracellular glycosyltransferase reactions must be coordinated tightly given the lack of a membrane to prevent the loss of substrates/products combined with the lack of nucleotide donors to fuel the reaction process. The following description outlines the processes by which prokaryotic GTs synthesize carbohydrates destined for either protein glycosylation or macromolecular structures. These polysaccharides are typically synthesized by similar mechanisms. However, it should be noted that in bacteria, N-glycosylation occurs independently of protein translocation (47). Biosynthesis begins in the cytoplasm on a lipid-linked carrier. Undecaprenyl is used in the case of peptidoglycan and LPS, whereas a C24-polyisoprenyl is used for protein glycosylation (45-48). Sugars are added to these carriers by successive transfers of either monomeric sugars from nucleotide precursors or by en bloc transfer of assembled oligosaccharides from other lipid-monophosphate carriers. The GTs involved in this process for LPS with mammalian-like structures which help the bacterium mimic host cell polysaccharides for the purpose of evasion/suppression of the host immune response (7, 8). When the oligo/polysaccharide precursors are assembled, they either remain in the cytoplasm or are transported across the membrane(s). However, the mechanism of transfer across the membrane(s) is not understood clearly. At least for capsular and lipopolysaccharides from E. coli and Salmonella enterica, it seems to involve the coordinated process of several membrane spanning and/or ABC transporter proteins (48, 49). Electron microscopy and X-ray crystallography studies have allowed the visualization of the core Wza-Wzc complex for capsular polysaccharide export in E. coli (49). When on the outer-surface of these cells, the oligo/polysaccharides are released into the external environment or transferred to their target proteins/macromolecular structures by the action of external glycosyltransferases. The recently solved three-dimensional structure of the peptidoglycan biosynthesis domain of the penicillin-binding protein (18, 26) of viruses. First, some bacteriophages can glycosylate their own DNA to avoid host restriction endonucleases. This function became particularly apparent when the first structurally solved GT, T4 bacteriophage-encoded α-glucosyltransferase (22) was crystallized more recently in the presence of a short DNA segment (50). An α-glucosyltransferase with the same fold and similar function has since been described in the same T4 virus (51). Second, viral GTs can modify host structures that result in evasion of the immune response or promoting the transmissibility of the released viruses. Modification of host structures in bacteria has been reported to aid in serotype conversion and immunity to infection by other viruses. This phenomenon has been studied extensively with respect to LPS modification in Salmonella and prokaryotes.
Shigella bacterial species (reviewed by Reference 52). Third, viral GTs can alter host metabolisms to promote the release of increased numbers of progeny viruses. This theory is perhaps best exemplified by the modification of ecdysteroid by a baculovirus-encoded glucosyltransferase. Ecdysteroid is an insect hormone involved in the development of Lepidoptera sp. from the larval to the molting or pupating stages. Inactivation of glucosyltransferase through the addition of glucose by virally-encoded UDP-glucosyltransferase, EGT, prevents this development. It allows the virus to monopolize insect resources and facilitates easier spread of the virus when the larva disintegrate (reviewed by Reference 52). Last, some viruses possess GTs that assemble unique virus-encoded products that aid in immune evasion or infection of surrounding hosts. Typically, viral glycoproteins are produced by "hijacking" the host glycosylation pathways associated with the ER-Golgi apparatus. However, the synthesis of the major capsid protein of the Chlorella virus has been found to differ from this paradigm. Paramaecium bursaria chlorella virus-1 encodes at least five putative GTs, of which one of the gene products, A64-9, has been characterized structurally by X-ray crystallography (53). Four of the five GTs are predicted to be localized in the cytoplasm, whereas the last GT is membrane associated. The coordinated activity of these GTs is proposed to assemble the major capsid protein, Vp54, which is independent of the host ER-Golgi apparatus.

Virus-encoded GTs may actually be more common than believed previously because the list of known viral GTs is far from being complete. Viruses are constantly coevolving with their hosts and many can extract genes, which include those for glycosyltransferases, from the host genome for incorporation into their own. If they can confer a selective advantage to their hosts and many can extract genes, which include those for glycosyltransferases, from the host genome for incorporation into their own. They can confer a selective advantage to the virus, they could be incorporated permanently into their genomes, which lead to new virally encoded GT variants.

**Future Directions**

Although many important GTs in glycobiology have been discussed, a need exists for even more exploration of these enzymes, because specific roles are often not defined. Furthermore, it is increasingly apparent that many GTs are related directly to numerous acquired and inherited diseases. For example, the potent B cell toxin from Clostridium difficile is a GT that inactivates Rho-GTP through glucosylation (54). This GT leads to diarrhea, inflammation, and damage to colonic mucosa. In inherited diseases, aberrant glycosylation of O-linked mannose and GlcNAc on dystroglycan can lead to Walker-Warburg syndrome or muscle-eye-brain disease, respectively (55). Sequence variations in the coding genes of xylosyltransferases, XT-I and XT-II, have also been demonstrated to be responsible for altered proteoglycan metabolism. These variations have thus been identified as risk factors for diabetic nephropathy, osteoarthritis, or pseudohyphae elastidum (56). Although it is certainly an abbreviated list, these findings point to the important role of these GTs in disease modifiers in several different pathologies. Therefore, from a disease standpoint, it is prudent that we continue to outline the roles for existing and unknown GTs within a biological context. Then, the potential to cure these diseases, by genetic or drug administered therapy, can be assessed properly.

GTs are also promising for the generation of pharmacologically relevant glycoconjugates. Indeed, the discovery of the catalytic reversibility of AveB from Streptomyces avermitilis proved to be useful because it led to the production of a variety of avermectin variants that may have commercial use in controlling nematodes, insects, and arachnids (4). These results are particularly intriguing given the recently solved three-dimensional structures of two other antibiotic synthesis enzymes: the vancomycin and clindamycin GTs (16, 24) (Fig. 4d). The characterization of new GTs also holds medical relevance as a way to greatly expand existing candidates for vaccine development, because many of these are known to be natural glycoconjugates synthesized by GTs.

Characterization of GTs also has industrial implications. Glycosylation of biopharmaceuticals such as antibodies can have profound effects on their half-life, stability, and activity, which makes GTs attractive tools for engineering proteins that are ideal for prolonged or specialized industrial processes as exemplified in the production of human glycoproteins in yeast (57). Furthermore, the incorporation of several GTs in a single reaction mixture can lead to the synthesis of many and often complex polysaccharides as opposed to lengthy and laborious chemical methods that are less environmentally benign. This mechanism includes the use of metabolically engineered bacteria for large-scale synthesis of complex glycans (58, 59). Ultimately, all processes would be enhanced greatly if the precise catalytic mechanisms of GTs were understood better. To accomplish this task, new enzyme inhibitors and/or substrate analogs are needed. Elucidation of these mechanisms will certainly not only lend insight into the structure-function relationship of these enzymes, but also provide an increased knowledge of what makes GTs uniquely suited to perform certain functions.

Post-Translational Modifications to Regulate Protein Function

Hening Lin, Jintang Du, and Hong Jiang. Department of Chemistry and Chemical Biology, Cornell University, Ithaca, New York
doi: 10.1002/9780470048672.wecb467

Protein post-translational modifications (PTM) are very important to regulate protein function and to control numerous important biological processes. Here a brief review of commonly found enzyme-catalyzed PTM is given. These PTM include modifications that occur on protein side chains and those that involve protein backbones. The introduction of different PTM is followed by a summary of the molecular basis for the regulation of protein function by PTM. The focus is then given to a few major PTM that play important roles in eukaryotes, such as phosphorylation, methylation, acetylation, glycosylation, ubiquitylation, and proteolysis. For each modification, a description will be given about the residues modified, the enzymatic reaction mechanisms, the major known biological functions, and its relevance to human diseases. At the end, we discuss challenges in identifying new pathways regulated by known PTM and discovering new PTM.

Introduction

The central dogma of molecular biology, DNA is transcribed to mRNA which is then translated to proteins, implies the importance of proteins. After all, it is the proteins that carry out most of the biological functions of a cell. Thus controlling transcription and translation are very important, as they ultimately control what proteins are synthesized in cells and thus control the properties of cells. However, one should not overlook what happens to proteins after they are synthesized. Many chemical modifications can occur to proteins after translation. Collectively, these modifications are called post-translational modifications (PTM). PTM are very important in regulating protein function, which is reflected by the large number of genes devoted to catalyzing PTM. For example, in the human genome (with less than 30,000 genes total), more than 500 kinases catalyze protein phosphorylation (1), and more than 500 proteases catalyze the hydrolytic cleavage of proteins (2). Deregulation in PTM is the cause of various human diseases, as will be explained later in specific PTM sections. Here, a brief review is given on different types of PTM and on how PTM regulate protein function. Some basic principles will be highlighted so that readers who are unfamiliar with PTM can have a quick but comprehensive understanding of PTM. The recent book on PTM by Professor Walsh from Harvard Medical School provides a more complete description of PTM (3). Where appropriate, references on specific PTM will also be given in different sections for additional information. The abbreviations used are cataloged in Table 1 to help readers who are not familiar with the biological language.

Types of post-translational modifications

PTM can be enzyme-catalyzed and thus controlled carefully, or they can be nonenzymatic with less control. For example, protein glycation during hyperglycemia is a nonenzymatic PTM that accounts for some symptoms of diabetes (4). Protein nitrosylation on Cys residues is another nonenzymatic PTM that can affect protein function (5). Coordination by metal ions can also be considered as a PTM. For many proteins, metal binding is crucial for maintaining the correct structure or the enzymatic activity (6). Here, the focus will be given to enzyme-catalyzed PTM. Figures 1 and 2 show many commonly found enzyme-catalyzed PTM.

<thead>
<tr>
<th>Abbreviation</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>ABL</td>
<td>A tyrosine kinase encoded from abl (Abelson) gene, the fusion protein ABL-BCR is involved in inhibition of apoptosis in chronic myelogenous leukemia cells</td>
</tr>
<tr>
<td>AC</td>
<td>Adenylate cyclase, converts ATP to cyclic AMP</td>
</tr>
<tr>
<td>AcLys</td>
<td>Acetyllysine</td>
</tr>
<tr>
<td>ACP</td>
<td>Acyl carrier protein, found in fatty acid synthases and polyketide synthases, functions to carry the elongating fatty acyl chain</td>
</tr>
<tr>
<td>ADAM</td>
<td>A disintegrin and metalloprotease, a family of proteases that hydrolyze off extracellular portions of transmembrane proteins</td>
</tr>
<tr>
<td>ADP</td>
<td>Adenosine 5’-diphosphate</td>
</tr>
<tr>
<td>Apaf-1</td>
<td>Apoptotic protease activation factor-1, a cytosolic protein involved in cell death or apoptosis, interacts with cytochrome c to activate caspase 9</td>
</tr>
<tr>
<td>AT</td>
<td>Acyltransferase, found in fatty acid synthases and polyketide synthases, adds a malonyl group to the holo form of the ACP domain</td>
</tr>
<tr>
<td>ATP</td>
<td>Adenosine 5’-triphosphate</td>
</tr>
<tr>
<td>Bcl2</td>
<td>Named from B-cell lymphoma 2, an antiapoptotic protein</td>
</tr>
<tr>
<td>BCR</td>
<td>A protein encoded from breakpoint cluster region gene, has serine/threonine kinase activity. Fusion with abl protein causes leukemia</td>
</tr>
<tr>
<td>cAMP</td>
<td>3’-5’-cyclic adenosine monophosphate</td>
</tr>
<tr>
<td>CARD</td>
<td>Caspase recruitment domain, mediates the formation of larger protein complexes via direct interactions between individual cards, involved in the regulation of caspase activation and apoptosis</td>
</tr>
<tr>
<td>CARM1</td>
<td>Coactivator-associated arginine(R) methyltransferase 1, methylates Arg17 and Arg26 residues on Histone H3</td>
</tr>
<tr>
<td>Cbl-b</td>
<td>Ubiquitously expressed homolog of Cbl, a mammalian protein involved in cell signaling and protein ubiquitination, named after Casitas B-lineage Lymphoma</td>
</tr>
<tr>
<td>CBP</td>
<td>CREB binding protein, a transcriptional co-activating protein</td>
</tr>
<tr>
<td>CD2</td>
<td>Cellular differentiation marker 2, a cell adhesion protein found on the surface of T cells and natural killer cells</td>
</tr>
<tr>
<td>CDK</td>
<td>Cell-division kinases, serine/threonine kinases, activated by association with cyclins and involved in regulation of the cell cycle, transcription and mRNA processing</td>
</tr>
<tr>
<td>CHD1</td>
<td>Chromodomain helicase DNA-binding protein 1, interacts with methylated Lys4 on Histone H3</td>
</tr>
<tr>
<td>CLOCK</td>
<td>A protein named from circadian locomotor output cycles kaput gene, regulating circadian rhythm</td>
</tr>
<tr>
<td>CML</td>
<td>Chronic myelogenous leukemia, a form of leukemia characterized by the increased and unregulated growth of predominantly myeloid cells in the bone marrow and the accumulation of these cells in the blood</td>
</tr>
<tr>
<td>CREB</td>
<td>Camp response element binding proteins, as transcription factors, bind to certain sequences called camp response elements (CRE) in DNA and thereby increase or decrease the transcription of certain genes</td>
</tr>
</tbody>

<tbody>
<tr>
<td>Cyto c</td>
<td>Cytochrome c, a small heme protein associated with the inner membrane of the mitochondria and released in response to pro-apoptotic stimuli</td>
</tr>
<tr>
<td>DED</td>
<td>Death effector domain, a protein interaction domain found in inactive procaspases and proteins that regulate caspase activation in the apoptosis cascade</td>
</tr>
<tr>
<td>DH</td>
<td>Dehydratase, found in fatty acid synthases and polyketide synthases, dehydrates the ω-H of acyl thioester</td>
</tr>
<tr>
<td>DNAse</td>
<td>Deoxyribonuclease, catalyzes the hydrolytic cleavage of phosphodiester linkages in the DNA backbone</td>
</tr>
<tr>
<td>ER</td>
<td>Endoplasmic reticulum</td>
</tr>
<tr>
<td>ER</td>
<td>Enoylreductase, found in fatty acid synthases and polyketide synthases, reduces the enoyl of enoyl thioester to the saturated thioester</td>
</tr>
<tr>
<td>ERK</td>
<td>Extracellular signal-regulated kinase, activates many transcription factors and some downstream protein kinases, involved in functions including the regulation of mitosis, meiosis, and postmitotic functions in differentiated cells</td>
</tr>
<tr>
<td>Factor IX</td>
<td>One of the serine proteases of the coagulation system</td>
</tr>
<tr>
<td>FAD</td>
<td>Flavin adenine dinucleotide</td>
</tr>
<tr>
<td>FADD</td>
<td>Fas-associated protein with death domain, connects the Fas-receptor and other death receptors to caspase-8 through its death domain to form the death inducing signaling complex during apoptosis</td>
</tr>
<tr>
<td>FHA domain</td>
<td>Forkhead-associated domain, a phosphospecific protein-protein interaction motif involved in checkpoint control of the cell cycle</td>
</tr>
<tr>
<td>GcoS</td>
<td>A yeast transcriptional adaptor that has histone acetyltransferase activity</td>
</tr>
<tr>
<td>GDP</td>
<td>Guanosine-5’-diphosphate</td>
</tr>
<tr>
<td>GFP</td>
<td>Green fluorescent protein</td>
</tr>
<tr>
<td>GPCR</td>
<td>G protein-coupled receptor, a transmembrane receptor that senses molecules outside the cell and activates inside signal transduction pathways and cellular responses</td>
</tr>
<tr>
<td>GPl</td>
<td>Glycosylphosphatidylinositol, a glycolipid that can be attached to the C-terminus of a protein during post-translational modification</td>
</tr>
<tr>
<td>GPK</td>
<td>Glycogen phosphorylase kinase, a serine/threonine-specific protein kinase which activates glycogen phosphorylase by phosphorylation</td>
</tr>
<tr>
<td>Grb2</td>
<td>Growth factor receptor-bound protein 2, an adaptor protein involved in signal transduction/cell communication</td>
</tr>
<tr>
<td>I-2P</td>
<td>Guanosine-5’-bisphosphate</td>
</tr>
<tr>
<td>HDAcS</td>
<td>Histone deacetylases, remove acetyl groups from ε-N-acetyl-lysine residues on histones</td>
</tr>
<tr>
<td>hDOT1L</td>
<td>Human DOT1-like protein, methylates histone H3 at Lys79. (DOT1: Yeast disruptor of telomeric silencing-1)</td>
</tr>
<tr>
<td>HECT</td>
<td>Homologous to E6-AP C terminus, mediates E2 binding and ubiquitination</td>
</tr>
<tr>
<td>HIF</td>
<td>Hypoxia inducible factor, a transcription factor that responds to changes in available oxygen in the cellular environment, specifically to decreases in oxygen or hypoxia</td>
</tr>

</table>

As can be observed from Fig. 1, most PTM happen to protein side chains. Typically, the side chains involved are nucleophilic, such as Cys (palmitoylation, isoprenylation, disulfide bond formation, ADP-ribosylation), Lys (acetylation, methylation, ubiquitinylation), Arg (methylation, ACP-ribosylation), Asp/Glu (methylated, polyADP-ribosylation), Ser/Thr (phosphorylation, O-glycosylation), and Tyr (phosphorylation). Weaker nucleophiles are also used, such as the side chain amide nitrogen in Asn (in N-glycosylation), the C-2 position of Trp (in C-glycosylation), and the C-2 position of His (in diphthamide). In amider mediated reactions catalyzed by transglutaminases and polyglutamylation/polyglycylation reactions that happen to Glu residues, the ε-NH$_2$ from Lys or α-NH$_2$ from Glu/Gly acts as the nucleophile, whereas the side chain of Glu or Glu serves as the electrophile. In addition, several amino acid side chains can be oxidized, such as Pro, Lys, Asn, Tyr, Trp, and Cys, to give oxidized amino acids.

A few PTM reactions also involve changes in protein backbone. These reactions include the hydrolytic cleavage of the peptide backbone by proteases, the anchoring of proteins to glycosylphosphatidylinositol (GPI) or cholesterol, and the C-terminal amide formation by oxidative cleavage of glycine residues. Some PTM involve changes in both the side chain and the main chain, such as the formation of 4-methylidene-5-imiazole-5-one (MIO) prosthetic group in deaminases and aminomutases, the formation of the fluorophore in GFP (green fluorescent protein), and the formation of pyruvamide in decarboxylases (Fig. 2).

Molecular basis for the regulation of protein function by PTM

As with all other chemical species, protein structure determines protein function. PTM can regulate protein function because they can change protein structure. The structure change introduced by PTM can be local and small. For example, methylation of Lys residues makes the side chain more hydrophobic without changing protein backbone conformation significantly (at least based on crystal structures in which methylated and unmethylated histone peptides are bound by another protein [2]), whereas phosphorylation can change the backbone conformation within a limited region of a protein by charge-pairing with nearby Arg residues or by interacting with main chain NH and helical
Post-Translational Modifications to Regulate Protein Function

Changing protein structure to turn on/off catalytic activity of enzymes

The best-known PTM that is widely used to regulate enzymatic activity is phosphorylation. Phosphorylation regulates the activity of many enzymes by different mechanisms. For example, glycogen phosphorylase is activated allosterically by phosphorylation at Ser14, whereas *Escherichia coli* isocitrate dehydrogenase is inhibited by phosphorylation because of the block of substrate access to the active site (9). The most interesting and very important catalytic activity regulated by phosphorylation is protein kinase activity. Most protein kinases are activated by phosphorylation of Thr/Tyr residue(s) in the activation segment. The structural changes induced by phosphorylation, which are illustrated in Fig. 3 with ERK (extracellular signal-regulated kinase), convert the inactive kinases to active kinases (8). The regulation of protein kinase activity by phosphorylation bears enormous biological significance because protein phosphorylation is important in signal transduction, and the control of downstream kinase activity via phosphorylation by upstream kinase is one major method to propagate signals to downstream partners, as will be elaborated later.

Proteolysis is another way to control enzymatic activity, although unlike phosphorylation, the change in activity is irreversible. Many proteases are synthesized as inactive precursors (zymogens) that have to be cleaved by proteolysis to become active. These precursors include proteases that are secreted into digestive tracts or lysosomes, the catalytic active subunit(s) in the eukaryotic 20S proteasome that are activated by self-cleavage (10), and the effector caspases involved in apoptosis that are activated by initiator caspases-mediated cleavage (11).

Changing protein structure to create or to mask recognition motifs

Many PTM exert their biological functions by creating recognition motifs to recruit binding partners (12) or by masking recognition motifs to disrupt existing interactions. Phosphorylated Ser/Thr residues can be recognized by proteins that contain 14-3-3 domains, FHA (forkhead-associated) domains, SMAD (proteins homologs of both the drosophila protein, mothers against decapentaplegic (MAD) and the *Caenorhabditis elegans* protein Sma) domains, and several other domains (13). Phosphorylated Tyr residues can recruit proteins that contain SH2 (Src homology 2) domains and PTB (phosphotyrosine binding) domains (14). Acetyl Lys residues can be recognized by proteins with bromodomains (15, 16), and methylated Lys residue can be recognized by proteins with chromodomains and Tudor domains (17). The ubiquitin and ubiquitin-like protein tags can also be recognized by various protein domains that mediate the biological function of modification with these protein tags (18, 19). The structures of a few domains dedicated to recognition of post-translationally modified residues are shown in Fig. 4. Typically, domains that recognize post-translationally modified residues have specificities in that they recognize not only the modified residue, but also the local structure in which the residue resides. The specific recognition of PTM in different contexts is the key to understand many biological consequences of PTM, as will be explained in more detail in particular PTM sections later.

In addition to creating recognition motifs to recruit proteins, a few PTM can also increase interaction with other species, such as the lipid bilayer of different cellular membranes. These modifications include the formation of GPI-anchored proteins (20), protein myristoylation on the α-amino group of the N-terminal dipole (8). In contrast, some PTM can alter protein overall structure more dramatically, such as the proteolytic cleavage of proteins into smaller fragments, or the addition of protein tags like ubiquitin. These structure changes, small or big, are the basis for the biological functions of different PTM and typically lead to one or more of the consequences described below.
Post-Translational Modifications to Regulate Protein Function

Figure 4 Structures of a few dedicated domains that recognize post-translationally modified residues. (a) SH2 domain of v-Src in complex with pTyr peptide (pTyr-Val-Pro-Met-Leu). Residues Arg12, Arg32, Ser34, Thr36, and Lys60 from the SH2 domain interact with pTyr (figure made using PDB 1SHA); (b) Bromodomain of yeast histone acetyltransferase Gcn5 in complex with AcLys peptide (histone H4 residues 15–29, AK(Ac)RHRKILRNSIQGI). Bromodomain residues Pro351, Gln354, Tyr364, Met372, Val399, and Asn407 interact with AcLys (with some of the interaction is mediated by water molecules, figure made using PDB 1E6I); (c) Chromodomain of HP1 in the complex with histone H3 Me3Lys9 (figure made using PDB 1KNE). Chromodomain residues Tyr 24, Trp 45, Tyr 48 and Gln 52 bind MeLys; (d) UBA domain of Cbl-b in complex with ubiquitin (figure made using PDB 200B). UBA domain residues Asp933, Ala937, Met940, Phe946, and Lys950 interact with ubiquitin residues Leu8, Ile44, Ala46, Gly47, Gln49, His68, and Val70. UBA: ubiquitin binding associated.

Gly (21), protein C-terminal prenylation on Cys residues (22), and protein palmitoylation on Cys residues that are close to membrane surface (23). These lipid modifications occur to many signaling proteins, which include G protein-coupled receptors and small G proteins, and they play important roles in signal transduction and membrane trafficking (24).

Adding functional groups to allow catalysis

Typically, proteins are formed with the most common 20 amino acids, which only offer a limited number of choices of functional groups for catalyzing different reactions. The limit in the number of functional groups is complemented by the use of various cosymes or cofactors, many of which are attached covalently to the corresponding enzymes. One class of PTM with this function is the addition of “swinging arm” prosthetic groups (biotin, phosphopantetheine, and lipoic acid) to proteins (25). Biotin is used as a carrier of CO2 in carboxylation reactions, and the disulfide bond in lipoic group is used as an electron carrier and acyl carrier in 2-keto acid dehydrogenases. The phosphopantetheine group provides a thiolate as the carrier of acyl chains and is used in fatty acids synthases, polyketide synthases, and nonribosomal peptide synthetases (26). Although a thiolate side chain can also be provided by Cys, the longer phosphopantetheine can shuttle the acyl chains to different catalytic domains, which allows multiple reactions to occur in sequence on the acyl chains (Fig. 5). This “swinging arm” catalysis, which is also enabled by bioinlilation and lipoylation, cannot be achieved by natural proteinogenic amino acids with shorter side chains.

Another type of PTM provides new functional groups for enzyme catalysis by oxidation of side chain. These include TOPA (2,4,5-trihydroxyphenylalanine) quinone in amine oxidases (27), tryptophan tryptophanyl quinone in methylenecarboxylases, and formylglycine in sulfatases. (28) Main chain modifications can also generate prosthetic groups for enzyme catalysis, such as the MIO group in His/Phe ammonia-lyase (29, 30) and Tyr aminomutases, (31) and the pyruvyl group in decarboxylases (Fig. 6) (32). The formation of these cofactors by PTM extends the catalytic power of enzymes greatly, which enables them to catalyze chemistry that is difficult with just the side chains of the 20 amino acids commonly found in proteins.

Locking proteins into the correct structures or increasing protein stability

The major type of PTM that has this function is protein disulfide bond formation (33). Disulfide bonds are more stable thermodynamically than the reduced thiolis in an oxidizing environment. In eukaryotes, proteins that undergo the secretory pathway start to form disulfide bonds once they are translocated into the endoplasmic reticulum (ER) lumen, which is an oxidizing environment. These disulfide bonds help to stabilize
Post-Translational Modifications to Regulate Protein Function

Figure 5  Fatty acid biosynthesis catalyzed by fatty acid synthases. The growing acyl chain is tethered to the phosphopantetheinylated ACP domain, which enables it to undergo cycles of condensation, ketone reduction, dehydration, and enol reduction catalyzed by different domains: AT, acyltransferase; ACP, acyl-carrier protein; KS, ketosynthase; KR, ketoreductase; DH, dehydratase; ER, enoylreductase.

Figure 6  Post-translationally generated cofactors provide functional groups to allow catalysis. The mechanisms of TOPA quinone in amine oxidases, MIO in deaminase, and pyruvamide in decarboxylase are shown.
the desired protein structure by locking the protein in a certain conformation, and perhaps to assist protein folding too. Many secreted proteins later undergo proteolysis in the Golgi to give smaller fragments (see the proteolysis section below). In this case, disulfide bonds also serve to link the fragments covalently to maintain a certain structure. One textbook example is insulin, which is produced as a single peptide chain that later undergoes several proteolysis steps, and the mature insulin consists of two chains connected via two disulfide bonds (Fig. 7) (34). The light and heavy chains of antibodies are connected by disulfide bonds. Another PTM that can increase protein stability is glycosylation. For example, erythropoietin N-glycosylation has been found to increase its in vivo lifetime (35), which is probably because of the blocking of tissue proteases action by carbohydrate modifications.

Exploration of major PTM

In this section, a few major PTM will be explored in more details. For each PTM discussed, a brief introduction on the PTM reaction and the enzymes catalyzing the reaction will be given. A few biological processes that involve the PTM will be explained to demonstrate the important function of the PTM in biology.

Phosphorylation

Protein phosphorylation typically occurs on Ser, Thr, and Tyr residues (Fig. 1), although His and Asp residues can also be phosphorylated as in bacteria two-component signal transduction systems. The universal phosphate donor is adenine triphosphate (ATP, Fig. 8), and the reaction is catalyzed by more than 500 kinases in humans. Many kinases are Ser/Thr specific, some are Tyr specific, whereas some have dual specificity. It was reported that inositol pyrophosphate (IP7) can also serve as phosphate donor in protein phosphorylation (36). However, the reaction is not enzyme catalyzed and the physiologic relevance is not proven yet.

The large number of protein kinases in the human genome reflects that this PTM is widely occurring and regulates numerous biological processes. The most well understood function is signal transduction, because phosphorylation of proteins can turn on/off catalytic activity or create recognition motif to recruit other protein partners, thus allowing signal to propagate. In accord with its role in signal transduction, protein phosphorylation is reversible so that the signaling process can be terminated as needed. The removal of the phosphate group is catalyzed by phosphatases (Fig. 8).

Two signaling processes will be discussed here to illustrate how protein phosphorylation can play a critical role in cell signaling. A more detailed description of these two signaling processes can be found in the Molecular Cell Biology textbook by Lodish et al. (34). The first one, which is shown in Fig. 9, involves protein kinase A (PKA), which can be activated by cyclic AMP (cAMP) (37). PKA at resting state exists as an inactive tetramer that consists of two copies of a regulatory subunit and two copies of the catalytic subunit. Hormones that signal through G-protein coupled receptors can activate the trimeric G protein, which in turn can activate an effector enzyme, adenylate cyclase (38). Adenylate cyclase catalyzes the formation of cAMP from ATP (39), which results in the increase in cAMP concentration. Binding of cAMP to the regulatory subunits of PKA dissociate the inactive tetramer, which releases the catalytic subunit of PKA. The catalytic subunit can then be activated by phosphorylation at the activation loop. Activated PKA can phosphorylate many different substrates and produce both short-term and long-term effects. Short-term effects come from the change of the catalytic activities of substrate proteins on phosphorylation by PKA. The substrates of PKA include proteins involved in glycogen synthesis and degradation, such as glycogen phosphorylase kinase and glycogen synthase...

Figure 8 Kinase-catalyzed phosphorylation and phosphatase-catalyzed dephosphorylation reactions. (a) Catalytic mechanisms of protein kinases; (b) Catalytic mechanism of bimetallic pSer/pThr or dual specificity protein phosphatases; (c) Catalytic mechanism of pTyr phosphatases.

(40) Phosphorylation of these proteins by PKA leads to activation of glycogen degradation and inhibition of glycogen synthesis. Long-term effects come from the changes in gene transcription. PKA can affect transcription by phosphorylating CREB (cAMP response element binding proteins) and other transcription factors (41). On phosphorylation, CREB can bind to specific regions of the chromosomal DNA, and it can recruit the basal transcription machinery via CBP/CREB binding protein/P300 to activate the transcription of certain genes.

The second example of cell-signaling process that involves protein phosphorylation is receptor tyrosine kinase signaling (Fig. 10) (42). Receptor tyrosine kinases are transmembrane proteins with an extracellular ligand-binding domain and an intracellular tyrosine kinase domain. Ligand binding to the extracellular domain triggers receptor dimerization and/or activation, so that the intracellular catalytic domains from two receptor protein molecules can phosphorylate each other at the activation segment. This transphosphorylation activates the catalytic domain so that it can phosphorylate other Tyr residues in the receptor and other substrate proteins. These phosphorylated Tyr residues then recruit protein-binding partners that contain SH2 or PTB domains that recognize specific phosphorylated Tyr residues. One of the proteins recruited is Grb2 (growth factor receptor-bound protein 2), which contains an SH2 domain. Grb2 in turn recruits Sos (son of sevenless), which is a guanine nucleotide exchange factor for the G protein Ras. Sos catalyzes the exchange of Ras-bound GDP (guanosine-5’-diphosphate) for GTP (guanosine-5’-triphosphate), which converts Ras to the activated form. Activated Ras can bind to and activate Raf, which is the most upstream kinase in the MAP kinase (Mitogen-activated protein kinase) cascade (43). By phosphorylation of MEK (MAPK/ERK kinase, a dual specificity MAP kinase kinase) on the activation segment, Raf activates MEK, which in turn...
Post-Translational Modifications to Regulate Protein Function

Figure 9 The signaling process that involves G protein-coupled receptors (GPCR) and PKA. (1) Binding of hormone produces conformational change in the GPCR; (2) GPCR binds to Gs protein; (3) GDP bound to Gs is replaced by GTP and the β and γ subunits of Gs dissociate from the α subunit; (4) Gs subunit binds to adenylate cyclase (AC), which activates the synthesis of cAMP (4a), the hormone tends to dissociate, and hydrolysis of GTP to GDP causes Gs α to dissociate from adenylate cyclase and binds to Gβγ, which regenerates a conformation of Gs that can be activated by an GPCR hormone complex (4b); (5) dissociation of regulatory subunits (R) from PKA as cAMP concentration increases; (6) subsequent activation of the catalytic subunits (C) by phosphorylation in the activation loop generates the fully active kinase; (7) activated PKA can phosphorylate glycogen phosphorylase kinase (GPK) and other enzymes, which leads to activation of glycogen degradation and inhibition of glycogen synthesis; and (8) PKA can affect transcription by phosphorylating the transcription factor CREB.

phosphorylates and activates ERK. Activated ERK can phosphorylate many transcription factors, which leads to changes in gene transcription and ultimately cell division/differentiation.

The two examples mentioned above illustrate basic principles how protein phosphorylation serves specific biological purposes. Although different kinases might be involved in diverse pathways, the molecular mechanism for the regulation of protein function by phosphorylation is similar: By changing protein structure, phosphorylation can turn on/off the catalytic activity of a protein, or create/mask recognition motif for binding by other molecules.

The 500 or so protein kinases in the human genome regulate numerous biological processes. Consequently, deregulation of protein phosphorylation can lead to various diseases, among which cancer is the most prominent one. Accordingly, kinase inhibitors are being sought for treating various cancers. One best understood example is chronic myeloid leukemia, which is caused by chromosomal abnormality that fuses a kinase ABL (encoded from Abelson gene) with another protein BCR (encoded from breakpoint cluster region gene) (44). The BCR-ABL fusion protein was shown to be sufficient to cause chronic myeloid leukemia in mice. Imatinib mesylate (Gleevec; Novartis Pharmaceuticals, East Hanover, N.J) is a clinically used BCR-ABL inhibitor to treat CML (chronic myelogenous leukemia). The receptor tyrosine kinase and MAP kinase-signaling pathway mentioned above are key pathways that regulate cell proliferation and differentiation; frequently, tumor cells have mutations in proteins involved in this pathway (45). This pathway has thus been studied intensively for the search of cancer drugs. Other kinases, such as cell-division kinases (CDKs), have also been targeted for therapeutics (46). In addition, because phosphatases reverse the effects of kinases, mutations in phosphatases have been indicated in human diseases such as cancer, diabetes, and neurologic disorders (47).
Post-Translational Modifications to Regulate Protein Function

Figure 10  Receptor tyrosine kinase signaling process and the activation of MAP Kinase. (1) Binding of hormone to the receptor causes activation of the kinase activity of the receptor, which leads to phosphorylation of Tyr residues; (2) pTyr residues recruit GRB2, which in turn recruit Sos; (3) Sos promotes exchange of GTP for GDP in Ras, which leads to the active Ras-GTP complex. Then, Sos dissociates from the active Ras; (4) active Ras binds to and activate the kinase Raf; (4a) hormone can dissociate from the receptor; (4b) activated Raf phosphorylates and activates MEK; (6) activated MEK phosphorylates and activates of MAP kinase; (7) activated MAP kinase can phosphorylate transcription factors (TF); and (8) phosphorylated translation factors then bind to DNA and lead to changes in gene transcription and ultimately cell division/differentiation.

Acetylation

Acetylation of Lys residues is a very well known PTM because of histone acetylation, which is involved in transcriptional regulation of genes. The acetyl group comes from Acetyl-CoA, and typically, the acetyl acceptor is Lys residues (Fig. 11). Histone acetylation correlates with transcription activation, and accordingly, histone acetyltransferases (HATs) are normally multidomain proteins associated with transcription activator/coactivator complexes (48). The correlation of histone acetylation with transcription activation can be explained by the relaxation of the chromatin structure on histone acetylation and the recruitment of other proteins via acetyl Lys. In eukaryotic cells, chromosomal DNA wrap around core histone octamers consisted of two copies each of histone H2A, H2B, H3 and H4 (49). The complex formed between the histone octamer and the DNA associated with it is called a nucleosome. Nucleosomes can pack into a more condensed structure. Evidence suggests that the tight packing suppresses transcription, whereas transcription activation correlates with relaxed chromatin structure. The N-terminal tails of the histones have many Lys and Arg residues, among other residues, that can be modified post-translationally. No detailed structure information is available to explain how histone tail modification affects nucleosome packing. However, intuitively, masking the positive charges on histones by Lys acetylation can decrease the interaction with negatively charged DNA, which loosens the chromatin structure (50). In addition, acetylated Lys residues can be recognized by proteins that contain bromodomains (Fig. 4) (16, 51), which serve to recruit other proteins (including chromatin remodeling complexes) that help to activate the transcription of the gene.

Histone acetylation not only affects transcription, but also affects other processes that involve DNA, such as nucleosome assembly, heterochromation formation, and DNA repair (52). The acetylation/deacetylation of different Lys residues can have different biological effects. For example, histone H4 Lys5, 8, and 12 acetylation are involved in nucleosome assembly, heterochromation formation, and DNA repair (52). The acetylation/deacetylation of different Lys residues can have different biological effects. For example, histone H4 Lys5, 8, and 12 acetylation is involved in nucleosome assembly, heterochromation formation, and DNA repair (52).

Proteins other than histones can also be modified by Lys acetylation. Many transcription factors, cytoskeleton proteins, metabolic enzymes, and signaling proteins are acetylated (50).
Post-Translational Modifications to Regulate Protein Function

Figure 11  (a) Lys acetylation catalyzed by acetyltransferases; (b) mechanism of Zn-dependent HDACs-catalyzed deacetylation; (c) mechanism of sirtuins-catalyzed deacetylation.

Transcription factors are known to be substrates of HATs, whereas the enzymes responsible for the acetylation of non-nuclear proteins in many cases are not well known (55). The number of proteins that are regulated by acetylation will continue to increase as methods to detect protein acetylation improve. Acetylation of nonnuclear proteins can change protein–protein interaction, regulate enzymatic activity, and increase protein stability by suppressing ubiquitinylation (55).

Lys acetylation can be reversed by the action of deacetylases. Many deacetylases are Zn-dependent enzymes that use Zn\(^{2+}\) in the active site to activate water molecules to hydrolyze the amide bond (Fig. 11) (56). Recently, another type of deacetylases that are nicotinamide adenine dinucleotide (NAD)-dependent, also known as sirtuins, have been identified (57, 58). Their unique ability to couple NAD degradation to Lys deacetylation (Fig. 11) suggests that this type of enzyme can sense the metabolic state (for example, NAD concentration) of the cell and use that information to regulate the acetylation state and thus the function of the substrate proteins. In addition to Lys side chain acetylation, protein N-terminal can also be acetylated (59). In eukaryotic cells, the first residue Met in most proteins is cleaved by N-terminal methionine peptidase. The newly released N-terminal amino group is then acetylated. This modification can happen co-translationally before the mature peptide chain is released from the ribosome. The function of this modification in most cases is still not understood, although deletion of the genes involved in this modification has clear phenotypes (59).

Because of the involvement of protein Lys acetylation in regulation of transcription, protein–protein interaction, enzymatic activity, and protein stability, the deregulation of protein acetylation has been associated with many diseases, such as cancer and neurodegeneration (60, 61). Frequently, mutations in
histone acetyltransferases are found in cancer (60). Chromosomal abnormalities that generate fusions of acetyltransferases are known to lead to acute myeloid leukemia. These abnormalities include the fusions of M-02 (monocytic leukemia zinc finger protein) with CBF (CREB binding protein) or p300, and fusion of M-02 with the transcription factor TIF2 (transcription intermediary factor 2) (61). M-02, CBF, p300, and TIF2 all contain histone acetyltransferase domains. Presumably, the generation of these aberrant fusion proteins disrupts normal gene transcription, which leads to leukemia. Depletion of histone deacetylases is also suggested to be associated with cancer (61).

A histone deacetylase inhibitor, SAHA (Vorinostat, Merck & Co., Inc., Whitehouse Station, N.J.), was approved by Food and Drug Administration recently for treatment of cutaneous T-cell lymphoma (62).

**Methylation**

Although methylation can happen to several different residues (3, 63), most attention has been given to protein Lys/Arg methylation because the methylation of Lys/Arg in histones controls gene transcription. For Lys and Arg methylation, multiple methyl groups can be added to the same Lys or Arg residue (Fig. 12). The methyl group comes from S-adenosyl methionine (SAM), which is a versatile small molecule that is used in many enzymatic transformations (64). Almost all Lys methyltransferases belong to the SET (suppressor of variegation-Enhancer of zeste-Trithorax) family of methyltransferases, whereas the protein Arg methyltransferases belong to a different class (65–67). Both histone Lys/Arg methylation and acetylation are associated with transcription regulation. In contrast to histone acetylation, which usually correlates with transcription activation, histone methylation can lead either to transcription activation or to suppression (17, 68). The effect of histone methylation, which is based on current understanding, is mediated by proteins that are recruited by methylated Lys or Arg residues. Tudor domains and chromodomains are known to recognize methylated Lys/Arg residues via both charge interaction and cation interaction (69–73). The methylated Lys/Arg residue is more hydrophobic and sterically bulkier than free Lys/Arg, and it can be differentiated by the domains that recognize methylated Lys/Arg residues (69, 74). Sequences that surround the methylate Lys residues are also read by the chromo domains and Tudor domains (69–71).

This finding explains why different Lys residues could recruit different proteins on methylation and thus have different biological effects. For example, H3K4 methylation activates transcription by recruiting chromodomains and helicase-DNA-binding protein 1 (CHD1) specifically in yeast whereas H3K9 methylation represses transcription by recruiting heterochromatin protein 1 (HP1) (75–77). Nonhistone proteins are known to be methylated on Lys residues, which include transcription factors, such as p53 (78–80), TATA box-binding protein-associated factor (TBF1) (81), and translation factors (63). The p53 protein is methylated by different methyltransferases (Seth, 78; Smyd2 (79), and Setd8 (80)) on different Lys residues (Lys372, 370, and 382, respectively). These different methylation events either activate or repress p53 activity. Arg methylation has been found frequently in nonhistone proteins. For example, PRMT1 has been reported to methylate the transcription factor STAT1 (signal transducers and activators of transcription) (82), PRMT4 and CARM1 (coactivator-associated arginine methyltransferase-1) can methylate CBP/p300 (83), and heterogenous nuclear ribonucleoproteins (hnRNPs) and small nuclear ribonucleoproteins (snRNPs) that are involved in pre-mRNA splicing are also Arg methylated (67). The biological functions of these Lys/Arg methylations in most cases can also be explained by the effect of methylation to block or create interaction with other proteins or nucleic acids.

Compared with acetylation, methylation is more stable. For this reason, it was thought that methylation could be a permanent epigenetic mark. The recent discovery of two types of Lys demethylases suggests that methylation is also a reversible PTM. The first Lys demethylase discovered is LSD1 (lysine-specific demethylase 1), which is a FAD (flavin adenine dinucleotide)-dependent enzyme similar to amine oxidases (Fig. 12) (84). It is believed that LSD1 uses two-electron oxidation mechanism and thus cannot demethylate tri-methylated Lys residues (85). The second type of Lys demethylase, which contains the jmjC (jumonji domain-containing) domain, is a nonheme Fe(II)-dependent enzyme that is capable of doing one-electron oxidation, and thus, it can demethylate trimethylated Lys residues (86). The effect of Arg methylation was proposed to be reversed by protein Arg deminase 4 (PAD4), which generate citrulline via demethylamination (87, 88). However, later studies indicate that PAD4 as well as other PAD enzymes do not catalyze demethylamination with appreciable rates in vitro (88–91). A recent report showed that Arg methylation can be truly reversed by jmjC domain containing demethylases, which suggests that PADs are probably not required for Arg demethylation (92). Thus, both Lys and Arg methylation are reversible modifications.

Similar to Lys acetylation, abnormality in Lys methylation has been considered a contributing factor to cancer (93, 94). Decrease in H3 Lys9 and H4 Lys20 methylation is found in cancer cells. Both H3 Lys9 and H4 Lys20 methylation are associated with heterochromatin formation. Presumably, the decrease in the methylation leads to defects in heterochromatin formation, which in turn lead to chromosomal instability and tumor formation (93). Histone methyltransferase fusion proteins generated from chromosomal translocation are found frequently in leukemia and are thought to contribute to the development of leukemia. For example, the H3 Lys79 methyltransferase HDMT1 (human DOT1-like protein) fusion found in mixed lineage leukemia is sufficient to cause leukemic transformation (95). The close association of methylation and cancer suggests that protein methyltransferases and demethylases can be potential therapeutic targets.

**Glycosylation**

In eukaryotic cells, glycosylation has many membrane and secreted proteins (i.e., proteins that transit through the ER and the Golgi secretory pathway). Glycosylation can occur either on Asn residues (N-glycosylation, Fig. 13), Ser/Thr and post-translationally hydroxylated Lys and Pro residues (O-glycosylation, Fig. 14), or Trp residues (C-glycosylation, Fig. 14). N-glycosylation is a complicated process and involves...

three stages: 1) the formation of donor substrate with 14 sugar units (Glc3Man9GlcNAc2-PP-dolichol), which occurs in both the cytosolic and the luminal faces of ER (96); 2) the transfer of the tetradecasaccharyl group to the Asn residues found in the consensus sequence Asn-X-Ser/Thr, which occurs in the ER (97); and 3) the hydrolytic removal of the terminal sugar residues on the tetradecasaccharide, the addition of more sugar units (Fig. 13) (98), and the sulfation and phosphorylation of the carbohydrate moieties in the ER and Golgi (99).
Post-Translational Modifications to Regulate Protein Function

(1) The formation of the donor substrate with 14 sugar units (Glc3Man9GlcNAc2-PP-dolichol), (2) the reaction scheme that shows the transfer of the tetradecasaccharyl group to the Asn residues found in the consensus sequence Asn-X-Ser/Thr in proteins; (3) hydrolytic removal of the terminal sugar residues on the tetradecasaccharide and addition of more sugar units in the ER and Golgi. OSTase, oligosaccharyltransferase.

Trimming steps can generate different sets of N-linked carbohydrates, such as the high-mannose type glycans, the complex type glycans, and the hybrid type glycans (Fig. 13) (99). Each stage is achieved by the function of multiple proteins. For example, up to nine proteins are required for the transfer of the tetradecasaccharyl group in yeast (100).

Different from N-glycosylation, O-glycosylation starts with the addition of a single sugar residue, which can be followed by the addition of more sugars (101). Similar to N-glycosylation, most O-glycosylation also occurs to proteins that transit through ER and Golgi. However, the addition of a single GlcNAc residue to Ser/Thr is a type of O-glycosylation that occurs to cytosolic proteins (102). This cytosolic O-glycosylation has drawn much attention recently because it can regulate the activity of the substrate proteins, especially because it can compete with protein phosphorylation for the same Ser/Thr on substrate proteins (103).

C-glycosylation is the addition of a single mannosyl group to the indole C-2 position of Trp residues of membrane and secreted proteins (104). The Trp residue that is C-mannosylated reside in a consensus Trp-X-X-Trp sequence, and the first Trp is C-mannosylated. About a dozen proteins in humans are C-mannosylated. The enzyme that catalyzes the modification has not been cloned yet, and currently, the function of this modification is not clear.

The large number of enzymes involved in protein glycosylation and the fact that this complicated N-glycosylation pathway is conserved throughout eukaryotic species suggest that glycosylation has important functions. Deficiency in protein glycosylation causes several diseases in humans, such as lysosomal storage diseases (105), congenital disorders of glycosylation, and leukocytes adhesion deficiency II (106). In addition, changes in glycosylation patterns are associated with cancer and inflammation (107). Protein glycosylation can serve several different biological purposes. One purpose is to help proteins that transit through the secretory pathway to fold correctly. Particularly, the removal of the glucose residue by glucosidase II and the reglucosylation in the ER have been well known to help secreted proteins to fold and make sure only correctly folded proteins are secreted (Fig. 13) (108).
Post-Translational Modifications to Regulate Protein Function

O-fucosyltransferase I that modifies Notch protein was reported to have chaperon activity that helps Notch folding and secretion, and this chaperon activity is independent of its catalytic activity (109). Glycosylation is also important for sorting secreted proteins. For example, the phosphorylation of Man on N-glycan (Fig. 16) creates a recognition signal for sorting lysosomal proteins to lysosome. Glycosylation is also believed to increase the protein stability, as has been shown for erythropoietin mentioned earlier. Glycosylation is also proposed to affect ligand receptor interaction and thus regulates cell–cell signaling. However, a detailed molecular understanding about the effect of glycosylation on ligand receptor interaction is hard to obtain in most cases. In two well-studied cases, human CD2 (cellular differentiation marker 2) and IgG (immunoglobulin G), N-glycosylation is found to affect the interaction with their ligands or receptors. Structural data show that the carbohydrate portion does not contact the binding partner directly. Instead, glycosylation affects the binding by changing the conformation of the glycosylated proteins (110–112).

Ubiquitylation
Ubiquitin is an abundant small protein (76 amino acids) found in all eukaryotes. It can be conjugated to many proteins covalently and regulates important biological processes. The addition of ubiquitin to substrate proteins goes through an E1–E2–E3 enzymatic cascade (Fig. 17) (113). E1, which is also called ubiquitin-activating protein (UAP), uses ATP to adenylate the C-terminal Gly of ubiquitin and then captures the activated ubiquitin with a Cys residue in the active site. Most eukaryotic species only have one E1 enzyme responsible for activating all the ubiquitin molecules needed. The ubiquitin-E1 conjugate then is recognized by several dozens of E2 enzymes, which capture ubiquitin from E1 via a transthiolation reaction. The ubiquitin-conjugated E2 enzymes are then recognized by many different E3 enzymes, which recruit the substrate proteins and transfer ubiquitin from E2 to Lys residues of the substrate proteins, either directly or indirectly (Fig. 17). Two major families of E3 enzymes exist: the RING (really interesting new gene) E3s and HECT (homologous to E6AP C terminus) E3s. The Pfam database lists more than 400 RING proteins and 70 HECT proteins. Many E3s form complexes with other proteins. One well-understood E3 complex is the SKF (Skp1-Cullin-F Box)
RING E3, for which a crystal structure was reported (114). In humans, multiple Cullins and multiple F Box proteins exist (115). Considering the different combinations, the number of possible E3 complexes can be much more than the number of E3 enzymes (3). E3s decide which substrate proteins get ubiquitylated, thus the large number of E3s and E3 complexes reflects the diverse substrate proteins that must be recognized.

Ubiquitin itself has 7 Lys residues (Lys6, 11, 27, 29, 33, 48, and 63) that can be used for ubiquitin attachment, which lead to polyubiquitylation of substrate proteins. Polyubiquitin chain assembled via different Lys residues have different biological functions (116), as will be explained later. Which Lys residue is used in the polyubiquitin chain is controlled by the specific E3 involved. E3 presumably also controls the length of the polyubiquitin chain, although the detailed chain assembly mechanism is still not clear (117). Ubiquitylation can be reversed by the action of ubiquitin-specific proteases (UBPs). About 60 UBPs exist in the human genome, which presumably recognize different types of ubiquitin modifications at various cellular locations (118).
The biological function of ubiquitylation was recognized originally as targeting proteins to the proteasome for degradation. The importance of this function can be illustrated by many examples. In cell division, progression through the cell cycle is driven by cell division kinases, the activities of which are controlled by a group of proteins called cyclins. Different cyclins function only at certain stages of the cell cycle. Then, they must be degraded, which requires polyubiquitylation by specific E3 enzymes (119). A loss in the ubiquitylation and degradation of cyclins is associated with cancer. Misfolded proteins must be degraded by the ubiquitin and proteasome system. A aggregation of misfolded proteins is known to cause neurodegeneration, such as Parkinson’s disease (116). Ubiquitylation and proteasome degradation of proteins are also important for other biological processes, such as hypoxia and circadian clock.

Ubiquitylation is required for the degradation of hypoxia inducible factor (HIF) on hydroxylation at high oxygen levels (120). Maintaining the circadian clock requires the ubiquitylation and degradation of proteins that inhibit the CLOCK (a protein named from circadian locomotor output cycles kaput gene) transcription factor (121).

It is becoming clear that the biological function of ubiquitylation is not limited to proteasome degradation. Other functions have been discovered, such as promoting membrane protein endocytosis, targeting membrane protein to lysosome for degradation, and regulating cytoplasm/nuclear shuttling (116, 122). It is now generally believed that polyubiquitylation via Lys48 of ubiquitin is a signal for proteasomal degradation, and this action requires minimally 4 ubiquitin units in the chain (123). In contrast, monoubiquitylation, multiple
monoubiquitylation on different Lys residues of substrate proteins, and polyubiquitylation via Lys 63 of ubiquitin typically signal proteasome-independent pathways (116). How can so many different functions be achieved? The diverse sets of ubiquitin binding domains (UBDs) provide the molecular explanation to this question (19). Presumably, different UBDs recognize different types of ubiquitin modifications (monoubiquitylation vs. polyubiquitylation, and Lys48-linked vs. Lys63-linked polyubiquitylation, for example), and thus they mediate different functional consequences of ubiquitylation. UBD on yeast proteins Rad23, Rpd10, and Dsk2 recognize the Lys48-linked polyubiquitin chain and deliver the modified substrate proteins to the 26 S proteasome (124). The UBD on the vacuolar proteins recognize monoubiquitylation or Lys63-linked polyubiquitin chain on membrane proteins, which mediate their sorting into lysosome or vacuole. Binding of the Lys63-linked polyubiquitin chain on inhibitor of NF-κB kinase (IKK) by other proteins has been proposed to activate IKK and thus turn on NF-kB signaling (116). The recognition of ubiquitin by UBDs can also explain some “unusual” functions of protein ubiquitylation. For example, Lys48-linked polyubiquitylation of a yeast transcription factor Met4p does not signal for proteasome degradation, but instead it inactivates the transcription factor. It inactivates the proteasomal pathway (125).

In generalization of the function of ubiquitylation, we can say that ubiquitin is an “information-rich protein tag” that can be read by different proteins that contain UBD domains (3), and the exact consequence of ubiquitylation is determined by how the tag is recognized. Besides ubiquitin, eukaryotic cells also have about a dozen known ubiquitin-like protein tags, with SUMO being the best studied one. In addition, many proteins have built-in ubiquitin-like domains. The logic that underlies the biological functions of these ubiquitin-like proteins/domains will likely be the same as what is learned from ubiquitin (3).

**Proteolysis**

Hydrolytic cleavage of proteins by proteases is an irreversible PTM. The large number (more than 500) of proteases in the human genome indicates that proteolysis occurs often. Proteases can be classified into four types based on catalytic mechanisms (Fig. 18): Ser/Thr proteases, Cys proteases, Asp proteases, and metalloproteases.

At first glance, proteolysis may seem to be an uncontrolled destruction process like the digestion of food proteins in the gut. In fact, proteolysis in cells is under tight regulation. Even proteases secreted to the digestive tract must be controlled to avoid self-destruction. Typically, proteases are made in the inactive forms (zymogens) that can be activated by proteolysis. Inside eukaryotic cells, two major locations exist for proteolytic degradation of unwanted proteins: the 26 S proteosome and the lysosome (126, 127). Access to the two degradation organelles is controlled tightly. The lysosome is an acidic membrane organelle that contains many proteases and is responsible for degradation of endocytosed membrane proteins, such as activated receptor tyrosine kinases and G protein-coupled receptors that are ubiquitylated and sorted to the lysosome (described in...
Figure 18

Catalytic mechanisms of different proteases:

- Ser/Thr proteases
- Cys proteases
- Asp proteases
- Metalloproteases (Zn-dependent)
The eukaryotic 26 S proteasome. Subunit compositions of the 19 S regulatory particle of *Saccharomyces cerevisiae* is shown on the left. The α and β rings of the 20 S proteasome, each of which consists of seven different subunits, are included to indicate how the base 19 S complex is linked to the core 20 S protease complex. The crystal structure of the 20 S degradation chamber is shown in both side and top views (figure made using PDB 1RYP).

In autophagy, the lysosome is responsible for degrading cellular organelles and some cytosolic protein complexes (126). The 26 S proteasome (Fig. 19) has a 20 S degradation chamber that consists of four rings αβαβαβαβαβ. In eukaryotes, each α ring has seven different α subunits, and each β ring has seven different β subunits. Three β subunits are catalytically active Thr proteases that are responsible for the degradation of subproteins. By forming this chamber, the active sites of the proteases are buried inside the chamber to avoid proteolysis of proteins that should not be digested. Access to the degradation chamber is controlled by the 19 S regulatory complex that caps both ends of the degradation chamber. The regulatory complex contains subunits that recognize polyubiquitylated substrates, subunits that recycle the ubiquitin tag, and subunits that use ATP hydrolysis to unfold and translocate the protein into the degradation chamber. Degradation of the unwanted proteins by the 26 S proteasome or lysosome is a timely fashion is very important. For example, cyclins that activate cell division kinases have to be polyubiquitylated and degraded by the proteasome at specific times to drive cell cycle progression (119). Degradation of activated membrane receptors in the lysosome is important to avoid over stimulation (130, 131). Misfolded proteins must be degraded by the proteasome or lysosome (in autophagy). Failure to do so is thought to contribute to neurodegeneration disorders such as Parkinson’s disease and Alzheimer’s disease (126).

In addition to the “destructive” proteolysis processes in the proteasome and lysosome, many “constructive” proteolysis processes occur in cells. In both prokaryotes and eukaryotes, secreted proteins contain a signal peptide at the N-terminus that directs them to the secretory pathway. This signal peptide must be cleaved later by signal peptidases (typically serine proteases) so that the protein can transit further in the secretory pathway (132). Many secreted proteins, which include insulin, TGF-β1, transforming growth factor β1, nerve growth factor β1, albumin, Factor IX, insulin receptor, and Notch, also contain a propeptide that is cleaved by proprotein convertases in the Golgi (133). Selective proteolysis also occurs at the cell membrane in signal transduction processes. Notch protein, on binding to its ligand Delta/aggregated membrane proteins on neighboring cells), is cleaved by one of the ADAM (a disintegrase and metalloprotease) proteins at a site close to the transmembrane region. This cleavage activates Notch for regulated intramembrane proteolysis, which cuts within the membrane-spanning region of Notch and releases the intracellular domain of Notch from the cytoplasm membrane. Then, the intracellular domain translocates into the nucleus where it acts as a transcription factor to turn on genes required for development (Fig. 20) (134).

Regulated intramembrane proteolysis is catalyzed by the membrane protein complex called presenilin that contains Asp protease subunits. Presenilin is also responsible for cleavage of the amyloid-β precursor proteins in Alzheimer’s disease. This proteolysis-triggered proteolysis signaling occurs often. Similar signaling pathways are present also in bacteria. For example, the release of the transcription factor σE is achieved via the sequential cleavage of the membrane protein RseA by DegS (a Ser protease) and YaeL (a Zn protease) (135).

Similar to the MAP kinase cascades for protein phosphorylation, protease cascades exist, in which downstream proteases are activated by the action of upstream proteases (3). One of the most famous cascades is the caspase cascade that leads to apoptosis (Fig. 22) (111, 136). Caspases are Cys proteases that cleave the amide bond specifically after an Asp residue. Two types of caspases exist; initiator caspases (Caspase 2, 8, 9, 10) and effector caspases (Caspase 3, 6, 7). Both initiator and effector caspases are activated by upstream caspases and cleave other downstream caspases to amplify the apoptotic response.
caspases are produced in zymogen forms. Initiator caspases use their N-terminal DED (death effector domain) and CARD (caspase recruitment domain) domains to interact with other proteins to receive apoptosis signals. The signals cause the dimerization of the initiator caspases and activate them so that they can cleave themselves and the effector caspases after specific Asp residues. Cleavage by the initiator caspases activates the effector caspases, which then cleave their substrate proteins to carry out cell apoptosis. The substrate proteins of effector caspases include the inhibitor of caspases-activated DNAse (deoxyribonuclease), Bcl2 (named from B-cell lymphoma 2, an antiapoptotic protein), and PARP-1 (poly(ADP-ribose) polymerase-1, an enzyme catalyzing protein poly(ADP-ribosyl)ation and required for DNA repair). Cleavage of the inhibitor of DNAse by effector caspases activates its catalytic activity, resulting in the fragmentation of chromosomal DNA, which is a hallmark of apoptosis. The caspases cascade and apoptosis is very important for the development and homeostasis of metazoans. Decreased ability of cells to undergo apoptosis will lead to cancer, whereas too much apoptosis can lead to autoimmune diseases (137).

Identifying new pathways regulated by known PTM and discovering new PTM

The brief description above on a few major PTM demonstrates clearly that PTM can regulate many important biological processes. So far, a fairly good understanding of many aspects of PTM has been obtained. What remaining challenges must be addressed?

One direction is to figure out the molecular details of many of the biological processes that are regulated by PTM. Structural biology and biochemistry is needed to answer questions like what structural changes are induced by a particular PTM and how the structure changes lead to changes in activity or recognition by binding partners. Much progress has been made in this direction but still more remains to be figured out. For example, in protein ubiquitylation, no structural details about E1 exist, it is not clear how the polyubiquitin chain is made (117), and it is not clear how specificities of different ubiquitin binding domains are achieved (19).

Another direction is to identify the proteomes that are modified by a specific PTM. Advancement in protein identification by mass spectrometry (MS) has greatly facilitated studies in this direction and many efforts have been invested. Generally, an affinity purification method is used to enrich proteins that are modified by a specific PTM, and then these proteins are identified by MS. For example, phosphotyrosine-specific antibodies have been used to enrich proteins that are modified on Tyr residues, and metal affinity columns have been used to isolate all phosphopeptides (138). These isolated phosphopeptides can then be identified by MS. A His6 tag has been fused to the N-terminus of ubiquitin and used to isolate ubiquitylated proteins that are then identified by MS (139). GlcNAc with an azide group attached has been used to label proteins that are O-GlcNAc modified, and then a biotin tag is conjugated to the modified protein via Staudinger ligation. O-GlcNAc modified proteins can be pulled out using streptavidin beads and identified using MS. Using this method, close to 200 O-GlcNAc modified proteins were identified (140). A clever method to detect protein S-acylation has been reported recently (141). These proteomic studies have provided much information. However, to understand the function of a PTM in cell physiology completely, it is desirable to know which enzyme is responsible for the modification of a particular substrate protein. With the availability of bioinformatics tools and completed genome sequences, it is now relatively straightforward to identify all the enzymes in a genome that share similar biochemical function. For example, we now know that the human genome
Post-Translational Modifications to Regulate Protein Function

contains more than 500 protein kinases, more than 500 pro-
teases, and ∼400 ubiquitin E3s. But without knowing what
substrate proteins they modify, it will be very difficult (if not im-
possible) to understand their biological functions on a molecular
level. Currently, no efficient and reliable method exists yet to
identify the substrate proteins for an enzyme. A straightforward
method is to make a library of short peptides and try to identify
consensus sequences that are recognized by an enzyme (142,
143). The disadvantage is that the structure of a short peptide
may be different from the structure of the same sequence present
in a folded protein. Thus, the reliability of this method must be
validated by other methods. Shokat and coworkers (144) have
used a clever approach to identify kinase substrates (Fig. 22).
This approach uses a bulky ATP analog that can be used only
by a kinase mutant as a cosubstrate. By incubating 32P-labeled
ATP analog and the kinase mutant with cell extract, the substrate
proteins of the specific kinase can be labeled. Identification of
the substrate proteins may be difficult though because the ra-
diolabeled substrate proteins cannot be enriched/purified easily
for identification by MS. It is not clear whether this method can
be applied easily to other PTM enzymes.

Parallel to the efforts of identifying substrate proteins for a
particular enzyme, the activity-based small molecule probes pio-
nereed by Cravatt and coworkers can facilitate the identification
of the biological functions of an enzyme that catalyzes protein
post-translational modifications (145). The major advantage of
this type of probes is that potentially they can detect enzymes
that are in the active states, and thus can provide snapshots of
enzymes that are in the active states at different development
stages or different types of cells. Among enzymes that catalyze
PTM, so far probes have been developed for studying proteases
(145, 146), kinases (147), pTyr phosphatases (148), and protein
Arg deiminases (149).

Perhaps a more challenging question is how can we discover
new PTM reactions. In principle, there are analytic tools that
can be used to research this topic. One such tool is top-down
FT-MS, which determines the molecular weight of the whole
protein with high accuracy. By comparing the obtained tan-
dem MS (MS/MS) result with the expected MS/MS result,
post-translational modifications can be identified (150). Crys-
tallography can also discover new PTM, if a protein expressed
in the proper host can be crystallized. Some rare modifications
or protein side chains were discovered this way (151). How-
ever, the success of using these methods would require that
Post-Translational Modifications to Regulate Protein Function

Shokat’s (144) “bump and hole” method to identify substrates for kinases.

A significant portion of the protein population is modified and the modification is stable. This condition cannot be met by all PTM. Thus, discovering new PTM poses a great challenge to chemical biologists. Undoubtedly, new PTM reactions are waiting to be discovered and the identification of these new PTM, together with the identification of new pathways that are regulated by known PTM, will advance our understanding about the molecular logic of living systems.

Post-Translational Modifications to Regulate Protein Function

Molecular Chaperones

R. John Ellis, University of Warwick, Coventry, United Kingdom

doi: 10.1002/9780470048672.wecb068

The generic tendency of proteins to aggregate into nonfunctional, and sometimes cytotoxic, structures poses a universal problem for all types of cells. This problem is exacerbated by the high total concentrations of macromolecules found within most intracellular compartments, but it is solved by the actions of certain proteins that function as molecular chaperones. Different chaperones act by distinct mechanisms on both the folding of polypeptide chains and their subsequent assembly into oligomeric structures. Many chaperones, but not all, are also stress (or heat shock) proteins because the need for a chaperone function increases under stress conditions that cause proteins to unfold.

Proteins have evolved over billions of years to function inside highly complex, intracellular environments, but their properties commonly are studied after purification and after exposure to much simpler and very different conditions in the test tube. Christian Anfinsen received the Nobel Prize for chemistry in 1972 for discovering that some purified denatured proteins will refold into their biologically active conformations when the concentration of the denaturing agent is lowered (1). This classic type of refolding experiment has been repeated many times, and it is clear that most proteins are capable of refolding correctly in dilute media in the absence of either other macromolecules or an added energy source. The same conclusion applies to the assembly of large multisubunit structures such as viruses and ribosomes. These observations were codified in the statement that proteins are capable of spontaneous self-assembly, the term "assembly" is used here to describe both the folding of individual polypeptide chains and their association into oligomers. The principle of protein self-assembly states that all the information for a protein chain to reach its correct conformation is encoded in its aminoacyl sequence and is an important corollary of the central dogma of molecular biology. If self-assembly did not occur, molecular biology would be in deep trouble because it would have to be postulated that protein folding and assembly requires direction by an external agent. Generally, it was assumed that proteins also fold and assemble spontaneously inside the cell, but observations made in the late 1970s and early 1980s challenged this assumption. Some proteins were found to bind to preexisting native proteins before folding or after folding but before assembling. Such binding prevents the proteins from aggregating into nonfunctional structures, which is a problem aggravated by the macromolecular crowding found in most intracellular compartments (2, 3). The term "molecular chaperone" (often abbreviated to "chaperone") was proposed to describe these helper proteins (4, 5), and the concept advanced that all cells require a chaperone function to prevent some proteins from misbehaving (6). Thus the original view that proteins fold and assemble inside the cell by a process of spontaneous self-assembly has been replaced by the concept that many proteins use an assisted self-assembly process. Note that the concept of protein self-assembly itself is unaffected by this change of paradigm—proteins contain all the information required for their correct folding and assembly. Their problem is to avoid aggregation.

Biologic Background

Protein aggregation is defined as the association of two or more polypeptide chains to form nonfunctional structures. Some aggregates are cytotoxic and cause neurodegenerative disease. Protein aggregation is at least a second-order process, so it is very sensitive to the concentration of interacting chains. Aggregation is also a highly specific process, so that only identical or very similar chains aggregate with one another. Because the free energy difference between folded and unfolded states is small, most folded proteins are stable only marginally and are easily unfolded into aggregation-prone states. All cells require a chaperone function to combat aggregation because two universal features of the intracellular environment, where proteins fold and assemble, aggravate both of these properties of aggregation. These features are the synthesis of proteins on polyribosomes and macromolecular crowding.

Polyribosomes

The linear DNA base sequence information encoded in genes is copied into a linear sequence of ribonucleotides in messenger RNA (mRNA) by the process of transcription. Ribosomes bind one at a time near to the 5' end of each mRNA molecule and translate the ribonucleotide base sequence into an aminoacyl sequence according to the genetic code. Each mRNA is bound to more than one ribosome at a time, forming a polyribosome, often abbreviated to polysome. Typically the rate of
polypeptide chain synthesis is between 5 and 20 amino acid residues added per second, but the rate of protein folding is much faster. Thus, incomplete chains may fold into nonfunctional conformations before the entire chain is made. The fact that polypeptide chains are made by polynucleotides ensures that partly folded identical chains are within touching distance when they are synthesized, which results in the possibility that chains may aggregate with one another. The advantage of simultaneously making several polypeptide chains from one molecule of mRNA has been earned at the risk of both misfolding and aggregation. Some chaperones reduce this risk by binding to incomplete and newly synthesized polypeptide chains before they complete their folding.

Macromolecular crowding

This term is used to highlight that the total concentration of macromolecules inside cells is very high, which is in the range 80–400 g/L. Such high total concentrations occur in all intracellular compartments where proteins fold and assemble. Generally, it is not appreciated that such a degree of crowding stimulates macromolecular association reactions, by levels that can be two to three orders-of-magnitude greater than those in uncrowded media (2, 3). Such association reactions include protein aggregation, and during some, but not all, protein refolding experiments, a fraction of the chains aggregate with one another, even though such experiments are almost always done in uncrowded media. Refolding experiments show the concentration and temperature-dependence of protein aggregation, so protein chemists solve this problem by reducing the concentration of chains and lowering the temperature. Cells cannot do this but employ molecular chaperones to combat the enhanced tendency to aggregate, which is caused by macromolecular crowding.

Origin of the molecular chaperone concept

The term “molecular chaperone” first appeared in 1978 to describe the properties of a nuclear protein called nucleoplasmin found in amphibian eggs (4). This protein assists the assembly of nucleosomes from histones and DNA that occurs when these eggs divide rapidly after fertilization. Nucleosomes are held together by the electrostatic bonds that are disrupted by high concentrations of salt. If the isolated histones and DNA are then incubated together at physiologic concentrations of salt, a dramatic failure of self-assembly exists—an insoluble aggregate forms instead of nucleosomes. Eggs solve this problem by breaking the concentration of chains and lowering the temperature. Cells cannot do this but employ molecular chaperones to combat the enhanced tendency to aggregate, which is caused by macromolecular crowding.

Definitions

The molecular chaperone function currently is defined as the ability of all cells to prevent and/or reverse incorrect interactions that may result when potentiallyinteractive surfaces are exposed to the environment (5). These surfaces occur on growing and newly released polypeptide chains, on mature proteins unfolded by environmental stresses, and on folded proteins in near-native and native conformations. The same concept applies to other macromolecules that can undergo incorrect interactions, especially RNA. Incorrect interactions are defined as those that result in products that do not carry out the functions for which they have been selected in evolution.

Molecular chaperones currently are defined as a large and diverse group of proteins that share the functional property of assisting the noncovalent folding/unfolding and the association/dissociation of other macromolecular structures but are not components of these structures when these are performing their normal biologic functions (7). This definition differs from the original one (6) in that includes unfolding and disassembly processes. This change was necessary because of the discovery that some chaperones are required for processes such as the remodeling of chromatin during fertilization, the disassembly of clathrin coats, and the dissociation of insoluble aggregates. Some molecular chaperones are also stress or heat shock proteins (hsps), because the requirement for chaperone function increases under conditions such as heat shock and other environmental stresses that cause some proteins to unfold and aggregate.

The above definition of molecular chaperone is entirely functional and contains no constraints on the mechanisms by which different chaperones may act. The term “noncovalent” is used to exclude those proteins that carry out posttranslational covalent modifications. Protein disulfide isomerase may seem to be an exception, but it is both a covalent modification enzyme and a molecular chaperone. It is helpful to think of a molecular chaperone as a function rather than as a molecule. Thus, no reason exists why a chaperone function should not be a property of the same molecule that has other functions. Other examples include peptidyl-prolyl isomerase, which possesses both enzymatic and chaperone activities in different regions of the molecule, and the alpha-crystallins, which combine two essential functions in the same molecule in the lens of the eye—contributing to the transparency and the refractive index required for vision as well as the ability to promote protein folding.
as to the chaperone function that combats the loss of transparency as the protein chains aggregate with increasing age. The proteasome particle has a chaperone-like activity involved in unfolding proteins prior to their proteolysis. A recent proposal is that some chaperones also possess extracellular cell-cell signaling functions, based on many experiments that show that some coevolved applied chaperones elicit responses from cultured cells (10). It remains an open question as to how many other effects chaperones may have.

Classes of Chaperone

It is convenient to divide chaperones into two broad classes: those that assist the folding of newly synthesized or stress-denatured proteins and those that assist the assembly of oligomeric structures. Some of these chaperones are highly specific for their protein substrates, whereas others are not. Many proteins have been termed chaperones, usually on the basis of their in vitro properties, but no comprehensive list is available.

Chaperones involved in protein folding—small chaperones

Some chaperones assist the folding of both nascent chains bound to ribosomes, newly synthesized chains released from ribosomes (i.e., in both cotranslational and posttranslational modes), as well as mature proteins unfolded by environmental stresses and some membrane proteins (11–12–13). The chaperones working in these cotranslational and posttranslational modes are distinct, and they can be termed small and large chaperones, respectively, because this is a case where size is important for function. Small chaperones are less than 200 kDa in size and include trigger factor, nascent chain-associated complex, prefoldin, the hsp70 and hsp40 families, and their associated cochaperones. Cochaperones are defined as proteins that bind to chaperones to modulate their activity; they may or may not also be chaperones in their own right. Large chaperones are more than 800 kDa in size and include DnaK, which allows the latter to bind another molecule of ATP, and GrpE, a nucleotide exchange factor that is a cochaperone but not a chaperone. DnaK binds to DnaJ through its J domain and increases the rate of ATP hydrolysis, which facilitates peptide binding. DnaJ, like all the hsp40 proteins, acts as a chaperone in its own right because it also binds to hydrophobic peptides. Thus, DnaK and DnaJ cooperate to bind each other to nascent chains; all hsp70 chaperones are thought to cooperate with hsp40 chaperones. The role of GrpE is to stimulate release of ADP from DnaK, which allows the latter to bind another molecule of ATP and to release the peptide. In the eukaryotic cytosol, the role of GrpE is fulfilled by an unrelated cochaperone called Bag-1. Some Archaea lack hsp70 proteins, but it is speculated that their role in protein folding may be replaced by that of an unrelated chaperone called prefoldin.

Some chaperones are highly specific for their protein substrates, whereas others are not. Many proteins have been termed chaperones, usually on the basis of their in vitro properties, but no comprehensive list is available.

Molecular Chaperones

because it is associated with the ribosomal large subunit at the tunnel from which the chains emerge (14). A cell of Escherichia coli contains about 20,000 copies of this chaperone, which is enough to bind to all nascent chains. Trigger factor shows peptidyl-prolyl isomerase activity and contains a hydrophobic groove that binds transiently to regions of the nascent chain enriched in aromatic residues. It binds to nascent chains as short as 57 residues and dissociates in an ATP-independent manner after the chain is released from the ribosome; this binding does not require prolyl residues in the nascent chain. The isomerase activity may provide a means to keep nascent chains that contain prolyl residues in a flexible state. The eukaryotic cytosol lacks the trigger factor, but its function may be replaced by that of a heterodimeric complex of 33-kDa and 22-kDa subunits, termed the nascent chain-associated complex. Like the trigger factor, this complex binds transiently to short nascent chains, but unlike the trigger factor, it does not possess peptidyl-prolyl isomerase activity.

Cells lacking the trigger factor show no phenotype; but this is because its function can be replaced by that of the other major small chaperone, hsp70 (15). The hsp70 family has many 70-kDa proteins distributed between the cytoplasm of bacteria and some Archaea, the cytosol of Eukarya, and eukaryotic organelles such as the endoplasmic reticulum, mitochondria, and chloroplasts. Some members are also stress proteins. Unlike the trigger factor, most hsp70 members do not bind to ribosomes but do bind to short regions of hydrophobic residues exposed on nascent and newly synthesized chains. Such regions occur statistically about every 40 residues and are recognized by a peptide-binding cleft in hsp70.

Most information is available about the hsp70 member in E. coli, termed DnaK. Like all hsp70 chaperones, DnaK contains an ATPase site and occupation of this site by ATP promotes rapid but reversible peptide binding. ATP hydrolysis tightens the binding through conformational changes in DnaK. The cycling of ATP between these states is regulated by a 41-kD cochaperone—one of the hsp40 family, termed DnaJ in E. coli, and GrpE, a nucleotide exchange factor that is a cochaperone but not a chaperone. DnaJ binds to DnaK through its J domain and increases the rate of ATP hydrolysis, which facilitates peptide binding. DnaJ, like all the hsp40 proteins, acts as a chaperone in its own right because it also binds to hydrophobic peptides. Thus, DnaK and DnaJ cooperate to bind each other to nascent chains; all hsp70 chaperones are thought to cooperate with hsp40 chaperones. The role of GrpE is to stimulate release of ADP from DnaK, which allows the latter to bind another molecule of ATP and to release the peptide. In the eukaryotic cytosol, the role of GrpE is fulfilled by an unrelated cochaperone called Bag-1. Some Archaea lack hsp70 proteins, but it is speculated that their role in protein folding may be replaced by that of an unrelated chaperone called prefoldin.

Enough DnaK is in a cell of E. coli for one molecule to bind to each nascent chain. DnaK binds to longer chains than the trigger factor, and so it probably binds after the trigger factor. When the gene for the trigger factor is deleted, the fraction of nascent and newly synthesized chains that bind to DnaK increases from about 15% to about 40%. However, removal of the genes for both the trigger factor and the DnaK in the

same cell causes the aggregation of many newly synthesized chains and is lethal to the cell (15). This observation suggests that the redundancy of important control systems is as good a design principle for cells as it is for passenger planes. An exception to this principle is the GroEL chaperone (see the discussion in the next section), whose gene is essential for the survival of E. coli. Small chaperones function essentially by reducing the time that potentially interactive surfaces on neighboring chains are exposed by cycling these chains on and off until they have folded; they do not seem to change the conformation of the chains. The other major class of chaperones involved in protein folding, however, functions by a much more sophisticated mechanism enabled by its large size.

**Large chaperones involved in protein folding—the chaperonins**

Most information is available for GroEL and GroES, the chaperonin and cochaperonin found in E. coli, but the general principles of their mechanism (Fig. 2) are suspected to apply also to the thermosome found in Archaea and to the TCP-1 complex (also called the TRiC or CCT complex) found in the eukaryotic cytosol. GroEL (800 kDa) consists of two heptameric rings of identical 57-kDa ATPase subunits stacked back to back, which contain a cage in each ring (17). The term “cage” is used because the walls surrounding each central cavity contain gaps, perhaps to allow water to enter and to exit. Each subunit contains three domains. The equatorial domain contains the nucleotide binding site and is connected by a flexible intermediate domain with the apical domain. The latter presents several hydrophobic side chains at the top of the ring oriented toward the cavity of the cage, which is an arrangement that permits either a partly folded polypeptide chain or a molecule of GroES to bind but prevents binding to another GroEL oligomer. GroES is a single heptameric ring of 10-kDa subunits that cycle on and off either end of the GroEL in a manner regulated by the ATPase activity of GroEL. A single ATPase unit is essential for the survival of E. coli. The reaction cycle starts with a GroEL–GroES complex containing ADP bound to the cis ring (Fig. 2, step 1).
Molecular Chaperones

Figure 1. Models for the chaperone-assisted folding of newly synthesized polypeptides in the cytosol. (a) Bacteria. TF, trigger factor; N, native protein. Most nascent chains probably interact with TF, and most small proteins (about 65–80% of total chain types) may fold rapidly during synthesis without additional chaperone assistance. Longer chains (10–20% of total chain types) interact subsequently with DnaK and DnaJ and fold after one or several cycles of ATP-dependent binding and release. About 10–15% of total chains fold within the chaperonin GroEL/GroES system. GroEL does not bind to nascent chains and is likely to receive its substrates after their release from DnaK. (b) Archaea. PFD, prefoldin; NAC, nascent-chain associated complex. Only some archaean species contain DnaK/DnaJ. The existence of a ribosome-bound NAC homologue and the binding of prefoldin to nascent chains have not been shown. (c) Eukarya. Like TF, NAC probably interacts with many nascent chains. Most smaller chains may fold without additional chaperone assistance. About 15–20% of chains reach their native states after assistance by hsp70 and hsp40, and a specific fraction of these are then transferred to hsp90. About 10% of chains are passed to the TRiC system in a reaction involving PFD. Reprinted from Reference (12) with permission from the American Association for the Advancement of Science.
rate of interactions that lead to compaction of the folding chain. Current estimates suggest that the fraction of newly synthesized polypeptide chains that bind in vivo to either hsp70 proteins or the chaperonins is in the range 10–20%. Whether most newly synthesized chains bind to other, as yet undiscovered, chaperones or fold unassisted because their sequences have evolved to avoid aggregation is unknown. Nor is it understood what determines that only a few defined polypeptides bind to GroEL in the intact cell. Some mycoplasmas lack genes for GroEL and GroES, perhaps because the limited number of proteins they contain do not include ones prone to aggregation.

Chaperones assisting oligomeric assembly

The nuclear compartment contains high concentrations of negatively charged nucleic acids bound to positively charged proteins that together form chromatin and various ribonucleoprotein particles. Besides nucleoplasm, several other chaperones assist the assembly and disassembly of these structures by preventing incorrect ionic interactions between them, whereas cytosolic assembly chaperones assist the assembly of ribosomes, proteasomes, and proteins such as hemoglobin (7, 20, 21). The continuing emphasis on the role of chaperones in protein folding may explain the relative dearth of information about assembly chaperones.

Common misconceptions

As with any new field, misconceptions abound. The literature contains statements of the form “chaperones fold proteins,” which suggests to the uninformed that chaperones possess steric information essential for protein folding; such grammatical forms should be avoided. Molecular chaperones and stress proteins are sometimes used as though they were interchangeable categories, but although many proteins share both chaperone and stress functions, this is not the case. A common error is to use the term “chaperonin” as synonymous with the term “chaperone,” but it should be noted that the chaperonins are just one particular family of chaperone defined by sequence similarity, i.e., the family that contains GroEL, hsp60, and TCP-1. The occasional use of the nonsense term “molecular chaperonin” in some respectable journals suggests that some people use these terms casually and without reference either to their meaning or to their history. It should be obvious that the word “molecular” is used to qualify “chaperone” because in common usage, “chaperone” refers to a person. So the term “molecular chaperonin” is as nonsensical as the term “molecular immunoglobulin.”

Another common misconception is that molecular chaperones are necessarily promiscuous, i.e., that each assists the assembly of many different types of polypeptide chains. This assumption is true for the hsp70, hsp40, and GroE chaperonin families but not for hsp90, PapD, hsp47, Lsm, Syc, ExbB, Pim, PrsA, and prosequences, which are specific for their substrates. Similarly, it is not a universal property of chaperones that they hydrolyze ATP: hsp100, hsp90, and hsp70, and the chaperonins hydrolyze ATP, but they trigger factor, hsp40, prefoldin, calnexin, protein disulfide isomerase, and PapD do not.

The term “chemical chaperone” has been proposed to describe small molecules such as glycerol, dimethylsulfoxide, and trimethylamine N-oxide that act as protein-stabilizing agents. This terminology is unfortunate and confuses students, because proteins are also chemicals. This term should be replaced by the term “kosmotrope” that physical chemists use to describe small molecules that stabilise proteins.

Amyloids are β-sheet rich fibrillar protein structures that result from the self-assembly of polypeptides and proteins. A wide range of proteins are known to form amyloid fibrils in vivo and an even larger number do so in vitro. More than 20 different human diseases involve amyloid formation, and the amyloid fibril or intermediates populated during its assembly are cytotoxic. All amyloid fibrils share common structural features despite exhibiting considerable variation in primary sequence. These features include a crossed β-sheet organization in which the individual β-strands are arranged perpendicular to the fiber axis such that the hydrogen bonds are oriented parallel to the fibril axis, resistance to proteolysis, and the ability to bind to certain dyes. Normally, the aggregation of proteins into amyloid is a pathological event; however, evidence indicates that naturally occurring amyloids may also play a beneficial biological role in vivo.

A wide range of human diseases result from the inability of specific proteins to fold into their correct biologically active three-dimensional structures or result from the failure of proteins to remain in their properly folded states. These conditions are referred to broadly as protein misfolding diseases, and they result from a variety of causes. In some cases, the efficiency of folding may be compromised by a range of posttranslational events that lead to insufficient production of active proteins; however, many protein misfolding diseases are caused by the transformation of normally soluble proteins or polypeptides into ordered aggregates. The latter diseases are referred to commonly as amyloidoses. They represent a large group of diseases characterized by the deposition of insoluble ordered protein deposits that are known as amyloid fibrils or amyloid plaques (Table 1). The term "amyloid" was used first by Rudolph Virchow in 1854 when he used the word to describe a macroscopic tissue abnormality that exhibited a positive iodine staining reaction. For reviews of the history of amyloid, see References 1 and 2. Today the term amyloid refers to a specific type of protein quaternary cross-β structure that results from the self-assembly of peptides, polypeptides, and proteins into ordered aggregates. The first recognition of amyloid as something more than just an amorphous deposit was made in 1927, when polarized light microscopy was used to show that Congo Red-stained amyloid from a variety of tissues exhibited positive birefringence (3). These early observations of Congo Red birefringence promoted electron microscopic (EM) investigations of human amyloid. The first EM studies revealed a common fibrillar ultrastructure among the various amyloid deposits investigated (4). Since then, our understanding of the general architecture of amyloid fibrils has increased dramatically with the advancement and refinement of experimental techniques (5–12). Research into amyloid has exploded in recent years into a large and dynamic field that continues to grow and to develop. Because space limitations prevent a comprehensive discussion of this fascinating area of chemical biology, we will avoid in-depth discussions of specific amyloid diseases, or of the computational and theoretical studies that are emerging. The development of inhibitors of amyloid is an active area of research, but space limitations prevent a detailed discussion. We do note, however, that several amyloid inhibitors are in various stages of clinic trials, and their development bears watching.

In this article, we provide a brief overview of the fundamental aspects of amyloids by focusing on the common features of amyloid fibrils, which include their mechanisms of formation and their cytotoxicity. From the vast and ever-growing amyloid literature, we cite several key papers and some interesting historical references, and we provide citations to several recent review articles.
Protein Misfolding, Amyloid Formation

A Diverse Range of Proteins Form Amyloid

Amyloids are formed when normally soluble proteins or polypeptides aggregate and deposit as amyloid plaques in the tissues of affected individuals. In vivo, amyloid deposits consist of one major protein and, usually, a set of common minor components that are derived largely from building blocks of the basement membrane, which includes proteoglycans (10, 13, 14). Minor protein components of in vivo amyloid deposits include serum amyloid P component, collagen, and apolipoprotein E. In vitro, highly purified proteins can self-assemble into amyloid fibrils in the absence of these other components. A wide range of proteins are known to form amyloid in vivo, and even more proteins can form amyloid in vitro (Table 1). Indeed, it has been proposed that nearly all proteins can form amyloid under appropriate conditions, and the cross-β structure has been hypothesized to represent a default free energy minimum for the conformation of a polypeptide chain (15). Thus, it has been suggested that amyloid was an important early fold in pre-biotic evolution and perhaps has existed for as long as proteins (16).

</table>
Despite the vast differences in the amino acid sequence of amyloid-forming polypeptides, all amyloid fibrils share common structural features and ligand binding properties. These properties include a crossed β-sheet organization in which the individual β-strands are arranged perpendicular to the fiber axis such that the hydrogen bonds are oriented parallel to the fibril axis, resistance to proteolysis, and the ability to bind to the dyes Congo Red and thioflavin-T (5–12, 17, 18). Typically, amyloid fibrils are 5 to 10 nm wide, unbranched, and variable in length. Transmission electron microscopy (TEM) and atomic force microscopy (AFM) studies have shown that amyloid fibrils are usually made up of protofilaments, each of which are typically 2–5 nm in diameter. Normally, the protofilaments twist together into rope-like structures with 2–6 protofilaments per fibril or self associate in a lateral fashion to generate long ribbons (7, 10, 11). The submicroscopic packing of the protofilaments varies according to differences in the primary amino acid sequence of the polypeptide and the environmental conditions in which amyloid formation is triggered. Because of the noncrystalline and insoluble nature of amyloids, it has been difficult to obtain detailed molecular structures of amyloidogenic proteins in their fibril form using conventional biophysical techniques such as X-ray crystallography and solution-state nuclear magnetic resonance (NMR) spectroscopy. Solid state NMR methods have been applied to the study of amyloid fibrils and have proven to be enormously useful, most notably in studies of the Aβ peptide (8, 19, 20). Solid-state NMR studies of synthetic amyloid fibrils have demonstrated that fibrils formed from peptides can be composed of parallel or antiparallel β-sheets, depends on the length and amphility of the peptide (20). Exciting recent work has led to high-resolution X-ray structures of several 7-mer polypeptides derived from amyloidogenic proteins (9, 12). These new structures reveal an extremely well-packed interface between pairs of β-sheets and the expected cross-β structure. It is not yet clear that these exceptionally well-packed structures will be representative of amyloid fibrils formed by larger polypeptides and proteins. One theory is that large globular proteins, like lysozyme (21), β2 microglobulin (22), and cystatins (23, 24) undergo three-dimensional domain swapping during amyloid fibril formation. Studies of amyloid-like fibrils of ribonucle-ase A with a Q10 hinge-loop expansion demonstrate domain swapping and functional native-like domains. This study indicates that the native-like conformation of the primary sequence can be maintained in the non-cross-β regions of the protein chain (25). It is, however, not clear whether the subunits of other domain-swapped amyloid-like fibrils might also consist of native-like polypeptide structures. How the non–cross-β regions of the protein chain are accommodated in the amyloid fibril is still unknown.
Protein Misfolding, Amyloid Formation

The highly ordered structures of amyloids allow the specific binding of histological dyes like Congo Red and thioflavin-T (3, 17, 18). Dye-binding studies have played a major role in amyloid research and form the basis of simple convenient assays; however, they are not without their pitfalls. For many years, Congo Red birefringence has been the standard test for the presence of amyloid (3, 17). Recent studies argue that Congo Red also binds to native proteins and lacks secondary structure specificity, which indicates that the dye is not specific for amyloid (26). Congo Red can also affect the rate of amyloid formation, either enhancing or inhibiting fibril formation, which emphasizes even more that it should be used with caution as a diagnostic tool for studying amyloid fibrils in vitro (27). Thioflavin-T is also used extensively for characterizing the presence of amyloid fibrils and their rate of formation (18). This dye, which can be detected by fluorescence, is a better alternative for in vitro fibril detection than Congo Red. Studies by confocal microscopy that used polarized light have indicated that thioflavin-T binds to amyloid with the long axis of the dye parallel to that of the fibril axis (i.e., perpendicular to the direction of the individual strands). The dye likely binds by inserting itself into the grooves formed between sidechains at positions i and i + 2 on the surface of the cross-β structure (28). For a flat β-sheet, approximately four strands are sufficient to generate a groove long enough to accommodate one molecule of thioflavin-T. It is thought that the steric constraints imposed by these surface grooves account for the relative specificity of the dye for the cross-β structure of amyloid fibrils.

Medically, amyloid diseases can be divided into three broad classes: neurodegenerative, systemic, and local amyloidosis (10). In neurodegenerative diseases, amyloids are deposited in the brain. Important examples in this class include the spongiiform encephalopathies, Huntington’s, Alzheimer’s, and Parkinson’s disease. In systemic amyloidoses, aggregation occurs in multiple organs and tissues. A subset of systemic amyloidoses includes senile systemic amyloidosis; lysozyme amyloidosis; A.L amyloidosis, which is caused by the aggregation of immunoglobulin light chains or fragments thereof; familial transthyretin-associated amyloidosis, which develops from de- position of wild-type or one of more than 50 mutated forms of transthyretin (TTR); and diseases of chronic inflammation, in which an N-terminal fragment of the acute phase protein serum amyloid A forms amyloid deposits. In the non-neurological, lo- calized amyloidoses, amyloid deposition occurs in one target organ, which is usually proximal to the production site of the amyloidogenic peptide. Common examples of this third class include medullary thyroid carcinoma, which is associated with amyloid deposition of prealbumin; familial amyloidosis, which is caused by a familial nanocrine factor; amyloid formation by the γ-crystallins associated with cataracts; type 2 diabetes, which is characterized by deposition of β-sheet amyloid polypeptide (1A PP also known as amylin); as well as many others (Table 1). Some diseases are sporadic whereas others are hereditary. The associ- ation between amyloid fibril formation and disease pathogenesis is common for all amyloidoses, and the cytotoxic properties of amyloidogenic peptides are well documented (29, 30). The ex- act mechanism of amyloid-induced cell death is, however, still not completely clear.

The proteins and polypeptides that form amyloid can be di- vided into two broad structural classes: namely those that adopt a well-defined tertiary fold in their normally soluble state and those that are flexible and intrinsically disordered in their un- aggregated state. Normally, proteins that adopt a well-defined globular fold in their unaggregated state require a partial unfolding event to become aggregation competent. Particu- larly well-characterized examples include TTR, β2 microglob- ulin (responsible for dialysis-related amyloid), and lysozyme (21, 22, 31–35). Molecules that bind and stabilize the native states are potential therapeutic agents for amyloid diseases that develop from folded proteins, because they reduce the ten- dency to populate the amyloidogenic precursor states (31). In some cases, natively unfolded polypeptides also seem to re- quire a partial fold to form amyloid. Studies on tau (associ- ated with neurofibrillary tangles) and Aβ (which forms amyloid deposits in Alzheimer’s disease) suggest that amyloid forma- tion in these systems is preceded by formation of a helical intermediate (36, 37).

Common Features of Amyloid Formation

An increasing number of studies on a variety of amyloidogenic peptides and proteins argue that underlying commonalities exist in mechanisms of amyloid formation at least in vitro, which are independent of the details of the polypeptide sequence. This finding is true for both of the structural classes of amyloids defined above. The exact mechanism of amyloid formation has not been determined fully; however, extensive experimental ev- idence indicates that amyloid formation proceeds by a variation of the so-called nucleation-dependent polymerization pathway (38, 39). The kinetics of amyloid formation are complex and typically exhibit a lengthy lag phase during which little or no amyloid is formed, which is followed by a much more rapid growth phase. Oligomeric nuclei are formed during the slow lag phase. Once a critical assembly of precursors form an ac- tive seed, a second, more rapid phase of fibril polymerization occurs, which leads to the classic amyloid morphology. Amy-loid formation can be accelerated substantially by the addition of preformed seeds (40). Often, the lag phase can be abolished by seeding a solution of unaggregated peptide with a small amount of preformed fibrils (Fig 1). Seeding is generally, although not completely, specific. Fibrils often preferentially, but not always, seed reactions that contain the same polypeptides from which they were formed. This finding indicates that primary structure similarity is important for binding interactions between seeds and polypeptide monomers. Although the general ultrastructure of all amyloids seem similar, clear morphological differences exist between amyloid fibrils formed from different proteins. These variations in morphology are caused by differences in the molecular packing and the organization of fibril subunits, as influenced by the polypeptide primary sequence. Other external environmental factors such as solution pH, ionic strength, tem- perature, and agitation have also been shown to affect fibrillar morphologies of amyloids produced in vitro.
There is a rich experimental and theoretical literature exists on protein assembly and aggregation, and various kinetic models have been used to rationalize the time course of amyloid formation (38-41). Perhaps the classic example of a protein assembly reaction is that of actin, which is described by a nucleation-dependent mechanism. The nucleation-dependent model comprises three steps: 1) association of monomers into oligomers, 2) conversion of the oligomers to a nucleus, and 3) growth of the final fibril by addition of monomers to the end. The nucleation-dependent polymerization model cannot explain all amyloid formation reactions. The existence of the characteristic lag phase is not well predicted. Double nucleation schemes, which were developed initially by Mozzarelli et al. (42) during their pioneering studies of hemoglobin S polymerization, have been invoked to explain the existence of a lag time. Double nucleation models include primary nucleation steps similar to the nucleation-dependent polymerization model, but they also invoke a second nucleation step that is dependent on the presence of fibrils (i.e., the fibrils can act as secondary nucleation sites). The second step is unimportant before fibrils are formed but becomes increasingly important as the amount of fibrils increases. This mechanism was used early on to model amyloid formation kinetics; however, the dependence of the lag phase on protein concentration in amyloid formation is not always well predicted by this model. In particular, the model predicts a lag time that scales much more strongly with monomer concentration than is sometimes observed. Variants of the original double nucleation scheme have been developed that can account for the weakened concentration dependence. Irrespective of the details, the view that amyloid formation proceeds by a cooperative, nucleation-polymerization mechanism is widely accepted (10, 40).

The structure shared by amyloid fibrils and the common themes in its assembly provide a unifying mechanism of cell toxicity: thus, a better understanding of the amyloid assembly process at the molecular level should give invaluable insight into the identification and the development of effective therapeutic innovations for a wide variety of human amyloid diseases. Amyloid fibrils or their precursors are toxic and are directly responsible for cell death. The majority view in the field is that partially structured oligomers that appear as intermediates in the aggregation process may be the toxic entities, rather than the mature fibrils (43-49). In this view, amyloid may represent a relatively benign state that sequesters the protein, and if true, may suggest that several compounds that have been developed to inhibit the assembly of amyloid fibrils could actually be harmful if they lead to the build up of toxic prefibrillar intermediates. It is important to realize, however, that good evidence suggests both fibrils and prefibrillar species can be toxic, at least in some cases. For example, the pathological effects in the systemic amyloidoses are caused by disruption of organ function by the formation of large amyloid deposits. In addition, the results of several recent studies are very difficult to reconcile with the “only oligomers are toxic” model. For example, the Tottori and English Familial Alzheimer disease mutations are associated with aggressive early onset of Alzheimer’s disease, yet their effect is to increase the rate of fibril formation without increasing meta-stable intermediates. Thus, a detailed understanding of the mechanism of amyloid fibril formation and the identification of the toxic species and their mode of action are subjects of major importance and are currently the focus of considerable research.

Until very recently, the aggregation of proteins into ordered amyloid fibrils was thought to be a pathological event that leads to cytotoxicity and highly debilitating diseases; however, amyloid need not always be deleterious. Amyloid-like structures may have applications in bio-nanotechnology, which includes roles as templates for the assembly of novel structures, as materials, and as cell-supporting matrices (51, 52). In addition, evidence now suggests that naturally occurring amyloids can play beneficial biological roles in vivo. Several functional amyloid fibrils derived from a diverse range of single and multi-cellular organisms have been identified and described recently (49). A list of functional amyloid and amyloid-like structures is provided in Table 1.

A particularly well studied example of functional amyloid is provided by Curli assembly (53). Curli amyloids are assembled by bacteria such as Escherichia coli and Salmonella. Once assembled on the extracellular surface, Curli amyloid fibers function as natural cell adhesion molecules that link together bacterial cells into robust cellular networks of biofilms. Other examples of functional amyloids include the silk fibers observed commonly in spider webs; the Chorion proteins of egg shells; Factor XII, which is an activator of the hemostatic system; and other naturally produced adhesives and materials (54).

In humans, the formation of Pmel17 amyloid has been shown to be important for melanin formation (55). Melanin is a natural pigment for skin coloration, UV protection, and chemical detoxification, and it is synthesized in melanosomes. Pmel17 amyloid fibrils have been shown to protect melanosomes against pigment melanin toxicity by decreasing the diffusion of toxic melanin precursor molecules out of the cell. The formation and the degradation of functional amyloids seem to be highly regulated, which is hardly surprising given the toxicity associated with nonfunctional amyloids (54, 55).

Figure 1: Schematic representation of the progress of fibril formation. The solid line represents an unseeded reaction. A distinct lag phase is observed followed by a rapid growth phase. Seeding (dashed line) can bypass the lag phase.
A amyloid structures can also act as nonchromosomal genetic elements, which lead to non-Mendelian inheritance. This finding can have drastic and disastrous effects in the prion diseases. However, several amyloid forming prions have been suggested to be potentially functional, which include the yeast proteins Het-s and p-prion. The Het-s prion, which is found in 80% of wild isolates, carries heterokaryon incompatibility to prevent infection by incapacitating fungal viruses (56, 57). The p-prion, which has been shown to be necessary for meiosis and for cell survival in the stationary phase (58), has also been proposed to be potentially beneficial for fungal cells. Other prion proteins, like Sup35p, Ure2p and Rnq1p, which have been demonstrated to form amyloid formers in the cytoplasm in a non-Mendelian epigenetic fashion, have been argued to provide evolutionary advantages for host cells (59-61). This hypothesis is intriguing and will no doubt be the focus of much attention.

The study of the assembly, degradation, and regulation of functional amyloids may well provide important clues for controlling aberrant amyloid formation, and a greater understanding of the diverse physiological applications of the amyloid fold may open potential new avenues for the treatment of amyloid diseases. The discovery of functional amyloids has interesting implications, which may open potential new avenues for the treatment of amyloid diseases. The discovery of functional amyloids has interesting implications. Whether this issue is critical remains to be determined.

Evolutionarily conserved membrane-embedded enzymes somehow use water to hydrolyze peptide bonds that reside within the lipid bilayer. These proteases are stitched into the membrane and bear little or no sequence similarity to other known proteases with one exception: All known intramembrane proteases apparently have converged on catalytic mechanisms that resemble those of proteases that reside in the aqueous milieu. The identities of these residues suggest that the intramembrane proteases use catalytic functionalities similar to those found in their soluble counterparts. However, in contrast to classical proteases, residues essential for catalysis lie within predicted hydrophobic transmembrane domains. Current research is focused on elucidating the range of biologic roles of these proteases, identifying their substrates, and understanding their structure and mechanism of action. Such knowledge is important because the intramembrane proteases discovered thus far play critical regulatory roles in biology and contribute to human disease.

Proteases catalyze the hydrolysis of the amide bonds that link amino acids together in peptides and proteins, and this process requires the concerted effort of key residues within the active site of the enzyme. These hydrolytic enzymes are classified into four general types based on their catalytic residues and mechanism of action: 1) serine/threonine proteases, 2) cysteine proteases, 3) aspartyl proteases, and 4) metalloproteases. Each of these four main protease categories contains hundreds of known examples and has representatives in all forms of life (1). Until recently, all the identified proteases had been water-soluble enzymes: Either the entire enzyme normally is found in an aqueous environment or a membrane anchor holds down an otherwise aqueous protease. In recent years, however, new proteases have been discovered that apparently are embedded within the hydrophobic environment of the lipid bilayer and yet somehow carry out hydrolysis on the transmembrane region of their substrates in the generally water-excluding environment of the membrane. Another unusual feature of this process are the substrates, which typically are folded into an α-helix, a conformation that makes the backbone amide bonds inaccessible to nucleophilic attack because of steric hindrance by the amino acid side chains. These intramembrane-cleaving proteases (I-CLiPs) therefore must create an environment for water and the hydrophilic residues needed for catalysis and must bend or unwind their substrates to make the amide bonds susceptible to hydrolysis. Supporting these mechanistic notions is the observation that these newly discovered I-CLiPs apparently are variations on familiar themes in protease biochemistry: Despite the novelty of being membrane-embedded and cleaving transmembrane domains, the residues essential for catalysis by these I-CLiPs are virtually the same as those found in aqueous proteases.

The S2P Family of Metalloproteases

The first discovery of an I-CLiP arose from studies on the regulation of sterol and fatty acid metabolism. Sterol regulatory element binding proteins (SREBPs) are transcription factors that promote the expression of genes involved in the synthesis of cholesterol and fatty acids (3). Coordinated gene expression is controlled through negative feedback inhibition by cholesterol to ensure that lipids and sterols are produced only when needed. SREBPs are synthesized as a precursor protein that contains three distinct domains: a domain exposed to the cytosol that binds DNA and activates transcription, two transmembrane regions, and a regulatory domain involved in the feedback control by cholesterol (Fig. 1). When cholesterol levels are high, the SREBP precursor is kept in the endoplasmic reticulum (ER) by a multipass membrane protein called SCAP (SREBP cleavage-activating protein) (4). Reduced cholesterol levels result in the dissociation of Insig from SCAP, which allows SCAP to shepherd SREBP to the Golgi apparatus. Proteolysis of SREBP in the Golgi results in the release of the transcription factor and its translocation to the nucleus.

Proteolytic release of SREBPs occurs in two steps (Fig. 1). First, the luminal loop between the two transmembrane regions is cleaved by the membrane-tethered Site-1 protease (S1P) (6).
The release of the transcription factor requires subsequent cleavage by the Site-2 protease (S2P), which performs a hydrolysis of an amide bond predicted to lie three residues within the transmembrane domain (7). The requirement for a prior proteolytic event is a common theme with I-CLiPs. Complementation identified S2P as a multipass membrane protein that contains a conserved HEXXH sequence characteristic of zinc metalloproteases (8). The two histidines and the glutamate are required for S2P activity, consistent with known metalloprotease biochemistry in which the two histidines coordinate with zinc and the zinc in turn activates the glutamate for interaction with the catalytic water. Additional analysis led to the discovery of a conserved aspartate located ∼300 residues from the HEXXH sequence that is likewise critical for S2P activity and thought to be a third residue involved in zinc coordination (9). The involvement of zinc in S2P activity has not been demonstrated, and a cell-free assay for S2P activity has not been reported yet; therefore, S2P has not been shown directly to act as a protease (however, see below about bacterial S2Ps). Nevertheless, extensive genetic analysis has not uncovered any other proteins required for S2P cleavage of SREBP. Similar to SREBP, sequential processing by S1P and S2P of the otherwise membrane-associated transcription factor ATf6 are essential steps in the ER stress response (10).

More support for the proteolytic function of S2P comes from the discovery of a family of related proteins in bacteria (11). These prokaryotic proteins play an essential role in the proteolysis of otherwise membrane-bound transcription factors needed for sporulation. These factors control gene expression in the mother cell after engulfment of the forespore. The cleavage of pro-αk and the release of the transcription factor requires the multipass membrane protein SpoIVFB in Bacillus subtilis, and this protein likewise contains the HEXXH motif and a second conserved region with an aspartate, both of which are essential for proteolysis. Another bacterial S2P family member, YaeL (also called RseP) in Escherichia coli, similarly requires HEXXH and a conserved aspartate to play a role in coordinating cell growth and cell division, through intramembrane proteolysis of RseA, a factor critical for responding to extracytoplasmic stress (12). Interestingly, the membrane orientations of the substrates SREBP and αk are opposite to each other, which correlates with that of their respective enzymes, S2P and SpoIVFB, which similarly are thought to have opposite orientations (11). This opposition implies that the catalytic region must align with the peptide substrate with proper relative directionality. Although SpoIVFB and YaeL are both S2P-like enzymes that cleave transmembrane proteins during sporulation, the regulation of this key intramembrane proteolytic event for these two I-CLiPs is quite different. For cleavage of RseA by YaeL/RseP, the regulation is similar to that in SREBP cleavage by S2P: Intramembrane proteolysis requires a prior cleavage event outside the membrane by another protease called DegS (13). In contrast, SpoIVFB apparently does not require a prior proteolysis and regulation occurs more directly at the level of SpoIVFB. Two membrane proteins, Boa and SpoIiFA, serve to inhibit SpoIVFB activity, and this inhibition is released by the proteolysis of SpoIiFA by other proteases (14, 15) (Fig. 2).

As mentioned above, the α-helical conformation of the transmembrane substrate renders the amide bonds inaccessible to attack by a catalytic residue or water, which requires some bending or unwinding of the helix before proteolysis can occur. The SREBP substrate contains a conserved asparagine-proline (NP) sequence within its transmembrane region that is critical for proteolytic processing by S2P (16). These two residues have the lowest propensity to form α-helices, which suggests that the NP-containing SREBP transmembrane region may be metastable. After S1P cleavage and dissociation of the other transmembrane region, the NP sequence may facilitate unwinding of the residues immediately upstream, including the leucine-cysteine bond that gets cleaved. Unwinding may result in a protrusion of this bond to the membrane surface and access by the active site residues of S2P.

So far, one member of the S2P family has been purified to homogeneity with preservation of proteolytic activity (17). The purification of this protease, the E. coli YaeL/RseP, should allow a more rigorous and direct determination of substrate sequence requirements. Moreover, the ability to purify an I-CLiP and reconstitute activity in an appropriate detergent and usually in the presence of added lipids is an important step toward studying these unusual membrane-embedded proteases in terms

Figure 1  S2P contains conserved HEXXH and LDG motifs found in metalloproteases. SREBP first is cleaved by S1P in the luminal loop. The regulatory domain (Reg) interacts with the cholesterol-sensing SCAP to ensure that S1P proteolysis only occurs when cholesterol levels are low. Subsequent intramembrane proteolysis releases this transcription factor for the expression of genes essential to cholesterol and fatty acid synthesis.
Intramembrane Proteolysis

When the mother cell engulfs the forespore, a signaling pathway that involves the transcription factor $\sigma^G$ is initiated in the forespore that triggers the synthesis of the IVB serine protease. This protease degrades SpoIVFA, which along with BofA serves to inhibit SpoIVFB. With the inhibition of the S2P-like protease released, SpoIVFB cleaves pro-$\sigma^G$, which allows this transcription factor to signal in the mother cell for more factors needed for spore maturation.

of structural biology. Indeed, one such protease has been seduced to crystallize, which provided the first detailed structures of an I-CLiP (see the section below on the Rhomboid serine proteases).

$\gamma$-Secretases: Presenilin-Containing Aspartyl Protease Complexes

A key step in the pathogenesis of Alzheimer’s disease is APP proteolysis that results in the formation of the amyloid-$\beta$ peptide (Aβ), the principle protein component of the characteristic cerebral plaques of the disease (18). The N-terminus of Aβ is produced from the amyloid $\beta$-protein precursor (APP) by the action of $\beta$-secretase, which leads to membrane shedding of the large luminal/extracellular APP domain (Fig. 3a). The 99-residue remnant (C99) then is cleaved in the middle of its transmembrane region by $\gamma$-secretase, which releases Aβ and is cleaved again near the inner leaflet at the $\epsilon$ site to release the APP intracellular domain (AICD). As described below, chemical probes played important roles in the characterization, identification, purification, and mechanistic understanding of the I-CLiP that now is known as the $\gamma$-secretase complex.

Two contemporaneous observations provided critical clues for the identification of the elusive $\gamma$-secretase, a subject of intense interest as a potential therapeutic target. First, the knock-out of presenilin genes eliminated the $\gamma$-secretase cleavage of APP (19). Second, the types of compounds that could inhibit $\gamma$-secretase contained moieties typically found in aspartyl protease inhibitors (20). These findings led to the identification of two conserved transmembrane aspartates in the multipass presenilin that are critical for $\gamma$-secretase cleavage of APP (Fig. 3a), which suggests that presenilins might be the responsible aspartyl proteases (21). Presenilin is cut into two pieces, an N-terminal fragment (NTF) and a C-terminal fragment (CTF), the formation of which results in the liberation of AICD.

Figure 3  Presenilin, the $\gamma$-secretase complex, and the proteolysis of APP to Aβ. (a) Presenilin is processed into two pieces, an N-terminal fragment (NTF, dark portion) and a C-terminal fragment (CTF, light portion) that remain associated. Each fragment donates one aspartate that is essential for $\gamma$-secretase activity. APP is cleaved first in the extracellular domain by $\beta$-secretase, and the remnant is cleaved twice within the membrane by $\gamma$-secretase to produce the Aβ peptide of Alzheimer’s disease (secreted) and the intracellular domain (AICD, freed into the cytosol). (b) Presenilin interacts with three other membrane proteins, nicastrin, Aph-1, and Pen-2, to form active $\gamma$-secretase.

Intramembrane Proteolysis

**Figure 4** Chemical tools for the study of γ-secretase. Transition-state analog inhibitors include hydroxyl-containing moieties that interact with the catalytic aspartates of aspartyl proteases. Helical peptide mimics the APP transmembrane domain and interact with the substrate docking site on the protease. These potent inhibitors were converted into affinity labeling reagents that contain a chemically reactive bromoacetyl or photoreactive benzophenone for covalent attachment to the protein target and a biotin moiety to allow isolation and detection of the labeled protein. Both types of chemical probes interacted with the two presenilin subunits but at distinct locations, which suggests that both the active site and the docking site of γ-secretase lie at the interface between these subunits.
Unlike the other intramembrane proteases, the enzyme does not recognize by process so many different substrates. The broad substrate specificity to be unique among intramembrane proteases in its ability to cleave so many different substrates and its apparently poor substrate recognition (see below). In the interacting with ligands such as the protease Delta and Jagged triggers a shedding of the ectodomain by membrane-anchored metalloprotease-mediated cleavage at S2. The remnant then is cleaved at least twice, at the S3 and S4 sites, to release the Notch counterpart of Aβ (Aβ) and the intracellular domain (NICD). The latter translocates to the nucleus where it interacts with transcription factors to influence gene expression relevant to cell differentiation.

Figure 6. Model for how inhibitors and substrates interact with presenilin. Helical peptides are docking site inhibitors (DSIs) and interact on the outside of the presenilin molecule at the NTF/CTF heterodimeric interface. Transition-state analog inhibitors (TSAs) interact on the inside of the presenilin molecule where the active site resides. The active site, which contains water and two aspartates, is thought to be sequestered away from the hydrophobic environment of the lipid bilayer. These findings have implications for how substrate interacts with the enzyme. The transmembrane domain of the substrate (S) interacts with the docking site and passes either in whole or in part into the active site for proteolysis.

Up until recently, all the action seemed to be taking place on presenilin. However, an elegant study has demonstrated that nicastrin also plays a critical role in substrate recognition (54). The ectodomain of nicastrin bears sequence resemblance to aminopeptidases, although certain catalytic residues are not conserved. Nevertheless, nicastrin recognizes the N-terminus of γ-secretase substrates derived from APP and Notch, and mutation of the aminopeptidase domain prevents this interaction. One conserved glutamate is especially important because this residue forms an ion pair with the amino terminus of the substrate. The sequence of the substrate N-terminus apparently is not critical for the interaction, but a free amino group is. Indeed, the simple formylation of the substrate N-terminus is enough to prevent effective substrate interaction and proteolytic processing. Thus, nicastrin can be thought of as a kind of gatekeeper for the γ-secretase complex: Type I membrane proteins that have not shed their ectodomains cannot interact properly with nicastrin and do not gain access to the active site.

Although γ-secretase has in many ways been an attractive target for Alzheimer therapeutics (see inhibitor in clinical trials, Fig. 7), interference with Notch processing and signaling may lead to toxicities that preclude the clinical use of inhibitors of this protease. Long-term treatment with γ-secretase inhibitors causes severe gastrointestinal toxicity and interferes with the maturation of B- and T-lymphocytes in mice, effects that are indeed because of the inhibition of Notch processing and signaling (55, 56). However, compounds that can modulate the enzyme to alter or block Aβ production with little or no effect on Notch would bypass this potential roadblock to therapeutics. Recent studies suggest that the protease complex contains allosteric binding sites that can alter substrate selectivity and the sites of substrate proteolysis. Certain nonsteroidal anti-inflammatory drugs (NSAIDs; e.g., ibuprofen, indomethacin, and sulindac sulfide) can reduce the production of the highly aggregation-prone Aβ peptides.

Figure 7. γ-secretase inhibitor (LY-450,139) and NSAID-like modulator (R-flurbiprofen) in clinical trials for Alzheimer’s disease.
A (A2) peptide and increase a 38-residue form of Aβ, a pharmacologically independent of inhibition of cyclooxygenase (57). The alteration of the proteolytic cleavage site is observed with isolated or purified γ-secretase (58-60), which indicates that the compounds can interact directly with the protease complex to exert these effects. Enzyme kinetic studies and displacement experiments suggest that the selective NSAIDs can be noncompetitive with respect to APP substrate (60) and to a transition-state analog inhibitor, which suggests an interaction with a site distinct from the active site (61). The site of cleavage within the Notch transmembrane domain is affected similarly, but this subtle change does not inhibit the release of the intracellular domain and thus does not affect Notch signaling (62).

For this reason, these agents may be safer as Alzheimer thera
pagnics than inhibitors that block the active site or the docking site. Indeed, one compound, R-flurbiprofen (Fig. 7), has advanced recently to Phase III clinical trials. Surprisingly, the site of proteolytic cleavage by the presenilin homologue SPP also can be modulated by the same NSAIDs that affect γ-secretase. Because SPP apparently does not require other protein cofactors, these findings suggest that presenilin is the site of NSAID binding within the γ-secretase complex and that SPP and presenilin share a conserved drug binding site for the allosteric modulation of substrate cleavage sites (63).

Another type of allosteric modulator is compounds that seem like kinase inhibitors and interact with a nucleotide binding site on the γ-secretase complex. The discovery that ATP can increase Aβ production in membrane preparations prompted the testing of a variety of compounds that interact with ATP binding sites on other proteins (64). In this focused screen, the α2-kinase inhibitor Gleevec emerged as a selective inhibitor of Aβ production in cells without affecting the proteolysis of Notch. In light of these findings, ATP and other nucleotides were tested for effects on purified γ-secretase preparations and found to increase selectively the proteolytic processing of a purified recombinant Aβ-based substrate without affecting the proteolysis of a Notch counterpart (65). Furthermore, certain compounds known to interact with ATP binding sites were found to inhibit selectively the APP processing via a γ-secretase in purified protease preparations. These and other results suggest that the γ-secretase complex contains a nucleotide binding site and that this site allows the allosteric regulation of γ-secretase processing of APP with respect to Notch. Whether this regulation is physiologically important is unclear, but the pharmacologic relevance is profound and may lead to new therapeutic candidates for Alzheimer’s disease.

The purification of the γ-secretase complex (59) has allowed the first glimpse into its structure. Electron microscopy and single particle analysis reveals that the complex has a globular structure that at low resolution (∼15 Å) appears rather amorphous (66). A similar structure, elucidated in a similar manner but of poorer resolution (∼45 Å), also has been reported (67). Nevertheless, two important features can be gleaned. The first is a rather large interior cavity of ∼20 Å diameter that is presumed where the active site resides, a characteristic reminiscent of the proteasome. The second is the presence of two small openings that may be the site of entry for water. Other structural features have been revealed by cysteine mutagenesis with the cross-linking of chemical probes (68, 69). The generation of a cysteine-less version of presenilin (that retains the ability to assemble with other complex members, to undergo endo-proteolysis to NTF and CTF, and to process APP) allowed incorporation of single cysteine residues at various sites near the key aspartates. Disulfide formation with thiol-containing reagents then provided information about the relative accessibility of these sites from the aqueous milieu, which allowed the construction of a model in which water can funnel down to where the aspartates reside. More detailed information likely will require a crystal structure of presenilin or a presenilin homologue (see below).

**SPP Aspartyl Proteases**

The concept of presenilin as the catalytic component for γ-secretase was strengthened considerably when signal peptide protease (SPP) was found to be a similar intramembrane aspartyl protease. SPP clears remnant signal peptides from the membrane after their production by signal peptidase (Fig. 8). However, this process apparently also plays a role in immune surveillance, in which signal peptides from the major histocompatibility complex (MHC) type I are cleaved by SPP and the peptide products are presented onto the cell surface as an indication to natural killer cells whether MHC synthesis is proceeding normally (70). In addition, SPP is exploited by the hepatitis C virus for the maturation of its core protein, which suggests that this protease may be a suitable target for antiviral therapy (71).

SPP was identified by affinity labeling with a peptidomimetic inhibitor, and the protein sequence displayed intriguing parallels with presenilin (Fig. 8) (72). SPP contains two conserved aspartates, each predicted to lie in the middle of a transmembrane domain, and the aspartate-containing sequences resemble those found in presenilins. The predicted topology of SPP also resembles that of presenilins, placing the key aspartates in the same relative position to each other in the membrane. As with SPP compared with its bacterial relatives, the orientation of the aspartate-containing transmembrane domains of SPP apparently is opposite that of presenilins, again in correlation with the orientation of SPP substrates, which is opposite that of γ-secretase substrates. Interestingly, before the identification of SPP, a computational search for presenilin-like proteins netted an entire family of so-called presenilin homologs (PSHs) (73); however, it is not yet clear if all these proteins have catalytic activity. Two homologs, SPP-like proteases SPLL2a and SPLL2b, recently have been found to cleave tumor necrosis factor a (74), although the biologic role of this proteolysis is unknown.

SPP seems to be less complicated than γ-secretase. The expression of human SPP in yeast reconstituted the protease activity, which suggests that the protein has activity on its own and does not require other mammalian protein cofactors (72). Moreover, unlike presenilins, SPP is not processed into two pieces. Thus, SPP may be a more tractable enzyme for understanding this type of intramembrane aspartyl protease and may shed light on γ-secretase structure and function. Indeed, the catalytic sites of the two proteases seem remarkably similar; their activities...
Intramembrane Proteolysis

Figure 8  Comparison of signal peptide peptidase (SPP) with presenilin and the γ-secretase complex. Signal peptides are removed from membrane proteins via signal peptidase (SP), and these peptides are released from the membrane by SPP-mediated intramembrane proteolysis. SPP, like presenilin, contains two aspartates that are essential for protease activity, but the conserved aspartate-containing motifs are in the opposite orientation compared with their presenilin counterparts. Consistent with the flipped orientation of SPP vis-à-vis presenilin, the substrates of these two proteases also run in the opposite direction. Unlike presenilin, SPP apparently does not require other protein cofactors or cleavage into two subunits for proteolytic activity. Are inhibited by some of the same active site-directed peptidomimetics (75, 76) and helical peptides (77), and activity can be modulated by the same NSAIDs that affect γ-secretase (77). SPP forms a homodimer very rapidly in cells, and this dimer is stable enough to allow isolation and analysis (78). Moreover, this dimer can be labeled specifically by a transition-state analog inhibitor, which suggests that the dimer is catalytically active. The functional importance of this dimer, however, is unclear; dimerization may not be necessary for proteolytic activity. In terms of substrate recognition, however, SPP does display an important difference with γ-secretase: the apparent requirement for helix-breaking residues that should facilitate the ability of the enzyme to access the site of hydrolysis (79).

Rhomboid Serine Proteases

The study of a conserved growth factor signaling pathway also led to intramembrane proteolysis. Epidermal growth factor (EGF) receptor ligands are synthesized as single-pass membrane proteins, but signaling requires the proteolytic release and secretion of the ligand for interaction with its cognate receptor. In vertebrates, this release and secretion is accomplished by membrane-tethered metalloproteases. Genetic analysis in Drosophila, however, identified two essential players, dubbed Star and Rhomboid-1, in the proteolysis of an EGF ortholog Spitz. No other components apparently are required. Full-length Spitz remains in the ER until it is ushered by Star to the Golgi apparatus where it encounters Rhomboid-1 (80). Rhomboid-mediated proteolysis in the Golgi then is followed by secretion for intercellular communication. But how does Rhomboid allow cleavage of Spitz?

Mutational analysis of conserved non-glycine residues revealed a tantalizing requirement for a serine, a histidine, and an asparagine, which together might serve as a catalytic triad typically found in serine proteases (81) (although subsequent studies supported Ser-His dyad (82)) (Fig 9). These three residues were predicted to reside about the same depth within the membrane and thus have the potential to interact with each other. Consistent with this idea, the cleavage site of Spitz was estimated to be at an equivalent depth in the transmembrane region, and Spitz...
Rhomboids contain a conserved serine and histidine, which comprise a putative catalytic dyad of a serine protease. Rhomboid-1 cleaves within the transmembrane region of the Drosophila EGF-like growth factor Spitz. Cleavage was sensitive only to serine protease inhibitors. Moreover, a careful analysis of concentration dependence revealed that expression of catalytic amounts of Rhomboid-1 still allowed Spitz proteolysis. Taken together, Rhomboid-1 apparently is a novel intramembrane serine protease.

What determines Rhomboid substrate specificity, and how is this proteolytic event regulated? Most of the Spitz transmembrane region could be swapped with that of a nonsubstrate protein without affecting cleavage by Rhomboid; however, the N-terminal quarter of the transmembrane region was critical for substrate recognition (83). Indeed, incorporation of this substrate motif into Delta allowed this Notch ligand to be processed by Rhomboid. Additional examination of the substrate motif led to the tentative identification of a critical glycine-alanine, which suggests that, as with S2P and SPP, Rhomboid seems to require helix-destabilizing residues within the transmembrane domain of its substrates. Rhomboid activity is distinguished from that of the other I-CLiPs because Rhomboid does not require prior substrate cleavage by another protease. Rhomboid regulation apparently occurs mainly by the translocation of the substrate from the ER to the Golgi (mediated by Star) and the spatial control of Rhomboid transcription.

Like S2P, Rhomboid genes have been conserved throughout evolution. Surprisingly, despite overall low homology with eukaryotic Rhomboids, several bacterial Rhomboids could cleave Drosophila Rhomboid substrates and mutation of the putative catalytic triad residues abolished protease activity, which illustrates the evolutionary conservation of the serine protease function of Rhomboid. The natural substrates for the bacterial Rhomboids are unknown. As for substrates of eukaryotic Rhomboid-1 homologues, two mitochondrial membrane proteins have been identified as substrates for the yeast Rhomboid RBD1 (85–87). The RBD1-mediated release of one of these substrates is essential for the remodeling of the mitochondrial membrane, and the human orthology of RBD1, PARL, could restore the substrate proteolysis and proper growth rates and mitochondrial morphology in a yeast RBD1 mutant (86), which suggests that the role of these Rhomboids in mitochondrial function has been conserved evolutionarily. Indeed, a recent study identified a mitochondrial protein DPA1 as a likely substrate for PARL, the cleavage of this substrate being critical to cristae remodeling and cytochrome c release during apoptosis (88). In Toxoplasma, TgROM5, one of five nonmitochondrial Rhomboids in these parasites, cleaves a cell surface adhesion protein as a key step in cell invasion; similar findings in the related Plasmodium falciparum, the malarial parasite, recently have been reported (89), which suggests that Rhomboids are potential targets for treating infections by these deadly pathogens.

Most recently, the first crystal structures of an I-CLiP have been reported by three different research groups, all on the E. coli Rhomboid GlpG (90–92). These structures show remarkable similarities and important differences that provide insight into how this class of membrane-embedded protease carries out hydrolysis in the lipid bilayer. The structures all reveal that the key serine and histidine implicated as the catalytic dyad indeed are coordinated with each other and lie at a depth within the membrane consistent with where Rhomboids cleave their substrates.
transmembrane substrates (Fig. 10). A cavity is open to the periplasmic space with the catalytic dyad at the bottom of this opening, and this cavity contains multiple water molecules. How substrate enters this cavity is not entirely clear, but the position of the transmembrane domain 5 varies in the different structures and the movement of this domain can provide a space through which substrate may reach the catalytic dyad. Indeed, one reported structure contains a bound lipid in this space (S2) with the phosphate group residing near the Ser–His dyad and a key Asn residue that may contribute to the oxygen hole that stabilizes intermediates and transition-states during serine protease catalysis. These exciting structural findings validate the molecular and biochemical studies on Rhomboids and suggest that such approaches have been providing true mechanistic insight into the workings of other I-CLiPs. Moreover, these structures offer details that inspire specific hypotheses about how Rhomboids handle substrates to hydrolyze transmembrane domains.

Perspective

I-CLiPs are membrane-embedded enzymes that hydrolyze transmembrane substrates, and the residues essential to catalysis reside within the boundaries of the lipid bilayer. These enzymes seem to recapitulate the mechanisms of soluble proteases, and the first crystal structures of an E. coli Rhomboid support this notion, at least for the serine I-CLiPs. All I-CLiPs would be predicted to contain an initial substrate docking site, but to date evidence for such a docking site has been provided only for γ-secretase. The I-CLiPs discovered so far each play critical roles in biology and are regulated closely, but the means of control vary. They all are involved in cell signaling but do so in a variety of ways. Membrane topology seems to dictate the types of substrates that can be cleaved, but this concept remains speculative. Most I-CLiPs seem to require helix-breaking residues near the cleavage sites of their substrates, although γ-secretase may be a notable exception.

Critical remaining issues include the identity of substrates for the I-CLiP family members whose roles are unknown. For instance, although an entire family of PSHs and Rhomboids may be a notable exception.

Acknowledgment

I would like to acknowledge a postdoctoral fellow in my lab, Dr. Raquel Lieberman, for rendering details that inspire specific hypotheses about how Rhomboids handle substrates to hydrolyze transmembrane domains.

Zinc-dependent metalloproteases constitute a large family of enzymes, part of the protease superfamily. Fundamental to the structural integrity and catalytic activity of metalloproteases is the presence of both zinc and calcium ions in the structure of the protein. This article will focus on matrix metalloproteinases that are involved in extracellular matrix (ECM) catabolism and serve as important enzymes in many aspects of biology, ranging from cell proliferation, differentiation, and proliferation to cancer, tumor metastasis, inflammation, and other pathologic states. Despite their key role in many normal and pathologic processes, the molecular mechanisms by which zinc-dependent proteases hydrolyze their physiologic substrates are only known partly. Recent theoretical analyses have suggested reaction models for which limited and controversial experimental evidence exists. Here we will discuss the importance of quantifying the biophysical properties and the structural dynamic behavior of these enzymes to reveal their underlying molecular mechanisms. Such molecular knowledge holds promise in providing the basis for the novel design of specific antagonists as drug candidates for these important enzymes. In addition, we will discuss the use of real-time spectroscopic tools for studying the reactive metal sites in these enzymes.

Introduction

Metalloproteinases catalyze the hydrolysis of the peptide bond, which is the most stable chemical bond in nature (1, 2). Thermo-dynamic analysis of its hydrolysis reveals that although the free energy is relatively low, ∼2.4 kcal/mol, and the spontaneous reaction is exothermic, the scissile bond cleavage is hindered by a high-activation energy barrier of ∼20 kcal/mol (3). Thus, it may have taken 400 years to achieve the spontaneous bond cleavage in the absence of enzymes. Remarkably, metalloproteinases accelerate peptide bond hydrolysis by a factor of 10^16, which enables this process to be completed within milliseconds (4).

The zinc-dependent metalloproteases comprise a large family of enzymes with a wide variety of biologic roles. For example, important metalloproteases for cell viability include the bacterial metalloendopeptidase thermolysin, the digestive exopeptidases, carboxypeptidase A or B, and the matrix metalloproteinases (MMPs) (Table 1). MMPs are members of the metzincin superfamily of greater than 770 zinc endopeptidases, which includes astacins, serinelysins, adamalysins, leishmanolysins, and snapalysins. Metzincins are characterized by an absolutely conserved methionine residue C-terminal to the third histidine in the consensus sequence HEXXHXXGXXH/D, where the histidine residues chelate a catalytic zinc ion. Because of the extensive experimental and theoretical literature available, we will deliberately limit our discussion to MMPs that act within the extracellular matrix (ECM) milieu. A ample evidence

Astacins, bacterial serralysins, matrix metalloproteinases (MMPs), ADAMs (a disintegrating and metalloproteinase), ADAMTS (a disintegrating and metalloproteinase with thrombospondin motifs). MMPs are involved in the catabolism of extracellular matrix (ECM) molecules and the activation of other MMPs; they also promote several cell surfaces and serve as soluble regulators of cell behavior in bioactive molecules. The ADAMs are major ectodomain sheddases; they release a variety of cell surface proteins, including growth factors, cytokines, cell adhesion molecules, and receptors. ADAMs can also cleave and remodel components of the extracellular matrix.
exists on the role of MMPs in normal and pathologic processes, including embryogenesis, wound healing, inflammation, arthritis, connective tissue diseases, inflammation, cardiovascular and autoimmune diseases, and cancer (6-14). The MMP family consists of more than 25 enzymes, with differences in substrate preference, domain structure, and sequence homology. As depicted in Fig. 1, MMPs are multidomain proteins with a signal peptide, a "pro" domain that maintains enzyme latency until it is removed or disrupted, and a catalytic domain that is common to the entire family. Additional domains observed in different MMP structures include fibronectin-type III-like, hemopexin-like, and transmembrane domains (15, 16). MMPs catalyze the hydrolysis of peptide bonds of a large range of biologic substrates, including collagen, gelatin, fibronectin, elastin, growth factors, cytokines, and chemokines. Notably, the broad association between MMP peptide hydrolysis activity and several serious diseases has made MMPs an attractive target for developing novel drugs aimed at inhibiting MMP activity (17).

In MMPs, the hydrolysis of a peptide bond is mediated by a catalytic zinc ion that resides in a structurally conserved catalytic cleft of the enzyme. Zinc is the second-most abundant transition metal in biology, after iron. It plays structural, chemical, and regulatory roles in biologic systems and is an essential ingredient at the active site in many enzymes (18, 19). Zinc plays a role in gene expression, stabilizes the structure of proteins and nucleic acids, preserves the integrity of subcellular organelles, participates in the transport process, and plays important roles in viral and immune phenomena (20). Moreover, zinc exhibits flexible coordination geometry and facilitates fast ligand exchange, and it is a Lewis acid with intermediate polarizability lacking redox activity (5). All the above characteristics give zinc its versatility, which enables it to form different types of chemical and bonding interactions. The families, motifs, enzymology, and protein structures containing one or two zinc ions have been discussed (5, 18, 21).

The structural and chemical knowledge regarding enzymatic peptide cleavage in zinc-dependent metalloproteinases is limited, and experimental evidence is controversial, partly because the zinc atom is spectroscopically silent and hence difficult to study using conventional spectroscopic and analytical tools (20). In addition, most structural and biochemical studies carried out so far were limited to nondynamic structure/function characterization, thus preventing qualitative and quantitative analysis of the evolving intermediates formed during peptide cleavage mediated at the catalytic zinc-binding site. Most of our mechanistic knowledge comes from theoretical calculations derived from crystal structures. Unfortunately, this process results in controversial proposals as to how proteases hydrolyze their peptide substrates. Thus, in the absence of direct experimental tools that would enable us to characterize the reaction in real time, it will be difficult, not to say impossible, to elucidate the underlying reaction mechanisms.

Here we will discuss the progress achieved so far in our mechanistic understanding of peptide hydrolysis reactions by metalloproteinases. We will focus on the need for comparative structure-function analyses of individual metalloproteinases to reveal the reaction mechanisms. Finally, we will describe new frontiers in the biophysics and chemistry of metalloproteinases and the application of such studies to reveal directly reaction mechanisms and their relevance to drug discovery.

**Structures of Available Matrix Metalloproteinases**

To date, the crystal structures of 12 different MMPs have been solved. Full structures were obtained for MMP-1 (2CLT), MMP-2 (1CK7), and MMP-7 (1MMP). As for the rest, only the catalytic domains in the presence of different inhibitors were determined. The hemopexin-like domains of MMP-2 (1RTG), MMP-9 (1TV), and MMP-13 (1PEX) were crystallized, and structures were determined separately. Nuclear magnetic resonance (NMR) structures of the catalytic domains of MMP-1 (1LYK), MMP-2 (1HOV), MMP-3 (1UMS), MMP-12 (1YCM), and MMP-13 (1UEB) have also become available.

The overall structures of all MMP catalytic domains known so far are very similar (Fig. 2). These MMP catalytic domains are shaped like an oblate ellipsoid, with a small active-site cleft, harboring the catalytic zinc ion, notched into the flat ellipsoid surface. The active site cleft is defined by helix Hb, which provides two histidine residues that coordinate to the catalytic zinc ion, and the catalytic Glu in between, all belonging to the zinc-binding consensus sequence HEXXH (GXXH) (5, 22, 23). The active-site helix ends at a Gly residue, where the peptide chain bends, presenting the third zinc-liganding His. The zinc ion also coordinates to a water molecule that...
Metalloproteinases, Biophysics and Chemistry of

**Figure 2** Ribbon structure of the MMP catalytic domain. The catalytic domain of MMP-8 (1ZP5) is superimposed with the catalytic domains of MMP-3 (green) (1HY7), MMP-12 (yellow) (1UTT), MT1-MMP (orange) (1AQ0), and MT3-MMP (pink) (1RM8); only the active site-conserved motif is shown for clarity. The catalytic and structural zinc (center and top) and the two calcium ions are displayed as red and blue spheres, respectively.

is used to hydrolyze the peptide bond of the substrate (see the discussion in the next chapter). The water molecule is also held in place by the side chain of the active site Glu. Another basic feature of the MMP active site is the presence of three substrate-binding subsites. The surface of the protease that can accommodate a single side chain of a substrate residue is called the subsite. Subsites are numbered S1–Sn upward toward the N terminus of the substrate (nonprimed sites) and S1’–Sn’ toward the C terminus (primed sites), beginning from the sites on each side of the scissile bond. These subsites accommodate the side chains of the peptide to be cleaved, and the local structural characteristics and electrostatic environment of the individual subsites effectively determine the specificity of the substrate.

A detailed description of the fine structural differences between different MMPs can be found in recent reviews and publications (12, 15, 24). More relevant to the current article are the insights gained from integrating structural data obtained by different methods, more specifically by comparing X-ray structures (possibly more than one) with the solution structures obtained from NMR, to obtain a structural model that is beyond a single structural datum. Examples can be found in recent studies done by Rush et al. on MMP-1 and MMP-13 (25) and Bertini et al. on MMP-12 (26); both looked into the structure of these different MMPs complexed with various inhibitors by using both NMR and X-ray techniques. The backbone generalized order parameter (S2), a parameter related to the amplitude of fast (picosecond to nanosecond) movements of NH vectors, peak multiplicity, and weak or missing peaks, suggested active site mobility of inhibitor-free MMP-1 when compared with the structure of the inhibited enzyme. The data indicated that a slow conformational change in the active site results in a concerted motion of helix hB and the zinc-ligated histidines. Furthermore, the presence of an inhibitor that binds by chelating zinc effectively removes this motion, while maximizing the interaction of the inhibitor with the enzyme. The mobility of the random coil region in the vicinity of the active site was maintained even in the presence of a bound inhibitor. On the other hand, a comparison of the crystal structures of three MMP-12-inhibitor complexes indicated that the conformational heterogeneity observed is largely independent of the type of inhibitor. These studies have shown that flexibility/conformational heterogeneity in crucial parts of the catalytic domain is the rule rather than an exception in MMPs, and its extent may be underestimated by inspection of one X-ray structure.

**Reaction Mechanisms of Metalloproteinase-Mediated Peptide Hydrolysis**

All proteinases achieve catalysis by providing a favorable electrostatic environment where the chemical reaction occurs. The bottleneck is the formation of the nucleophile, which in turn, attacks the carbonyl of the peptide that is properly located at the binding site and thus initiates bond cleavage (Scheme 1). A II well-characterized proteinases are categorized, based on the nature of the most prominent functional group at the active site, into one of four families: serine, cysteine, aspartic, and metalloproteinase. Cysteine proteinases use a low pKa cysteine as a reactive nucleophile (27); serine proteases use the serine hydroxyl as the catalyst in conjugation with a hydrogen bond network that allows the general base catalysis (28, 29); a catalytically active diad of aspartates facilitates hydrolysis in aspartic proteinases, and metalloproteinases use zinc to promote catalysis.

The mechanism by which metalloproteinases execute catalysis has been of interest for many years. Most studies focused on carboxypeptidase A and thermolysin-like proteases for which extensive structural, chemical, and biochemical data are available. The first peptide hydrolysis mechanisms to be proposed...
were based on the available X-ray structures that have facilitated establishing structural models for the different reaction steps (30). Crystallographic analyses of enzyme-inhibitor complexes were used to reveal how enzymes interact with their substrates. Suitably chosen inhibitors were used to provide structural models for various stages in catalysis, including the Michaelis complex, transition states, and products. A classical example of a complex between an enzyme and a substrate analogue was described by Shomah et al. (31). In this study the X-ray crystal structure of the complex between carboxypeptidase A (CPA) and 5-aminoo-(4-butyrylcarboxy)l-2-benzyl-4-oxo-6-phenyl-hexanoyl (BBP), the ketomethyl enzyme substrate analogue of the peptide substrate N-[(4-butyrylcarboxy)-6-phenylalanine] in peptide hydrolysis (32, 33). A second alternative pathway for peptide cleavage by carboxypeptidase-A proposed by Lipscomb and MocK by performing semiempirical theoretical calculations (43). The proton transfer step to the nitrogen of the peptide, following the nucleophilic attack of the peptide carbonyl group by a hydroxide, was calculated to be rate limiting. It was shown that under kinetic control both reactions are feasible; however, a calculated thermodynamic enthalpy difference of ~20 kcal/mol indicated that the reaction path suggested by Lipscomb is more stable than the other.

Biochemical studies and enzyme modification work, including mutagenesis of active site residues, zinc ion substitution, steady-state kinetics with different types of substrates, O18 exchange studies and others, together with the X-ray data, led to the proposition of two major types of hydrolysis mechanisms. The first mechanism to be proposed soon after the first crystal structure of carboxypeptidase A was published was the direct nucleophilic attack (also called the "Zinc-carbonyl mechanism" or "acyl pathway") on the peptide carbonyl by the conserved active site Glu resulting in the formation of an anhydride intermediate. A cumulative evidencing from O18 exchange studies during the late 1960s and 1970s have ruled out the involvement of an anhydride intermediate in peptide hydrolysis (32, 33). A second type of mechanism proposed is the general-acid-general-base (GAGB) mechanism (the "Zinc-hydroxide mechanism" or the "promoted water pathway") in which a water molecule initially attacks the carbonyl while, or after, losing a proton. This mechanism results in the formation of a gem-diol intermediate (34-36). Alternative paths for the GAGB mechanism were proposed and can be categorized into two groups. One alternative, following Christianson and Lipscomb (37), suggests that the substrate binds directly to the zinc ion while not replacing the water molecule that occupied the fourth coordination site of the zinc in the native structure. This water molecule is activated by the metal ion or by the conserved active site Glu (or both); it loses a proton and attacks the peptide carbonyl. According to this mechanism, the zinc ion has two roles: polarizing the carbonyl group of the substrate and facilitating the deprotonation of the water nucleophile. The second GAGB mechanism, following MocK and Zhang (38), suggests that the substrate carbonyl binds to the zinc ion and is activated by a nucleophilic attack initiated by a water molecule that is deprotonated by the C-terminal carboxylate of the substrate itself, not by the conserved binding site Glu or by the zinc ion. In the latter, the role of zinc is minimized to the polarization of the carbonyl group of the substrate only, and the conserved active site Glu is not given any active role. Mock and Zhang's (38) and MocK and Tsay's (39) proposed mechanism was based on enzyme kinetic experiments that showed significant pH dependencies of the inhibition constants of transition-state analog inhibitors. However, several studies implied the importance of the active site Glu residue in achieving the enzymatic activity. Mutagenesis studies show that all of the active site residues, only the modification of active site Glu residue completely abolishes catalysis (40, 41).

As observed in other systems, the obvious difficulty in elucidating reaction mechanisms based on static structural snapshots subsequently initiated structural-dynamic theoretical studies of metalloproteases. The active site chemistry of zinc-dependent enzymes has been studied using a variety of theoretical approaches. For example, mixed quantum mechanical/molecular calculations and classical molecular dynamics simulations have been employed, especially studies using density functional methods on redox-active metal centers (42).

Because of the availability of detailed structural information, the majority of theoretical studies focused on carboxypeptidase A and thermolysin-like proteases, and only one study investigated the mechanism of peptide hydrolysis by human MMP-3. Recently, Klithain-Vardi et al. compared the two GAGB alternative pathways for peptide cleavage by carboxypeptidase-A proposed by Lipscomb and MocK by performing semiempirical theoretical calculations (43). The proton transfer step to the nitrogen of the peptide, following the nucleophilic attack of the peptide carbonyl group by a hydroxide, was calculated to be rate limiting. It was shown that under kinetic control both reactions are feasible; however, a calculated thermodynamic enthalpy difference of ~20 kcal/mol indicated that the reaction path suggested by Lipscomb is more stable than the other.

Pelmenschikov and Siegbahn investigated the mechanism underlying peptide hydrolysis by human MMP-3 via quantum chemical methods (3) using the crystal structure of the inhibited enzyme with the transition state analogue pipieridin sulfonamide inhibitor as the structural reference. The importance of the weakly bound water molecule as a potent electrophile for the zinc-coordinated substrate oxygen was revealed by reducing the activation barrier by about 5 kcal/mol. Furthermore, the conserved active site Glu residue was confirmed to play a key role by acting as a base during the reaction water deprotonation. Interestingly, the zinc ion was shown to retain pentacoordinated geometry during the reaction, with distorted trigonal bipyramidal coordination, whereas a tetrahedral coordination sphere was suggested for the final product (Fig. 3). Remarkably, the formation of a pentacoordinated zink-protein complex is followed by distinct electronic transitions mediated by water and the conserved Glu residue. Essentially a single-step reaction mechanism has been obtained with an energy barrier of 13.1 kcal/mol. This work provided novel structural-dynamic insights into the reaction mechanism governing peptide hydrolysis. Naturally, such a theoretical model must be confirmed by experimental results, especially when the use of long-lived inhibitor-enzyme complexes (instead of enzyme-substrate complexes) may provide only structural models for different stages.
in catalysis. Such models are obviously not true intermediates; hence, in the absence of supporting experimental data, the obtained results must be interpreted with caution.

After more than 40 years of research on the structure/function of metalloproteases, tremendous advances in our understanding have been achieved. A consensus exists regarding the basics of peptide hydrolysis: 1) A water-formed hydroxyl nucleophilically attacks the peptide backbone carbonyl, 2) a carbonyl oxyanion is formed and coordinates the catalytic zinc ion, 3) the backbone amide is protonated, and 4) the zinc ion reduces the activation energy of this reaction by polarizing the oxygen carbonyl and by coordinating the negative charge of the intermediates evolving throughout the reaction (44). However, our understanding is far from complete, and several major questions remain unanswered: Is the catalytic water molecule bound to the zinc ion before proton abstraction by the conserved active site Glu base catalyst? Is the water-bound molecule pushed and replaced by the carbonyl oxygen of the peptide, or is a penta-coordinative complex consisting of both water and peptide formed? Finally, although it is thought that protein function depends on protein flexibility, precisely how the molecule dynamics contribute to the catalytic mechanism remains unclear. Although internal protein dynamics are connected intimately to enzymatic catalysis, enzyme motions linked to substrate turnover remain largely unknown. Because of the scarcity of adequate experimental tools, the field is presented with a great challenge regarding quantification of protein conformational transitions during catalysis. In the next section we discuss the use of a real-time multidisciplinary structural-spectroscopic approach to study reactive sites in metalloproteases during catalysis.

**Time-Resolved, Structural Analysis—Correlation of Reaction Kinetics–Protein Conformations and Evolution of Reaction Intermediates**

Enzymes are flexible molecules whose structures exhibit dynamic fluctuations on a wide range of timescales. This inherent mobility of a protein fold was shown to be manifested in the various steps constituting the catalytic cycle. The nature of this linkage between protein structure movement and function undoubtedly is complex and might involve the formation of a coupled network of interactions that bring the substrate closer, orient it properly, and provide a favorable electrostatic environment in which the chemical reaction can occur (45). However, the molecular details that link the catalytic chemistry to key kinetic, electronic, and structural events have remained elusive because of the difficulties associated with probing time-dependent, structure-function aspects of enzymatic reactions.
Figure 4  A schematic representation of the experimental approach for time-resolved XAS measurements. XAS provides local structural and electronic information about the nearest coordination environment surrounding the catalytic metal ion within the active site of a metalloprotein in solution. Spectral analysis of the various spectral regions yields complementary electronic and structural information, which allows the determination of the oxidation state of the X-ray absorbing metal atom and precise determination of distances between the absorbing metal atom and the protein atoms that surround it. Time-dependent XAS provides insight into the lifetimes and local atomic structures of metal–protein complexes during enzymatic reactions on millisecond to minute time scales. (a) The drawing describes a conventional stopped-flow machine that is used to rapidly mix the reaction components (e.g., enzyme and substrate) and derive kinetic traces as shown in (b). (b) The enzymatic reaction is studied by pre-steady-state kinetic analysis to dissect out the time frame of individual kinetic phases. (c) The stopped-flow apparatus is equipped with a freeze-quench device. Sample aliquots are collected after mixing and rapidly freeze into X-ray sample holders by the freeze-quench device. (d) Frozen samples are subjected to X-ray data collection and analysis.

By using this argument, a single crystal structure generally is insufficient to enable the elucidation of enzymatic catalysis reaction mechanisms at an atomic level of detail. Typically, the catalytic cycle involves a series of intermediates and transition states, and for many of these states, no detailed structural information is available. Furthermore, determining the energies of the various stationary points in the cycle is highly nontrivial, from a theoretical or experimental point of view. For these reasons, as of today, a complete characterization of reactive enzymatic chemistry is unavailable.

Concentrating on metalloenzymes, we have developed a strategy based on stopped flow X-ray absorption spectroscopy (XAS) to elucidate in detail the molecular mechanisms at work during substrate turnover (Fig. 4). Importantly, XAS provides local structural and electronic information about the nearest coordination environment surrounding the catalytic metal ion within the active site of a metalloprotein in solution. When the X-rays hit a sample, the electromagnetic radiation interacts with the electrons bound in the metal atom. The radiation can be scattered by these electrons, or it can be absorbed, thereby exciting the electrons. At certain energies, the absorption increases drastically and gives rise to an absorption edge. Such edges occur when the energy of the X-ray beam is just sufficient to cause excitation of a core electron of the absorbing atom (in this case zinc) to a continuum state, for example, to produce a photoelectron. The energies of the absorbed radiation at these edges correspond to the binding energies of electrons in the K (or L) shell of the zinc ion. When the photoelectron leaves the absorbing atom, its wave is backscattered by the neighboring atoms (in this case, the zinc-bound protein atoms). The constructive and destructive interference of these outgoing photoelectrons with the scattered waves from atoms surrounding the central metal atom gives rise to the extended X-ray absorption fine structure (EXAFS) oscillation pattern. Spectral analysis of the edge and EXAFS regions yields complementary electronic and structural information. Analysis of the edge region enables us to determine the oxidation state of the X-ray absorbing metal atom (in other words, the position of the absorption edge), whereas analysis of the EXAFS region provides precise information regarding distances between the absorbing metal atoms and the...
The design and production of highly selective inhibitors for this highly structurally homologous catalytic sites residing in these enzymes may aid in the process of discovering new drugs. One may therefore inquire as to whether structurally homologous enzymes display similar dynamic profiles during binding and catalysis or whether functionally related enzymes that share similar structures can be distinguished based on their dynamic nature.

So far only a few reports have indicated distinct differences regarding the reaction chemistry and mechanisms among highly structural homologous MMP active sites. Studies by Fasciaglione et al. demonstrate that the protein-linked behavior (in different pH environments) for $k_{cat}$, $K_m$, and $K_i$ is different among various MMPs, including MMP-9 and MMP-2. In addition, the authors found that to have a fully consistent description of the enzymatic action of the various MMPs, they had to apply three protonating groups that are involved in the modulations of substrate interaction and catalysis. These results indicate that the details regarding active site modifications at the zinc ion are different for various MMPs and are of enormous importance for elucidating the mode of action of individual MMPs. Similar conclusions may be drawn from the recent study of Solomon et al. (52), which compares the inhibition mode of the mechanism-based inhibitor SB-3CT with the highly homologous catalytic sites of TACE and MMP-2. Importantly, it was shown that the zinc ion of TACE is different regarding the length of the $Zn$-$S(SB-3CT)$ bond distance and the total effective charge of the catalytic zinc ion. In addition, SB-3CT inhibits TACE in a noncompetitive fashion by inducing marked conformational changes in the structure. For MMP-2, SB-3CT behaves as a competitive inhibitor, and no significant conformational changes are observed. Examination of the second shell amino acids surrounding the catalytic zinc ion of these enzymes indicated that the active site of TACE is more polar than that of MMP-2 and other MMPs. On the basis of these results, it was proposed that, although a seemingly high structural similarity exists between TACE and MMP-2, these enzymes are significantly and other MMPs. On the basis of these results, it was proposed that, although a seemingly high structural similarity exists between TACE and MMP-2, these enzymes are significantly diverse in the electronic and chemical properties within their active sites.

Comparative Structural-Dynamic Analysis and Its Relevance to Drug Discovery

Conducting real-time structural analysis on metalloproteinases was found to be a novel and effective approach for studying the highly structurally homologous catalytic sites residing in these enzymes via comparative structural–dynamic analysis. Remarkably, such high structural homology (Fig 2.) often hinders the design and production of highly selective inhibitors for this enzyme family. Thus, linking distinct protein conformational transitions with catalysis of individual enzymes is of great importance for revealing the molecular mechanisms underlying individual enzymes that may aid in the process of discovering new drugs. One may therefore inquire as to whether structurally homologous enzymes display similar dynamic profiles during binding and catalysis or whether functionally related enzymes that share similar structures can be distinguished based on their dynamic nature.

Overall, these results raise the possibility that the highly structural analogous catalytic centers in MMPs exhibit different structural conformations and electronic behavior during catalysis and inhibition. Yet, an open question is as follows: How can such differences be quantified? Comparative TRXAS analysis might provide the answer. By performing a comparative TRXAS analysis of functionally related enzymes that share similar structures, it might be possible to identify the intermediate states, the active site key amino acid residues, and the thermodynamic parameters of individual enzymes that are critical for efficient catalysis as well as for inhibition. Furthermore, the mobility so fundamental to protein structures is a major complicating factor to the general structure-based drug design approach. MMP’s active site dynamics were observed in the NMR structures of inhibitor-free MMP-1, MMP-3, and...
MMP-13 (25). The impact on drug design was clearly illustrated in MMP X-ray structures that demonstrate the ability of side chains in the active site to undergo conformational changes that accommodate a bound inhibitor. Thus, an inhibitor predicted to have poor inhibition activity against a specific MMP based on a poor fit in the specificity pocket (S1) may be accommodated in the binding site because of the mobility of the protein. By applying the time-resolved structural–dynamic approach to study catalysis as well as inhibition pathways, we can characterize unique reaction intermediates at the active site, as well as distinct conformational intermediates of the protein side chains, and can provide critical information about protein flexibility that additionally might be used for the design of potent and selective inhibitors. This approach departs from traditional drug design strategies used for metalloenzymes that target the catalytic metal with potent zinc-chelating peptidomimetic compounds.

Concluding Remarks

Here we reviewed the advances that have been made in the field of metalloproteinase chemistry over the past decades. Focusing on the critical need to understand better the chemical workings of these biologic machines at atomic detail, we noted the importance of quantifying the biophysical properties and the structural dynamic behavior of these enzymes to reveal their underlying molecular mechanisms. A fundamental challenge for better understanding the functioning of proteins/enzymes is to characterize proteins as dynamic objects. In this article, we have presented novel experimental approaches that go beyond static structures, with the ultimate goal of characterizing macromolecules reacting at atomic resolution. More specifically, we have combined time-resolved X-ray spectroscopy with X-ray crystallography, enzymology, and computational mechanistic investigations to determine the structures and chemistry of transient intermediates as they evolve during the catalytic cycle. Our recent progress in the field of MMP reaction mechanisms demonstrates how a combined approach that uses a variety of biophysical techniques advances our fundamental understanding of complex biologic molecules.

Relatively few design principles underlie the mechanisms of inhibition of a myriad range of protease inhibitors. Protease inhibitors tend to be competitive and to compete with substrate binding, either through direct competition or deformation of the protease active site. Although protein inhibitors can gain potency through the burial of a large surface area and specificity through contacts with specific exosites, small-molecule inhibitors primarily gain potency through interactions with the catalytic machinery of the enzyme and specificity through interactions with the substrate binding sites. Incorporation of these design principles into chemical probes and drugs have improved greatly our ability to create potent and specific protease inhibitors.

Proteolytic enzymes are ubiquitous in all organisms and constitute 2–4% of the encoded gene products. They are critical for diverse biologic processes such as digestion, blood clotting, host defense, pathogenic infection, viral replication, wound healing, and disease progression, to name a few. Because proteases trigger an irreversible event—the cleavage of a protein—their activity must be controlled tightly. Dysregulated proteolytic activity causes a disruption in the homeostatic balance of a biologic system and can result in any number of poor biologic outcomes. As a result, nature has developed several strategies for inhibiting proteases to control proteolysis. Similar approaches have often been employed in the development of synthetic protease inhibitors. To a large extent, the same design principles that work well for naturally occurring protease inhibitors work well for inhibitors developed in the laboratory.

This review aims to survey the mechanisms by which protease inhibitors function. To achieve this goal, we have divided inhibitors into categories based on their mechanism, to illustrate that a relatively small number of design principles can be combined to develop new and effective protease inhibitors. These divisions are somewhat arbitrary, as many inhibitors could be grouped into several classes. Because of space limitations, the list of mechanisms is not exhaustive in its treatment of all inhibitors, but it aims to be illustrative of the many ways proteases can be inhibited. Although beyond the scope of this review, it is also important to keep in mind that spatial and temporal regulation of proteolytic activity is critically important in biology. Beyond the many levels of transcriptional and translational control, proteases are expressed as inactive (or nearly inactive)zymogens, and they are not activated until needed. Furthermore, they are often localized to cellular structures such as the cell membrane or stored in specific organelles such as lysosomes or granules to minimize unwanted proteolysis. Background on the four major classes of proteases (serine, cysteine, aspartic, and metalloproteases) as well as on the basic mechanisms of enzyme inhibition is abundant; please consult the “Further Reading” list at the end of the chapter. Figure 1 provides an overview of basic substrate and protease nomenclature, whereas Tables 1 and 2 list many of the inhibitors discussed in the text (1–21).

Mechanisms of Naturally Occurring Protein Protease Inhibitors

Competitive inhibition

Standard mechanism

The most thoroughly studied mechanism of protein protease inhibitors is that of the standard mechanism (or Canonical or Laskowski mechanism) inhibitors of serine proteases (1) (Fig. 2). Standard mechanism inhibitors include the K unit, Kunitz, and Bowman-Birk family of inhibitors and bind in a lock-and-key fashion. All standard mechanism inhibitors insert a reactive loop into the active site of the protease, which is complementary to the substrate specificity of the target protease and binds in an extended β-sheet with the enzyme in a substrate-like manner. While bound to the protease, the “scissile bond” of standard mechanism inhibitors is hydrolyzed very slowly, but products are not released and the amide bond is re-ligated. The standard mechanism is an efficient way to inhibit serine proteases, and it is thus used by many structurally

Protease Inhibitors, Mechanisms of

Figure 1  Diagram of a protease active site. A protease cleaves a peptide at the scissile bond, and has a number of specificity subsites, which determine protease specificity. Substrates bind to a protease with their non-prime residues on the N-terminal side of the scissile bond and their prime-side residues C-terminal to the scissile bond. The catalytic residues determine the class of protease. Serine, cysteine, and threonine proteases hydrolyze a peptide bond via a covalent acyl-enzyme intermediate, and aspartic, glutamic and metalloproteases activate a water molecule to hydrolyze the peptide bond in a non-covalent manner.

disparate protein scaffolds to create potent inhibitors. However, most standard mechanism protease inhibitors tend to have relatively broad specificity within subclasses of serine proteases. For example, the bovine pancreatic trypsin inhibitor (BPTI) efficiently inhibits almost all trypsin-fold serine proteases with P1-Arg specificity, and it can also inhibit chymotrypsin (Phe P1 specificity) with a $K_i$ of 10 nM (22).

Standard mechanism inhibitors are classified strictly as inhibitors of serine proteases. There have been reports of inhibitors of other classes of proteases that have similar mechanisms to those of standard mechanism inhibitors, though. Initial studies on the streptomyces metalloprotease inhibitor (SMPI) suggest that it inhibits the metalloprotease thermolysin through a substrate-like binding mechanism (2). Similarly, staphostatin B, a cysteine protease inhibitor from Staphylococcus aureus, binds in a substrate-like manner in the active site of diphosphopain cysteine proteases. However, staphostatin B has a glycine P1 residue, which adopts a backbone conformation that seems to prevent nucleophilic attack of the scissile bond (3).

Noncanonical competitive inhibitors

Several protease inhibitors bind in the active site of the protease, but they do not bind in a substrate-like manner, instead forming interactions with the catalytic residues in a noncatalytically competent manner, and thus, they are not considered standard mechanism inhibitors.

The cystatins, which are a superfamily of proteins that inhibit papain-like cysteine proteases, are a classic example of these inhibitors. The cystatins (Fig. 3) insert a wedge-like face of the inhibitor that consists of the protein N-terminus and two hairpin loops into the V-shaped active site of a cysteine protease. The N-terminal residues bind in the S3-S1 pockets in a substrate-like manner, but the peptide then turns away from the catalytic residues and out of the active site. The two hairpin loops bind to the prime side of the active site, which provides most of the binding energy for the interaction. Thus, both the prime and the nonprime sides of the active site are occupied, but no interactions are actually made with the catalytic machinery of the enzyme (23).

Tissue inhibitors of metalloproteases (TIMPs)

TIMPs inhibit matrix metalloproteases (MMPs) via a two-step mechanism in a manner somewhat similar to that of cystatins (Fig. 3). While the N-terminal residues of cystatins bind to the nonprime side of cysteine proteases, TIMPs N-termini bind in the P1-P3 pockets of the protease, coordinate the catalytic...

1. Inhibition constants for covalent inhibitors are given as $k_{	ext{inact}} / K_i$.

2. Values are for D-Phe-Pro-(4AngGly)P(OPh)$_2$NH$_2$.

Zn$^{2+}$ ion, and exclude a catalytic water molecule from the active site. Meanwhile a second loop of the TIMP binds in both the P3 and the P2 pockets, and it binds to the N-terminus of the MMP. Despite the similarities in mechanistic architecture between TIMPs and cystatins (hairpin loops and N-terminal residues in substrate binding pockets), TIMPs interfere with the catalytic machinery of MMPs by chelating the catalytic Zn$^{2+}$ (5).

The ascaris pepsin inhibitor-3 is an aspin, which is a family of inhibitors of aspartic proteases that protect worms from host gastric enzymes. Like the cystatins, the aspins are competitive inhibitors that bind in the substrate-binding subsites, but they do not have an amide bond that is available for nucleophilic attack. They gain most of their inhibitory activity by inserting their 3 N-terminal residues in the S1'–S3' subsites of the protease (6) (Fig. 3). Although cystatins and aspins do not interact directly with the catalytic residues of cysteine proteases, many protease inhibitors, such as cytotoxic T-lymphocyte antigen 2-α and the cathepsin propeptides, do interact with the catalytic machinery of the enzyme, but they do so in a proteolitically noncompetent manner. These inhibitors have long lengths of peptide that span the active site cleft in the reverse orientation (from C-terminus to N-terminus).
Competitive inhibition with exosite binding

Several protease inhibitors are competitive, and they bind in the protease active site, but also they have secondary binding sites outside the active site, which are critical to inhibition. Exosite binding provides two major benefits: 1) It increases the surface area of the interaction, which leads to a greater affinity, and 2) it can provide a greatly increased amount of specificity.

Ecotin is a dimeric serine protease inhibitor found in E. coli, which effectively inhibits many trypsin fold serine proteases, regardless of primary specificity, and is thought to protect E. coli from attack by host proteases. It inhibits serine proteases through a standard mechanism at a primary binding site, but it also has a secondary binding site that can contribute 5 kcal/mol of binding energy to the very tight enzyme-inhibitor complex (Fig. 4). Surprisingly, the individual binding energies of the two binding sites are not additive; the effect of the secondary binding site on affinity was found to be inversely proportional to the strength of binding at the primary site. The secondary binding site seems to provide compensatory effects that can overcome suboptimal binding at the primary binding site. If binding at the primary site is not optimal, the secondary binding interaction tends to be stronger. In this case, the secondary binding site actually makes the inhibitor less specific, or more capable of inhibiting a broad range of proteases, and it protects bacteria from several host proteases (25).

Many blood-meal parasites have developed specific inhibitors of clotting enzymes to prevent blood clotting of the host. These inhibitors often use mechanisms of inhibition described above, but they have domains that bind to protease exosites and provide...
a high degree of target specificity. Rhodnin, which is a thrombin inhibitor from the assassin bug Rhodnius prolixus, has two Kazal-type inhibitory domains and a common standard mechanism to inhibit serine protease inhibitor domains. Although the N-terminal domain binds and inhibits via the standard mechanism, the second Kazal-type domain has evolved to bind to exosite I on thrombin. The binding affinities of the individual domains are roughly additive, and the resultant inhibitor has a K<sub>i</sub> of 0.2 mM and exquisite specificity for thrombin (26). Hirudin, from Hirudo medicinalis and tick anti-coagulant peptide (TAP) from Ornithodoros moubata, specifically inhibit thrombin and factor Xα (Xkα), respectively (8, 27). They do so by similar mechanisms; they insert the N-terminal tail of the protein in the protease active site (analogous to apo-1 inhibition of pepstatin), whereas the body of the inhibitor binds to specific exosites, either exosite I on thrombin (Fig. 4) or the autolysis loop on FXa. Because the secondary binding sites are specific to each clotting factor, the inhibitors show a high degree of specificity.

Inhibitor of apoptosis (IAP) proteins inhibit caspases, which are dimeric cysteine proteases responsible for programmed cell death, or apoptosis. IAPs are multidomain proteins that have multiple BIR domain repeats. One family member, the X-linked IAP (XIAP), has three BIR domains, and uses different BIR domains to inhibit different caspases through disparate mechanisms. The XIAP-BIR2 domain and its N-terminal peptide extension are responsible for inhibition of the “executioner” caspases-3 and caspase-7. The N-terminal peptide extension binds in the active site in reverse orientation, which is similar to the inhibition mechanism of cathepsin proteases. Meanwhile, the BIR2 domain binds to an exosite on the caspase dimer (Fig. 4). The BIR2 domain needs both exosite-binding capability and the N-terminal extension to inhibit efficiently its target caspsases (28).

The XIAP-BIR3 domain is responsible for inhibition of the initiator caspase-9, but it functions via a completely different mechanism. The BIR3 domain is an allosteric inhibitor of caspase-9: it binds to the dimer interface and prevents dimerization and subsequent activation of the enzyme (9) (Fig. 4). Caspase-9 is at the apex of the apoptotic cascade that leads to the activation of executioner caspases. As such, BIR3 can provide an extra level of regulation by sequestering monomers in a catalytically inactive conformation and ensuring that no unwanted caspase-9 activity occurs.

Activity-dependent inhibition
Sometimes called suicide substrates, several protein inhibitors of proteases require proteolytic activity of the enzymes they inhibit, which leads to either covalent modification of the enzyme or release of charged groups that inhibit the catalytic machinery. In either case, this sort of activity-dependent inhibition is powerful and fundamentally different than the competitive mechanisms outlined above; the inhibitor acts as a substrate and then uses the enzymes’ catalytic machinery to trap and then inhibit the enzyme.

The potato metallocarboxypeptidase inhibitor (and metallo-carboxypeptidase inhibitors from leeches and ticks) inhibit carboxypeptidase B after a proteolytic processing event. These inhibitors bind their four C-terminal residues in the protease subunits S3–S1'. The C-terminal residue, Gly39, is processed, but it does not diffuse from the active site. In a type of product inhibition, Gly39 instead stays in the S1' pocket and chelates the catalytic Zn<sup>2+</sup> – which creates a protease-activated reversible inhibitor (29).

The inhibitor α-2-macroglobin and its relatives are responsible for clearing excess proteases from plasma. Less an inhibitor than a “protease sponge,” α2-M is a large protein, which is a tetramer of about 600 kD that has four ball loops on its surface. When a protease cleaves one of these reactive loops, it triggers a conformational change, and the protease becomes cross-linked to the inhibitor through surface lysines and arginines. The enzyme is still active; small-molecule substrates can still be hydrolyzed by proteases complexed with α2-M, but protein substrates are occluded from the active site and the complex is cleared quickly from the blood (30).

The serpins are a family of inhibitors that inhibit covalently and irreversibly primarily serine proteases (1) (the serpin CmL inhibits cysteine proteases). Serpins have a large reactive center loop (RCL) that is presented to a protease for proteolytic processing. During productive cleavage of the RCL, the N-terminal half of the RCL, which is still attached to the protease as an acyl–enzyme intermediate, is inserted into a β-sheet in the body of the inhibitor. The resulting free-energy change is enough to translocate the protease (which is still covalently attached to the RCL) to the distal side of the inhibitor, and the resulting steric collisions completely deform the protease active site, which thus leaves the protease tethered to the serpin and completely inactive (Fig. 5). The serpin inhibitory mechanism is completely irreversible. Because of the drastic nature and irreversibility of this mechanism, serpins function as protease scavengers, which protect cells and tissues from unwanted proteolytic activity. These types of inhibitors, which take advantage of the catalytic activity of a protease to trap and inhibit the enzyme, are effective and powerful inhibitors. As discussed in the following section, many small-molecule irreversible and protease-activated inhibitors have been developed that rely on the same fundamental mechanism of using enzyme activity to trap and inactivate a protease.

Mechanisms of Small-Molecule Protease Inhibitors
To develop both tools for chemical biology and possible drugs, significant effort has gone into the discovery and development of small-molecule protease inhibitors. The two critical components in the design of a protease inhibitor, and indeed any enzyme inhibitor, are potency and specificity. It has been challenging to create potent and specific protease inhibitors for clinical use because of the high degree of similarity among families of proteases, but even relatively nonspecific protease inhibitors have been invaluable in teasing apart the roles proteases play in complex biologic processes. A novel effective strategy for developing protease inhibitors has been to take peptide substrates that target the active site and to
Protease Inhibitors, Mechanisms of  

Serpin Inhibition of a Serine Protease

Figure 5  Serpins inhibit serine proteases by binding a reactive center loop in the active site, forming a covalent complex with the enzyme, undergoing a large conformational change, and irreversibly distorting the active site of the protease.

Figure 6  An effective strategy for developing synthetic protease inhibitors is to combine a peptide or peptidomimetic specificity element with a warhead that binds (either reversibly or irreversibly) to the catalytic machinery of a protease.

and have been developed into therapeutic agents; the proteosome inhibitor Bortezomib (Fig. 7) has been approved for the treatment of multiple myeloma (31).

Class-specific transition-state analogs have been developed to interfere specifically with the catalytic residues of each class of proteases. Aspartic protease inhibitors have long been designed around substrate polypeptides, with a replacement of the scissile amide bond with a noncleavable transition-state isostere. The first specific inhibitor for aspartic proteases, pepstatin A, was discovered from Actinomycetes, as an inhibitor for pepsin. It also showed strong inhibitory activity against several other aspartic proteases. Pepstatin A is a peptide, but the scissile bond is replaced with a statine group [(3 S,4 S)-4-amino-3-hydroxyl-6-methyl heptanoic acid)] (Fig. 7). Instead of a trigonal carbonyl, statines have a chiral hydroxyl group, which give it the ability to mimic the tetrahedral state of the substrate transition state (32). Other transition state isosteres, including homostatines, hydroxyethenies, diols, and phosphinates have been developed for aspartic proteases, and functionalizing these classes of inhibitors with peptidomimetic groups to bind to the substrate binding regions, has resulted in the development of numerous drugs, most notably HIV protease drugs (33) (Fig. 7).

Transition-state inhibitors

Transition-state inhibitors stably mimic the transition state of the enzymatic reaction, and thereby interact with the substrate-binding and catalytic machinery of the enzyme in a low-energy conformation. Transition-state analogs are competitive, reversible inhibitors, although some have extremely low Kᵢ's and very slow off-rates. All proteases activate a nucleophile to attack a carbonyl, which leads to the formation of a tetrahedral intermediate that then collapses to form the enzyme products—two peptides. Thus, synthetic small molecules that mimic the tetrahedral intermediate of the protease reaction are attractive transition-state analogs. A classic class of protease transition-state inhibitors uses a boronic acid scaffold (4, 10). Boronic acid adopts a stable tetrahedral conformation in the protease active site that is resistant to nucleophilic attack. Boronic acid inhibitors, which are derivatized with different specificity elements, have been developed against every class of protease and turn them into inhibitors by interfering with the catalytic machinery of the enzyme (Fig. 6). Although sometimes hampered by specificity problems, these types of inhibitors can be useful biologic probes, can help validate an enzyme as a drug target, and can act as lead compounds for additional drug development.

Transition-state inhibitors stably mimic the transition state of the enzymatic reaction, and thereby interact with the substrate-binding and catalytic machinery of the enzyme in a low-energy conformation. Transition-state analogs— inhibitors that stably adopt a conformation that mimics the transition state of an enzyme-substrate intermediate—have traditionally been an effective way to develop inhibitors. In addition, several irreversible inhibitors have been developed that bind covalently to cysteine, serine, and threonine proteases, which are proteases that form a covalent acyl–enzyme complex during peptide bond hydrolysis.

Aldehyde Transition State Inhibitor

Statine Group of Pepstatin

Hydroxyethylene Group of Idinavir

Figure 7  Various transition-state protease inhibitors. Bortezomib is an approved drug for the treatment of multiple myeloma. It is a boronic acid analog that inhibits the proteosome, a threonine protease. The boronic acid moiety can adopt a tetrahedral conformation in the active site. Pepstatin is a peptidyl aspartic acid inhibitor. The reactive statine group binds to the catalytic machinery, and the chiral hydroxyl group of the statine mimics the tetrahedral geometry of the transition state. Idinavir is an approved HIV 1 Protease inhibitor that binds to the active site via a hydroxyethylene transition state isostere. Aldehydes are also transition state analogs, which are susceptible to nucleophilic attack. In cysteine, serine and threonine proteases, this results in a covalent, reversible inhibition mechanism.

substrate analogs that form a covalent hemiacetal linkage (or hemithio acetal linkage in cysteine proteases) between the aldehyde of the inhibitor and the active site nucleophile of the protease. The resulting tetrahedral adduct mimics the transition state of the normal enzymatic reaction. The tetrahedral intermediate can collapse and regenerate a free inhibitor; therefore, the enzyme-inhibitor complex is in equilibrium with a free enzyme and a free inhibitor. Many aldehyde inhibitors, such as leupeptin, are nonspecific and inhibit many proteases, but medicinal chemistry efforts taking advantage of unique protease specificity elements have led to several very specific aldehyde protease inhibitors (10). Transition-state inhibitors, especially those with peptidyl or peptidomimetic extensions, are slow-binding inhibitors, and the protease-inhibitor binding mechanism includes one or more weakly bound intermediates before the formation of the tightly bound E•I complex. This slow-binding inhibition is a hallmark of inhibitors that bind in the active site in a substrate-like manner. In this way, transition-state analogs mimic the association mechanism of many of the naturally occurring protein inhibitors described above, particularly standard-mechanism inhibitors.

Irreversible inhibitors

Serine, cysteine, and threonine proteases, which perform a direct nucleophilic attack on the scissile bond (as opposed to the water-mediated nucleophilic attack performed by aspartic and metalloproteases) are excellent targets for covalent, irreversible inhibitors. Although pharmaceutical companies have been hesitant to pursue covalent inhibitors as drugs because of concerns over their possible cross-reactivity and potential for the development of an unwanted host immune response, it has been shown that a high degree of specificity can be built into these compounds. Furthermore, they are excellent biologic tools: when functionalized with fluorescent dyes or biotin, covalent inhibitors are effective imaging and pull-down reagents and they have been used to determine the presence and roles of
active proteases in many biologic systems. Powers and coworkers (15) authoritatively reviewed these inhibitors, with detailed analysis of their mechanisms of action, structure-activity relationships, and their effectiveness in vivo.

Covalent irreversible inhibitors of cysteine, serine, and threonine proteases are capable of either alkylating or acylating their target enzymes (Fig. 8). Alkylating agents are very effective cysteine protease inhibitors, and they include chloromethyl ketones, fluoromethyl ketones, diazomethyl ketones, acyloxymethyl ketones, epoxides, and vinyl sulfones. The nucleophilic active site cysteine attacks an activated carbon and forms an irreversible carbon-sulfur bond. Because the active site serine of serine proteases is generally less nucleophilic than the corresponding catalytic cysteine, alkylating agents primarily target cysteine proteases. An exception is the chloromethyl ketones, which are capable of inhibiting serine proteases, although they have a slightly different mechanism of inhibition. After a nucleophilic attack of the carbonyl of the inhibitor, the inhibitor alkylates the catalytic histidine. The enzyme can then be deacylated, but the alkylation of the catalytic histidine results in a covalently bound inhibitor.

Inhibitors that acylate proteases present a carbonyl bond for nucleophilic attack, but because of either the poor electrophilicity of the acyl-enzyme intermediate or the inhibitor adopting a conformation unfavorable for deacylation, the enzyme reaction coordinate is trapped in the acyl-enzyme intermediate state. These inhibitors can inhibit both serine and cysteine proteases, and they can generally be sorted into two classes. Peptidyl-acylating agents have a peptide-like specificity element to target the inhibitor to a specific enzyme, but they have a modified scissile bond, such as an aza-group, a carbamate, or an acyl hydroxamate, that are resistant to deacylation. Several heterocyclic acylating agents also exist, such as isocoumarins, β-lactams, cephalosporins, and penems, which have their carbonyl groups enclosed in a ring structure. During nucleophilic attack, the ring is sprung open, and geometric or electrostatic effects can cause a stable acyl–enzyme complex.

Figure 8. Irreversible inhibitors of proteases. Serine and cysteine proteases can be acylated by aza-peptides, which release an alcohol, but cannot be deacylated due to the relative unreactivity of the (thio) acyl-enzyme intermediate. Reactive carbons, such as the epoxide of E64, can alkylate the thiol of cysteine proteases. Phosphonate inhibitors form covalent bonds with the active site serine of serine proteases. Phosphonates are specific for serine proteases as a result of the rigid and well-defined oxyanion hole of the protease, which can stabilize the resulting negative charge. Mechanism-based inhibitors make two covalent bonds with their target protease. The cephalosporin above inhibits elastase (23). After an initial acylation event that opens the β-lactam ring, there are a number of isomerization steps that eventually lead to a Michael addition to His57. Therefore, even if the serine is deacylated, the enzyme is completely inactive.
Protease Inhibitors, Mechanisms of

Phosphonates (Fig. 8) and sulfonates represent a third class of covalent irreversible inhibitors. These inhibitors adopt a stable tetrahedral geometry and are covalently bound transition-state analogs. They often have a peptide-like specificity element, and the electrophilicity of the leaving groups can be modified to tune the reactivity of the inhibitor. These inhibitors are specific for serine proteases, because the serine protease active site has a well-defined oxyanion hole, which stabilizes the transition-state mimic.

A final group of covalent small-molecule inhibitors of proteases are mechanism-based inhibitors. These inhibitors are enzyme-activated irreversible inhibitors, and they involve a "two-hit" mechanism that completely inhibits the protease. Some isocoumarins and β-lactam derivatives have been shown to be mechanistic inhibitors of serine proteases. A classic example is the inhibition of elastase by several cephalosporin derivatives developed at Merck (Fig. 8). The catalytic serine attacks and opens the β-lactam ring of the cephalosporin, which through various isomerization steps, allows for a Michael addition to the active site histidine and the formation of a stable enzyme–inhibitor complex (34). These mechanism-based inhibitors require an initial acylation event to take place before the irreversible inhibitory event. In this way, these small molecules have an analogous mechanism of inhibition to the naturally occurring serpins and α-2-macroglobin, which also act as suicide substrates.

Reversible, competitive inhibitors

Concerns about toxicity, cross-reactivity, and immunogenicity have hampered the development of irreversible therapeutics that target proteases. Therefore, many noncovalent, reversible, competitive protease inhibitors have been developed. Most of these inhibitors interact with both the catalytic residues and the substrate binding sites, as binding to either individual element usually will not provide enough specificity or potency. In some cases, such as small-molecule peptidomimetic inhibitors of thrombin (35) (Fig. 9), binding to the substrate binding sites of the protease has provided sufficient potency, but this is likely because of the buried nature and unique specificity of the thrombin active site. In most cases, though, binding to the catalytic machinery provides potency, whereas the substrate binding sites provide opportunities for specificity. Metalloprotease inhibitors provide a representative example of reversible, competitive, small-molecule inhibitors. Metalloproteases have been the targets of multiple large-scale drug discovery efforts, and many inhibitors have been developed, with varying results. Many inhibitors of the angiotensin-converting enzyme (ACE) have been brought to market to combat hypertension and myocardial infarction. Conversely, the first generation of matrix metalloprotease (MMP) inhibitors failed in clinical trials for the treatment of cancer, in part because the inhibitors had cross-reactivity with other metalloproteases. The common
Inhibitors Developed via Protein Engineering

Protein engineering has allowed for the development of many new protease inhibitors with increased potency and specificity and for diverse mechanisms of action. Because of the relatively shallow active sites, homology, and broad specificity of many proteases, larger molecules are attractive inhibitors in that they can bury more surface area during binding and hopefully gain more potency and specificity.

One strategy has been to improve the specificity of naturally occurring protease inhibitors, either through rational design or via phage display. Mutations to residues that interact with the protease active site have drastic effects on inhibitor affinity, but specificity tends to be gained through evolution of secondary interactions. The standard mechanism serine protease inhibitors ecallin (40) andeginol (41) have been refined at both of their primary and secondary interaction sites, which drastically improve their specificity for a single protease. Although not altering the primary mechanism of action of the inhibitors, the engineering of secondary binding sites gives these inhibitors a mechanism of inhibition similar to that of the anticoagulant inhibitors such as hirudin, and greatly improves inhibitor specificity.

A similar strategy has been to develop polypeptide-based inhibitors of proteases. Typically consisting of 10–20 amino acids, and often containing disulfide bonds to rigidify the inhibitors and decrease the entropic cost of binding, constrained peptides have been developed to inhibit aspartic, cysteine, serine, and threonine proteases. Although peptides are not ideal drug molecules because of their susceptibility to proteolysis, the relatively small size of constrained peptides allows for the creation of extremely diverse libraries. Furthermore, they are amenable to the incorporation of non-natural or D-amino acids, which thus greatly increases potential diversity. The mechanisms of action of these inhibitors have sometimes mimicked known biologic mechanisms, and sometimes they have been completely novel. Constrained peptide phage display libraries have yielded standard mechanism inhibitors of the serine protease chymotrypsin (42) and urokinase-type plasminogen activator (uPA) (43) with moderate potency and specificity. Cyclic peptides have also been shown to inhibit competitively the aspartic protease renin, and they are thought to bind to the enzyme in a substrate-like manner (44).

Constrained peptides that mimic natural inhibitors are essentially a reduction of naturally occurring inhibitors to just their reactive elements. But several allosteric peptide inhibitors have been developed that have novel intramolecular inhibition, which reveal information about enzyme function, and suggest new ways of regulating proteolysis. Constrained peptide libraries have yielded two extremely potent exosite inhibitors of the clotting enzyme factor VIIa (FVIIa) (45, 46). The two inhibitors are bound to two different sites outside of the active site of the enzyme, and they have unique mechanisms of inhibition. One inhibitor, A-183, functioned by forcing a loop near the active site into an inactive conformation and by occluding substrate binding to the enzyme. The other inhibitor, E-76, was a non-competitive inhibitor of FVIIa’s natural substrate, factor X, and...
it seems to work by locking the enzyme in a zymogen-like conformation. In another example of allosteric inhibition, an α-helical peptide was designed to disrupt—and thus prevent activation of—the dimerization of the protease from Kaposi’s sarcoma-associated herpes virus (KSHV) (47). The mechanisms of inhibition of these peptide inhibitors clearly overlap with those of both small-molecule and naturally occurring allosteric inhibitors; namely they lock their target enzymes in an inactive, closed, or zymogen state. The allure of allosteric inhibition is founded in the idea that it is possible to find multiple sites on an enzyme to regulate activity, and these molecules have done this by using established mechanisms to inhibit new proteases. A third approach has been to mature specific protease inhibitors on other natural protein scaffolds, such as antibodies. Antibody inhibitors have been raised against metalloproteases (48), cysteine proteases (49), and serine proteases (50), and to this point, characterized inhibitors have either been monoclonal antibodies raised from hybridomas or from phage-display libraries. The mechanisms of inhibition are familiar; protease antibody inhibitors either interfere with multimerization (and thus activation) of a protease (51), bind to loops and protein–protein interaction sites to occlude substrate binding, or bind in the protease active site. The benefit of using antibodies as inhibitors is that they are exquisitely specific—antibodies have evolved to bind specifically to their antigen—and are useful biologic tools for imaging and in vivo experiments. And that they have been able to mimic the mechanism of inhibition of naturally occurring protease inhibitors suggests that specific antibody inhibitors can be developed for many proteases.

Conclusions and Future Directions

Relatively few design principles underlie the mechanisms of inhibition of an awe-inspiring range of protease inhibitors. Protease inhibitors tend to compete with substrate binding, either through direct competition or deformation of the protease active site. Although protein inhibitors can gain potency through the burial of a large surface area and specificity through contacts with specific exosites, small-molecule inhibitors primarily gain potency through interactions with the catalytic machinery of the enzyme and specificity through interactions with the substrate binding sites. The search for novel modes of enzyme control, such as allosteric regulation, is particularly exciting, with the hope that these regulatory sites will be more amenable to the design of specific inhibitors. The design of new inhibitors based on these principles is critically important. A great deal remains to be learned about the role of proteases in biology, and effective, reliable chemical tools are needed to tease apart these processes. The failure of MMP inhibitors in clinical trials stemmed from toxicity problems (cross-reactivity that could be eliminated with more specific inhibitors), and just as critically, an incomplete understanding of which MMP was important to what stage of cancer growth and metastasis. A more thorough understanding of the role of individual proteases might have alleviated some of these issues. Because of their critical roles in biology, proteases are attractive drug targets. Although only a handful of anti-protease drug targets have approved inhibitors on the market thus far (DPPIV, HIV, ACE, and prostate-specific protease inhibitors), several drug discovery efforts that target proteases are underway, which aim to treat, for example, viral infections, parasitic infections, thrombosis, osteoporosis, neurodegenerative diseases, and cancer. As our understanding of the targets and the design principles of their inhibitors improve, more treatments are sure to follow (7, 12–14, 16–21).

doi: 10.1002/9780470048672.wecb534

Serine proteases are among the largest group of proteolytic enzymes in the human genome that play vital roles in health and disease. Regulation of their activity in vivo is mediated by a diverse group of serine protease inhibitors. An overview of the interplay between serine proteases and their inhibitors is provided. In addition, approaches to characterize this relationship are discussed with subsequent emphasis on how such measures apply to pathologies that result from defect of serine proteases or their inhibitors.

Cylindrical life is brokered on the activity of proteins, and, in turn, control over their concentration and state is vital. Enzymes that hydrolyze peptide bonds, the proteases, are therefore critical ingredients of the genome. Proteases may act as nonspecific agents of digestion or high-selectivity mediators of posttranslational modification. Proteases are a diverse group of enzymes. Over 180 phylogenetically distinct families of proteases have been identified by the MEROPS protease classification system on the basis of protein fold and additionally separated through phylogenetic relationship (1). Of these families, the largest contingent comprises serine proteases, which are named based on their application of the hydroxyl group of a serine side chain as catalytic nucleophile. Regulation of protease function in vivo is mediated by a minimum of 90 families of protease inhibitors. Together, these two groups control biological functions both inside and outside of the cell. Genetic defects in either protease or inhibitor, therefore, can result in significant pathology with potentially multiple biological pathways impacted.

Serine Proteases and their Inhibitors

More than a third of all known proteolytic enzymes are serine proteases (2). The family name stems from the nucleophilic serine residue within the active site, which attacks the carbonyl moiety of the substrate peptide bond to form an acyl-enzyme intermediate. Nucleophilicity of the catalytic serine is commonly dependent on a catalytic triad of aspartic acid, histidine, and serine—commonly referred to as a charge relay system (3). First observed by Blow over 30 years ago in the structure of chymotrypsin (4), the same combination has been found in four other three-dimensional protein folds that catalyze hydrolysis of peptide bonds. Examples of these folds are observed in trypsin, subtilisin, prolyl oligopeptidase, and ClpP protease. Many other enzyme families use the same catalytic triad, such as asparaginases, esterases, acylases, and β-lactamases (5). Mutagenesis of the aspartic acid to alanine impacts peptide bond hydrolysis to a greater extent than ester hydrolysis, which indicates that a complete catalytic triad is required for the hydrolysis of the stronger peptide bond. It should be noted that several serine protease families use a dyad mechanism in which lysine or histidine is paired with the catalytic serine. Yet, other serine proteases present novel catalytic triads, such as a pair of histidines combined with the nucleophilic serine. In nearly all reported cases, the active site serine can be rendered inactive by generic inhibitors such as diisopropylfluorophosphate and phenylmethanesulfonyl fluoride. We will focus on the most abundant serine protease and serine protease inhibitor families in the human genome. The reader is also referred throughout the text to other recent and more expansive reviews and to the MEROPS database for a more detailed description of the impressive diversity of serine protease and inhibitor structure, function, and activity.

A typical genome contains 2–4% of genes that encode for proteolytic enzymes. The entire complement of peptidases within a genome is referred to as the degradome (6). Of these proteases, a select subset of peptidases underwent considerable gene duplication and divergence. The trypsin-like serine peptidases (Clan PA Family 51 Subfamily A in MEROPS nomenclature) are the largest group of homologous peptidases in the human genome responsible for various critical biological processes. Similar degradation composition is observed in all vertebrates, which indicates that expansion of the S1A peptidase family occurred before emergence of the lineage roughly 450 million years ago. Of 699 peptidases in humans, 178 are serine peptidases, and 138 of them belong to the S1A peptidase family. The chymotrypsin-like fold of the S1A peptidase family presents an ideal catalytic platform that enables high turnover, substrate...
selectivity, and various modes of regulation in a package readily combined with additional protein domains.

Clan PA: S1 peptidases—the trypsins

Chymotrypsin-fold proteases are the largest family of peptidases known. Pioneering studies used digestive enzymes such as trypsin and chymotrypsin, which cleave polypeptide chains on the C-terminal side of a positively charged side chain (arginine or lysine) or large hydrophobic residue (phenylalanine, tryptophan, or tyrosine), respectively. In Schechter & Berger nomenclature, the peptide bond hydrolyzed lies between the P1 and P1’ residues of the substrate and is numbered increasingly toward both the N- and C-terminal directions. Interaction occurs in the similarly numbered subsite (S) in the protease. For example, the S2 pocket binds the P2 residue, which is the second amino acid on the N-terminal side of the scissile bond. Determination of other polypeptide sequences of several serine proteases revealed a large family of enzymes. Trypsins and chymotrypsins belong to the S1A family of clan PA, whereas the S1B family comprises various bacterial proteases and the HTRA subgroup of proteases responsible for intracellular protein turnover.

Both subfamilies share the two β-barrel architecture. Two Greek-key β-barrels comprise the chymotrypsin fold and are homologous in a nontraditional manner (Fig. 1a). β-strand topology of the fold reveals a Greek-key architecture in both barrels, yet this topology originates from sequences that run in the opposite direction.

Hence, the two halves of the structure are mirror images in protein fold space. Both barrels are functionally partitioned with one end involved in catalysis and a second in regulation. The active site lies in the cleft between them.

The conventional catalytic triad in S1 family peptidases mediates peptide bond hydrolysis (Fig. 1b). Hydrogen bonding between residues Asp-102 and His-57 (chymotrypsin numbering is used) facilitates abstraction of the proton from Ser-195 and creates a potent nucleophile. Stabilization of the catalytic triad is mediated through a network of additional hydrogen bonds provided by several highly conserved amino acid residues that surround the triad, particularly Thr-54, Ala-56, and Ser-214, and buttress it along a disulfide bridge between residues 42 and 58. The reaction proceeds via pair tetrahedral intermediates. The first step, nucleophilic attack by the serine yields an oxoacyl tetrahedral intermediate stabilized by the backbone amides of Gly-193 and Ser-195. Collapse of the tetrahedral intermediate generates an acyl-enzyme intermediate, and stabilization of the newly created N-terminus is mediated by His-57, Hartley and Kilby provided evidence for the acyl-enzyme intermediate in 1954 (9). In these initial experiments, a pre-steady state burst of product correctly identified that a bond to a hydroxyl moiety.

The second half of the reaction is a reversal of the first step, in which a water molecule displaces the free polypeptide fragment and attacks the acyl-enzyme intermediate. Again, the oxoacyl intermediate stabilizes the second tetrahedral intermediate, and collapse of this intermediate liberates a new C-terminus in the substrate. Central to the regulation of peptidase activity is zymogen activation.

Activation of most chymotrypsin-like serine peptidases requires proteolytic processing of an inactive zymogen precursor protein. Cleavage of the proprotein occurs at an identical position in all known members of the family: between residues 15 and 16. The nascent N-terminus induces conformational change in the enzyme through formation of an intramolecular electrostatic interaction with Asp-194 that stabilizes the oxoacyl enzyme and substrate-binding site. Zymogen activation provides a powerful mechanism of regulation that endows temporal control over protease activity, an ability to escape premature enzyme inhibition, and places these enzymes within the context of chains of proteolytic events. Many proteases of the coagulation and immune pathways are regulated more through allosteric mechanisms that involve monovalent cations (Na+), divalent cations (Ca2+), glycosaminoglycans, and protein cofactors (11). These properties derive from the structure of the chymotrypsin fold and combine to produce proteolytic networks responsible for key biological processes responsible for human health.

Several vital processes rely on clan PA peptidases. Chief among them are blood coagulation and the immune response, which involve cascades of sequential zymogen activation. In both systems, the chymotrypsin-fold peptidase domain is combined with one more associated protein domains, including apoproteins, CUB, EGF, fibronectin, kringles, sufl, and von Willebrand factors. These protein domains are on the N-terminus as an extension of the propeptide segment of the peptidase. Such a trend of N-terminal-associated domains in the S1A peptidase family is common across all forms of life. The domain architecture pairs well with the zymogen activation mechanism, which liberates the proper N-terminus to enable catalytic activity. Often, the associated protein domains remain attached to
the peptidase domain through a covalent disulphide bond on the opposing surface of the protease active site. Many associated domains are entirely encoded by a single exon in their peptidase gene and suggest an important role for exon shuffling during molecular evolution of clan PA.

S1 peptidases in the human genome are, for the most part, primary selectivity toward amino acids in length derived from the two-domain architecture. An N-terminal proline and hydroxyproline residues from peptides (20). Substrate selectivity for peptides shorter than 30 amino acids in the digestive system signals proinflammatory responses typi- cally mediated by trypsin-like S1 peptidases. Trypsinases are major components in secretory granules of mast cells that are unique among clan PA peptidases because of their homote- trameric quaternary structure (13). Like trypsin, trypsinases mediate proinflammatory signaling through protease-activated recep- tors 2, yet definition of other substrates in health and disease states remain elusive. Matriptases are membrane-bound S1 pep- tidases that bear primary substrate selectivity similar to trypsin (14). A gain, physiological substrates of this subfamily of pep- tidases are largely unknown, yet high gene expression levels for matriptases are associated with various cancer types. Simi- lar association with cancer has led to great interest in the large family of kallikreins (15), a family commonly known for its role in regulation of blood pressure through the kinin system (16). The enzymes are mediators of directed apoptosis by natural killer cells and cytotoxic T cells that play key roles in the defense against viral infection (17). Notably, unique among clan PA is the primary selectivity of granzymes toward acidic residues in the P1 position of the substrates. Of the wide diversity of pro- teases in clan PA Family S1, the mediators of immunity and blood coagulation have been particularly well studied.

Clan SC: peptidase diversity in the α/β fold

Clan SC peptidases are α/β hydrolase-fold enzymes that con- sist of parallel β-strands surrounded by α-helices. The α/β hydrolase-fold provides a versatile catalytic platform that, in additional to achieving proteolytic activity, can either act as an esterase, lipase, dehalogenase, haloperoxidase, lyase, or pro- oxidase hydrolase (18). Six phylogenetically distinct families of clan SC are known, and only four of them have known structure. Catalytic amenability of the α/β hydrolase-fold may underlie why clan SC peptidases are the second largest family of ser- ine peptidases in the human genome. Other mechanistic classes need not use the catalytic serine and instead use cysteine or glutamic acid (19). Clan SC peptidases present an identical geo- metry to the catalytic triad observed in clans PA and S1, yet this conformation is ordered differently in the polypeptide se- quence. Substrate selectivity develops from the α-helices that surround the central β-sheet core. Within clan SC, carboxypep- tidases from family S10 are unique for their ability to maintain catalytic activity in acidic environments. Nearly all serine pep- tidases have activity restricted within the range of neutral to alkaline pH. Many clan SC peptidases hydrolyze substrates on the C-terminal side of a proline residue with several excep- tions. Both endoproteolytic and exoproteolytic activities occur in clan SC, which contrasts the trend in other serine pepti- dase families in which members are primarily one or the other. For examples of differing selectivity in clan SC, pro- pyl oligopeptidase from family S9 cleaves peptide bonds within peptides, and prolyl aminopeptidase from family S9 cleaves peptide bonds within proteins (20). N-terminal proline and hydroxyproline residues from peptides (20). Substrate selectivity for peptides shorter than 30 amino acids in length derived from the two-domain architecture. An N-terminal seven-bladed propeller restricts access to the C-terminal α/β hydrolase domain and, in turn, the site of peptide bond hydrolysis (21). On the basis of their selectivity toward smaller peptides and not full-length proteins, clan SC pep- tidases are thought to be particularly important in cell signaling mechanisms.

In humans, clan SC peptidases are often associated with proline-specific N-terminal processing of peptides and proteins, yet many present a nonproteolytic function. S9 is the largest family clan SC peptidases with 43 homologs in the human genome. Of these homologs, prolyl oligopeptidase (POP) and dipeptidyl peptidase IV (DPP-IV) are the best characterized. The crystal structure of POP revealed the two-domain architecture and basis for substrate selectivity. Notably, no naturally occurring inhibitor of this family of proteases has been found. A pu- taive role for POP has been suggested in the metabolism of vari- ous neuropeptides (22). DPP-IV presents a similar two-domain architecture (23). DPP-IV is a transmembrane protein responsi- ble for processing hormones, growth factors, and neuropeptides. POP family peptidases have been identified in the human genome, and their biological roles remain to be uncovered. Of three S28 family peptidases in human, dipeptidyl peptidase II (DPP-II) catalyzes release of two N-terminal amino acids when proline or alanine is in the P1 po- sition. Eight S33 family peptidases in the human genome, however, many of them do not display peptidase activity. For example, several of these enzymes catalyze hydrolysis of epox- ide bonds into diols and play a role in detoxification or cellular signaling (24).

Clan SB: family SB—subtilisins

Clan SB peptidases are prevalent in plant and bacterial genomes, with few representatives in a given animal genome. However, these proprotein convertases are vital for protein processing in all metazoans. The archetype of clan SB is subtilisin. Subtilisin was originally discovered in the gram-positive bacterium Bacil- lus subtilis and like chymotrypsin was one of the earliest protein crystal structures determined (25). The catalytic triad of aspartic acid, histidine, and serine is found in the exact geometric orga- nization observed in the peptidases of clans PA and SC, yet the surrounding protein fold bears no similarity (Fig 2). Clan SB also contains a second family of peptidases S53, the serine endoproteases. In these peptidases, the histidine general base is substituted by a glutamic acid, and the tetrahedral intermediate is stabilized by a negatively charged carbonyl group from an aspartic acid
Serine Protease and Serine Protease Inhibitors

Figure 2 Subtilisin (PDB 1SCN) presents an identical catalytic triad to that observed in other serine proteases and enzymes yet within an entirely different protein fold.

Serine Protease Inhibitors

Over 90 phylogenetically distinct families of protease inhibitors have been classified by the MEROPS database. We will focus the current discussion on the most abundant and well-characterized groups.

Canonical mechanism: kunitz- and kazal-type inhibitors

In general, protease inhibitors interact with the peptidase in a canonical substrate-like manner with the protease. In this situation, three to four residues interact in an antiparallel β-sheet fashion within the enzyme active site. Many of these protease inhibitors are small proteins typically 30 to 120 amino acids in length (29). Often, these smaller proteases inhibitors contain many disulfide bonds. Many proteases have extremely high melting temperatures (≥80 °C) and retain their native conformation in the presence of strong chaotropes. Despite heterogeneity of sequence, each of these inhibitors presents a nearly identical conformation in reactive site loop that restricts proteolytic activity. In this process, the reactive site loop does not undergo conformational change when in complex with the protease and the P1 residue is positioned to place the carbonyl oxygen at a very short distance to Ser-195. The carbonyl oxygen, in turn, points toward the oxyanion hole that forms H-bonds with the amide groups of Gly-193 and Ser-195. The amide nitrogen of the P1 residue is directed toward the Oγ of Ser-195 not facing Ser-214 as typically observed in natural substrates. The latter change is thought to shorten during the catalytic cleavage process (30). The loop may be combined with other structural elements to mediate inhibition, including a β-hairpin following the loop or a disulfide bond in close proximity to the scissile bond. During interaction with the protease, the scissile bond remains intact and may undergo a slight deformation from planarity or a more distorted Michaelis complex depending on the enzyme and inhibitor pairing. Few specific contacts define the interaction between protease and inhibitor outside of the active site, where most are typically hydrophobic. In turn, composition of the reactive site loop contributes the most significant energetic in the binding process. Altering the P1 residue by mutagenesis, therefore, can be used to shift the inhibition profile dramatically. Lack of additional contacts ensures that most serine protease inhibitors regulate activity of multiple proteases in vivo.

MEROPS identifies Kunitz-type inhibitors as families I2 and I3, yet they seem to have developed separately in evolutionary history. Families I2 and I3 are referred to as “Kunitz-A” and “Kunitz-P” for their origin from animals and plants, respectively. Aprotinin, also known as bovine pancreatic trypsin inhibitor, was one of the first protease inhibitors identified and isolated by Kraut and coworkers in 1930. The I2 family is considerably more homogenous and thought to inhibit only S1 peptidases. In contrast, the I3 family is split into two phylogenetic groups, I3A and I3B, both of which typically inhibit S1 peptidases. In addition to the I3 inhibitor, was the...
complex of soybean trypsin inhibitor with trypsin by Sweet and colleagues (31). The structure presents a β-barrel architecture capped by a pair of β-strands stabilized by two disulfide bonds (Fig. 3). The physiologic function of the Kunitz-type proteases remains unknown for many family members other than those in man. Prevention against digestion or invasion from pathogens has been suggested based on a common abundance in seeds. In man, tissue factor pathway inhibitor is a key Kunitz-type inhibitor responsible for regulating blood clot formation. On the basis of their specificity, Kunitz-type inhibitors were among the first examined for therapeutic application. Aprotinin was approved for clinical application in coronary-artery bypass graft surgery in 1993. Fifteen years later, considerable controversy has developed over its use given an associated risk of mortality and the availability of less expensive lysine analogs that achieve the same goals (32).

Kazal-type inhibitors are classified as family 11 by the MEROPS database. The name is derived from pancreatic secretory inhibitor, which is now termed SPINK1, originally isolated by Kazal and coworkers in 1948. The SPINK family (serine protease inhibitor, Kazal) plays important roles in the digestive system, lungs, skin, and likely many other tissues in the body. Six SPINKs can be identified in the human genome, and each contains multiple repeats of the Kazal-type fold. Mutations in SPINK1 are associated with hereditary pancreatitis (33). Netherton syndrome is a rare disorder that affects the skin of patients and results in ichthyosiform dermatosis and hair shaft abnormalities. Patients with Netherton syndrome are found to have a mutation on chromosome 5 in the SPINK5 gene, which encodes a protein that is a serine protease inhibitor. Kazal-type domains are often found within a single polypeptide chain, they need not inhibit the same type of protease or protease specificity. For example, dog bikazin contains two Kazal-type domains in which one domain prefers trypsin, and the other prefers chymotrypsin.

Bait-and-trap mechanism: serpins

Serpins are found in all kingdoms of life, yet their presence in a given organism is not, which suggests the family has undergone significant gene transfer and loss. The family name was coined by Carrell and Travis as an acronym of serine protease inhibitor (36). Serpins are the most abundant form of serine protease inhibitor in the human genome. With the exception of fungi, all multicellular eukaryotes seem to possess one or more serpin genes. However, despite their ubiquity, few physiological functions are ascribed to serpins outside those known in man, and, in particular, they are associated with pathologies. Most serpins are irreversible inhibitors of serine proteases of the S1 family of peptides with select family members inhibiting S9 of subtilisins and chymotrypsin. Several members of the serpin family have lost their ability to act as inhibitors and acquired new functions such as ovalbumin and pigment epithelium-derived factor. The unique mechanism of protease inhibition by serpins has received considerable attention. Serpins consist of a conserved core of three β-sheets and eight or nine α-helices that act collectively in the inhibitory mechanism. As with the Kazal- and Kunitz-type inhibitors, the mechanism involves a surface exposed loop that is termed the reactive center loop (RCL). The RCL presents a short stretch of polypeptide sequence bearing the P1–P1' scissile bond. Like other serine protease inhibitor families, the P1 residue dominates the thermodynamics that govern the interaction between protease and inhibitor. Exposure of the P1 residue to solvent is typically brokered by 15 amino acids N-terminal to the P1 residue and 5 residues on the C-terminal “prime” side of the scissile bond. Evidence for dramatic conformational change in the inhibitory mechanism was first provided by the crystal structure of the cleaved form of α2-antitrypsin (37). In this structure and unlike the native form, the reactive center loop was not solvent exposed but occurred as an additional β-strand within the core of the structure. Dramatic conformational change of both inhibitor and protease is the most recognizable feature of the serpin mechanism (Fig. 4). A first formation of the Michaelis-Menten encounter complex, the reactive center loop is cleared, and an acyl enzyme intermediate is formed as in the normal serine protease catalytic mechanism. However, after bond hydrolysis, the RCL rapidly inserts into the central β-sheet of the serpin, which yields an overall stability enhancement to the inhibitor and traps the acyl-enzyme intermediate. It largely unknown how this change in conformation occurs. Several studies suggest the complex undergoes transient exchange between expelled and partially inserted states (38). Integration of the β-strand into the structure flips the protease from the “top” of the structure to the complete opposite side of the serpin. Because of this, the local environment of the catalytic triad is distorted and therefore cannot complete the catalytic cycle (39). When the process is finished, the previously adjacent P1 and P1' residues are separated by over 70 Å. During this process, the protease has been
Serine Protease and Serine Protease Inhibitors

Figure 4 A large conformational change defines the mechanism of serpin inhibition. Conversion of the Michaelis complex (PDB 1OPH) into cleaved trapped conformation (PDB 1EZX) traps the RCL of serpin into the \( \beta \)-strand core of inhibitor. A significant gain in stability, therefore, is imparted to the entire serpin structure.

converted from a metastable free state into a more energetically favored relaxed bound state. Serpins have a considerably lower melting temperature \((T_m \sim 60^\circ C)\) in isolation than when cleaved \((T_m >100^\circ C)\). Unrelated in sequence or structure, the macroglobulin family of protease inhibitors similarly applies scissile bond cleavage, yet the subsequent step involves entrapment of the protease in a cage-like architecture \((40)\). Although most serpins apply this mechanism to inhibit serine proteases irreversibly, a select group has been shown to act reversibly. For example, protein C inhibitor, also known as PAI-1, acts as a reversible inhibitor to the single-chain urokinase-type plasminogen activator. Moreover, several serpins are known to integrate their cleaved RCL into another serpin molecule in trans \((41)\). In turn, serpins can undergo polymerization, which becomes relevant in several pathological conditions.

Serpins play key regulatory functions in man. \( \alpha_1 \)-antitrypsin serves a major role in protecting the connective tissue of the lungs from leukocyte-released elastase. The C1 inhibitor restricts proteases of the immune system from unwanted proteolysis and inflammation. Two plasminogen activator inhibitors control fibrinolysis. Viral serpins have also been described that broker their survival and propagation through restricting these same proteolytic pathways. Control of blood clot formation is through antithrombin. However, unlike other serpin family members, the interaction between clotting factor protease and antithrombin is greatly facilitated by heparin or heparin sulfate glycosaminoglycans, which bind to the inhibitor to mediate this effect \((42)\). In turn, antithrombin is directed toward regulation of protease activity at cell surfaces such as the vascular endothelium, which display heparin in various forms.

Exosite recognition: hirudin and other anticoagulant molecules

Numerous strategies have evolved in different pathogenic and parasitic organisms to alter the coagulation cascade for their own benefit. Snake and leech venoms have yielded a plethora of serine proteases and serine protease inhibitors that bear this trait. Many inhibitors function through hijacking the macromolecular recognition regions in blood clotting factors, the earliest known example of which is hirudin, a 66-amino acid residue protein that is an extremely tight binding and selective inhibitor of the blood coagulation protease thrombin. Indeed, the use of leeches in medicine dates back to the Greeks in 200 B.C. However, it was not until 1884 that Haycraft isolated the anticoagulant agent from medicinal leech saliva and termed this agent hirudin. Selective and tight binding results from the cooperative binding at both the anion binding exosite responsible for fibrinogen recognition and active site of thrombin. Notably, unlike nearly all other protease inhibitors, active site recognition involves formation of a parallel \( \beta \)-sheet. Hirudin has been derivatized and modified in various ways to develop direct thrombin inhibitors. Two recombinant forms, lepirudin and desirudin, are available for clinical use to prevent deep-vein thrombosis after surgery and treat heparin-induced thrombocytopenia. However, various problems have limited their use, including bleeding problems,
Characterization of Protease-Inhibitor Interactions

Defining the selectivity and potency of an inhibitor relies on accurate characterization of the protease. In particular, values of $k_{\text{on}}$ and $k_{\text{off}}$ are readily obtained using basic enzymology and various commercially available chromogenic and fluorogenic substrates. Proteases act on a single substrate during the catalytic cycle. Therefore, models to interpret data follow classical descriptions of competitive, noncompetitive, and mixed inhibition. As with traditional enzymology, curve-fitting measures combined with graphical validation of data is suggested as a more accurate approach than the use of initial rates analysis. Use of IC₅₀ is to be avoided as the values of this measure are only a crude comparison between reversible inhibitors. For serine proteases, the use of irreversible inhibitors, such as chloromethyl ketones, are extremely useful for determining the amount of active protease in a given protein preparation. Many serine protease inhibitors form stable complexes with their target proteases that can be resolved via gel electrophoresis as a simple and effective means of visualization. However, many protease-inhibitor interactions require more advanced data treatment. Some examples include slow tight-binding mechanisms and higher-order stoichiometries of inhibition (44). Lastly, conformational change can be measured through various biophysical techniques including UV and fluorescence spectroscopy, circular dichroism, and isothermal titration calorimetry.

Serine Proteases and their Inhibitors

As illustrated above, the human genome encodes a large and diverse population of serine proteases and serine protease inhibitors. Design of small-molecule inhibitors to restrict proteolytic activity continues to garner attention in the pharmaceutical industry. Given the many related proteases in the genome, this task is particularly challenging. Early work focused on active site-directed therapies. However, as evidenced by the naturally occurring serine protease inhibitors, active site recognition enables the regulation of multiple protease targets. Minimization of unwanted side effects is a significant hurdle. More recent effort has sought the development of therapeutics that focus on other regions of the protease. The crucial role for such regions in biological systems is demonstrated by the blood coagulation and immune system proteases, in which macromolecular recognition is dependent on exosites and the allosteric communication of these regions with the active site. Diversity of proteases and inhibitors results in a wide range of pathologies that result from disruption in either serine protease or serine protease inhibitor. The earliest descriptions of such imbalances are within the blood coagulation cascade. For example, hemophilia B results from deficiency in coagulation factor IX. In contrast, excessive activation of immune system serine proteases produces inflammatory states. Inhibitors of serine protease inhibitors can have consequences on multiple biological systems. However, overlapping inhibition by multiple families of inhibitor can, in certain instances, lessen the severity of the pathology. Genetic abnormalities in the serpins have also been associated with polymerization and therefore belong to the category of conformational disease. Emphysema, cirrhosis, and thrombosis may result from such aberrant conformational transitions. Neutrophil may also play a key role in familial enchephalopathy because of the formation of inclusion body-like material. Understanding the molecular mechanisms of limited proteolysis and their regulation in vivo remains a challenging and insightful venue to improve human health.

Thrombin

Enrico Di Cera, Department of Biochemistry and Molecular Biophysics, Washington University Medical School, St. Louis, Missouri
doi: 10.1002/9780470048672.wecb678

Thrombin is a Na⁺-activated, allosteric serine protease that plays opposing functional roles in blood coagulation. Binding of Na⁺ is the major driving force behind the procoagulant, prothrombotic, and signaling functions of the enzyme, but is dispensable for cleavage of the anticoagulant protein C. The anticoagulant function of thrombin is under the allosteric control of the cofactor thrombomodulin. Thrombin exists in three forms, E*, E, and E:Na⁺, which interconvert under the influence of ligand binding to distinct domains. Transitions among these forms control key functional aspects of the enzyme.

Thrombin is a serine protease of the chymotrypsin family, which includes enzymes involved in digestion and degradative processes, blood coagulation, cell-mediated immunity and cell death, complement, fibrinolysis, fertilization, and embryonic development (1). Once generated in the blood from its inactive precursor prothrombin, thrombin plays two important and paradoxically opposing functions. It acts as a procoagulant factor when it converts fibrinogen into an insoluble fibrin clot that anchors platelets to the site of lesion and initiates processes of wound repair. This action is reinforced and amplified by activation of the transglutaminase factor XIII that covalently stabilizes the fibrin clot, the inhibition of fibrinolysis via activation of TAFI, and the proteolytic activation of factors V, VIII, and XI (2). In contrast, thrombin acts as an anticoagulant through activation of protein C (3). This function unfolds via an interaction with thrombomodulin, which is a receptor on the membrane of endothelial cells. Binding of thrombomodulin suppresses the ability of thrombin to cleave fibrinogen and PAR1, but it enhances -1,000-fold the specificity of the enzyme toward the zymogen protein C. Activated protein C cleaves and inactivates factors Va and VIIa, two essential cofactors of coagulation factors Xa and IXa that are required for thrombin generation, thereby downregulating both the amplification and progression of the coagulation cascade. In addition, thrombin is inhibited irreversibly at the active site by the serine protease inhibitor antithrombin with the assistance of heparin and by the thrombin-specific heparin cofactor II. Important cellular effects are triggered by thrombin cleavage of protease-activated receptors (PARs) (4, 5), which are members of the G-protein-coupled receptor superfamily. Four PARs have been identified and share the same basic mechanism of activation: Thrombin and other proteases cleave at a specific site within the extracellular N-terminus, which exposes a new N-terminal tethered ligand domain that binds and activates the cleaved receptor. PAR1 is responsible for platelet activation in humans at low thrombin concentrations, and its action is reinforced by PAR4 at high enzyme concentrations. Activation of PAR1 and PAR4 triggers platelet activation and aggregation, and it mediates the prothrombotic role of thrombin in the blood. PAR3 is not present on human platelets, but it is expressed widely and abundantly in other cell types. PAR2 is the target of other proteases and clotting factors. In the mouse, signaling in platelets is mediated entirely by PAR4, with PAR3 facilitating PAR4 cleavage at low thrombin concentrations. The efficiency of the coagulation cascade depends on the balance between the procoagulant and anticoagulant pathways. Thrombin is the key arbiter of this balance by virtue of its dual role and has therefore received utmost attention in structure-function studies and as a target of anticoagulant therapy (6). Recent advances demonstrate that thrombin uses the transition among different conformations to perform its numerous physiological roles.

Thrombin, Na⁺ and Thrombomodulin

Thrombin requires Na⁺ for optimal activity (2) and is a member of the large family of monovalent cation activated enzymes (7, 8). Na⁺ binding converts thrombin from a low activity E (Na⁺-free) to a high activity E:Na⁺ (Na⁺-bound) form. Na⁺ binding is required for optimal cleavage of fibrinogen and activation of factors V, VIII, and XI necessary for the explosive generation of thrombin in the coagulation cascade, but it is dispensable for cleavage of protein C (9, 10). This finding proves that Na⁺ is the major driving force behind the procoagulant role of thrombin in the blood. Na⁺ binding also promotes the prothrombotic and signaling functions of the enzyme by enhancing cleavage of PAR1, PAR3, and PAR4. Because of the allosteric nature of thrombin, any effect that destabilizes Na⁺ binding stabilizes the E form and produces an anticoagulant effect by prolonging the clotting time (reduced
fibrogen cleavage and reducing platelet activation (reduced PAR1 cleavage). Several naturally occurring mutations of the prothrombin gene affect residues linked to Na\(^{+}\) binding (11) and are often associated with bleeding (2). The differential effect of Na\(^{+}\) on fibrogen and protein C cleavage has been the major driving force behind the rational design of anticoagulant thrombin mutants.

The anticoagulant role of thrombin is under the control of the endothelial receptor thrombomodulin (3). In the microcirculation, the density of this receptor is enhanced greatly, and thrombin is sequestered by engagement of its exosite 1, which is a structural domain separate from the active site. Binding of thrombomodulin to exosite 1 precludes interaction of fibrinogen or PAR1 and therefore shuts down both the procoagulant and prothrombotic functions of the enzyme. At the same time, the thrombin-thrombomodulin complex becomes an efficient activator of the anticoagulant protein C by markedly increasing the k\(_{\text{cat}}\) and the rate of diffusion of substrate into the active site. Activation of protein C produces a protease that rapidly inactivates factors Va and VIIa necessary for additional thrombin generation.

Thrombin is composed of two polypeptide chains of 36 (A chain) and 259 (B chain) residues that are covalently linked through a disulfide bond (Fig. 3). The standard orientation (12) puts the A chain in the back of the molecule, opposite to the front hemisphere of the B chain that hosts the entrance to the active site and all known functional epitopes of the enzyme. Trypsin-like specificity for Arg residues at P1 is conferred to the active site and defines exosite 1. Structural data illustrate the mode of interaction of fibrogen (13), thrombomodulin (14), PAR1 (15), and PAR3 (16) with this thrombin exosite. Exosite 2 resides on the pole of the enzyme opposite to exosite 1 and offers a binding epitope for the platelet receptor GP\(_{\text{b,IIa}}\), as well as for polyvalent ligands required for interaction of antithrombin and heparin cofactor II. Na\(^{+}\) binding 20 Å away from residues of the catalytic triad and within 5 Å from D189 in the S1 site that occupies the bottom of the catalytic pocket. The autoinhibitory loop shapes the lower rim of access to the active site and contributes to recognition of fibrogen. A loop homologous to the Ca\(^{2+}\) binding loop of digestive serine proteases resides 25 Å away from the active site and defines exosite 1. Structural data illustrate the mode of interaction of fibrogen (13), thrombomodulin (14), PAR1 (15), and PAR3 (16) with this thrombin exosite. Exosite 2 resides on the pole of the enzyme opposite to exosite 1 and defines most of the aryl binding specificity pocket and the active site linked to the occupancy of the Na\(^{+}\) binding site (11). An important consequence of the large Na\(^{+}\) binding causes a significant increase in intrinsic fluorescence of the enzyme with an initial rapid phase with a k\(_{\text{cat}}\), which is followed by a slow phase with a k\(_{\text{cat}}\) in the ms time scale that decreases hyperbolically as Na\(^{+}\) increases (2, 18).

These examples are signatures of a two-step mechanism for Na\(^{+}\) binding as follows in Scheme 1:

Thrombin exists in equilibrium between two forms, E\(^{+}\) and E, that interconvert with kinetic rate constants k\(_{1}\) and k\(_{-1}\) in the ms time scale. Of these forms, only E can interact with Na\(^{+}\) with a rate constant k\(_{2}\) to populate E:Na\(^{+}\), which may dissociate into the parent components with a rate constant k\(_{\text{diss}}\). The fast phase is caused by the E-E:Na\(^{+}\) interconversion that involves Na\(^{+}\) binding/dissociation, and the slow phase is caused by the E-E\(^{+}\) interconversion that precedes Na\(^{+}\) binding. E and E:Na\(^{+}\) in Scheme 1 are the two active forms of thrombin that account for the dependence of k\(_{\text{cat}}\) on [Na\(^{+}\)]. However, a third form E\(^{+}\) is present in solution regardless of Na\(^{+}\) or any other ligand. The E\(^{+}\)-E equilibrium of thrombin is an intrinsic property of the enzyme uncovered by its effect on the kinetics of Na\(^{+}\) binding. This example demonstrates how studies of Na\(^{+}\) binding to thrombin and related clotting proteases can advance significantly our understanding of the function and regulatory interactions of an entire class of enzymes.

Thermodynamic signatures of Na\(^{+}\) binding are of mechanistic and physiological importance and were also resolved from temperature studies of the kinetic mechanism. A large enthalpy change of \(-22\) kcal/mol is compensated by a large entropy loss of \(-64\) cal/molK. The enthalpy change is caused by formation of the six ligating interactions in the coordination shell, and the entropy change reflects the uptake and ordering of water molecules within the channel embedding the primary specificity pocket and the active site linked to the occupancy of the Na\(^{+}\) site (11). An important consequence of the large enthalpy change is that the equilibrium association constant for Na\(^{+}\) binding becomes 10 M\(^{-1}\) at 37°C, which implies that under physiological conditions of temperature and (NaCl)] = 140 mM, thrombin is only 60% bound to Na\(^{+}\). The fraction of thrombin in the procoagulant E:Na\(^{+}\) form is about 60%, and the anticoagulant form E accounts for about 40%. E\(^{+}\) makes only a little contribution and represents \(-1%\) of the population of thrombin molecules at 37°C.

Single-site Phe mutants of each of the nine Trp residues of thrombin were used to identify fluorophores responsible for the spectral changes associated with Na\(^{+}\) binding (18). The W141F and W215F mutants lose \(-70%\) of the total fluorescence change and retain only the slow phase. The environments of W141 and W215 change in the E\(^{+}\) to E conversion and more drastically in the conversion of E to E:Na\(^{+}\). W215 is the closest Trp residue to the bound Na\(^{+}\) (13 Å) and defines most of the (aryl) binding site involved in substrate recognition (Fig. 4). W141 is buried in the active site.
Molecular Basis of Thrombin Allostery

Structural information has begun to develop on how the Na⁺ site and exosite 1 communicate allosterically with the active site and each other. Structures of E and E:Na⁺ (11) are highly similar (r.m.s.d. 0.38 Å), but significant differences are worth mentioning. D189 in the E:Na⁺ form is optimally oriented for electrostatic coupling with the P1 Arg of substrate, which may account for the lower Kₜₐₜ observed in the presence of Na⁺. Subtle changes affect the catalytic triad. In the E form, the nucleophilic S195 side chain is rotated about 35° relative to the E:Na⁺ form, and the critical H-bond with the catalytic H57 is broken. Integrity of the H-bond is important for catalysis, and the unfavorable position of S195 in the E form may explain the lower kₜₐₜ observed in the absence of Na⁺. Importantly, the structures of E and E:Na⁺ offer a plausible explanation for the long-range communication between the Na⁺ site and the active site. In the E:Na⁺ form, a network of 11 water molecules connect the bound Na⁺ to the Oγ atom of S195, which is located <15 Å away, through H-bonds. In the E form, only seven water molecules occupy positions in the network equivalent to those observed in the E:Na⁺ form, and the connectivity is radically altered. Binding of Na⁺ organizes a network of water molecules that spans the interior of the enzyme for over 15 Å up to the catalytic S195. Ordering of this network shapes the structure of the enzyme as a whole. Ala scanning mutagenesis of the epitopes of thrombin energetically linked to Na⁺ binding and ligand recognition confirm this scenario and vouch for long-range allosteric communications involving the active site, the Na⁺ site and exosite 1 (11, 19).
kinetic and thermodynamic signatures of Na$^+$ binding detected experimentally.

A major advance in our understanding of thrombin allosteric changes in the active site, the S1 site, and the Na$^+$ site that are unprecedented in thrombin and the entire realm of serine proteases and offers a compelling model of the E$^*$ form. The changes impact the conformation of the enzyme in a significant way and are consistent with a global perturbation of the structure predicted from mutagenesis and kinetic studies. The 215-219 β-stand collapses into the primary specificity pocket (Fig. 2) and W215 packs against the hydrophobic pocket in the active site formed by W60, Y60a, H57, and L99. R221a in the Na$^+$ loop brings its guanidinium group in contact with D102 in S1 site to mimic the P1-$^*$ of an incoming substrate. R187 penetrates the Na$^+$ site to occupy the space available to the cation. The structure of D102 N portrays a conformation of thrombin that cannot bind Na$^+$ and ligands to the active site, as expected for the E$^*$ form. The drastic movement of W215 confirms the major role of this residue as a reporter of the E$^*$ and E-E:Na$^+$ interconversions.

Binding of thrombomodulin to exosite 1 enhances the $K_{\text{cat}}/K_m$ of thrombin for protein C $\sim 1,000$-fold, because of a 3,000-fold increase of the rate of substrate diffusion into the active site. Notwithstanding this massive functional effect, the structure of thrombin bound to a fragment of thrombomodulin at exosite 1 fails to reveal significant conformational changes in the active site or other regions [14]. Such changes might have been obliterated by the presence of the active site inhibitor used in the crystalization. However, the structure of thrombin solved with hirudin bound to exosite 1 and the active site free also fails to reveal significant conformational changes in the active site [21]. However, a recent structure of thrombin bound to a fragment of PAR3 bound to exosite 1 [16] reveals a rearrangement of the 60-loop that lines the upper rim of the active site entrance (Fig. 1). The indole ring of W60 d partially occludes access to the active site and restricts specificity toward physiologic substrates and inhibitors. When PAR3 binds to exosite 1, the 60-loop shifts 3.8 Å upward and causes a 180° flip of W60 d that projects the indole ring into the solvent and opens up the active site fully. This structure reveals the basis of the allosteric communication between exosite 1 and the active site clef as well as the role of W60 d to move like a flap and regulate substrate diffusion into the active site. The allosteric effect is relevant for the cofactor function of cleaved PAR3 on PAR4 activation (4, 5), and the effect of thrombomodulin on the cleavage of protein C by thrombin [3].

More details on how exosite 1 communicates long range with the active site and the Na$^+$ site have developed from the structure of thrombin D102 N bound to a fragment of PAR3 at exosite 1 [15]. The E$^*$ conformation of D102 N is converted into the active E$^*$ form by a massive conformational change that restores access to the active site and patency of the Na$^+$ site.

The structure reveals the details of this allosteric transition in terms of a network of polar interactions that can be traced from exosite 1 to the opposite side of the molecule almost 30 Å away.

Conclusions and Future Directions

Thrombin continues to provide a biologically important platform for the study of the most basic aspects of protease structure, function, and regulation. Much has been learned about thrombin function and regulatory interactions, and structural details have begun to develop on the molecular basis of thrombin allosteroy mediated by Na$^+$ and thrombomodulin. Kinetics studies on Na$^+$ binding have revealed the true complexity of thrombin in terms of its ability to assume multiple conformations in equilibrium. The structure of E$^*$ confirms the prediction from kinetic studies and future studies will certainly broaden our understanding of the molecular basis of long-range communications among the active site, the Na$^+$ site and exosite 1.

Advances in our basic knowledge of mechanisms of substrate recognition and cofactor interactions will eventually foster new strategies to control or exploit the multiple functions of thrombin for pharmacological intervention.

Several questions remain on thrombin structure, function, and regulation. Future studies should focus on validation of the nature of E$^*$ and establish if this is indeed an inactive form of thrombin that cannot bind substrate at the active site. Structural studies should address more directly the role of thrombomodulin using thrombin in the E$^*$ or E$^*$ forms. The physiological role of E$^*$ should be elucidated. More direct assessment of the thermodynamic signatures of thrombin interactions and regulatory transitions should rely on calorimetry. Finally, future studies should address the molecular basis of Na$^+$ and substrate specificity of thrombin and how they can be reengineered. Of particular importance will be the design of more potent anticoagulant thrombin mutants or mutants with selective activation of PARs.

doi: 10.1002/9780470048672.wecb527

The functional self-organization can be transcribed readily into hybrid nanostructures by using the sol-gel process. Accordingly, we have reported synthetic routes for preparing self-organized systems that have been "frozen" in a siloxane matrix, as a straightforward approach to design a novel class of solid hybrid nanomaterials. Nucleobases oligomerization can be an advantageous choice to reinforce the controlled communication between interconnected "dynamic supramolecular" and "fixing siloxane" systems. Moreover, the different interconverting outputs that nucleobases may form by oligomerization define a dynamic polyfunctional diversity that may be "extracted selectively" by sol-gel polymerization in solid state under the intrinsic stability of the different nucleobase-pairing and G-quadruplex-based systems. The nucleobase-type hybrid materials presented in this review unlock the door to the new self-organized materials world paralleling that of biology.

Introduction

In a broadest sense, the self-assembly and the self-organization via noncovalent interactions must play an important role in critical areas as genetic code, biological information storage, transfer biomolecule (protein, DNA, RNA, etc.) synthesis, and so on. The formation of duplex DNA from its single-stranded constituents, the stabilization of the high-ordered hairpins loops in RNA, and the functional self-assembly of protein-nucleic acid complexes are a result of a large collection of intermolecular forces. These forces include hydrogen bonding, aromatic π-stacking, charge interactions, van der Waals forces, or hydrophobic effects. Moreover, the high fidelity observed in these self-organized biomacromolecular architectures is largely caused by the high selective molecular recognition processes of natural base-pairing interactions via Watson-Crick H-bonding or of specific protein folding via amide H-bonding, and so on. Among these systems, the nucleobases (1–5) and the nucleosides (6, 7) as well as DNA or RNA (8–10) are well-known, fascinating compounds with a high ability to form controlled multiple intermolecular H-bonding of complementary nature, −C-H–O, hydrophobic, and stacking interactions.

The adenine-uracil interaction that involves two hydrogen bonds ($K_a \approx 10^2 - 10^3 \text{ M}^{-1} \text{ CDCl}_3$) is weak and nonspecific compared with the guanine-cytosine interaction, which involves three hydrogen bonds ($K_a \approx 10^3 - 10^5 \text{ M}^{-1} \text{ CDCl}_3$) that are usually paired via Watson-Crick interactions (4, 5). Homopairing and heteropairing of adenine-uracil and guanine-cytosine derivatives, which result in the formation of interconverting dimers, trimers, and oligomers via the combination of H-bond pairings, seem inadequate to function in any predefined recognition scheme. Amazingly, a very diverse set of interconverting supramolecular entities (oligomers) may be generated by using only these four nucleobases.

Their remarkable self-association properties, via Watson-Crick and Hoogsteen pairing, play a critical role in the stabilization of higher-order RNA hairpins loops, double or triple helix DNA, and G-quartets or G-quadruplexes (3–6). Even though the Watson-Crick (WC) base-pairing is prevalent in natural systems, other H-bonding motifs are present in natural and artificial systems; these motifs include: reverse Watson-Crick (rWC), Hoogsteen (H), reverse Hoogsteen (rH), Wobble (Wo), or reverse Wobble (rWo) (4, 5).

During the last decades, several studies reported the preparation of synthetic discrete supramolecular assemblies (4–8), polymers (1–9), and hybrid materials (10–12) that possess bases of nucleic acids as side groups or chain-end, which are used as precursors to conceive self-organized hybrid materials at nanometric scale.
Nanosized supramolecular materials have received increasing attention during the last two decades (15-19). The supramolecular synthesis provides a powerful tool for the noncovalent generation of such functional supramolecular architectures (15). The supramolecular polymers offer solutions for material molding at the macroscopic level, but their manipulation at the molecular (supramolecular) and nanoscopic levels is still difficult to control (16). This finding represents a nice extension from material science to biologically interesting component molecules such as nucleic acids that could be of interest for complementary binding (sewing) of nucleic acid strands.

For all these reasons, this article will highlight some recent accomplishments in the field of self-organized hybrid materials, and it will focus on the evolution of discrete nucleobase derivatives from self-assembled dynamic libraries of different devices exchanging in solution to constitutional functional hybrid solid materials. The primary purpose of this review is to describe our recent work on nucleobase-based self-organized hybrid materials. The article begins by describing some recent advances in the area of hybrid supramolecular materials. Then, constitutional dynamic amplification of supramolecular architectures will be examined with particular emphasis on self-organized nucleobase-type systems, presenting combined features of structural adaptation in a specific hybrid nanoevironment (11). The last part will emphasize the assembly behavior of G-quadruplex superstructures (6, 7) and the transcription of structural information in hybrid materials of functional complexity (12). The final structures of the hybrid materials develop solely from a balance of thermodynamic and kinetic factors as opposed to an iterative processing on a ribosome.

Hybrid Supramolecular Materials

Hybrid organic-inorganic materials produced by sol-gel process are the subject of various investigations, which offer the opportunity to achieve nanostuctured materials first from robust macrotemplates during sol-gel process on their supramolecular surface. Silsesquioxane-based precursors, in which the functional organic and siloxane inorganic groups are linked covalently, are employed extensively for the controlled generation of self-organized materials. Rigid aromatic molecules (9), which are urea H-bonding ribbons (20-23), are used to transpose a supramolecular self-organization in a siloxane matrix by a sol-gel process.

Despite such impressive progress, considerable challenges still lie ahead and the more significant one is the “dynamic marriage” between supramolecular self-assembly and the polymerization process, which might communicate kinetically and sterochemically to convert to supramolecular self-organization and functions in hybrid materials. The weak supramolecular interactions (H-bonds, coordination, or van der Waals interactions, etc.) that position the molecular components give the supramolecular architectures typically less robust than the cross-linked covalent bonds formed in a specific polymerization process. Accordingly, the sole solution to overcome these difficulties is to improve the binding (association) efficiency of molecular components that generate supramolecular assemblies. At least in theory, an increased number of interactions between molecular components and the right selection of the solvent might improve the stability of the templating supramolecular systems, which communicate with the inorganic siloxane network (35).

Three heteroditopic nucleobase-type silsesquioxanes, A<sub>12</sub>, U<sub>12</sub>, G<sub>12</sub> receptors have been reported by our group recently (Fig. 1, 11, 12). They generate self-organized continual superstructures in solution and in the solid state based on the following encoded features: 1) specific molecular recognition, 2) the supramolecular H-bond directing interactions, and 3) covalently bonded triethoxyxilyl groups that allow by sol-gel processes to transpose the solution self-organized dynamic superstructures in the solid heteropolysiloxane materials.

Constitutional Self-Organization of Adenine-Uracil-Based Hybrid Materials

As suggested in the introduction, the nucleobase building blocks generate a very complex dynamic pool of oligomeric ribbon-type or cyclic supramolecular architectures that exchange in solution when simple molecular precursors are used (Fig. 3). The A<sub>12</sub> and U<sub>12</sub> molecules were designed as rigid H-bonding modules. For instance, by introducing bulky blocking alkoxysilanepropylcarboxamido groups in N9 (A) and N1 (U) positions,
we limit only the Watson-Crick and the Hoogsteen interactions as preferential H-bonding motifs. The A_{Si} and U_{Si} precursors generate self-organized superstructures based on two encoded features: 1) they contain a nucleobase moiety that can form ribbon-like oligomers via the combination of H-bond pairings; 2) the nucleobase moiety is bonded covalently to siloxane-terminated hydrophobic groups packing in alternate layers.

Figure 1. (a) Supramolecular \( \mathbb{A} \) and supramacromolecular \( \mathbb{B} \) polymers resulted from intermolecular and intermacromolecular self-organization. (b) cross-linking and multiple outputs generation after the polymerization of monomers in supramacromolecular polymers (11).

Figure 2. Molecular structures of nucleobase ureido-silsesquioxanes A_{Si}, U_{Si}, and G_{Si}.

The dynamic self-assembly processes of such supramolecular systems (Fig. 3) that undergo continuous reversible exchange between different self-organized entities in solution may in principle be connected to a kinetically controlled sol-gel process to extract and to select an amplified supramolecular device under a specific set of experimental conditions. Such "dynamic marriage" between supramolecular self-assembly and in sol-gel polymerization processes that might communicate synergistically leads to "constitutionally-driven hybrid materials."

Based on this structural information and on the crystal structures of similar alkynucleobase derivatives, the relative arrangement of molecules of A_{Si} and U_{Si} in powders and in the M_{Si}, M_{U} and M_{Si}−M_{U} hybrid materials is similar to analogous ureidocrown-ether (20-23) and ureidoarene (36) superstructures. The generation of hybrid materials M_{Si}, M_{U}, and M_{Si}−M_{U} can be achieved using mild sol-gel conditions. In a typical procedure, we have prepared solutions of precursors A, U, or an equimolar mixture of A:U (1:1, mol/mol) in acetone, then we added deionized water and benzylamine as a catalyst. The mixture was kept at room temperature under static conditions for 15 days. The solvent was then evaporated at room temperature to yield the hybrid materials M_{Si}, M_{U}, and M_{Si}−M_{U} as the white powders.

Figure 3

Supramolecular dimers, trimers, and oligomers generated by H-bonding self-assembly of (a) adenine, (b) uracil, and (c) adenine-uracil base-pair. (R = sugar, alkyl, etc.)

The X-ray powder diffraction (XPRD) experiments presented in Fig. 4 show that well-defined, long-range order is present in the precursors \( \text{A}_0 \) and \( \text{U}_0 \). The long-range order is less pronounced than in the precursor materials in the hybrid materials \( \text{M}_0, \text{M}_1, \) and \( \text{M}_2 \) after the sol-gel step: less well-defined peaks are present than for the precursor and the average peak width increases, which indicates smaller domains in which coherent scattering occurs (37). The small angles XRD pattern of the precursor \( \text{A}_0 \) presents two well-resolved Bragg diffraction peaks that correspond to two crystallographically distinct phases: \( \text{A}_0\text{WC} \) and \( \text{A}_0\text{H} \) oligomers (Fig. 4a). A freshly synthesized solid sample of \( \text{A}_0 \) is crystallized predominantly as Watson-Crick-Hoogsteen \( \text{A}_0\text{WC} \) oligomer. A second nonpredominant polymorph of the all-Hoogsteen \( \text{A}_0\text{H} \) oligomer is present in powder as a
Figure 4: Constitutional (a) Hoogsteen packing of the Adenine-M₈ hybrid material; (b) Watson-Crick packing of the Uracil-M₈ hybrid material, and (c) A₂WCU₂H packing of the Adenine-Uracil-M₈ hybrid material.
result of breaking of Watson-Crick H-bonds and of creating the new Hoogsteen H-bonds (38). The small angles XRPD pattern of hybrid material $M_0$ presents a unique, well-resolved Bragg diffraction peak (Fig. 4a), which corresponds to a crystallographically distinct and unique all-Hoogsteen phase ($A_{2wc}$). Adenine (39) 9-methyladenine (40) and 9-ethyladenine (41) crystallize through the formation of unique Hoogsteen H-bonds in two-dimensional layers. These layers, which are stratified alternatively, exhibit two types of interfaces in between: one contact surface because of the $\pi-\pi$ stacking of adenine tapes and other surface that results from hydrophobic interactions of alkyl groups, which are in van der Waals contact. Similarly, the structure of the $A_n$ oligomers is most likely dictated by hydrophobic interactions between the grafted ethoxysilanepropylcarboxamide groups (Fig. Sb). In a freshly prepared $A$ sample, the solvent logged between hydrophobic groups favors the extended ($A_{2wc}$) oligomers. The condensation process between the ethoxysilane groups during the sol-gel process do favor the more compact ($A_{2w}$) oligomers in which the hydrophobic groups are interlocked, which stabilizes the interaction between Hoogsteen H-bonded layers.

The small angles XRPD patterns of the precursor $U$ as well as of the hybrid material $M_0$ present one Bragg diffraction peak (Fig. 4b), which corresponds to a characteristic Watson-Crick ($U_{2wc}$) dimer. The two other possible structures, the reverse Watson-Crick dimer ($U_{2hc}$) and the quartet ($U_4$) (see Fig. 3), do not correlate with the experimental distance.

A freshly evaporated solid sample of an equimolecular mixture in acetone of $A$ and $U$ presents two Bragg diffraction peaks that correspond to $A_{2hc}U_{2h}$ and $A_{2w}U_{2wc}$ oligomers, respectively. The small angles XRPD pattern of the hybrid material $M_{A-U}$ presents a unique Bragg diffraction peak that corresponds to a characteristic interplanar distance of $A_{2wc}U_{2w}$ oligomer (Fig. 4c). Amazingly, the unique structure of the resulting hybrid material $M_{A-U}$ that corresponds with experimental results is consistent with the formation of the Hoogsteen base pairing between $U$ and $A$ and with the formation of the Watson-Crick base pairing between two adenine
Figure 5  Toward a constitutional transcription of base-pairing codes in hybrid materials: (a) Guide to the eye interplanar $d_{\text{Si-Si'}}$ distances calculated from the geometry of minimized structures versus experimental interplanar Bragg diffraction distances. The squares correspond to the unpolymerized powders of precursors A, U, and their 1:1 mixture $\text{AU}_{\text{mix}}$, whereas the circles correspond to hybrid materials $\text{MA}$, $\text{MU}$, and $\text{MA-U}$. (b) Postulated model of self-organization of parallel $\text{H}$-bonded nucleobase aggregates and hydrophobic propyltriethoxysilane layers.

Nucleobase oligomerization by $\text{H}$-bonding can be an advantageous choice to reinforce the controlled communication between interconnected “dynamic supramolecular” and “fixing siloxane” systems. Moreover, the hydrophobic interactions can play an important role to stabilize compact packed superstructures that may be “extracted selectively” under the intrinsic stability of the system or external stimuli by polymerization in solid state.

Amplification and Transcription of the Dynamic Supramolecular Chirality of the G-Quadruplex

G-quartets are formed by the hydrogen bonding self-assembly of four guanosine and are stabilized by alkali cations. They play an important role in biology and in nucleic acid telomers in particular, which are of potential interest to cancer therapy (6, 7). The role of cation templating is to stabilize by coordination to the eight carbonyl oxygens of two sandwiched G-quartets: the G-quadruplex is the columnar device formed by the vertical stacking of four G-quartets.

The G-quartet architecture represents a nice example of dynamic supramolecular system that has been used as building molecules. Early contributions by Etter et al. (42), Castellano et al. (43), and others have been confirmed recently by Zimmermann calculations (44) for nearly exclusive preference for Hoogsteen binding, inside the classic A-U base-pairing, within 1:1 base-pairing complexes between alkyladenine and alkylthymine derivatives. Factors that contribute to the preference for Hoogsteen geometry are the shorter CH—O contacts, which results in a favorable alignment of the dipoles and is a greater distance between secondary repulsive sites (43, 44). Although many have recognized that in the solid state, the uracil or thymine preferentially bind adenine through Hoogsteen binding; therefore, this result is particularly interesting because the $\text{A}_{\text{mix}}\text{U}_{\text{mix}}$ oligomer is amplified quantitatively from a dynamic pool of oligomers in solution via sol-gel transcription.

As a general rule, which is proved by the differences between the values of interplanar Bragg diffraction distances, the condensation process between the ethoxysilane groups during the sol-gel process results in the formation of the more compact hybrid materials $\text{MA}$, $\text{MU}$, and $\text{MA-U}$ compared with the unpolymerized A, U, and AU mix powders (Fig. 5).
Figure 6  (a) The cation-templated hierarchic self-assembly of guanine alkoxysilane gives the G-quartet and the G-quadruplex (b) transcribed in solid hybrid materials by sol-gel in the presence of templating K⁺ cation.

Nucleobase Self-Assembly Codes, Constitutional Transcription of

block for gelators (45), columnar polymeric aggregates (46), self-organized surfaces (47), prototypes of chemical dynamic devices (48), and so on.

In the last decades, G-quartets (6) and a similar folic acid quartet (49) have been proposed as powerful scaffolds for building synthetic ion channels. Although stable in organic solvents, they do not seem to have defined transport functions in hydrophobic membranes. Barrel-stave-, lipophilic calix(4)arene-8-aromatic-guanosine conjugates have been used to stabilize the formation of G-quartets (7). Very recently, new strategies based on reversible metathesis were used successfully by Kaucher et al. (50) to generate a rich array of interconverting ion-channel conductance states of a unimolecular G-quartet in a phospholipid membrane. Polymeric guanosine hydrogels that can be interconverted reversibly between gel and sol states may be used to synthesize adaptive functional nanostructures (45).

Despite such impressive progress, considerable challenges still lie ahead, and the more significant challenge is to improve the stability of G-quartet dynamic aggregates in polymeric devices such as films or membranes to extend (address) the transport studies at macroscopic level. Several studies reported the preparation of discrete supramolecular assemblies of nucleobases. However, the “dynamic communication” between the
supramolecular self-assembly of nucleobases and the polymerization processes, which kinetically and sterochemically might communicate, is not so trivial.

On the other hand, the G-quadruplex with a twisted supra molecular architecture represents a nice example of a dynamic chiral supramolecular system, when guanine and guanosine molecules are used. Molecular chirality may be used as a tool to assemble molecules and macromolecules into supramolecular structures with disymmetric shapes. The supramolecular chirality, which results from both the properties and the way in which the molecular components associate, is by constitution dynamic and therefore examples of large-scale transcription of such virtual chirality remain rare.

For all these reasons, the guanine building blocks and the sol-gel chemistry were used as molecular precursor to conceive hybrid chiral materials at nanometric and micrometric scales. Our efforts involved the synthesis and the self-assembly of a guaninesiloxane monomer \( \text{G}_{x} \text{O}_{y} \) in the G-quartet and G-quadruplex supramolecular architectures (Fig 6), which are fixed in a hybrid organic-inorganic material by using a sol-gel transcription process, followed by a second inorganic transcription in silica, by calcination.

The generation of G-quadruplex hybrid material can be achieved by mixing \( \text{G}_{x} \) derivative with potassium triflate in acetone, followed the sol-gel process performed at room temperature using benzylamine as catalyst. Then, the hybrid materials were calcined at 400°C to transcribe their superstructural features into inorganic silica replica materials.

We have observed a long-range amplification of the G-quadruplex supramolecular chirality into hybrid organic-inorganic twisted nanorods followed by the transcription into inorganic silica microsprings (12). We believe that in the first sol-gel step, the polycondensation reactions of the inorganic alkoxysilane network take place around tubular twisted superstructure of G-quadruplex. The dynamic G-quadruplex is fixed in a covalently bonded siloxane network, and the structural (constitutional) memory of G-quadruplex is transcribed in the hybrid materials. These fixed ("frozen") objects are chiral and self-correlate with a helical order to generate anisotropic mesophases interconnected via condensed siloxane bridges. We obtained by sol-gel process a hybrid material that features a twisted hexagonal rod-like morphology of about 2 µm length and 350–850 nm diameter (Fig 7). The mixture of these entities contains left and right twisted nanorods, which are a result of the nonpreferential disymmetric orientation of the G-quartets. They are chiral, and no inversion centers have been observed within the same entity. Amazingly, these materials are at nanometric or micrometric scale topologically analogous to its G-quadruplex supramolecular counterpart. Similar "communication processes" have been identified in the DNA transcription into inorganic materials (10).

After the sol-gel process, the preformed helical silica network has embedded probably enough chiral information to be amplified (reinforced) irreversibly during the calcination process when almost total condensation of Si–OH bonds occurs. By calcinations of the hybrid material, the templating twisted G-quadruplex architectures are eliminated, and inorganic silica anisotropic microsprings are obtained. They present the same helical topology, without inversion inside the helix. These objects have a different helical pitch, which depends strongly on...
the self-correlation between hexagonal twisted mesophase domains at the nanometric level.

Our findings showed a new way to transcribe the supramolecular chirality of a dynamic supramolecular architecture; the transfer of the supramolecular chirality of G-quadruplex at the nanometric and micrometric scale is reported, thereby creating nanosized hybrid structures or micrometerized inorganic superstructures, respectively. Moreover, we obtain chiral materials by using a starting achiral guaninesiloxane \( G_\text{G} \), as precursor of achiral G-quartet and of chiral supramolecular G-quadruplexes. Figures 7 and 8 represent the first pictures of the dynamic G-quadruplex transcribed at the nanometric level.

Finally, our results show a new way of embedding supramolecular chirality in materials, which is of interest for the development of a supramolecular approach to nanoscience and nanotechnology toward systems of increasing functional complexity.

Conclusions

The nanometric or the micrometric transcription of the supramolecular functional devices, although marked significant achievements, represent a young field. Whereas many elegant functional systems based on nucleobase self-assembly have been prepared in recent years, it is almost clear that the synthetic efforts might be developed to extend and to understand the key features of such self-organized systems and the nanometric and micrometric levels. As importantly, this work established that molecular precursors could be used to affect molecular recognition in organic-inorganic hybrid materials, differently to those found in typical biological DNA and RNA systems. Nanometric self-organization using molecular nucleobases is clearly different from biological nucleotide self-assembly. These initial hybrid nanomaterials presented in this paper paved the way to the development of new functional macroscopic materials that contain nucleobases as structural building blocks.

Some systems can be applied in the fields of ionics, electron, and energy transport studies (9) and in sensing technology. Finally, our results show a new way of embedding nucleobases self-assembly and supramolecular chirality of G-quadruplexes in hybrid materials, of interest for the development of a supramolecular approach to nanoscience (51). Likewise, the hybrid polymeric arrays with nucleobases functionalities represent an area where the best is surely best to come; it unlocks the door to the new materials world paralleling that of biology.

Acknowledgment

This work, which was conducted as part of the award “Dynamic Adaptable M materials for Separation and Sensing Mecysystems” made under the European Heads of Research Councils and European Science Foundation EURYI (European Young Investigator) Awards scheme in 2004, was supported by funds from the Participating Organizations of EURYI and the EC Sixth Framework Programme. Further Reading

Smell is an intriguing sense in many ways. Although it is not the dominant sense in humans, it has effects on emotion and memory which can be very profound. Odor has long baffled chemists who try to model it in mechanistic terms, and a great deal of research has been invested in trying to understand how various features of molecular structure provide different odor characters and intensities. Many models for prediction of odor properties from chemical structure exist, but none are accurate and precise consistently. The reasons for this are now becoming clearer. The greatest breakthroughs in our understanding of olfaction came with the discoveries of the gene family coding for the olfactory receptor proteins (1) and the combinatorial mode of operation of these receptors (2). Odorous molecules enter the nose either from the front, by inhalation, or from the back, by diffusion from the mouth and respiratory tract. In the nose, they interact with an array of receptors. Each receptor type responds to a range of odorants, and each odorant stimulates a range of receptors. The signals thus generated are coded onto centers, known as glomeruli, in the olfactory bulb. The olfactory signals pass on upward through the brain and are interpreted finally, in the cortex, as odor. During the neurotransmission process, many interactions occur between olfactory signals and cortical feedback mechanisms, which include effects from other senses. Therefore, it is not surprising that simple structure/odor correlations are so elusive.

Biologic Aspects of Olfaction

The process of olfaction begins when odorant molecules enter the nasal cavity either by inhaled air or by diffusion from the mouth. In the nose, these molecules activate receptors in the olfactory epithelium. The signals from the olfactory receptor cells are picked up by the olfactory bulb where mapping of receptor types onto glomeruli occurs. The signal patterns leave the olfactory bulb, travel upward through the brain, and are interpreted eventually as odor in the cortex. Within tens of milliseconds of presentation of an odorant to the nose, olfactory signals are generated in the epithelium; cortical activity is detectable within 100 milliseconds. Figure 1 shows the location of some key olfactory organs in humans.

What is odor?

Smell probably is the oldest of our senses. The ability to detect and to recognize specific chemicals gives even single-celled organisms useful information about their environment. For example, it is known (3) that sperm will swim toward certain odorous substances. The ability to analyze their environment...
by chemosensation allows organisms to identify opportunities and threats from chemical changes in their environment; therefore, chemosensation has an obvious survival value. Continual refinement of the mechanism throughout evolution has led to the highly developed sense that we humans know as smell. In this refined sense, usually odors are not derived from single chemical entities but from complex mixtures, and each mixture is perceived as a separate odor image (4, p. 63). Traditionally, the sense of smell is associated with the nose because that is where the signals are detected and research has tended to focus on the receptor events. However, it is now clear that the phenomenon of odor exists only in the higher brain and is a synthesis of inputs from the olfactory receptors, other senses, and various cortical feedback mechanisms. As stated by Wilson and Stevenson (4, p. 34), "With a relatively few exceptions, neither odor physico-chemical feature extraction at the receptor sheet, nor spatial maps of those features in the olfactory bulb, nor simple convergence of those features in cortical circuits are sufficient to account for the rich experience that is olfaction."

The nose

We tend to talk about the nose as a single entity; yet a septum exists that divides it into two physically separate cavities. On the roof of each of these cavities, and extending down onto the septum, is a patch of tissue known as the olfactory epithelium. Odorants can reach the epithelium either from in front, by inhalation of air from the environment (referred to as the orthonasal route), or by diffusion from the mouth and respiratory and gustatory tracts (referred to as the retronasal route). The latter is vital in flavor detection as the tongue contains receptors only for sweet, sour, salt, bitter, and umami tastes; the rest of what is referred to as taste, actually, is retronasal smell. On the sides of the nasal cavities are bony plates called turbinates that cause turbulence in the air flow and ensure that odorants reach the epithelium. The air flow through each nostril is always different because one is faster than the other; the fast flow alternates continually from one nostril to the other (5). This alternation provides a mechanism for increased sensitivity and discrimination based on transport phenomena because the timing and pattern of signal spread across the epithelium will depend, in part, on the air flow. It has been
shown that information on recognition features is exchanged at a higher level in the brain because a molecule whose odor has been learned using one nostril only will be recognized by the other nostril (6).

The olfactory epithelium and the olfactory receptors

The olfactory epithelium is a patch of greenish-yellow tissue several square centimeters in area and 100–200 micrometers thick. It contains receptor cells that run from the nasal cavity through the base of the skull (the cribriform plate) into the olfactory bulb. On the side of the nasal cavity, the receptor cells have hairs or cilia that are 20–200 micrometers long. These cilia are bathed in a mucus layer that is 35 micrometers thick and flows backward continually at a rate of 3–60 impulses/second; this rate of firing is increased when the cells are stimulated by an odorant.

The mucus also contains cytochrome P450s, which are oxidative enzymes, and proteins known as odor-binding proteins. The odor-binding proteins belong to the family of lipocalins. The role in olfaction of these two classes of proteins is not certain. It is possible that they serve only to remove excess odorants and therefore contribute to provision of the time-dimension of olfaction, which is an important feature in survival. However, other roles have also been postulated and will be discussed below.

The olfactory receptor proteins (ORs) belong to the family of 7-transmembrane G-protein coupled receptors (GPCRs). The gene family coding for the receptor proteins is the largest in the genome, which contains codes for over 1000 proteins (1). Most mammals express 800–900 of these proteins, but humans use a much reduced set, which contains only 350–400 proteins. Interestingly, the only other mammals (gorillas, chimpanzees, orangutans, and rhesus macaques) with such a restricted set of proteins are the only other mammals to have color vision. Variation between humans is such that statistically it is unlikely that any two humans use the same set of olfactory receptors (7).

Events that follow receptor activation involve the normal train of G-protein (G-off, in the case of olfaction), second messenger (cAMP or IP3, in the case of olfaction), and ion channel chemistry, which leads to polarization of the cell and hence generation of a discharge at the synapse that leads to the olfactory bulb (8). Intriguingly, it has been shown that the signal pattern elicited by a mixture of two substances is not necessarily a simple additive of the signals elicited by the two components individually, but receptors that are not activated by either component can be activated by the mixture (9).

The olfactory bulb

The olfactory bulb sits at the base of the brain on the cribriform plate. Humans have two olfactory bulbs, the right bulb that receives signals from the left olfactory epithelium, and the left bulb that receives signals from the right olfactory epithelium. In the bulb, centers called glomeruli exist, each of which receives signals from only one type of receptor cell, irrespective of where those receptors are located on the epithelium. Olfactory receptor cells have short lifetimes (about 2 weeks), and new receptor cells develop in such a way that each makes its connection with the correct glomerulus. Receptor types with similar substrate selectivities tend to be associated with glomeruli that are found close to each other in the olfactory bulb.

Higher processing

Olfactory signals that leave the olfactory bulbs travel by several routes to the higher centers of the brain where the phenomenon of odor develops eventually. Remarkably, the architecture of the olfactory parts of the brain is consistent across all mammalian species; research on other animals throws considerable light on the function in humans. The entire process is well reviewed by Wilson and Stevenson (4) and by Delano and Sobel (10).

The signals travel initially to the piriform cortex and the amygdala; hence, both the thalamus and the limbic system are involved. It is postulated that the direct link to the limbic system accounts for the influence of odor on memory and emotion. From the piriform cortex, signals go to the amygdala, then to the thalamus, and directly to the orbitofrontal cortex. Processed signals from the thalamus also go to the orbitofrontal cortex. This structure also receives signals directly from the amygdala. Many of these signal pathways are two-way in nature with signals that come down from higher centers that affect the ascending signals. This accounts for the well-known effects of experience, expectancy, and context in distorting odor perception. A classic example is the inability of experts to describe the aroma of a white wine correctly to which a tasteless red dye has been added (11). Interference from other senses is also important to determine the ultimate odor percept. For instance, 70% of odorants also stimulate the trigeminal system in the nasal cavity and visual input has been shown to affect olfactory signal processing (12). Essentially, recognition of “odor” is a process of matching pattern of this final signal combination against reference patterns stored in the brain. For example, in perfumery, it is well known that development of an odor language is essential to train perfumers, and their powers of discrimination improve as their language improves.

Anosmia

Anosmia, the inability to smell, can be divided into two classes. General anosmia, the inability to smell any odors at all, usually is the result of disease or accident. More common is specific anosmia, in which an individual cannot detect a specific chemical substance that most people can detect or displays a threshold of detection for it which is significantly above the normal range. At one time, specific anosmias were linked to the concept of primary odors (13), but confirmation of the combinatorial mechanism of olfaction has put paid to this concept. Interestingly, it has been demonstrated that exposure to the substance can affect anosmia and individuals can begin to smell materials to which they were previously anosmic. This effect has been demonstrated for androstenone, amyl acetate, geranyl nitrile, and isoborneol (14–18).
Chemical Aspects of Olfaction

For various reasons, it is very difficult to develop an understanding of the chemistry involved in olfaction. The olfactory receptors are found in the membrane of the receptor cells; therefore, their active states are not amenable to structural determination by X-ray diffraction or other physical tools. Odor is a mental image rather than a physical property that can be measured and quantified. Odor perception is a multistep process. Olfaction is combinatorial in nature. All of these facts indicate that building of either substrate or receptor models are fraught with significant difficulties.

Olfaction, however, is a very obvious property of any chemical compound, and thus, speculation about the mechanism of perception is very tempting. Experienced fragrance chemists can predict odor type with much better than random accuracy, and a commercial driver exists in terms of design of novel materials for the fragrance industry. Therefore, it is not surprising that many structure/odor correlations and olfaction models have been reported and debated, often very hotly, in the literature.

Not all of the olfaction models in the literature are far too simplistic and too mechanical in nature, and none of them have succeeded in accounting for all of the observations about olfaction. As described, recent advances in our understanding have confirmed that odor perception, as predicted by Polak (19), starts with a combinatorial mechanism at the receptor level (1) and involves pattern recognition in the higher brain (4). No single odorant-receptor interaction will be the sole determinant of odor perception, and even knowledge of the pattern elicited at the olfactory bulb is insufficient to enable prediction of the cortical image of odor. Therefore, structure/odor models are and, for the foreseeable future, will remain statistical tools rather than mechanistic indicators.

Odor measurement

To understand olfaction at a chemical level, it is necessary to have good data that link chemical structure to odor properties. This task is much more difficult than it would seem, for instance, to a chemist who sniffs a sample that he has just synthesized in the laboratory and applies an odor descriptor to the molecular structure of his synthetic target. These difficulties stem from both chemical and sensory issues. Techniques for odor measurement and the difficulties involved have been reviewed by Neuner-Jehle and Etzweiler (20).

Chemical purity and organoleptic purity are not synonymous. For example, the aldehyde (Structure 1) was discovered when a sample of the alcohol (Structure 2) was found to have the expected muguet (lily of the valley) odor (21). The alcohol was prepared from 4-tert-amylcyclohex-1-yl)acetaldehyde.

\[
4\text{-tert-amylcyclohex-1-yl)acetaldehyde} \rightarrow 2\text{-tert-amylcyclohex-1-yl)alcohol} \rightarrow 2\text{-tert-amylcyclohex-1-yl)acetaldehyde}
\]

Figure 2: Synthesis of 2-(4-tert-amylcyclohex-1-yl)acetaldehyde.

A good example of subjectivity in odor character measurement is provided by O’Hoff et al. (22). When 27 panelists were asked to allocate the odor of the cyclic ether (Structure 5) to one of various odor categories, 14 participants described it as minty/amphicaceous; 6 participants described it as fruity; 3 participants described it as musky/woody. Therefore, classification as minty (based on the largest subject group) would only be correct for 50% of the panel. Similarly, it is easy to demonstrate that Bangalol (Givaudan, Vernier, Geneva, Switzerland) (Structure 6) is perceived by some subjects as sandalwood in character but by others as musk (23). Odor intensity is also subjective. For example, the average odor threshold for (-)-geosmin (Structure 7) was found to be one tenth that for the (+)-enantiomer (Structure 8). However, some individuals were
40 times more sensitive to one enantiomer than to the other, some experienced similar thresholds for both enantiomers, and some were more sensitive to the \( (+) \)-enantiomer (24). As with all sensory magnitude estimation, odor intensity measurement must take into account the fact that humans adjust mental scales unconsciously to suit the task in hand.

Odor classification is particularly difficult. For the senses of touch or sight, it is easy to pick physical reference points (hardness of standard substances, wavelength of light, etc.) and then to classify sensory properties in relation to these points. No such classification exists in odor. No primary odors and no physical reference points exist. Consequently, all odor classification is by comparison with other odors. For example, it might make sense to see apples and pears as subclasses of fruit in botanical terms, but in terms of their odors, putting apple and pear under the general heading of fruity odors leads to difficulties in structure/odor correlation (25). Indeed, the brain sees each new odor as a new percept rather than as a combination of existing percepts (4). Therefore, odor classification, although a useful tool in perfumery, is essentially meaningless scientifically. For example, mixing together in suitable proportions, hexylcinnamic aldehyde (Structure 9) (fatty odor), benzyl acetate (Structure 10) (floral odor), and indole (Structure 11) (fecal odor) will give a perfume that is recognizable as jasmine in character. However, a sample of pure cis-jasmone (Structure 12) would also attract the descriptor of jasmine. So, of what value is the term "jasmine"?

**Transport to the receptors**

It is self-evident that transport properties must be of importance in olfaction because if odorants cannot reach the olfactory epithelium, they will not be detected by the olfactory receptors and no odor will result. Volatility is the most obvious requirement, and for organic compounds, this requirement results in a cutoff point at about 18–20 carbon atoms in the molecule equivalent to a molecular weight of about 300 Daltons. Larger molecules are simply not volatile enough to reach the olfactory epithelium in sufficient concentration to be perceived. Solubility is also important; partially because water solubility implies a polar molecular structure, and this, in turn, implies a low vapor pressure relative to the molecular weight because of intermolecular hydrogen bonding. However, solubility properties per se also seem to be important, which is perhaps related to the ability of molecules to cross the aqueous mucus layer to reach the receptor proteins. Fragrance molecules generally have \( \log P \) in the region of 2–5.

**Odor-binding proteins**

Proteins that belong to the lipocalin family and are present in the olfactory mucosa were first identified as involved in binding of pyrazines and so were first named pyrazine-binding proteins (26). However, it soon became clear that they are capable of binding a very wide range of odorant molecules, and the name odorant-binding proteins (OBPs) was coined (27–30). Possible roles of odor-binding proteins include transport of odorants across the mucus to the receptor, signal attenuation, or removal of excess odorant, or it is also possible that the receptor proteins distinguish between free and liganded lipocalins rather than detecting free odorants. However, because no lipocalins are present in the experiments of Spehr et al. (1), it is clear that odorants can be detected by receptor proteins in the absence of OBPs. OBPs are more important to insects than to mammals. For instance, Drosophila melanogaster has about 50 different types of OBPs and 70 different types of ORs, whereas mammals have only about five types of OBPs and a potential pool of about 1000 different ORs (31). No kinetic studies have been carried out on OBP solubilization of odorants, but if simple model systems are relevant, then the work of Rebek on self-assembling clathrates (32–35) would suggest, by analogy, that the time required for trapping and release of odorants by OBPs might be rather long in terms of the total time involved in olfaction. Overall, insufficient information exists to enable a clear picture of the role of OBPs to be drawn.

**Cytochromes**

The most obvious role for oxidative enzymes in the olfactory mucosa would be removal of excess or spent signal material. However, some evidence suggests that products of cytochrome oxidation are detected by the olfactory receptors and thus constitute a part of odor perception (36).

**The receptor event**

Based on homology models in humans and in mice, Lancet and coworkers have suggested that odorant binding to olfactory receptor proteins occurs in the transmembrane part of the receptor protein, which bridges between amino acid residues of helices 2 to 7 (37, 38). Interestingly, this region is the same region in which 11-cis-retinal binds in rhodopsin and also corresponds with the binding sites of other GPCRs (39). Furthermore, it is also in broad agreement with binding sites proposed in several reported model studies on specific odorant/olfactory receptor binding (vide infra).

The olfactory receptors are tuned broadly because each receptor type responds to a range of odorants, and each odorant fires a range of receptor types (16). For some receptor/protein/odorant combinations, the binding affinity is concentration dependent (40, 41), and this can correlate with observed changes in character as concentration varies (2, pp. 71–74).
Structure/activity approaches

The relationship between molecular structure and odor has been the subject of much research during the last 150 years. The motivation has come partly from commercial interest to learn how to design improved ingredients for fragrances and partly from the scientific interest to understand the sense of smell. Attempts to translate structure/odor models into mechanism and vice versa have led to much confusion and to very heated debates. It is now clear that structure/odor models are useful tools to aid the design of novel odorants but that understanding of the mechanism of olfaction will come from biochemistry, molecular biology, and neuroscience rather than from these models. Conversely, developments in our understanding of receptor events in olfaction will not necessarily improve the structure/odor models.

The structure/activity relationship (SAR) tools employed in odor research are essentially the same standard tools used in all applications, and the models developed fall into the categories of substrate and receptor models. The pharmaceutical industry is the leader in SAR techniques, and the fragrance industry tends to follow its lead. Early models were substrate based, but the discovery of the genes that code for the olfactory receptor proteins has also allowed receptor models to be constructed.

Substrate modeling

For substrate models, classic chemical methods such as Hansch analysis are used, as are statistical techniques such as principal components analysis (PCA). Hansch uses regression analysis to correlate electronic, steric, and hydrophobic properties with the biologic activity in question, whereas PCA is a statistical technique that reduces multidimensional input (physical properties of molecules) to two or three dimensions that aids in correlation with the biologic activity. Molecular modeling tools such as COMFA (comparative molecular field analysis) and the olfactophore approach, the odor equivalent of pharmacophores, have also been used successfully. In these techniques, the stereoelectronic properties of a test set of molecules are used to build a model of an idealized substrate with which putative novel materials can then be compared. A comparison of Hansch analysis, PCA and COMFA in the correlation of structure with fruity odors provides a useful introduction to the three techniques and shows that, in this instance at least, they provide similar results (42). A good illustration of the use of the olfactophore approach is K. Hart and Eichenberger’s design of a novel marine odorant using the technique (43). The approaches used in structure/odor modeling have been comprehensively reviewed by Rossiter et al. (44), Frater et al. (45), and Kraft et al. (46).

The commercial driver for substrate models has been the search for novel fragrance ingredients, and odor has tended to be the defined biologic activity. However, the combinatorial mechanism of olfaction presents a serious obstacle for such substrate modeling and renders it almost meaningless in terms of understanding the mechanism of olfaction. Medicinal chemists who work on drug SARs usually are targeting a specific active site in a single protein. Fragrance chemists must target interactions of odorants simultaneously with the active sites of an unknown number of proteins because no single protein–single percept relationship exists. This lack of relationship can be the case even with animals simpler than humans. For example, it has been shown that the fruit fly Drosophila requires simultaneous activation of two different receptors to detect carbon dioxide (47).

Frustrating factors abound in structure/odor correlation. Sometimes, a small structural change in a molecule produces a large odor change whereas in other cases, gross structural changes produce little change in odor (44). Sometimes the chemical functional group in a molecule is important, as in the ester group and the fruity odor (25), whereas as other times the shape of the molecule is more important, as for the camphor odor (48). Absolute stereochemistry of a molecule sometimes affects its odor and sometimes it does not (49). Similarly, the effects on odor of a given change in molecular structure are unpredictable (50). In general, SARs suffer from the limitations of being interpolative and their reliability is proportional inversely to the number of steps in the process being modeled. In view of all of this and all of that has been said above about the process of olfaction, its combinatorial nature, its subjectivity, the difficulty in measuring odor and the fact that odor is a mental construction rather than a physical reality, it might be expected that structure/odor models would be impossible to find. However, many useful models do exist. The following accounts provide a few examples of useful models. For a more comprehensive list, the reader is referred to the reviews cited above.

The most consistently accurate structure/odor model is Amoore’s camphor model (48). As shown in Fig. 3, the model indicates that hydrophobic molecules with an ellipsoidal shape that have a long axis of 9.5 Å and a short axis of 7.5 Å will possess a camphoraceous odor. Another example of a simple but effective model is Boelens’s model for jasmine odors (51). Shown in Fig. 4, this model proposes that, to possess a jasmine odor, a molecule should contain a central carbon atom surrounded by a strongly polar group, a weakly polar group, and an alkyl chain.

The first published model for the ambrengis odor is that of Ohloff’s triaxial rule (52). This model proposes that, to possess an ambrengis odor, a molecule should have a trans-decalin structure with three axial substituents in a 1,2,4-relationship, as shown in Fig. 5 and that one of these should be an oxygen function. A more sophisticated model is that of Brusker et al., which is based on the electron topological theory of odor (53).

They propose that ambrengis odors have two hydrogen atoms

Figure 1

Amoore’s model for camphoraceous odorants.
that the charge on Hi should be negative, and that the charge atom should be between 0.24 and 0.31 of that of an electron, the molecule, that the coefficients of both of these hydrogen three atoms make a significant contribution to the LUMO of odorant successfully (61).

(55–60). Bajgrowicz et al. built an olfactophore model around hydrophobe and the distance between it and the alcohol function techniques to define more closely the exact requirements of the model has been refined by many workers that use different SAR center of hydrophobic bulk at a set distance from it. This basic suggests a model that involve s an alcohol function with a representative for decalin systems similar to the natural ambergris odor (54). Ohloff’s model is reasonably repre-
sions of which are shown in Figure 5.

and one atom located at the corners of a triangle, the dimen-
sions of which are shown in Fig 5. They also require that all three atoms make a significant contribution to the LUMO of the molecule, that the coefficients of both of these hydrogen atoms should coincide, that the negative charge on the oxygen atom should be between 0.24 and 0.31 of that of an electron, that the charge on H, should be negative, and that the charge density over the triangle should be $-0.1\text{e/Å}^2$. More recently, Bajgrowicz and Broger constructed an olfactophore model for the ambergris odor (54). Ohloff’s model is reasonably repre-
sentative for decalin systems similar to the natural ambergris chemicals. However, many ambergris odorants are known now for which this model in inapplicable. Therefore, the more recent models are of more use when studying the ambergris odor.

Even a cursory inspection of the known sandalwood odorants suggests a model that involves an alcohol function with a center of hydrophobic bulk at a set distance from it. This basic model has been refined by many workers that use different SAR techniques to define more closely the exact requirements of the hydrophobe and the distance between it and the alcohol function (55-60). Bajgrowicz et al. built an olfactophore model around this basic concept and used it to design a potent new sandalwood odorant successfully (61).

Receptor modeling

The ability to insert active olfactory receptors into functioning cells means that it is now possible to profile the activity of receptor proteins and move from the realm of gueswork into experimental reality. For example, Sans et al. have profiled and compared the selectivity of two human olfactory receptors that belong to different phylogenetic classes (62). They found that the class I receptor, OR51D1 has a relatively narrow range, which accepts alcohols, esters, ketones, and acids with a molecular length that corresponds to a chain of 8 or 9 carbon atoms; whereas the class II receptor, OR1G1, is much more broadly tuned and responds to a wide range of functional groups and with a preference for slightly longer carbon chains of 8 or 9 atoms. They also found that some odorants are capable of acting as antagonists and of blocking receptor activity from other molecules that would function normally as agonists. This finding is similar to that of Spehr et al. (1) who observed the same phenomenon with hOR17-4. Therefore, it seems likely that such antagonism is widespread and this will have implications for the perception of odor in mixtures. Because almost everything we smell is a mixture, such interactions are of considerable importance.

Models of the receptor sites are based on analogy with those of other GPCRs and of rhodopsin in particular. Using homology modeling, it would seem that the odorants are most likely to be bound in the regions between the 3-, 4-, 5-, and 6-transmembrane sections, and the region of rhodopsin is where 11-cis-retinal is bound. A good example of this approach is that of Pilpel and Lancet (63).

Several assumptions are made when building such models. For example, it is assumed that the tertiary structure adopted by rhodopsin in crystalline form is similar to that which it adopts when in the cell membrane; that olfactory receptor pro-
top's distance for receptor modeling, it would seem that the odorants are most likely to be bound in the regions between the 3-, 4-, 5-, and 6-transmembrane sections, and the region of rhodopsin is where 11-cis-retinal is bound. A good example of this approach is that of Pilpel and Lancet (63).

Several assumptions are made when building such models. For example, it is assumed that the tertiary structure adopted by rhodopsin in crystalline form is similar to that which it adopts when in the cell membrane; that olfactory receptor proteins adopt a similar tertiary structure to that of rhodopsin, and that ligand docking in olfactory receptors is similar to cofac-
top docking in rhodopsin. However, Vaidhevi et al. (64) have used MembStruk and HierDock software (which can be ob-
tained from William A Goddard III at Caltech, Pasadena, CA) to show that consistency exists between GPCRs of different types (mouse and rat olfactory receptors, the human sweet receptor, endothelial differential gene 6, and the $\beta$-adrenergic receptor) (64). They also showed that these modeling techniques work across this range of receptors and they used these models to predict the tertiary structure and binding site of rhodopsin with a reasonable degree of accuracy. Moreover, it is possible to test receptor models experimentally by comparing the predic-
tions of the model with the measured selectivity of the receptor in a live cell. Research in this area over the last decade has yielded significant results and we can be confident that we now have a reasonable concept of how olfactory receptors recognize their agonists.

One of the first exercises of this type was the work of Singer and Shepherd on the rat receptor OR5 which is known to respond to Lyral (International Flavors and Fragrances of Union Beach, New Jersey) (65). They proposed a model for the binding site of Lyral that involved transmembrane helices III to VII. However, a later model identified a somewhat different site using only helices IV, V, and VI (66). Floriano et al. investigated the mouse receptor OR525 (67). Using HierDock software, they identified binding sites and cal-
culated binding energies for 24 potential agonists. The binding site was found to involve 10 amino acids from transmembrane helices III-VI and the energies indicated that hexanol and hep-
tanol should bind most strongly. Experiments with the receptor in cells showed that, indeed, of the 24 test materials, only these two alcohols elicited a response. They then went on to screen an additional six mouse receptors (56, S1B, S19, S25, S18, S19, S25,
Also supported by mutation data. Extrapolating these results to examples studied, the selectivity of the receptors were determined largely by two of these positions. This latter result is consistent with the HierDock calculated binding energies and experimental receptor activation. They confirmed that the crucial transmembrane helices are III–VI and that extra-cellular loops II and III also contribute to binding. In the results from modeling were confirmed by materials remained in the binding site whereas others migrated out. Correlation with testing of the results was 100%. Those molecules found to be agonists whereas those that migrated out failed to activate the receptor in vivo. Moreover, the model elucidated the route into the binding site from the extracellular side of the protein. Similarly to the results from modeling were confirmed by in vivo testing of the receptors.

A new dimension in modeling was introduced by Lai et al. who built a dynamic model of rat receptor OR17 (72). They incorporated 10 potential aldehydic ligands into the binding site and then set the whole assembly into normal motion. Some test materials remained in the binding site whereas others migrated out. Correlation with in vivo results was 100%. Those molecules that the model predicted would remain in the binding site were found to be agonists whereas those that migrated out failed to activate the receptor in vivo. Moreover, the model elucidated the route into the binding site from the extracellular side of the protein. Similarly to the results from modeling were confirmed by in vivo testing of the receptors.

A consistent feature exists in all of these models, in that, for a good odorant/receptor fit, each model requires a polar group in the odorant that can form a hydrogen bond or similar interaction with a donor site in the receptor and the rest of the fit is determined by a spatial match with the shape of the (largely hydrophobic) binding pocket. Saturated hydrocarbons presumably lack the polar interaction and, in some cases at least, it would seem that weaker nonbonded interactions, such as π-stacking exist in the hydrophobic pocket.

Adaptation to different environmental temperatures establishes specific requirements on the stability of DNA and protein macromolecules. Organismal strategies of thermophilic adaptation, structure- and sequence-based, and their physical origins provide a consistent picture of the evolution of protein thermostability. A strong correlation between the optimal growth temperature (OGT) and the frequency of ApG dinucleotides in both sense and antisense strands of genomic DNA along with the absence of any “thermophilic” bias in the nucleotide composition highlights a key role of base stacking in the thermostabilization of the DNA double helix. The codon bias provides an excess of ApG pairs, which ensures the thermophilic adaptation of genomic DNA. The concentration of seven amino acids, Ile, Val, Tyr, Trp, Arg, Glu, Leu (IVYWREL), serves as a universal proteomic predictor of the OGT prokaryotes. The IVYWREL combination manifests a generic “thermophilic” trend in amino acid composition: the increase of hydrophobic and charged residues at the expense of polar ones. This so-called “from both ends of the hydrophobicity scale” trend is a result of the positive (stabilizing the native state) and the negative (destabilizing misfolded conformations) components of protein design. The pressure to preserve energies of important native and non-native contacts results in a correlation in mutations of amino acid residues involved into these contacts. A comparison of energy (Myiazawa–Jernigan potential) and substitution (BLOSUM62) matrices reveals a high rate of substitutions between amino acids that strongly attract each other (native contacts) and between residues that strongly repel each other (non-native contacts).

What makes thermophilic adaptation so attractive for researchers from the very beginning of protein and DNA molecular studies (1, 2)? Although life exists in different extreme conditions, such as temperature, pressure, salinity, radioactivity (3), the adaptation to extreme temperatures is an outstanding phenomenon. Indeed, organisms belonging to one level of organization, prokaryotes, thrive under environmental temperatures that cover the entire range from −10 to +110 °C, one third of the absolute temperature interval. A significant difference in the optimal growth temperature of prokaryotes results in a distinct stability of their proteins and DNA, which makes them a central subject in the studies of mechanisms of molecular adaptation.

The thermostabilization of biomolecules is a result of the mutual contribution from fundamental interactions [e.g., hydrophobic forces (4, 5) or ionic interactions (3, 6, 7)] that stabilize individual molecules and prevent their aggregation (6), structural modifications [such as DNA superhelicity (8, 9) and posttranslational modification of proteins], interactions with an environment (10), intermolecular interactions (11), and oligomerization (12). The possible dependence of fundamental interactions, for example, hydrophobic forces, on temperature may also affect stability. However, it remains a subject of controversy as to how and to what extent the dependence of the interaction strength on temperature should be taken into account (13–16). This article reviews the very basic level of protein and DNA thermostability,
fundamental interactions, and their sequence/structure determinants.

**Basics of Protein and DNA Thermostability**

Various factors that contribute to protein thermostability, such as van der Waals interactions (17), core hydrophobicity (18–20), networks of hydrogen bonds (4, 5, 21), amount of secondary structure (4, 22), ionic interactions (6, 7, 23), packing density (24), and decreased length of surface loops (25), have been a subject of intense study for several decades. The major challenge, however, is to find out how the above factors are chosen and their combinations are formed by natural selection responding to the environmental temperature and depending on the evolutionary history of the organism (26).

Thermostabilization of double-stranded DNA is provided by base pairing (1) and base stacking (see Reference 27 and references therein) complemented by positive supercoiling by reverse gyrase (in hyperthermophiles (8, 9, 28)) and by stabilization via interactions with histone-like proteins (29, 30). The relative contribution of base pairing and base stacking into the thermostability of double-stranded DNA has been a subject of extensive studies for more than four decades (1, 27, 31). We will consider here this question, based on the results of recent experimental and computational works (31, 32).

**Sequence/Structure Signals of Thermophilic Adaptation**

Major “recipes” for increasing the thermostability observed in previous computational sequence/structure analysis and confirmed in experiment vary from the optimization of hydrophobic core interactions (18–20) to the introduction of additional ion pairs (7, 32). Respectively, thermophilic trends known so far include a large difference between the proportion of charged (DEKR) versus polar (noncharged, N/Q/G) residues (34, 35), an increase of long and branched side chain hydrophobic residues (36), an excess of some aromatic amino acid (35), and an over-representation of Pro (37). Recently, Satterson/mine et al. (37) illuminated the importance of structure dependence in the relationship between amino acid composition and optimal growth temperature (OGT) of the organism. In particular, the difference in amino acid frequencies between core and surface residues is getting more pronounced under higher temperatures (38), but not during adaptation to a cold environment (37). It also was demonstrated that amino acid biases in thermophilic adaptation are independent of the (G+C) content of coding nucleotide sequences, and the (G+C) content itself is not a determinant of the thermophilic adaptation of the double-stranded DNA (39–41).

**Experimental (Re)Design of Thermostable Proteins**

All experimental techniques of protein thermostabilization can be related to one of three major directions (40). First, the rational design concept is based on using previously known stabilizing factors. The limited predictive power of the rational design concept prompts one to test all potentially thermostabilizing mutations by using site-directed mutagenesis. The second approach is a directed evolution approach. Selective pressure or screening for a desired trait applied after random mutagenesis and/or DNA shuffling provides another possibility for engineering protein stability. Limited sequence space, amenable to testing in directed evolution, makes it necessary to eliminate more effectively the neutral and deleterious mutations, to increase the number of recombination events, and to improve the selection tools. Third, the “consensus concept” is based on the assumption that consensus amino acid contributes more to the stability of the protein chain than the nonconsensus amino acid at a given position in the alignment of the amino acid sequences.

**Physics and Evolution of Thermophilic Adaptation**

The tight connection between the “recipes” for thermostability immediately raises a question about the common evolutionary and/or physical basis for the variety of mechanisms of thermophilic adaptation. To address this question, one has to go beyond the analysis of specific stabilizing interactions and their various combinations. Conceptually, then, two major directions lead to the selection of proteins with high thermal stability. First, thermostable proteins have a structural bias such as enhanced packing. Second, stabilization is achieved by a few particularly strong, strategically placed interactions. The choice between these directions is affected by several evolutionary and environmental factors, and thermostabilization is a result of the intimate interaction between the physics of protein stability and the phylogenetics of the host organism.

**Physical Basics of Protein Thermostability**

Given a structural similarity between meso- and thermophilic orthologs, the variation of the stability across different proteins stems from the differences in the physical mechanisms of thermostability (3). Sequence/structure analysis and the unfolding simulations of hyperthermophilic proteins and their mesophilic homologues (43) reveal two major mechanisms of thermostabilization (Table 1). The first mechanism is “structure-based.” Some hyperthermophilic proteins are significantly more stable than their mesophilic homologues because of their high compactness (44). In this case, no single type of interaction is extremely strong and dominates stabilization, but the sheer number of interactions provides enhanced stability. Structure-based thermostability is nonspecific in the sense that no or minimal special features of sequences are needed to achieve thermostability, which makes it robust under a wide range of environmental conditions. A possible evolutionary disadvantage of such a robust stabilization mechanism is that it makes the protein less adaptable to rapid and specific changes in environmental conditions. The second mechanism is “sequence-based.” This way, several substitutions made in sequences of mesophilic proteins provide the formation of “staples,” that is, specific and strong...
Designability of structure is reflected in the certain properties of protein structure that indicates how many sequences can fold into that structure at various levels of stability (46, 47). Designability is a property of protein structure that correlates with the second order of C (Tr²C), of the contact matrix of a structure, C (44, 46). In particular, designability correlates with the compactness of a structure (number of contacts per residue). It was demonstrated (44) that more designable structures provide initial advantage because a greater number of sequences can fold into them with low energy. Therefore, a sequence search in the design of a thermostable protein will be less severe given a highly designable structure. A high contact density of LUCA domains (48) is suggestive, which shows that nature used high designability in the creation of the first thermostable proteins for ancient species. The role of designability in the design of ancient thermostable proteins is corroborated additionally by the high-throughput analysis of major folds (43). The Van der Waals contact density in hyperthermophilic archaea Pyrococcus is higher than in hyperthermophilic (T. maritima and A. aeolicus) or mesophilic (E. coli) bacteria. It indicates that on the organismal level, archaea used a structure-based mechanism and developed a respective strategy of thermophilic adaptation. What evolutionary scenario can one imagine for the emergence of another, sequence-based, strategy of adaptation? When mesophilic organisms recolonized in a hot environment, it was necessary to find a fast and effective way of tuning protein stability. To increase the stability of the protein without a redesign of the whole structure is possible via making sequence substitutions that introduce “staples,” a restricted set of a strong specific interaction (e.g., ion pairs). Hyperthermophilic bacteria (T. maritima and A. aeolicus), which recolonized in hot conditions, exemplify a sequence-based strategy. A high-throughput comparison of T. maritima and A. aeolicus proteomes with those of hyperthermophilic archaea shows the crucial role of sequence-based strategy in achieving the thermostability of proteins in hyperthermophilic bacteria (43). An analysis of the phylogenetic relationships between hyperthermophilic archaea and bacteria provides additional evidence for different organismal strategies of adaptation. 24% and 16% of the genes of T. maritima and A. aeolicus, respectively, were transferred to bacteria via lateral gene transfer (LGT) from archaea (49, 50), and corresponding bacterial proteins are the most similar to those of archaea. The importance of LGT in specific biochemical and environmental adaptations was demonstrated undoubtly by the comparison of complete genomes, codon analysis within genomes, and phylogenetic trees based on single gene families (see Reference 51 and references therein). Alternatively, it may be problematic to assess the relative contributions of LGT and vertical inheritance. For example, T. maritima and A. aeolicus belong to two lineages (Thermotogales and Aquificales) believed to have diverged earliest from the rest of bacteria. Therefore, it is possible that T. maritima and A. aeolicus retained ancestral genes and share some primitive features with archaea, whereas these genes were lost in the rest of the bacterial species. However, regardless of the
scenario working in Thermotoga and Aquilae (genes are received via LGT or, alternatively, are descendants of retained ancestral ones), the so-called "archaeal" parts of their genomes are reflective of the hyperthermophilic lifestyle and the distant evolutionary past (51). In particular, the archaean parts of the above bacterial proteomes (extracted according to the listing in the taxonomic distributions of the homolog TaxMap, available at http://www.ncbi.nlm.nih.gov) exhibit compositional features typical for structure-based strategy, whereas the bacterial parts follow a sequence-based strategy of thermophilic adaptation (43). Later events in protein evolution affected structures/sequences of both archaean and bacterial species which combine strategies of adaptation (52) or use complementary mechanisms of stability (53).

Genomics/Proteomics of Thermophilic Adaptation

A better understanding of how nature adapts life to elevated temperatures of the environment helps us to get a deeper insight into the basic physical laws that govern protein design. In particular, the explosion of information on crystalized proteins and complete genomes/proteomes makes it realistic to perform high-throughput analysis of sequences and structures. In this part, we will show how 1) alignments of proteomic sequences reveal a signal of a new entropic mechanism of thermostability, 2) exhaustive enumeration of all possible combinations of amino acid residues identifies a particular combination of them, which can serve as the best predictor of the optimal growth temperature (OGT) prokaryotes, and 3) correlation analysis which can serve as the best predictor of the optimal growth temperature of hyperthermophiles.

2) exhaustive enumeration of all possible combinations of amino acid residues identifies a particular combination of them, which can serve as the best predictor of the optimal growth temperature (OGT) prokaryotes (43). Later events in protein evolution affected structures/sequences of both archaean and bacterial species which combine strategies of adaptation (52) or use complementary mechanisms of stability (53).

Entropic Mechanism of Protein Thermostability

The compositional bias toward increasing charged residues in hyperthermophilic proteomes compared with mesophilic ones is well documented. However, the enrichment in positively charged residues is almost entirely because of lysines (34) (see Table 2). If only the total content of arginine (Arg) plus lysine (Lys) residues would matter in determining the stability of hyperthermophilic proteins, then no preference for the Lys over the Arg should exist. Arg and Lys are similar residues by their physical and chemical features; both residues are charged and have the same maximal number [81] of possible rotamers. An examination of the substitutions of types Arg/Lys versus Lys/Arg in the alignments of mesophilic sequences versus hyperthermophilic ones (Fig. 1) sheds light on the relationship between Arg and Lys content. The number before the slash (Table 3) is the percentage of amino acid residues in the mesophilic sequence, for example, Arg that was replaced by the other amino acid in the hyperthermophilic sequence, for example, Lys. The number after the slash reflects the same data for the opposite replacement, for example, Lys in the mesophilic sequence replaced by Arg in the hyperthermophilic sequence. Numbers in parenthesis show the ratio of forward to backward substitutions. The control groups are pairs Leu/Thr and Ser/Thr. Residues in each pair possess similar physical and chemical features (Leu/Thr are hydrophobic; Ser/Thr are polar), and both have the same maximal number of possible rotamers (9 and 3, respectively). In nine hyperthermophilic organisms, the pairs RK/KR demonstrate a remarkable bias toward the replacement of arginine in the mesophilic sequence with lysine in the hyperthermophilic sequence (Fig. 1) and hints to the specific role of lysine in protein stabilization. The complementary all-atom unfolding simulations show that lysines have a much greater number of accessible rotamers than arginines of similar degree of burial in folded states of proteins (53). Significant residual dynamics of lysine in folded states of proteins makes the entropic cost to fold lysine-rich proteins less favorable compared with arginine-rich ones. The arginine-to-lysine replacement stabilizes the folded state, preserving, however, the charged nature of the substitution.

Table 2 Percentage of charged amino acids and (G + C) content of 10 hyperthermophilic archaea (A), 2 hyperthermophilic bacteria (B), and mesophilic bacteria E. coli. A strong prevalence of lysine over arginine in proteomes of hyperthermophiles is obtained for nine organisms. A bold font marks the exception from the general trend

Protein and DNA Thermostability, Physics and Evolution of

Proteome Sequence Determinant of Thermophilic Adaptation

The availability of complete genomes/proteomes makes it possible to search systematically for the combination of amino acid residues, which is most important for protein thermostability (41, 54). An exhaustive enumeration of all possible subsets of 20 amino acids is performed by representing sets of amino acids by vectors, where each component $a_i$ of the vector takes the value of 1 if the amino acid of type $i$ is presented in the set and 0 otherwise. Thus, $2^{20} - 2 = 524,286$ linearly independent non-trivial combinations exist. Given $F_{i,j}$, the fraction of amino acid $i$ in proteome $j$, total fraction $F$ of the amino acids from a particular subset, $F = \sum_i a_i F_{i,j}$, linear regression between the values of $F$ and the optimal growth temperature (OGT) of the organism allows us to determine the best predictor of OGT.

For 86 complete proteomes of prokaryotes thriving under temperatures from $-335$ to $110^\circ$C, the combination of Ile, Val, Trp, and Leu (IVWL) amino acids, which is presented in the set and 0 otherwise. Thus, $2^{20} - 2 = 524,286$ linearly independent non-trivial combinations exist. Given $F_{i,j}$, the fraction of amino acid $i$ in proteome $j$, total fraction $F$ of the amino acids from a particular subset, $F = \sum_i a_i F_{i,j}$, linear regression between the values of $F$ and the optimal growth temperature (OGT) of the organism allows us to determine the best predictor of OGT.

when Ala (A) or a combination Ala, Gin (A,G) replaces Glu (E) or a combination Val, Gin (V,E). The correlation coefficient R is 0.18 and 0.23, respectively.

Finally, the fundamental question in thermophilic adaptation is a relationship between the amino acid composition of proteins and the nucleotide composition of coding DNA sequences (39-41). The availability of prokaryotic complete genomes, which consist mostly of coding DNA (on average ~85% of the total genome size), clarifies a relationship between the thermophilic adaptation of protein and DNA. If the NVYRELL predictor depends on nucleotide composition only, it must remain the same after the reshuffling of coding sequences given a nucleotide composition. However, the reshuffling of nucleotide sequences results in a non-NVYRELL thermostability predictor (32). Therefore, amino acid composition and thermal adaptation of proteins are not affected by the nucleotide composition of DNA sequences. The amino acid composition of the proteome, on the contrary, introduces a bias in the purine loading (A + G content) of nucleotide sequences. Indeed, purine loading of coding sequences reversely translated from protein sequences without codon bias, for example, by using synonymous codons with equal probabilities, is very close to a natural nucleotide sequence. The correlation coefficient between the purine loading and OGT is 0.48 and 0.6 in sequences without codon bias and natural ones, respectively (32).

Major Role of Stacking in DNA Thermostability

Pairing and stacking are two major factors of DNA stability. In a base pairing, the G+C pair contains three hydrogen bonds compared with the A+T pair that has two hydrogen bonds. The classical Marmur and Doty work (1) gives a linear relationship between the (G + C) content of the double-stranded DNA and its melting temperature, which strongly suggests that stability of the G+C and A+T pairs is different independently of their neighbors. This result originated a belief that DNA thermostability is provided mainly by pairing interactions and is achieved via (G + C) loading. Furthermore, the role of (G + C) content in establishing specific "thermophilic" biases in the amino acid composition of corresponding proteins was discussed extensively. A high-throughput analysis of genomic sequences conclusively demonstrates the absence of any connection between the (G + C) content and the OGT of the organism (39-41). The only bias in the nucleotide composition that correlates with the OGT is the (A + G) content (purine loading). It was shown, however, that purine loading is determined chiefly by the amino acid composition of proteins (32). Thus, thermostabilization of DNA does not work on the level of nucleotide composition.

The next step in the description of the DNA sequence is the analysis of the pair-wise nearest-neighbor correlations, for example, the normalized probabilities to find successive pairs of the nucleotides A and T. For all 16 possible successive dinucleotides in the coding strand of DNA, only the functions cCG and cCT correlate with OGT. The excess probabilities to find A+G and C+T pairs in the coding DNA are increasing significantly with OGT, correlation coefficient R = 0.68 and 0.601 (Fig. 2, upper row). Remarkably, the codon bias explains the observed sequence correlations in the coding parts of DNA. First, correlation in the nucleotide sequences does not depend on sequence correlations in amino acid sequences because removing an effect of the codon interface does not destroy a correlation between cAG, cCT and OGT, R = 0.736/0.574 (Fig. 2, middle row). Second, the correlation in DNA sequences stems from the neighboring nucleotides within a codon. Indeed, removing the natural codon bias results in eliminating the correlation between cAG, cCT and OGT, R = 0.177/0.216 (Fig. 2, bottom row). Thus, the codon bias establishes an excessive use of codons that contain successive A+G or C+T pairs, which is manifested in the correlation of OGT with the optimal growth temperature. The above sequence correlations in the coding strand of DNA sequences point to base stacking as a major factor of DNA thermostabilization. A+G dinucleotides have a low energy characteristic for a purine-purine stacking. The cCT correlation also shows, although indirectly, the role of stacking in thermostabilization. Indeed, the abundance of C+T pairs in the sense strand points to the equal enrichment of the antisense strand with A+G pairs because of the opposite directionality of sense and antisense strands of DNA. Therefore, the thermostabilization of double-stranded DNA is based on the stacking interactions provided by A+G pairs that are spread in different locations of both sense and antisense strands. This picture holds also for the whole DNA of prokaryotes, including its coding and noncoding parts. Therefore, in the scenario of thermophilic adaptation of double-stranded DNA, the stacking interactions play a major role. The codon bias provides an increase in the number of A+G dinucleotides with OGT in both sense and antisense strands of the DNA double helix. The necessity for A+G pairs can be explained by their low free energies of stacking obtained both theoretically (56) and experimentally (57). First, the study of the free energy contribution to the nucleic base stacking in aqueous solution shows that the free energy of stacking in order of decreasing stability follows the order purine-purine > purine-pyrimidine-pyrimidine-purine-pyrimidine-pyrimidine in general, and the free energy of A+G stacking is one of the lowest in particular (56). Second, the experimental study on the coaxial stacking contribution to the stabilization of gel-immobilized duplexes reveals that adenine stacking with other bases is significantly stronger than the stacking of other bases (57). The reasons for the discrepancy between the latter and the parameters of duplex stability obtained in the nearest neighbor approximation are yet to be explored (see Reference 27 and References 16-19 therein).

Recent experimental efforts also corroborate a major role of the base stacking (31) in DNA thermostability and the independence of the latter on G+C base pairing (1). In particular, DNA stacking parameters are determined directly (31) for the temperatures from below room temperature to close to melting temperature and for the salt concentrations from 15 to 100 mM Na+ . It seems that base stacking is the main stabilizing factor in the double-stranded DNA that determines the temperature and the salt dependence of DNA stability parameters. The A+T pairing is always destabilizing, and G+C pairing contributes almost no stabilization (31). It is important to note that base stacking interactions always are stabilizing for both A+T and G+C-containing contacts in double-stranded DNA. Bioinformatics studies display the importance of stacking...
by showing the independence of the DNA thermostability on (C + G) content (32, 39–41) and by illuminating a specific role of ApG stacking in the thermostability of the DNA double helix via a consideration of pair-wise nearest neighbor correlations (32) or a regression analysis of the dinucleotide composition of genomic DNA (41).

**Minimalist Physical Model of Protein Thermostability**

It is of great importance for protein design to elucidate how physical principles work in the evolution of natural proteins and how they provide viability and adaptation to different environments. A analysis of individual prokaryotic and eukaryotic proteins reveals a direct connection between their stability (expressed in melting temperature, \( T_{\text{melt}} \)) and the average living temperature of the organism, \( T_{\text{env}} \) (4); hence, environmental temperature should be incorporated in the model of protein thermophili design. In terms of statistical physics, the stability of the native state of a protein is determined by the Boltzmann factor exp(\( -\Delta E/RT \)), where \( \Delta E \) is the energy gap between the native state and the lowest energy completely misfolded structure (58, 59). This factor imposes a requirement on the energy gap; it must increase with the temperature (Fig. 3), and, as a result, the unique lowest energy native state will be preserved from the destruction by thermal fluctuations. The widening of the energy gap can be achieved by lowering the energy of the native state (positive design) and by increasing the energy of the misfolded structures (negative design) or by both processes working simultaneously.

**Design of Model Proteins with Selected Thermal Stability**

The first approach to simulation of protein thermophilic adaptation is to start from a purely statistical–mechanical analysis of protein thermostability. A specific Monte Carlo procedure [the so-called P-design (60, 61)] exists that maximizes the Boltzmann probability \( P_{\text{nat}} \) of being in the lowest energy (native state) conformation, \( P_{\text{nat}}(T_{\text{env}}) \approx \frac{e^{-\Delta E/RT_{\text{env}}}}{e^{-\Delta E/RT_{\text{env}}}} \), where \( E_3 \) is the lowest energy among all conformations and \( T_{\text{env}} \) is the environmental temperature. It takes the environmental temperature \( T_{\text{env}} \) as an input physical parameter, introduces mutations in the amino acid sequence, and accepts or rejects them according to the Metropolis criterion. As a result, this procedure designs proteins stable at given \( T_{\text{env}} \). The stability of designed proteins is characterized by their melting temperature \( T_{\text{melt}} \) that can be found numerically from the condition \( P_{\text{nat}}(T_{\text{env}}) = 0.5 \).
“From Both Ends of the Hydrophobicity Scale” Trend in Thermophilic Adaptation

The design of model protein for thermostability by using an exactly solvable lattice model (103,346) compact conformations of $3 \times 3 \times 3$ lattice proteins (62) discovers the fundamental rules of thermophilic adaptation. First, the amino acid composition of designed proteins reveals a specific “thermophilic” trend: Thermostabilization is accompanied by an increase of the amount charged (DEKR) and the hydrophobic amino acids (MPCLVWIF) at the expense of weak hydrophobic and polar (AGNQSTHV) ones. Importantly, the amino acid composition of β3 proteomes of psycho-, meso-, thermo-, and hyperthermophilic prokaryotes reveals similar trend. Thus, the “from both ends of the hydrophobicity scale” trend, that is combining amino acids with the maximum variance in their hydrophobicity, observed in simulations is, indeed, crucial for the thermostabilization of proteins.

The “from both ends” trend is related to the positive and negative components of the design. The positive design is a major contributor to the temperature-dependent energy decrease of the native state, and the negative design ensures an increase of the average energy of misfolded conformations (when an increase occurs in the $T_{m}$). Interactions between strongly hydrophobic residues in the protein core and ion pairs formed by amino acids of the opposite charge on the protein surface are responsible for the positive design. The repulsion between charged residues of the similar sign contributes to the negative design by raising the average energy of misfolded conformations (see Fig. 3). Importantly, both positive and negative components of the design are based on the conservative native and non-native contacts between residues that play an especially important role in the stabilization of the native state and the destabilization of the misfolded conformations (62). Whereas identities of amino acids that form such a contact may vary from sequence to sequence, the strength (or interaction energy) of the key native and non-native contacts is preserved: These contacts are either strongly repulsive or strongly attractive for all sequences that fold into a given structure (see Fig. 6 in Reference 62).

Design simulations confirm an existence of the energy-conserved strongly attractive (native) and most repulsive (non-native) contacts (62). The standard deviation of the contact energy is the lowest for these contacts. When the design is performed under hyperthermophilic temperatures, it results in stronger and more conserved (lower dispersion of the energy) native and non-native interactions compared with the design under the mesophilic temperatures (see Fig. 7 in Reference 62). As a result, the gap between the energies of native and misfolded structures is widening and the thermostability of the structure is increasing in response to the elevated environmental temperature $T_{m}$.

Positive and Negative Design in Evolution and Thermal Adaptation of Natural Proteins

The requirement to preserve energy of key contacts in multiple sequences that fold into the same structure implies that amino acids forming such contacts should mutate in a correlated way. For example, correlated mutations may occur as swaps to keep specific attractive native and repulsive non-native interactions (see Fig. 8 in Reference 62). This scenario invokes a peculiar dependence between the amino acid substitution rates [e.g., BLOSUM matrices (63)] and the interaction energy between corresponding amino acid residues [e.g., the Miyazawa–Jernigan quasi-chemical potential (64)]. Frequent substitutions are expected between amino acids that strongly attract each other (to preserve specific stabilizing native contacts) and between amino acids that strongly repel each other (to preserve specific non-native repulsive contacts). The dependence of elements of substitution matrix BLOSUM (62, 63) for 190 pairs of amino acids (synonymous substitutions are excluded) versus their interaction energy as approximated by the knowledge-based Miyazawa–Jernigan potential (64) has a nonmonotonic nature (Fig. 4, top chart: the dependence is highlighted by the parabolic fit). The most frequent substitutions are observed between the most attractive and most repulsive amino acids. A blow-up of the right top part of Fig. 4 (bottom chart) shows that along with conserved substitutions that reflect a positive design (arginine to lysine and glutamic acid to aspartic acid substitutions), frequent substitutions exist between mutually repulsive amino acids with vastly different physical-chemical properties and encoded by very dissimilar amino codons, such as glutamine to arginine, serine to asparagine, and so forth (Fig. 4, bottom chart). The high frequencies of substitutions between residues that strongly repel each other explain the correlated mutations observed between the residues that are distant in the native structure (62). These residues may form important repulsive contacts, which increase the energies of the misfolded conformations (see Fig. 10 in Reference 62).

Whereas a positive design is used widely in experiments (65), the big challenge in using the negative design originates from the difficulties in the modeling of relevant misfolded conformations (66). Nevertheless, charged residues were used effectively in negative design (65, 66). Site-directed mutagenesis provides other, although indirect, evidence of the contribution of charged residues to negative design: The mutation of polar groups to negatively charged ones on the protein surface leads to structure stabilization even in the absence of the salt-bridge partners of the mutated group. It also has been shown (67–70) that surface electrostatic interactions provide a marginal contribution to stability of the native structure, hence, the possible importance of charged amino acids is in making unfavorable high-energy contacts in misfolded structures. In the case of thermophilic adaptation, positive and negative components of design work concurrently and provide stabilization of the structure via an “opening” of the energy gap from both sides: A decreasing energy of the native state and, at the same time, an increasing energy of misfolded conformations can both exist.

Conclusions

A deep understanding of the physical mechanisms and the evolution of thermophilic adaptation is crucial for the engineering and design of biologic catalysts with desired stability (20). This
knowledge also is important for establishing a trade-off between the stability and flexibility in a directed evolution of protein function (66, 71). Current predictors of the stability effects of protein mutations are based on empirical potentials that are calibrated to fit experimentally observed $\Delta\Delta G$ values (20, 72, 73). Although predictions of $\Delta\Delta G$s during mutation in the native state are in good agreement with experimentally observed ones, they lack the effect of mutations on misfolded conformations, the structure-dependence of mutation effects (37, 38), and the dependence of mutations on the evolutionary strategy of thermophilic adaptation (43).

Recent computational studies of thermophilic adaptation described in this article make use of genomic/proteomic data (32, 43, 53, 62), simulations of model lattice proteins (62), and off-lattice all-atom simulations of natural proteins (43, 53). High-throughput analysis reveals signals of novel mechanisms of protein [entropic mechanism (53)] and DNA [purine–purine base stacking (32)] thermostability and urges us to consider what evolutionary strategy was followed in the process of thermal adaptation (43). Proteomic analysis and simulations of thermophilic adaptation also demonstrate that negative design necessarily should be taken into account to properly predict the effect of protein mutations (62).

The term “symbiosis,” from the Greek: συµβίον = living together, was defined by Anton de Bary in his monograph “Die Erscheinung der Symbios” as “the living together of unlike organisms” (1). His studies were based on the formation of lichens, which are the result of an association between a fungus and an alga or cyanobacterium. The definition was coined in the end of the nineteenth century but is regarded by most symbiosis researchers as largely valid today. Accordingly, any specific association between two or more species can be classified as symbiosis. It should be noted that many scientists use symbiosis in a more restricted way to denote a mutually beneficial relationship. This article will give an overview of various biologic manifestations of symbiosis and discuss selected examples, where primary or secondary metabolites play a crucial role in the association.

Symbiosis and Its Variants

If the partners in a symbiosis differ in size, the larger member is termed “host” and the smaller member is termed “symbiont” or “symbiote.” The more common term “symbiont” will be used here. One general way to distinguish between various forms of symbiosis is to identify the location of the attachment of the symbiont to the host. Symbionts that live on the host surface, including internal surfaces like the digestive tube, participate in ectosymbiosis (Greek: εκτός = outside). If a symbiont is localized within the tissues of the host, the association is termed “endosymbiosis” (Greek: ενδόν = within). Endosymbionts can be found either in the extracellular space or intracellularly.
with beneficial mycorrhizal fungi (2) or nitrogen-fixing bacteria (3) living on and in their roots. A mutual relationship can consist of partners that benefit from the association but do not depend exclusively on each other for survival. This mutual relationship is called protocooperation (Greek: πρωτ = first; Latin: cooperatio = cooperation). Such a facultative mutualism is known from the association of fungi and photosynthesizing microorganisms in lichens (4). In contrast, an obligate mutualism, where host and symbiont cannot survive after separation, is known as endosymbiosis (Greek: εν = good). Examples are mitochondria, chloroplasts, and other bacterial intracellular symbionts of higher organisms. These so-called primary or obligate symbionts usually are ancient, if specialized supracellular host structures exist that harbor such symbionts, they often are termed bacteriosomes. In insects, evidence exists for obligate symbioses that last 30–270 million years, and the symbionts usually coevolve with their hosts (5–7). During this long time of host dependency, the genomes of primary symbionts can undergo massive restructuring, which results in extremely small genome sizes. In addition to primary symbionts, many hosts harbor secondary or facultative symbionts. They participate in an intermediate form of symbiosis, where the symbiont is not strictly necessary for the survival of their host and is not exclusively localized in specific tissues. Because of occasional horizontal transfer, the phylogenetic trees of such organisms often are not congruent with those of their hosts (8). Many secondary symbionts are transmitted maternally and can influence, positively or negatively, various host traits, such as nutrition, survival against natural enemies, or reproduction rates (9, 10).

On the opposite side of mutualism in the interaction spectrum of symbiosis is parasitism (Greek: παρα = besides; σίτ = fatted). Here one species, called the parasite, has physiological or structural properties that force it to live temporarily or during its whole life on (ectoparasitism) or inside (endoparasitism) another species, the host. Only the parasite benefits from this relationship. Different types of parasitism exist, including biotrophy, in which the host survives during the entire time of the association; pathotrophy, in which the host lives for a short time after contracting a parasite, and necrotophy, in which the host is killed before the symbiosis starts. Biotrophs and necrotrophs are known also as parasitoids. This term was coined in 1913 by the entomologist D. M. Rauter to distinguish between true parasites that live at the expense of their hosts without actually causing their death and the parasites that always kill their hosts (11). Among the parasitoids are two categories, which describe the behavior of the parasitoids toward the host. A first the initial paratization, the idiobiont parasitoid prevents any additional development of the host. This parasitization is typical for an immobile host life stage like an egg or a pupa. Most of these parasitoids are endoparasites. A literally, a koinobiont parasitoid allows the host to continue its development and often does not kill or consume the host until it starts to pupate or become an adult. These parasites, therefore, mostly live in or on an active and mobile host. Some primary parasitoids serve as hosts for yet another parasitoid. The latter is termed "secondary parasitoid" or "hyperparasitoid" and usually kills both the host and the primary parasitoid. Several other commonly used terms exist for different kinds of parasitism. Kleptoparasitism is a relationship in which the parasite steals food that a host has caught or otherwise prepared. An example is the brood parasitism, which is known from many species of cuckoo that use other birds for parenting (12). Social parasites take advantage of interactions between members of a social host species like ants or termites (13). A rather special type of parasitism is cheating or exploitation. Here, the parasite uses situations of nonspecific mutualism to its advantage. Some myco-heterotrophic plants, for instance, establish mycorrhiza-like interactions with fungal symbionts and take carbon from the fungi that the fungi obtain from other plants (14). Opportunism is a kind of parasitism where harmless parasites under special circumstances cause diseases or death of their hosts. The fungus Pneumocystis carinii can initiate pneumonia if the host is infected by HIV (15). As in mutualism, obligate and facultative symbionts exist in parasitism. Obligate parasites are not viable without their host, and facultative parasites are free-living organisms that sometimes benefit from their host.

A third form of symbiosis, in addition to mutualism and parasitism, is commensalism (Latin: com = with; mensa = table). In commensal relationships, one symbiotic partner benefits from the association and the other is unaffected. Different variants of such relationships have been described. Inquilinism is a kind of commensalism where the symbiont uses a host for housing, such as birds living in the holes of trees. A more indirect dependency exists if a symbiont uses something its host has created or even the main determinant for a symbiosis, in which case the term "chemosymbiosis" often is used. A wide spectrum of substances can be involved, ranging from simple inorganic ions to highly complex secondary metabolites. Similarly diverse can be their function, such as nutrition, chemical protection, localization cues, developmental signals, and others. The chemical ecology of symbiotic associations is a relatively unexplored field.
field, and particularly systems that involve microorganisms can be difficult to study because cultivation requirements often are unknown or impossible to reproduce. However, with the advent of culture-independent methods and innovative cultivation techniques, this situation recently has begun to change.

The following sections will give some representative examples where small molecules play an important role in the symbiotic interaction. Cases involving inorganic substances and primary metabolites will be discussed; secondary metabolism will be the subject of the subsequent section.

Inorganic compounds

A best-studied example for a symbiosis between plants and bacteria is the association between leguminous plants and various members of the α-proteobacterial order Rhizobiales (3). The bacteria colonize root nodules of the plants and differentiate morphologically into bacteroids. These bacteroids fix nitrogen from the atmosphere, convert it to ammonia and amino acids, and supply it to the host plant. The bacteria receive organic acids like malate or succinate as a carbon and energy source from the plant. It has to be noted that this symbiosis is not a strict mutualism. The nitrogen fixation is energetically costly to the rhizobia and reduces the resources that could be allocated to their own growth and reproduction (17, 18). Some soils contain rhizobial strains that fix little or no nitrogen (19). Because the strains can coinfect an individual plant together with nitrogen fixers (17), any of these strains could redirect the resources from nitrogen fixation to its own growth and fitness at the expense of its host and the other lineages. This parasitism is a kind of cheating parasitism. Hence, the legume needs ways to guide the evolution of rhizobia toward greater mutualism (20).

Mycorrhiza, an association between soil fungi and plant roots, is one of the best-studied symbioses. The fungi, termed “mycorrhizal,” colonize the roots of 80% of all land plants carry (vesicular-)arbuscular mycorrhiza (32). The mycorrhiza is densely vascularized surface. It allows an efficient exchange of metabolites and waste products between the worm and the sea water. The major interior tissue of the worm is the trophosome that is localized in a large sac formed by the body wall (32). The cells of the trophosome, termed “bacteriocytes,” are colonized densely by the bacterial endosymbiont (33, 34). Its amount is estimated to reach between 15% and 35% of the whole cell volume (35). The bacteria are supplied with various nutrients by the blood circulation of the worm, which is driven by a heart-like pump. The blood contains an unusual multiheme-moglobin system, which can transport both sulfide and oxygen (36, 37). The mutual contributions of the bacteria are manifold. One function is to oxidize the transported sulfide into sulfite to produce metabolic energy for both partners (33, 38, 40). Furthermore, the bacteria are indispensable in several assimilation processes by providing various enzymes that the worms lack. An example is the CO₂ absorbed by the worm, which is transported to the bacteria by the blood cycle, either directly (41) or via synthesized malate (42). The bacteria, in turn, employ enzymes of the Calvin-Benson cycle to convert the CO₂ to small organic compounds (38, 42, 43). These metabolites then are used by the host for its own metabolism and production of adenosine triphosphate (ATP). The assimilation of ammonia and nitrate also depends on the endosymbiont. Although the glutamine synthetase and glutamate dehydrogenase required for ammonia assimilation are present in both partners (44), the nitrate-reducing enzymes are provided exclusively by the bacteria (43–45). The symbiont also provides the necessary enzymes for a de novo synthesis of pyrimidine but lacks the enzymes of the salvage pathways that allow pyrimidine synthesis from nucleic acid degradation products (45, 46). The host, however, only possesses enzymes that catalyze the final steps of the de novo pathway but provides enzymes of the salvage pathway (46). The de novo synthesis of pyrimidine, thus, is regulated by the bacterial enzymes. Arginine is metabolized in a similar manner. The worm does not possess arginine decarboxylase or ornithine decarboxylase activities (47), and it is likely that it depends on the bacteria to realize this pathway.

In another gillless marine worm, the oligochaete Olavius algarvensis, three partners participate in an unusual mutualism. The worm harbors two different primary symbionts in immediate proximity below its cuticle between extensions of epidermal cells. By performing comparative 16S rRNA sequencing and
fluorescence in situ hybridization, two dominant clone groups of the γ- and δ-subclasses of the proteobacteria were found (48). The larger γ-proteobacterial symbiont possesses a high sequence similarity with endosymbionts from other gutless oligochaetes, like Oligolimnus loisei and Inanidrilus leukodermatus (49, 50), and is thioautotrophic, i.e., possesses a sulfur-oxidizing, CO₂-fixing metabolism (48). The smaller δ-proteobacterial symbiont is genetically very similar to free-living sulfate-reducing bacteria, and the sulfate-reducing function also could be demonstrated in O. algarvensis (48). The coexistence of these bacteria indicates that they are engaged in a synthetic sulfur cycle in which oxidized and reduced sulfur compounds are exchanged back and forth (48). The oligochaete benefits from this arrangement by obtaining de novo-synthesized organic compounds from the symbionts, which in turn assimilate its anaerobic end products. The constant internal source of reduced sulfur compounds allows the worm to colonize new habitats without a requirement of high sulfide concentrations.

Numerous additional examples exist of intimate symbioses that involve the exchange of inorganic compounds, including cyanobacteria (providing fixed nitrogen to lichens, the water fern Azolla, Gunnera spp. plants, cycads and some mosses, liver worts, and horn worts) (51), clams of the genera Solen and Codakia (providing sulfate to bacterial) (52, 53), the sponge Haliclona cymiformis (providing ammonia and nitrate to a rhodophyte alga) (54), corals (inorganic carbon to photosynthetic dinoflagellates for carbon fixation) (55, 56), rumen Halicllona sponge is thioautotrophic, i.e., possesses a sulfur-oxidizing, CO₂-fixing metabolism (48). The smaller δ-proteobacterial symbiont is genetically very similar to free-living sulfate-reducing bacteria, and the sulfate-reducing function also could be demonstrated in O. algarvensis (48). The coexistence of these bacteria indicates that they are engaged in a synthetic sulfur cycle in which oxidized and reduced sulfur compounds are exchanged back and forth (48). The oligochaete benefits from this arrangement by obtaining de novo-synthesized organic compounds from the symbionts, which in turn assimilate its anaerobic end products. The constant internal source of reduced sulfur compounds allows the worm to colonize new habitats without a requirement of high sulfide concentrations.

Numerous additional examples exist of intimate symbioses that involve the exchange of inorganic compounds, including cyanobacteria (providing fixed nitrogen to lichens, the water fern Azolla, Gunnera spp. plants, cycads and some mosses, liver worts, and horn worts) (51), clams of the genera Solen and Codakia (providing sulfate to bacterial) (52, 53), the sponge Haliclona cymiformis (providing ammonia and nitrate to a rhodophyte alga) (54), corals (inorganic carbon to photosynthetic dinoflagellates for carbon fixation) (55, 56), rumen bacteria (providing hydrogen and CO₂ to methanogenic archaea) (57), and “Chlororhabdium aggregatum,” an association of a sulfate-reducing and a photosynthetic sulfide-oxidizing bacterium (58).

Primary organic metabolites

Among the best-investigated chemosymbioses that involve primary metabolites are mutualisms of eukaryotic cells with their mitochondria and chloroplasts. M. lateralis synthesizes ATP, as well as heme and steroids, by oxidative phosphorylation, whereas chloroplasts provide plant and algal cells with glucose generated via the Calvin cycle by using the energy of light. A according to the endosymbiotic theory, these organelles developed from independent prokaryotic organisms that were absorbed by their host cells (59). Several lines of evidence, such as the phylogeny of plastid DNA sequences and the structure of the photosynthetic apparatus, suggest that chloroplasts developed from cyanobacteria. The origin of the mitochondria has been traced back to an archaebacterium. The two associations are typical examples of eusymbioses: The organelles are genetically very similar to free-living sulfate-reducing bacteria, their genome size of 4.2 Mb (66), much larger than that of the primary symbiont, and shows only beginning signs of erosion (67). It is possible to cultivate the bacterium in the absence of host cells (68). A phidids feed on a plant sap diet rich in carbohydrates but poor in vitamins and amino acids. They possess a bacteriosome that contains up to 80 large cells filled with bacteria of the genus Buchnera (69). They are transmitted maternally through the host generations, and neither of the mutual partners can re-produce independently (70). The association of the aphids with the endobacterial-like ancestor of the symbiont was established 200–250 million years ago (71). The genome size of Buchnera aphidicola strains measures only 420–640 kb, which is less than one seventh of that of the close relative E. coli (72). During evolution, the symbiont has lost numerous genes, including those that encode the biosynthesis of cell-surface components, regulatory genes, and genes for its own defense (73). Notably, B. aphidicola lacks several pathways for amino acids that the host can synthesize, although it retains genes for the production of all essential amino acids (7, 73). Evidence exists that the aphid exports synthesized glutamate to the symbiont as a nitrogen source, which allows it to produce its essential amino acids (73, 74). The strain B. aphidicola BCC of the aphid Cinara cedri has an exceptionally small genome of only 422 kb that even lacks essential tyrosine and riboflavin genes (75). It has been hypothesized to gradually lose its mutual properties and to
Carsonella rud-symbiotica” (76). The smallest known genome among insect by-product of some protists is hydrogen and CO₂ (79). These in their gut (78). The protozoan converts cellulose to acetate for a complex community of protozoans, bacteria, and archaea (80). The bacteria are embedded in the host membrane and wave synchronously to assist in host locomotion. Symbioses based on the degradation of organic material are generally common in animals with a diet rich in cellulose, such as ruminants and wood-boring insects. Besides protozoa, bacterial and fungal cellulose degraders have been identified in their guts. Several insects are known to actively ingest fungi to use their cellulases. This behavior might represent the first stage in the establishment of a symbiosis with such fungi stably residing in the gut (81).

An economically important chemical protocooperation of two different bacteria exists in yogurt preparation. A widely used starter for the production of fermented dairy products is the thermophilic lactic acid bacterium Streptococcus thermophilus. For the manufacturing of yogurt, it is generally used in association with other microorganisms, in particular with Lactobacillus delbrueckii ssp. bulgaricus). To enable the intense and rapid acidification of milk, the fast growing capacity of these bacteria is crucial. The association causes a positive effect on the growth of the other species. The growth of L. bulgaricus is stimulated by pyruvic acid, formic acid, and CO₂ that are produced by S. thermophilus (82). L. bulgaricus is a producer of amino acids and peptides that stimulate the growth of S. thermophilus (83). The symbiosis additionally results in enhanced aroma formation compared with the pure cultures.

The exchange of primary metabolites also is known from several nonmicrobial symbioses. Carbohydrates play an important role in many of these symbioses. Besides the ubiquitous example of flowering plants offering nectar, several plants are known that produce extracellular nectar to attract beneficial insects, in particular ants (84). Ants colonizing suchy myrmecophytes or ant plants protect their nutrient source by efficiently removing herbivores and even pathogenic fungi. Other nutrient sources provided by ant plants are food bodies rich in proteins or lipids. In a well-known functionally related association, ants obtain carbohydrates from honeydew secreted by aphids that they regularly milk and defend against predators (85).

Secondary metabolites

Sessile marine animals, such as sponges, ascidians, and bryozoa, are the source of numerous compounds with diverse pharmacological activities (86, 87). It has long been suspected that many of these natural products are produced, in fact, by symbiotic bacteria because the chemical structures often resemble those of compounds isolated from prokaryotes (87-89). The existence of a bacterial source for an invertebrate-derived natural product should have important biomedical implications, as this ultimately could allow one to create sustainable fermentation systems for drug development and production. Sponges are the most important sources of marine drug candidates. These animals can contain remarkable numbers of diverse microorganisms from various taxa representing up to 40-60% of the total biomass (90, 91). The microflora in most bateria is highly distinct but shows little variation among sponge species or geographic location, which indicates a long period of coexistence (92). At least a part of the microbial community is transferred vertically via the larval brood chamber (93). As with many other symbiotic systems, cultivation attempts have failed in most cases. Therefore, for most sponge-derived natural products, the actual producer is still unknown. Among the few successfully studied examples are the protein biosynthetic inhibitors anammone (Fig. 2a) and theopederins (Fig. 2b), potent cytotoxic polyketides isolated from Theonella swinhoei (94). A bacterial source was identified by metagenomic techniques, i.e., methods employing the DNA of entire organismic associations without prior separation of species (95, 96). The screening of a large metagenomic library prepared from total T. swinhoei DNA led, in this case, to the isolation of the biosynthetic gene cluster, which, where attributed to a bacterial producer (95). Another method employed to identify biosynthetic sources of natural products is mechanical cell separation and subsequent extraction of each cell type. In this way, the likely bacterial sources of several compounds were identified, including the polyketide swinholide (97), the nonribosomal peptide theopelalactam A (97), chlorinated dippeptides (Fig. 2a) (98, 99) and brominated diphenylethers (Fig. 2b) (97). One patent exists on the successful cultivation of an actinomycete symbiont from the sponge Acanthasteroyphora sp. producing anti-infective manzamine alkaloids (Fig. 2) (100).

A further pharmacologically relevant group of marine invertebrates is the phylum Ctenopora, also known as Bryozoa or Polyzoa. They are colonial filter feeders and each member is housed in a separate unit called a zoecium. The bryozoan Bugula neriifrons contains complex polyketides of the bryostatin series (Fig. 4), protein kinase C activators with potent anticancer activity (102, 103). Bryostatin 1 is one of the most promising drug candidates from marine invertebrates and has reached phase II clinical trials for combination therapy (104). The concentration of bryostatins is particularly high in larvae of B. neriifrons, where it is used as a defense against predators (105). However, in adults the concentration is very low or even undetectable when the animals lack larval brood chambers (106). 16S rDNA analysis and in situ hybridization revealed the presence of a y-proteobacterium, “Candidatus Endobugula serulata,” in the larvae (105-108). This bacterium was shown to harbor polyketide synthase genes that are good candidates for bryostatin biosynthesis because their presence is correlated strictly with high bryostatin levels (108).
A scidians are marine filter feeders with a rich natural products chemistry that live commonly associated with symbiotic bacteria (88, 89, 109). A well-studied symbiosis consists of photosynthetic Prochloron spp. cyanobacteria that occur in ascidians of the family Didemnidae (110). Prochloron spp. also can be found in bacterial mat structures of stromatoliths (111) but so far have not been detected outside of such structured environments. From didemnid ascidians, numerous cytotoxic cyclic peptides of the patellamide group (Fig. 5) were isolated (109, 112, 113). Mechanical separation of the Prochloron sp. symbiont from its host Lissoclinum patella and subsequent genome sequencing revealed a set of biosynthetic genes that after transfer into E. coli enabled this bacterium to produce two different patellamides (114). The genes also were identified in an independent study by screening a library of Prochloron sp. DNA constructed in E. coli for the presence of clones that synthesize patellamides (115). The patellamide gene cluster also has been engineered to produce a drug-like, non-natural cyclic peptide (116). So far, the ecological function of the peptides in the natural environment remains unknown.

The gorgonian soft coral Pseudopterogorgia elisabethae harbors dinoflagellates of the genus Symbiodinium. The symbiotic function of the dinoflagellate is to contribute to the nutrition of its host by sharing photoassimilates (55, 56). Extracts of the corals contain the pseudopterosins (Fig. 6), a family of diterpene glycosides with antiinflammatory and analgesic properties (117). The substances modulate degranulation and release mechanisms in immune cells (118). They have been included as antiirritants in a widely marketed cosmetic. The amounts and the specific composition of the pseudopterosins vary depending on the location of P. elisabethae (119). Their total amount can be as high as 20% of the dry mass. By applying radioactively labelled geranylgeranyldiphosphate (GGPP) to purified symbiont preparations, it was demonstrated that the biosynthesis of the pseudopterosins occurs in the dinoflagellate (120). Elisabetha-triene synthase, the enzyme catalyzing the conversion of GGPP...
Several remarkable natural product symbioses have been reported from terrestrial habitats. Ants of the genera Atta and Acromyrmex have an important function in sustaining a healthy symbiosis. The protective effect of pederin then might have driven a mutual facilitative symbiosis. Within each beetle species, most, but not all, females contain the complex polyketide pederin (Fig. 7). This was thought to be a defense mechanism against predators (9). Structural studies have shown that pederin is highly similar to a range of compounds isolated from marine sponges, such as the onnamides and the theopederins mentioned above (94). Isolation of the genes that encode pederin biosynthesis revealed that the substance is produced by a bacterial symbiont closely related to Pseudomonas aeruginosa (131). The symbiont is present only in pederin-producing females (132) and also can be detected in the eggs (133). P. aeruginosa does not produce pederin, and partial genome sequencing suggests that the symbiont or its free-living ancestor might have acquired the pederin genes by horizontal gene transfer (134). This mechanism also could account for the occurrence of similar compounds in beetles and sponges. Because P. aeruginosa is a pathogen of insects and other organisms (including humans), it is likely that the symbiosis developed after the beetle was infected by a pathogenic ancestor of the symbiont.

The protective effect of pederin then might have driven a mutual adaptation of both partners toward symbiosis. The symbiont confers a greater resistance against fungal infection because of the production of an antibiotic (128). Panderus and Pandraeus spp. rove beetles participate in an unusual facultative symbiosis. Within each beetle species, most, but not all, females contain the complex polyketide pederin (Fig. 7). In their hemolymph (130). The symbiont is highly toxic and is used as a defense against predators (9). Structurally, pederin is highly similar to a range of compounds isolated from marine sponges, such as the onnamides and the theopederins mentioned above (94). Isolation of the genes that encode pederin biosynthesis revealed that the substance is produced by a bacterial symbiont closely related to Pseudomonas aeruginosa (131). The symbiont is present only in pederin-producing females (132) and also can be detected in the eggs (133). P. aeruginosa does not produce pederin, and partial genome sequencing suggests that the symbiont or its free-living ancestor might have acquired the pederin genes by horizontal gene transfer (134). This mechanism also could account for the occurrence of similar compounds in beetles and sponges. Because P. aeruginosa is a pathogen of insects and other organisms (including humans), it is likely that the symbiosis developed after the beetle was infected by a pathogenic ancestor of the symbiont.

stages that emerge from the carcass and search for new insect hosts. Bacteria of both genera can be cultivated easily. They have been shown to synthesize various broad-spectrum antibiotics, lipases, phospholipases, and proteases that are believed to become secreted into the insect hemolymph when the bacteria enter the stationary phase. From these, hormetic photobacterins (Fig. 8a) (140), antibiotica, and nematicidal hydroxystilbenes (Fig. 8b) (141) are synthesized. Various broad-spectrum antibacterial xenorhabdins (Fig. 9a) (142), fungal xenocoumacins (Fig. 9b) (143), cytoxic polyquiniones (Fig. 9c) (144), protein biosynthetic potential (159). Their exact ecological functions, however, in most cases are poorly understood.

References

A great diversity of endophytic fungi colonizes the interior of most plants, red algae, and brown algae (155). The fungi often can be isolated and subsequently studied by placing leaf fragments on solid media. In addition to exchanged nutrients, several secondary metabolites have been shown to play an important role in this interaction. Fungi-derived alkaloids, such as pederin (Fig. 11a), lolitrem (Fig. 11b), enigmatic alkaloids (Fig. 11c), and lolitrems (Fig. 11d) (159) are produced in Convolvulaceae in a symbiosis with a clavicipitaceous fungus that is transmitted via the seeds (158). Numerous additional compounds have been identified from isolated endophytes, which documents their remarkable biosynthetic potential (159). Their exact ecological functions, however, in most cases are poorly understood.

Symbiosis: Topics in Chemical Biology

The mammalian sense of taste is crucial for evaluating food palatability and nutritional quality. To achieve the detection of relevant chemicals, evolution has shaped a set of receptor molecules that allow the detection of five basic taste qualities: sweet, umami, bitter, salty, and sour. Each taste modality has unique characteristics and serves a distinct function for an animal's nutrition. Therefore, we address the characteristics, the recent advances, the persisting difficulties, and the future perspectives of the basic taste qualities in separate paragraphs. Enormous progress has been made in the identification and the characterization of taste receptor molecules, and in the growing number of animal genomes accessible from databases, which has inspired us to devote a section of this review to discuss a series of sophisticated evolutionary studies on taste receptor molecules. Finally, evidence is accumulating to show that taste receptor and signal transduction molecules have nongustatory functions as well. The extragustatory expression of such genes and the resulting implications are summarized in the final section.

The chemical senses of olfaction and gustation were developed from phylogenetically old systems that enabled organisms to detect chemicals in their environment. The detectors were linked to behavioral patterns that enabled the organisms to escape noxious substances or to approach potential nutrients. These stereotypic mechanisms are still present in higher organisms, including mammals, although they compose more complex regulatory loops. The chemical sense of taste allows mammals to evaluate the food they consume. Each of the five basic taste modalities fulfills a particular task. Sweet and umami (glutamate and 5′-ribonucleotides) taste detects calorie-rich food that contains carbohydrates or protein. Therefore, both sweet and umami tastes are linked to pleasant feelings and to behaviors that facilitate food intake. Salty taste is part of a control loop that underlies electrolyte homeostasis. Salt intake compensates for salt loss through sweating and elimination. Like umami and sweet taste, salty taste is linked to liking and attraction promoting intake. Sour and bitter tastes are repulsive and seem to be part of a warning system. Sour taste prevents excessive intake of protons and balances the acid and bases in the body; also it prevents intoxication through consumption of spoiled food or unripe fruits. Bitter taste prevents ingestion of noxious compounds.

Taste sensation is initiated on contact of chemicals dissolved in saliva with cognate taste receptor molecules on the apical side of specialized epithelial cells (1). These taste receptor cells seem to be dedicated to only one of the basic taste modalities (2). They are assembled into groups of ~100 cells referred to as taste buds, which are structures embedded in the epithelium. On the tongue, taste buds are a part of morphologically, clearly visible epithelial protrusions and/or invaginations known as papillae. The contact of taste stimuli activates signal transduction cascades that result in the depolarization of the receptor cells and the release of the neurotransmitter ATP. ATP excites afferent nerves and allows taste information to be transmitted to the cerebral cortex, where neuronal activity creates the sensory perception (3, 4). In this scenario the taste receptor molecules have the important task of chemical recognition and discrimination. Organisms use these receptor molecules to convert chemical structures into biochemical reactions and, ultimately, to perceive taste.

In recent years, impressive progress has been made in the field of gustation, because of the discovery of the receptors for sweet, umami, bitter, and sour taste and the experimental tools that were created. Our objective here is to review the recent developments in the field with emphasis on taste receptors and their associated biochemical signal transduction cascades.
Sweet Taste

Sweet taste is elicited by many compounds of various chemical classes (Fig. 1). Sweeteners include monosaccharides and disaccharides such as glucose and sucrose; amino acids such as L-tryptophane, alanine, and glycine; proteins such as monellin and thaumatin; and many chemically diverse artificial sweeteners such as saccharin, cyclamate, aspartame, and alitame (5). This observation has fostered long-lasting speculations about how many receptors are necessary to detect the many structurally divergent compounds. Finally, an answer to this question was provided by the discovery of the TAS2R genes that encode a new family of the putative taste receptors (6). The gene family consists of the three members: TAS2R1, TAS2R2, and TAS2R3. TAS2R is the gene symbol proposed by the human genome project nomenclature committee for the gene family previously referred to as TRs; the corresponding mouse gene symbol is Tas1r. Genes are written in italics, whereas the protein is printed in normal letters. Many studies have demonstrated convincingly that the TAS2R2:TAS2R3 heteromer mediates the majority of human sweet taste perception.

The TAS2Rs are subclass 3 G-protein-coupled receptors that are related distantly to the Ca^2+ sensing receptor, the metabotropic glutamate receptors, GABA B and, and the V1R pheromone receptors. Consistent with their proposed role as taste receptors, behavioral experiments and neuronal recordings of Tas1r2 and Tas1r3 knockout mice showed that the deletion of either gene reduced strongly the nerve responses and the attractiveness of various sweeteners, whereas the deletion of the third family member Tas1r1 affected umami taste (7). Moreover, in situ hybridizations in rodents showed that Tas1r3 is co-expressed with either Tas1r2 or Tas1r3 in two nonoverlapping subsets of taste receptor cells (8). This finding led to the hypothesis that the functional sweet receptor could be a heteromer of two Tas1r subunits. Indeed, expression studies in HEK293 cells demonstrated subsequently that cells cotransfected with Tas1r2 and Tas1r3 or its human counterparts responded to various sweeteners (8, 9) and thereby confirmed that Tas1r2 and Tas1r3 form a functional sweet taste receptor. Both the human and the rodent receptors are activated by chemically diverse sweeteners such as monosaccharides, disaccharides, sweet amino acids, and artificial sweeteners (9). Notably, all tested compounds that taste sweet to humans activate the human TAS2R2:TAS2R3 receptor (9).

Interestingly, the human TA2R2:TA2R3, but not its mouse counterpart, are sensitive to the sweet proteins monellin, thaumatin, and brazzein, and to the artificial sweeteners neotame, cyclamate, and aspartame (9-11). This difference provides a molecular explanation for the previous observation that these compounds are sweet for humans but not attractive to rodents (9). The species difference also applies to the sweet inhibitor lactisole that blocks the sweet taste in humans but not in rats, and only inhibits the response of human TAS2R2:TAS2R3 to sweet stimuli (9).

Recently, these functional differences between the human and the rodent sweet receptor have been exploited to obtain insight into how this receptor can be activated by so many structurally different sweeteners. Replacement of the large, extracellular domain at the N-terminus of rat Tas1r2 by its human counterpart was sufficient to create a chimeric receptor that could be activated by the dipeptide derivatives aspartame, neotame, and the sweet-tasting protein monellin (10, 11). Similarly, replacement of the cysteine-rich region in mouse Tas1r3, which connects the N-terminal extracellular domain to the heptahedral domain by its human counterpart, created a receptor chimera that could be activated by the sweet protein brazzein (11). These findings suggest that the binding sites for aspartame, neotame, and monellin are located in the large extracellular domain of TAS2R1, whereas the binding site for brazzein may be located in the cysteine-rich domain of the TAS2R3 subunit. Additional analyses of receptor chimeras in combination with mutational studies and molecular modeling revealed that the sweet inhibitor lactisole and the sweetener cyclamate share an overlapping binding site in the heptahedral domain of the human TA2R3 subunit (12). Moreover, tryptophan fluorescence spectroscopy analysis of the purified extracellular N-terminal domains of Tas1r3 and Tas1r2 support the notion that sucrose, glucose, and sucralose interact with both domains (13). In summary, these results provide evidence that structurally diverse sweeteners use multiple binding sites to activate the sweet receptor (Fig. 1).

Umami Taste

In humans, umami taste (also referred to as amino acid taste) is elicited predominantly by L-glutamate and L-aspartate (14), whereas rodents respond to most L-amino acids (7). Interestingly, umami taste is enhanced by 5′-ribonucleotides such as inosine-5′-monophosphat (IMP) and guanosin-5′-monophosphat (GMP) (15). Thus, a genuine umami receptor should reflect these properties. Umami compounds are enriched during the ripening processes in many foods, including fruits, vegetables, cheese, and meat. Therefore, this taste quality helps us to choose the ripest fruits and the most palatable cheese for our meal.

In humans, some metabotropic glutamate receptor agonists such as ibotenate and L-AP4 elicit umami taste (15). Moreover, studies have demonstrated the expression of mGluR4 variants in taste buds of different species (16-21). These observations are consistent with the hypothesis that metabotropic glutamate receptors contribute to umami taste. In line with this assumption, the cDNA of an N-terminally truncated "taste" variant (mGluR4t) of the mGluR4 was isolated from rodent tongue tissue (20). Functional studies showed that it could be activated by L-AP4 and glutamate at concentrations that are typical for umami taste (20). Based on these data the truncated mGluR4 variant initially seemed to be an attractive candidate for an umami taste receptor, although several inconsistencies exist [c.f. (7)]. Most prominently, mGluR4 knockout mice show an increased preference for glutamate (22) instead of a reduced response as one would expect. Therefore, receptor activities cannot be enhanced by ribonucleotides.

Studies of Tas1r1 and Tas1r3 knockout mice provide clear evidence for their involvement in umami taste. The deletion of either receptor gene reduced strongly the attractiveness of the taste quality.
Figure 1  Schematic presentation of proposed binding sites for structurally different sweet tasting compounds at the human sweet taste receptor. Identification of the binding sites for aspartame, neotame, monnellin, brazzein, cyclamate, and lactisole are based on functional analysis of the rodent and human sweet receptor, chimeras created of them and specific receptor mutants, as well as data obtained through molecular modeling. Information about the sucrose, glucose, and sucralose binding sites have been derived from measuring agonist-induced conformational changes of the purified N-terminal ectodomains of the sweet receptor (see text for further details).

umami compounds in mice and in the corresponding nerve responses (7). In situ hybridizations in rodents demonstrated that Tas1r3 is coexpressed with Tas1r1 in a subset of taste receptor cells, which suggests that the umami receptor is a heteromer of TAS1R1 and TAS1R3. In vitro expression studies showed that cells cotransfected with cDNAs for human TAS1R1 and TAS1R3 responded to glutamate, aspartame, and l-AP4 (9), whereas cells transfected with the counterparts from mice acquired general sensitivity for l-amino acids (23). Remarkably, 5′-ribonucleotides such as IMP and GMP enhanced strongly the receptor responses, which is a hallmark of umami taste (9, 15). Thus, these functional properties of the TAS1R1/TAS1R3 receptor dimer of humans and rodents explain some of the most important properties of umami taste. It should be pointed out, however, that the response profiles of all the umami receptor candidates in transfected cells, i.e., TAS1R1/TAS1R3 and the various mGluRs found in taste tissue, differ from those observed in native taste cells (24). A complete description of umami taste transduction may involve combinations of the candidate receptors and/or as yet undiscovered taste receptors (24), or umami taste may be a delicious flavor formed by neuronal mechanisms in the brain (25).

Bitter Taste

Bitter compounds are numerous and structurally diverse (26). Estimates count thousands of these compounds in the human environment. Known bitter-tasting substances include fatty acids, peptides, amino acids, amines, azacycloalkanes, N-heterocyclic compounds, amides, ureas, thioureas, esters, lactones, carbonyl compounds, phenols, crown ethers, alkaloids, and metal ions. In mammals, these compounds are recognized by approximately 30 G-protein-coupled receptors belonging to the TAS2R gene family (27). These comparably few receptors face the enormous challenge to sense the numerous synthetic and natural bitter substances. One of the central questions in bitter taste research is how these few receptors enable the detection of so many different bitter-tasting compounds. Detailed knowledge about the molecular basis of TAS2R-tastant interaction is required to answer this question. As a first step toward a better understanding, the identification of as many bitter receptor-bitter agonist pairs as possible is necessary to establish a foundation for detailed structure-function analyses. The successful development of a variety of functional expression assays led to an enormous boost of deorphanizations of bitter taste receptors during the last few years. One of the difficulties in setting up efficient screening assays is the insufficient cell-surface targeting properties of
bitter taste receptor proteins (28), which have been observed for other chemosensory receptor gene families, such as odorant receptors (29) and pheromone receptors of the V2R type (30). These problems are circumvented commonly by the amino terminal extensions of taste receptors with amino termini of other GPCRs such as bovine rhodopsin (28) or rat somatostatin receptor 3 (31). The physiologic cell-surface targeting properties of hTAS2Rs seem to be individual and may depend on various cofactors (32). With such assays in place, nine human (see also Reference 33), two mouse, and one rat TAS2Rs have been de-orphanized (see Table 1) by various laboratories and different experimental approaches to date.

The first mammalian receptor-bitter agonist combinations identified was human TAS2R4 and mouse T2R5 (28). Both receptors responded selectively to one compound of a large panel of known bitter substances best. Whereas mT2R5 was only activated by cycloheximide, hTAS2R4 responded to denatonium benzoate and high concentrations of 6-n-propyl-thiouracil. This study indicated that mammalian TAS2Rs exhibit a strong selectivity for agonists, although, in the case of hTAS2R4, limited promiscuity might occur at high concentrations. The first hTAS2R identified to be activated by natural bitter substances was hTAS2R16 (31). Systematic testing of substances demonstrated that this receptor responded selectively to an entire group of chemically related compounds, the β-glucopyranosides. Thus, hTAS2R16 combines selectivity, even stereoselectivity for the β-p-glucopyranosides, with high concentrations of chemicals and that this information is not modified robustly by neuronal computation. This conclusion is supported strongly by experiments in transgenic mice. Mice are indifferent to β-glucopyranosides, such as salicin, but they taste this compound with similar sensitivity as humans do when they express the human cognate bitter taste receptor hTAS2R16 as transgene.

The more detailed structure-function analyses of several TAS2Rs together with their agonists will provide detailed insight into bitter receptor-agonist interactions required to understand how such few TAS2Rs can recognize so many bitter compounds and might pave the way for the development of bitter antagonists. The recent availability of computer modeling studies of bitter taste receptors with identified agonists docked into these structures increases our knowledge about structure-function relations (40, 41) and may help to guide future mutagenesis analyses.

Salt Taste

Two pathways for salt taste have been reported. Nerve recordings performed in rodents showed that the chorda tympani nerve, which innervates the fungiform papillae of the anterior tongue, responded strongly to stimulation with NaCl and that this effect was highly sensitive to amiloride (42, 43). The amiloride-sensitive response was selective for Na⁺ ions. Based on these observations, the non-voltage-gated, sodium-permeable, heteromeric (αβγ) epithelial sodium channel (ENaC) has been suggested to be a good candidate. In rodents, ENaC subunits are expressed in a specific subset of fungiform taste receptor cells. Whole-cell patch clamp analysis of isolated fungiform taste receptor cells demonstrated that amiloride inhibited Na⁺-induced currents in micromolar concentrations as expected for ENaC-mediated currents (44, 45). Furthermore, behavioral studies in mice and in rats showed that sodium taste is impaired partly by adding amiloride to a sodium salt solution, without affecting responses to other taste modalities (46, 47). In humans, the situation is less clear. Psychophysical analysis revealed only a limited reduction of salt taste by amiloride, and this seemed to be restricted to few subjects (48, 49).

The depicted chemical structures correspond to the agonists printed in bold.

In vallate and foliate papillae of rodents only α-ENaC could be easily detected, whereas β- and γ-ENaC are less abundant (50–52), which raises questions about the identity of the salt taste receptor of the posterior tongue. Moreover, NaCl-induced responses of the glossopharyngeal nerve that innervates the vallate and foliate papillae of the posterior tongue seemed to be almost insensitive to amiloride (43, 53). The amiloride-insensitive salt taste receptor is a constitutively active ion channel that is blocked by cetylpyridinium chloride. It is not selective for sodium ions but mediates H^+ and K^+ currents (54). Based on its sensitivity to the TRPV1 antagonists SB-366791, it has been suggested that the amiloride-insensitive salt taste receptor is a variant of the vanilloid receptor 1, TrpV1t (55). But because not all properties of amiloride-insensitive salt taste receptor are replicated by TRPV1 and TRPV1 gene-targeted mice preferred NaCl over water at concentrations avoided by wild types and salt taste in these animals was less blocked by amiloride (55, 56), the role of TrpV1t in salt taste remains questionable. Taken together, the molecular identity of the salt taste receptor or receptors cannot be taken for granted.

Sour Taste

Sour taste detects acids, i.e., protons. Several different sour taste receptor candidates such as acid-sensing ion channels (ASICs) (57), hyperpolarization-activated cyclic nucleotide-gated channels (HCNs) (58), and two pore domain potassium channels (K2Ps) (59, 60) have been described in the past. In addition, recent research identified two members of the polycystic kidney disease (PKD) family of the transient receptor potential superfamily (TRP) as strong sour taste “receptor” candidates or as part thereof. Immunohistochemistry and in situ hybridization revealed the presence of the polycystic-kidney-disease-like ion channel PKD1L1 in subsets of taste receptor cells of mouse fungiform, vallate, and foliate papillae. These cells differ from...
those expressing receptors for bitter, sweet, and umami taste (61, 62). Moreover, genetic ablation in mice of the cells expressing PKD1L2 was associated with a loss of response to acidic stimuli in both electrophysiologic recordings and behavioral experiments, whereas other taste modalities remained unaffected, which suggests that PKD1L2 cells are necessary for sour taste perception (62). Previous studies demonstrated that PKD2 polypeptides need to interact with PKD1 polypeptides for proper cell-surface expression (63, 64). Search for interaction partners for PKD1L2 in taste cells identified PKD1L3 in mouse valiate and foliulate papillae being coexpressed with PKD2L1 in the same cells (62, 65). PKD1L3 enhanced significantly the expression of PKD2L1 at the cell surface in vitro (61). In fungiform papillae and in the palate, expression of PKD1L3 could not be detected, which suggests that another polypeptide interacts with PKD2L1 in these structures. In accordance with the proposed involvement of PKD2L1/PKD1L3 in sour taste transduction, cells that express the two polypeptides responded to stimulation with acids (61). The data were consistent with the observation that sour taste in humans and rodents is stronger for weak acids, such as citric acid, than for strong acids, such as HCl (66, 67). However, subtle, important differences between the heterologously expressed PKD channel and the sour taste responses in native taste cells (68) require additional work to determine the precise role of the PKDs in sour taste transduction.

Molecular Evolution of Taste Receptor Genes

Taste reception varies enormously across vertebrates. Because the taste perception of a species is related essentially to its diet and environment, the studies of the variation of genes, which control taste reception among vertebrates will contribute greatly to our understanding of the relationship between the adaptation of organisms and the diversity of environmental chemicals.

Evolution dynamics of TAS2R gene family

To date, the complete repertoire of the TAS2R gene family has been reported in human, mouse, rat, dog, cow, opossum, chicken, frog, and several fish (69-72), in addition to a small number of TAS2R genes described in several primates (73-76). Comparisons of these gene repertoires revealed extremely high variation in the sizes of the TAS2R repertoire among species, ranging from 3 genes in chicken to 20-50 genes in mammals and amphibians (71, 72). This finding is consistent with the fact that bitter taste perception, as a warning sensor for bitter toxins, may suggest that detecting poisons in diet is not as important in ruminants as in other animals because of the high detoxification capacity of cow’s rumen microbes (72).

In terms of long-term evolution of the TAS2R gene family, the phylogenetic analysis showed several interesting evolutionary patterns (Fig. 2). First, the TA2SR gene family evolves after the birth-and-death process (71), which is characterized by frequent gene duplication and gene deactivation, similar to that found in the olfactory receptor gene family (77). Second, there might be multiple TAS2R genes in the common ancestor of tetrapods and teleosts (72). Third, the TAS2R repertoire expanded considerably in the common ancestor of tetrapods, followed by additional independent expansions in frogs and mammals, and contractions of TAS2R repertoire occurred in chicken (71, 72). Last but not least, based on a comparison of human and mouse TAS2R gene repertoires, some TA2SR genes exhibit one-to-one orthologous pairing, whereas other genes are part of lineage-specific (species-specific) clusters, in which the genes from the same species cluster together in the phylogenetic tree (78). These species-specific genes are also located closer to each other on chromosomes, which indicates that these newly duplicated genes resulted from tandem gene duplications (70, 78). Also, these genes seem to be under positive selection, which suggests that they are used for species-specific bitter tastants (78). On the other hand, one-to-one orthologous genes are subject to more selective constraints than lineage-specific (species-specific) genes, which indicates that each of the one-to-one orthologous genes possibly is detecting one or several distinct bitter tastants that are encountered by a wide range of animals (78). Although two recent evolutionary studies (71, 72), which extended the study of TAS2Rs outside of human and mouse to an additional nine vertebrate species, supports this hypothesis, it still awaits to be scrutinized additionally by functional research.

The comparative analysis of the TAS2R gene family between several primate species with rodents revealed that primate genes were under less selective pressure than rodent genes (73-76). First, the comparison of the gene birth/death rate between primates and mice shows that the proportion of pseudogenes in the TA2SR repertoire is lower in mice (15%) than in apes (21%-28%), which is in turn lower than that in humans (31%) (73, 74). Moreover, the prevalence of lineage-specific pseudo-genes in primates supports this conclusion (74). Second, based on the equal levels of nonsynonymous/synonymous substitution rate ratios for the TAS2R genes in primates, the functional constraints were more relaxed in the primate lineage than in the mouse lineage (73, 74, 76). This evolutionary pattern could be caused by the reduced effective population sizes in primates, which might cause less-effective purifying selection (73). The alternative explanation is that the reduced functional constraints in primates might be caused by reduced bitter taste needs because of a change of the environment and the diet (74). In fact, some ecologic studies support this explanation. For example, meat accounts for 2-13% of diet in chimpanzees, whereas it has never been found in other apes’ diet (76). Furthermore, this explanation has been strengthened by the findings that there were significant changes in human diet, such as increasing food from animal sources while decreasing food from plant sources, and the controlled use of fire to detoxify the food (76). Both factors may have caused a reduction in the importance of bitter taste and consequently triggered a functional relaxation in humans.

Evidence for the relaxation of selective constraints on TAS2R genes in apes and humans does not preclude the possibility
positive selection occurred on a few specific genes. Positive selection has been found in the gene for the human TAS2R16, the beta-glucopyranoside receptor (31). By analyzing the sequences from 60 human populations, Soranzo et al. detected signatures of positive selection on a more sensitive derived allele, which was found in all human populations except for African populations (79). This result might reflect the increased sensitivity of the derived TAS2R16 allele under the positive selection through an increased protection against harmful cyanogenic plant foods and natural toxins (79). In addition to the selective relaxation and positive selection, the most complex scenario of evolutionary forces has been observed in TAS2R38 gene, which is responsible largely for the human polymorphism in tasting phenylthiocarbamide (PTC) (34). Interestingly, chimpanzees are also known to have tasters and nontasters of PTC (80). Although humans and chimpanzees shared phenotypic polymorphism, they did not share the same evolutionary forces of maintaining non-taster alleles (80). By contrast, the nontaster allele was lost in chimpanzees, which favors the selective relaxation hypothesis in this lineage (80). As more human TAS2R genes are being studied, the understanding of the evolutionary forces behind each TAS2R will increase considerably.

Evolution dynamics of TAS1R gene family

In contrast to the TAS2R gene family, the TAS1R family is remarkably well conserved during evolution both in gene family size and in sequence divergence (72). In terms of gene family size, the number of TAS1R gene repertoire changes rarely in mammals, which might reflect the necessity of both sweet and umami tastes among mammals (72). But the number of TAS1R gene repertoire varies in some nonmammalian vertebrates, both with a few gene duplications observed in pufferfish and fugu and with gene loss events found in western clawed frog and chicken (72). In addition to the western clawed frog, which does not have any TAS1R genes, a loss of the TAS1R2 gene was identified in the chicken genome (72). In addition, cats and closely related carnivores are also known to lack the TAS1R2 genes (82), which might reflect the insensitivity to sweet taste stimuli in these species (72, 82). Thus, pseudogenization of TAS1R2 occurred multiple times independently in evolution.

In sequence divergence level, TAS1R genes evolve more slowly than TAS2R genes whatever the comparison between
species or within species. For interspecies comparison, the sequence divergence distance of orthologous pairs among human, mouse, rat, and opossum is significantly lower for TAS1R genes than TAS2R genes (72). Similarly in human populations, the mean pairwise differences per nucleotide between sequences of TAS2R are greater than those of TAS1R, which reveals the lower levels of nucleotide diversity in TAS1R family (83, 84). The positive selection has been suggested to operate separately on paralogous TAS1R genes and different alleles (72, 84), which is also the case in TAS2R genes, as mentioned above.

**Extragustatory Expression of Taste Receptors**

The role of taste perception in the oral cavity is to analyze the composition of food for its nutritional value and for the presence of potentially harmful substances prior to ingestion. However, evidence is accumulating that elements of the taste perception machinery, including taste receptor proteins, are expressed at several extragustatory sites as well. The anatomical organization of chemosensory structures is variable, apparently becoming less complex with growing distance from the primary gustatory areas. Taste buds located in gustatory papillae on the surface of the tongue, on the soft palate, and on the oro-pharynx are well-organized groups of about 60 to 100 cells (1). Laryngeal areas. Taste buds located in gustatory papillae on the surface of the tongue, on the soft palate, and on the oro-pharynx are well-organized groups of about 60 to 100 cells (1). Laryngeal taste buds, however, are smaller than lingual buds. Sbarbari et al. (86) observed that the sizes and shapes in rats changed from the most rostral part of the laryngeal inlet, where mostly buds were found, to structures called “chemosensory clusters” distally. These chemosensory clusters contained only 2-3 cells staining positive for PLC-α2, which is a molecule involved critically in sweet, umami, and bitter taste transduction (85). Rarely, solitary chemosensory cells were found in this part of the larynx but they become more numerous distally (86) and extend into the airway epithelium (87). Solitary chemosensory cells are also present in respiratory nasal epithelium and the vomeronasal epithelium (88, 89). A notable type of cells that express components of taste signal transduction are the brush cells, which line the stomach, the duodenum (90), and the pancreatic duct system (91). It should be noted here that, by anatomical criteria, brush cells might be related to, but they are not solitary chemosensory cells (92). Recently, secretory cells of the airway (93) and spermatozoa (94) have been identified to express taste signaling components as well.

Within the gastrointestinal tract of rodents, brush cells of the stomach, duodenum (90), and the pancreatic duct system (91) express the G-protein subunit α-gustducin, which has been demonstrated to be important for bitter, sweet, and umami taste transduction (95). By RT-PCR analyses of gastrointestinal tissues of rats and mice, a considerable number of TAS2R genes have been detected, although the cellular origin of the detected mRNAs was not directly addressed (96). A recent study identified TAS1R1, TAS1R2, TAS1R3, PLC-α2, and TRPM5 along with α-gustducin. In case of TAS1R2, expression was only weak and more restricted, which suggests that most components of the canonical sweet and umami taste transduction are present in the GI tract. However, using the transgenic expression of GFP under the control of the TRPM5 5′-flanking region for colocalization, experiments with the other taste transduction molecules revealed a less clear picture. Induction of TRPM5-driven GFP expression with PLC-α2 is limited, both molecules are indispensable for bitter, sweet, and umami taste transduction as shown by knockout mouse models, which suggests that at least in part a variant transduction mechanism acts in these cells. Moreover, this study identified that, in addition to brush cells, enterendocrine cells are positive for TRPM5-driven GFP expression (97). With respect to bitter taste receptor-mediated signal transduction, however, the mouse intestinal cell line STC-1, which expresses bitter taste receptor genes along with α-gustducin and β-transducin, reacts selectively to various bitter stimuli with transient calcium signals, which indicates the canonical transduction mechanism (96). As chemosensory cells of the gut are not innervated directly (90), and do not express the presynaptic marker SNAP25 (97), it is speculated that they might communicate via NO (98) or a currently unidentified messenger with neighboring cells/nerve fibers to control appetitive behavior or food passage through the gastrointestinal tract.

Morphologically, the α-gustducin expressing cells found in the nasal and vomeronasal epithelia resemble solitary chemosensory cells (SCCs) described in nonmammalian vertebrates (88). In addition to α-gustducin, some bitter taste receptor genes are expressed in SCCs, whereas the TAS1R1 and TAS1R2 subunits, which specifically constitute the sweet and umami receptor heteromers TA-S1R2/TAS1R3 and TAS1R1/TAS1R3, respectively, are absent from nasal chemosensory cells. It indicated already that, analogous to the warning function of bitter taste receptors, cells of the oral cavity, the function of TAS2R expression in nasal chemosensory cells in nasal respiratory epithelium might protect the animal from the aspiration of noxious substances. Indeed, intranasal irritation with bitter compounds not only elicited trigeminal responses but also resulted in pronounced respiratory effects (88). Another recent example for extragustatory expression and multiple functions of taste receptor molecules aside from pure gustation is PKD2L1, a mammalian sour taste sensor, which is also expressed in a discrete population of neurons surrounding the central canal of the spinal cord, perhaps involved in monitoring the pH of the cerebrospinal fluid (92).

In perspective, the growing number of reports on the extragustatory expression of components of the taste transduction cascade requires the careful analyses of taste-specific knock out models for nongustatory deficits.

**Perspectives**

During the last few years, the field of taste research has been progressing with enormous speed. Current research addresses structural details on receptor agonist interactions for bitter and sweet taste receptors. For the other taste modalities, including salt taste, where definitive proof for the proposed roles of candidate sensor molecules is still missing, more questions still need to be answered. A next big step in taste research will be to understand how taste information is processed along its
pathway from the periphery into higher order brain centers. In view of emerging extracellular functions of taste transduction molecules, it will be critical to understand how the different functions and cellular environments have modified the involved proteins and signaling mechanisms to serve multiple functions. More practically, the cloning of the taste receptors enabled recombinant receptor assays to be established. With these tools, the flavor industry will be able to design high throughput screens of complex compound libraries in order to identify new taste-active compounds. Sweet taste enhancers, glutamate substitutes and salt replacers, and specific bitter blockers might be the primary targets.

Bacterial Resistance to Antibiotics

Gerard D Wright, Antimicrobial Research Centre, Department of Biochemistry and Biomedical Sciences, McMaster University, Hamilton, Ontario, Canada
doi: 10.1002/9780470048672.wecb034

Microbes have evolved a myriad of mechanisms to overcome the toxic effects of antibiotics, which include the production of enzymes that modify or degrade antibiotics, complex membrane-associated efflux systems that can pump antibiotics out of the cell, modification of antibiotic targets, and the production of immunity proteins. The biochemical logic of resistance is often intimately linked with the mode of action of the antibiotics. As a result, chemical biology approaches for understanding resistance not only have application in our understanding of this phenomenon, but also they can guide the generation and deployment of new antibiotics. In this review, a survey of the chemical strategies employed by bacteria to resist antibiotics is presented with an emphasis on the molecular mechanisms of resistance enzymes and proteins.

Modern anti-infective chemotherapy is founded on the deployment of an arsenal of potent and safe small-molecule inhibitors of microbial growth. As a result, it is not an understatement to say that antibiotics and antibacterial agents have revolutionized health care during the last century. These compounds are, respectively, natural product and synthetic small molecules that inhibit bacterial growth. For simplicity, in this review, the term “antibiotic” will be used to refer to both natural products and synthetic molecules.

Since the first articulation of the concept of the “magic bullet” by Paul Ehrlich to describe the discovery and use of small-molecule inhibitors of microbial growth (1), there has been a concerted effort to identify new antibiotics in chemical libraries and from natural sources. Following Ehrlich’s efforts, the synthetic sulfa drugs that inhibit p-aminobenzoic acid biosynthesis dominated anti-infective therapy in the 1930s and early 1940s. The discovery of the highly potent fungal natural product penicillin, followed by peptide antibiotics such as gramicidin from soil bacteria (2), ushered in a period of roughly 15 years of intense natural product drug discovery that revealed almost all the chemical classes of antibiotics in current clinical use.

As has been well documented elsewhere (3, 4), there was a roughly a 25-year gap between the introduction of the quinolone antibiotics and the next new chemical class of antibiotics, the oxazolidinones. During this interval, innovation in antibiotic drug design and discovery was focused on the semisynthetic tailoring of natural product antibiotic scaffolds to improve pharmacologic properties and, most importantly, to overcome resistance to existing antibiotics.

Since the first use of antibiotics, bacterial insensitivity to these cytotoxic agents, both intrinsic and acquired, has been observed. Antibiotic resistance can be the result of an inability of the compound to enter the cell, active efflux from the cytosol, mutation or alteration of the primary molecular target, sequestration of the antibiotic, and enzymatic destruction or chemical modification of the compound (Table 1). Each of these mechanisms requires unique chemical strategies to achieve the same biological outcome: continued cell growth in the face of toxic compounds. This review will discuss the principal mechanisms of antibiotic resistance emphasizing the biochemical logic of the strategy to overcome the cytotoxic effects of antibiotics.

Biological Context of Antibiotic Resistance

Antibiotic resistance is a major clinical problem with great impact on the successful treatment of infectious disease (5). Resistance increases mortality and morbidity, and it lengthens hospital stays. Health-care costs associated with antibiotic-resistant infections range between $6000 and $30,000 USD per patient (6). Furthermore, the rate of resistance continues to rise in all important human pathogens year after year (7). Limits on the use of certain antibiotics and drug cycling can help in some cases to mitigate resistance; however, even when restricted-use protocols are in place, resistance continues to be a problem (8, 9). Therefore, once resistance emerges, it is a continuing clinical difficulty that must be managed.

Intrinsic antibiotic resistance

Paradoxically, it is the remarkable potency of these drugs that is their Achilles heel. Resistant bacteria are selected by exposure to antibiotics, which nondiscriminately kill off susceptible organisms. The resultant and powerful “adapt or die” evolutionary pressure selects for microbes with the ability to evade the toxic effects of these agents. This antibiotic insensitivity can be intrinsic, i.e., a consequence of the genetic or physiologic makeup of microorganisms, or it can be acquired from other sources, generally through the aegis of mobile genetic elements.

Intrinsic antibiotic resistance

Microbial metabolism is largely contained within the cell envelope and the cell interior. The intracellular physiology and biochemistry (ribosomes and protein translation, nucleic acid replication and transcription machinery, metabolic pathways, etc.) are, for the most part, conserved throughout the bacterial kingdom. On the other hand, the bacterial cell envelope is more structurally diverse. In particular, the presence of a relatively impermeable outer membrane in Gram-negative bacteria is a barrier to many classes of antibiotics. The bacterial outer membrane comprises an asymmetric bilayer with a phospholipid interior and a lipopolysaccharide (LPS) exterior. This anionic LPS layer is bridged through cationic metals providing an additional physical diffusion barrier for small and large molecules. Access to the interior of the cell is provided by a series of membrane proteins (e.g., porins) that recognize and allow the transport of nutrients and other metabolites. Antibiotics such as the glycopeptides, macrolides, and others have difficulty penetrating the outer membrane. As a result, Gram-negative bacteria are consequently intrinsically resistant to these drugs.

The absence of a sensitive microbial target is also a form of genetic intrinsic resistance. The oxirene antibiotic fosfomycin covalently modifies the target protein MurA on a sensitive and catalytically relevant Cys residue (Fig. 1) (10). MurA catalyzes the formation of N-acetylmuramic acid via enoyl-pyruvyl transfer of phosphoenol pyruvate onto the acceptor sugar N-acetylglucosamine, providing the necessary carboxylate anchor for attachment of the pentapeptide required for bacterial peptidoglycan (cell wall) formation. Bacteria that encode a MurA orthologue where the susceptible Cys is replaced by an Asp (e.g., Mycobacteria) are intrinsically genetically resistant to fosfomycin (Fig. 1) (11, 12).

Another confounding physiologic barrier to antibiotic action is the bacterial growth state. Most bacteria can grow in planktonic form where cells are free living and are uniformly exposed to antibiotics. Most antibiotic susceptibility tests are in fact performed on this cell state to determine the minimal inhibitory concentration (MIC) of antibiotic required to arrest cell growth. However, many important pathogens such as Staphylococcus aureus and Pseudomonas aeruginosa can form biofilms on surfaces (e.g., on catheters or mucosal layers of the lung) where most cells are metabolically quiescent and often highly resistant to antibiotics. Furthermore, other organisms can enter eukaryotic cells and thus evade host defense systems. For pathogens such as Mycobacterium tuberculosis and Chlamydia, it is essential for pathogenesis, whereas for others such as the enteric pathogens Salmonella and Escherichia, it exacerbates infection. Once inside the cell, these organisms often shift metabolic activities and can enter a relatively inactive state, sometimes for long periods of time. Successful antibiotic therapy, therefore, requires not only penetration of the eukaryotic cell without associated toxicity, but also sufficient antimicrobial activity to kill the often slow-growing bacterial cells in this environment.

These passive obstacles to antibiotic action complicate treatment of infectious disease in the absence of highly accurate diagnostic tools to identify the infectious pathogen. Intrinsic resistance is problematic but is predictable and easily identified in the preclinical drug discovery stages. As a result, the spectrum of susceptible microbial species is well known before the compound enters the clinic.

Acquired antibiotic resistance

In contrast to intrinsic resistance, which is genetically and physiologically “hard wired,” acquired antibiotic resistance occurs...
Bacterial Resistance to Antibiotics

Figure 1 The action of the antibiotic fosfomycin requires an active-site Cys residue in the target MurA. Substitution of Asp for Cys in some bacterial species results in intrinsic fosfomycin resistance.

Acquired resistance often requires the presence of the antibiotic for selection of resistant species within a susceptible genetic background. Resistance can emerge as a result of mutation of target genes on the chromosome (e.g., point mutations in DNA gyrase that confer fluoroquinone antibiotic resistance (13)) or by the presence of resistance genes that are captured on mobile and associated genetic elements such as plasmids, transposons, and integrons (14). The sequencing of entire bacterial genomes has revealed that these resistance-associated genetic elements can sometimes be components of the normal genetic makeup of a given bacterial species (especially transposons and integrons), but more often they are acquired as a result of selection in the face of antibiotic exposure. Conventional wisdom suggests that acquired resistance results in a genetic and physiologic burden that makes these organisms less fit in the absence of antibiotic selective pressure, although second site mutations can compensate (15).

One of the confounding issues with acquired resistance by way of mobile genetic elements is linkage of multiple resistance genes on a single element. R-Plasmids, integrons, and transposons often carry not only one resistance gene, but several (Fig. 2). As a result, selection of resistance to one antibiotic can inadvertently select for resistance to others, which can be especially problematic in clinical settings, can contribute to failure of antibiotic cycling countermeasure strategies within these institutions, and can add to the difficulty in eliminating antibiotic resistance once it has emerged.

Chemical Biology of Antibiotic Resistance

Antibiotic resistance can be the result of several molecular mechanisms (Table 1). Some of the most important of these mechanisms include enzyme-catalyzed antibiotic inactivation or modification, altered transport such as efflux, and others such as metabolic bypass and sequestration. Each of these mechanisms requires the synthesis of associated proteins to mediate resistance. These are often highly specialized and efficient, and frequently the corresponding genes can be acquired on mobile genetic elements. In this fashion, the antibiotic resistome (16), which is the collection of all resistance genes within the bacterial kingdom, has the potential to be shared and can cross species and genus boundaries.

In a simplistic but useful view, antibiotic molecules comprised a target-specific “warhead” and a bioactive delivery vehicle or scaffold (Fig. 3). The warhead interacts specifically with the target (protein, RNA, DNA, membrane) and forms key molecular interactions with it. These interactions can be covalent in the case of electrophilic chemical fragments such as β-lactams, β-lactones, and oxiranes, or noncovalent through hydrogen bonds, electrostatics, and so on. Consequently, alteration of the antibiotic at the warhead region or of the reciprocally vital antibiotic binding site on the target results in resistance. On the other hand, the delivery vehicle/scaffold portion of the antibiotic generally provides few essential interactions with the molecular target but instead contributes physical properties that enhance bioavailability (e.g., membrane permeability) or imparts structurally important features such as rigidity that ensure appropriate display and structure of the warhead. As a result, the scaffold portion of the antibiotic molecule tends to be more tolerant of chemical alteration. In fact, chemical modification of the molecular scaffold while preserving the antibiotic warhead has been the principal occupation of medicinal chemists since the first antibiotics were isolated from natural sources. The goal of these modifications is to improve pharmacology, evade resistance, and circumvent proprietary structure limitations. As a result, this region of the antibiotic molecule is generally not a principal target for resistance mechanisms; nonetheless, modification of key scaffold regions such as cyclizing bonds can result in resistance.

Next, various biochemical strategies employed by microorganisms to evade antibiotics are discussed with an emphasis on describing the chemical logic of the approach.
Bacterial Resistance to Antibiotics

Use of antibiotic A co-selects for resistance to antibiotics B-E

Figure 2 Integrons, transposons, and R-plasmids often collect multiple antibiotic resistance genes. As a result, selection of one resistance mechanism co-selects for resistance to additional resistance genes. The scheme shows a typical arrangement for an integron with associated integrase-encoding gene (int), a promoter to drive gene transcription (P), and antibiotic resistance elements (A-E).

Figure 3 Antibiotics consist of an active warhead and associated chemical scaffold.

Antibiotic Resistance by Enzymatic Mechanisms

One of the most effective and potent strategies in which microbes have evolved to evade antibiotics is the chemical modification of these cytotoxic compounds. This approach is generally very selective to the specific antibiotic or class, thereby avoiding undesirable side reactions and minimally perturbing normal bacterial metabolism. The general strategy is to destroy or otherwise mask the warhead, which results in resistance. The biochemical logic of several examples is discussed below.

Antibiotic destruction

One of the most potent and physiologically irreversible mechanisms of antibiotic resistance is via chemical destruction of the antibiotic warhead or scaffold. This destruction can occur through several mechanisms, but hydrolytic approaches predominate (Fig. 4). Resistance to the highly important β-lactam antibiotics by β-lactamases is the archetype of this class. The β-lactams include the natural product penicillin and cephalosporin scaffolds as well as the synthetic mono-bactams such as azetronam. The highly strained β-lactam ring is the antibiotic warhead, covalently modifying target transpeptidase and carboxypeptidase enzymes required for the synthesis and maturation of peptidoglycan (Fig. 5). This molecular strategy is analogous to the modification of MurA by fosfomycin as discussed above (Fig. 1), but in this case, covalent enzyme inactivation affects late-stage peptidoglycan biosynthesis on the outside of the cell rather than early-stage intracellular steps. The β-lactamases hydrolyze the thermodynamically activated β-lactam ring irreversibly incapacitating the antibiotics. Numerous β-lactamases have been cloned and characterized (recently reviewed in Reference 17). These enzymes are often secreted into the periplasmic region (the immediate extracellular space of the plasma membrane, bounded by the outer membrane in the case of Gram-negative bacteria) setting up a perimeter defense to intercept the antibiotics before they reach their molecular targets. The associated genes very frequently are on mobile genetic elements, but many bacteria also harbor orthologues within their genome (18).
Bacterial Resistance to Antibiotics

Figure 4 Hydrolytically sensitive antibiotics include the macrolides, oxirane, and β-lactams. The hydrolytically sensitive region is circled in each structural class.

Figure 5 Action of β-lactam antibiotics. Cell wall biosynthetic transpeptidases activate peptidoglycan peptides for cross-linking by formation of a covalent enzyme intermediate (A). The reactivity of the active-site Ser nucleophile is exploited by β-lactam antibiotics such as penicillin G (shown) to form a hydrolytically stable acylenzyme (B). The β-lactamases have mirrored the chemical strategy of proteases to cleave the β-lactam bond. The main β-lactamase families emulate Ser or metallo-protease mechanisms to perform ring-opening hydrolysis of the β-lactam ring, destroying the antibiotic warhead in the process (Fig. 6). The Ser enzymes mimic the first step in peptidoglycan transpeptidase reaction by formation of an acyl-enzyme intermediate. However, unlike the transpeptidase, this intermediate is short lived and subsequent hydrolysis releases the inactive antibiotic (Fig. 6).

Similarly, metallo-β-lactamases share with metallo-proteases activation of a hydrolytic water molecule by interaction with an active-site Zn²⁺ ion. These lactamases have gained clinical prominence in the past few years as a result of their association with carbapenem resistance. The carbapenems, such as meropenem and imipenem, are β-lactam antibiotics that have trans stereochemistry across the 6-5 bond rather than the cis geometry found in most other β-lactams (Fig. 7).
Bacterial Resistance to Antibiotics

β-Lactamases hydrolytically cleave the susceptible β-lactam ring using Ser and metallo-protease mode chemistry.

Comparison of the structures of amoxicillin and imipenem. The change in configuration across the 5-6 bond in imipenem maintains the ability to bind to penicillin binding proteins but provides insensitivity to many Ser-β-lactamases. As a result, these are drugs of choice for treatment of infections caused by β-lactam-resistant bacteria. However, carbapenems are susceptible to metallo-β-lactamases such as IMP and VIM that are becoming widely distributed among Gram-negative bacteria and are a growing clinical concern (19).

Hydrolitic enzymes are also known to inactivate the oxirane antibiotic fosfomycin and macrolides antibiotics such as erythromycin by ring-opening epoxidase and esterase activity, respectively (Fig. 4). The former mechanism is exemplified by the Mn$^{2+}$-dependent enzyme FosX from the soil bacterium Mesorhizobium loti (20). The bulk of clinically important macrolide antibiotic resistance occurs through ribosomal RNA methylation or efflux mechanisms. As a result, macrolide esterases are presently not a major clinical problem. However, the genes encoding this mode of resistance have been found on mobile genetic elements (21–23) and, because they confer high level resistance to this important class of antibiotic, there is cause for concern that this mechanism could increase in frequency.

Conceptually similar, although mechanistically distinct, is Vgb, a class B streptogramin inactivating enzyme. Streptogramins consist of two distinct structural classes of antibiotics: polyketide-peptide hybrids (type A streptogramins) and cyclic hexa or hepta depsipeptides (type B streptogramins). The type B streptogramins are cyclized through an ester linkage between the C-terminal carboxyl group and the secondary hydroxyl group of an invariant Thr residue at position 2. Both classes of streptogramins bind to the large subunit of the bacterial ribosome blocking the peptide transfer center (type A) and the peptide exit tunnel (type B). The warhead of the type B streptogramins consists primarily of the 3-hydroxyxypicolinic acid residue and the peptide backbone that blocks the entrance to the tunnel. Resistance to the type B streptogramins can occur through target modification or efflux, but also by the enzyme Vgb and orthologues (24). This enzyme linearizes the peptide backbone at the antibiotic’s thermodynamic weakest point, the ester linkage; however, unlike macrolide esterases, Vgb is not a hydrolase but a C-O lyase (25). The catalytic strategy likely involves acidification of the Thrα-proton by generation of the aci form of the amino acid followed by elimination of the carboxylate resulting in C-O bond cleavage and formation of the 2-amino-but-2-enic acid amide product (Fig. 8).

Antibiotic modification

Chemical modification of key groups on the antibiotic can also result in resistance. Modification generally occurs on the warhead region of the molecule, blocking effective interaction with...
Bacterial Resistance to Antibiotics

Figure 8 Inactivation of type B streptogramin antibiotics by Vgb lyase. The type B streptogramins such as pristinamycin Ia (shown) are cyclic depsipeptides. Vgb lyase catalyzes the cleavage of the C—O depsipeptide bond.

Typical modifications include acylation, phosphorylation, and adenylylation. These add steric bulk to the antibiotic, obscure key target binding elements, and can alter charge of the compound. As the reactions require cosubstrates such as ATP and acetylCoA, antibiotic modifying enzymes are generally located within the cell interior where access to these high energy substrates is secure. This strategy impacts several classes of antibiotics and, in some cases, there is significant conservation of general protein fold among enzymes that modify chemically diverse antibiotics.

Acetylation of antibiotics is a common mechanism of modification. The acyltransferases generally use the metabolically abundant acetyl-CoA as the preferred acyl-donor. The amino-glycoside antibiotic acetyltransferases (AACs), for example, modify important amines that make contact with the target 16S rRNA (Fig. 9), which results in a loss of positive charge and increased steric bulk that contribute to lowering the affinity of the antibiotics for the rRNA target by 600-fold (26). The AACs are members of the GCN5 superfamily of acetyltransferases that include such members as the eukaryotic histone acetyltransferases and serotonin acetyltransferase (27).

Strategically similar, but structurally distinct, are the chloramphenicol acetyltransferases (CATs). Chloramphenicol binds to the large ribosomal subunit at the nexus of the peptidyltransfer center and the peptide exit tunnel (28, 29). CATs are trimeric enzymes with active sites at the interface of the monomers that catalyze acetylation of the hydroxyl group on position 3 (31), which is essential for interaction with the ribosome (Fig. 10). The well-characterized type I–III CATs are robust and efficient modifiers of the antibiotic with $k_{cat}/K_m$ values that approach diffusion-controlled reactions (32). These CATs are structurally distinct from a group of chloramphenicol acetyltransferases that have been classified as xenobiotic acetyltransferases (XAT) in view of their broader substrate specificity and relatively inferior affinity for chloramphenicol (31). The XATs belong to the large hexapeptide repeat family of proteins that incorporate a left-handed $\beta$-helix domain (33). Although they show no primary sequence or tertiary structure homology, both CATs and XATs are trimers with active-site residues at the interface of the monomer subunits and both use a catalytically important His residue to assist in deprotonation of the antibiotic hydroxyl group undergoing acetylation. The streptogramin acetyltransferases (VATs) are also members of the XAT family (34) and are responsible for resistance to the type B streptogramins, notably the clinically used drug dalfopristin (Fig. 11) (35).

Phosphorylation is a common mechanism resulting in resistance to the aminoglycoside antibiotics. This chemical strategy also has been associated with resistance to the macrolides such as erythromycin, the tubactinomycins such as viomycin, and chloramphenicol. The aminoglycoside kinases share 3D structural similarity with the Ser/Thr/Tyr protein kinase family (36), and the conservation of kinase signature sequences in macrolide
Bacterial Resistance to Antibiotics

(a) Aminoglycoside antibiotic modifying enzymes. The aminoglycoside antibiotics such as kanamycin B (shown) bind to the 16S rRNA of the bacterial ribosome impairing cognate codon–anticodon discrimination (A). Resistance occurs via acetylation (AAC), phosphorylation (APH), or adenylylation (ANT) of the antibiotic (B). A wide variety of enzymes are known with different regiospecificities of chemical modification, and the sites of some clinically important enzymes are shown in panel C.

and tuberactinomycins kinases suggests that they will also share the family protein kinase 3D structure (37). Mirroring the effect of acetyl transfer, covalent modification of aminoglycosides alters charge and size, resulting in up to a 1300-fold decrease in affinity of the modified antibiotic for 16S rRNA (Fig. 9) [26].

(b) Like the aminoglycosides, the binding site of the macrolide antibiotics with the large ribosomal subunit has also been determined to atomic resolution by X-ray crystallography (29, 38, 39). Key interactions between the antibiotic and the 23S rRNA occur and are mediated through the essential desosamine sugar.
Bacterial Resistance to Antibiotics

Chloramphenicol modifying enzymes. Chloramphenicol binds to the 23S rRNA of the large ribosomal subunit (A). Chemical modification of the essential hydroxyl groups by acetyltransferase or kinase enzymes confers resistance (B).

Chemical modification of Type B streptogramins. These antibiotics bind to the large ribosome adjacent to the chloramphenicol binding site (A). A key interaction with the 23S rRNA is blocked by the action of VAT-dependent acetylation (B).

Macrolide kinases (MPHs) phosphorylate position 2' of the desosamine sugar, impairing binding with the target. Genes encoding these enzymes have been identified in mobile genetic elements in various bacterial pathogens (40-43). Using an analogous evasive strategy, macrolide producing and other soil bacteria encode macrolide glycosyltransferases that catalyze glucosylation of the same essential 2'-position on the desosamine by UDP-glucose (44-46) (Fig. 12). The net result is the same with either approach: steric blockade of the appropriate target-antibiotic interaction resulting in resistance.
Bacterial Resistance to Antibiotics

Figure 12 Macrolide modifying enzymes. Macrolide antibiotics such as erythromycin (shown) bind to the large ribosomal subunit through interactions with the 23S rRNA (A). Chemical modification of the essential desosamine sugar blocks ribosome binding (B).

Chloramphenicol phosphotransferase from the producing bacterium Streptomyces venezuelae (47) is unrelated to the protein kinase family but rather shows more similarity to small-molecule kinases such as shikimate kinase (48). Analogous to the CAT strategy, phosphorylation occurs at the hydroxyl position 3, blocking this essential group from interacting with the ribosome (Fig. 10).

Aminoglycosides and lincosamides such as clarithromycin can be modified by O-adenylylation in an ATP-dependent fashion resulting in resistance. Position 2′ of the aminoglycosides is the target for the clinically important ANT(2′) enzymes that confer resistance to antibiotics such as tobramycin and gentamicin. In analogy to other aminoglycoside modifications that result in resistance discussed above, the addition of the bulky and negatively charged adenosine diphosphate to the antibiotic attenuates ribosome binding (Fig. 9). The lincosamide antibiotics are frequently modified by AMP at position 3 in a reaction catalyzed by the Lin proteins (49, 50). This modification blocks a key interaction of the antibiotic with the 23S rRNA of the bacterial large subunit (Fig. 13) (29).

Antibiotic Modification by Oxidation/Reduction Mechanisms

Antibiotic resistance via redox reactions is not as common as chemical modification; however, there are some examples of this strategy in nonpathogenic bacteria. The streptogramin antibiotic producer Streptomyces virginiae can reduce a vital ketone group of group A streptogramins in an NADH-dependent manner resulting in formation of the vicinal diol, which lacks antibiotic activity (51). Redox-dependent inactivation of rifampin has also been described by a gene product from Rhodococcus equi (52).

Tetracycline resistance occurs primarily by efflux and target protection mechanisms (53); however, inactivation by the redox enzyme TetX has been reported (54). TetX is a monooxygenase that selectively hydroxylates tetracycline antibiotics (55), including the latest generation of antibiotics of the class the glycylcyclines (56). Tetracycline binds to the A-site of bacterial ribosomes interfering with translation. Binding of the invariant β-diketone functional group characteristic of the class to the ribosome occurs through the mediation of a divalent cation (likely Mg^{2+}) (Fig. 14). TetX catalyzes the mono-hydroxylation of the antibiotics at position 11a, effectively disrupting the Mg^{2+} binding site, resulting in resistance (Fig. 14). Furthermore, some tetracyclines undergo nonenzymatic degradation after mono-hydroxylation, resulting in irreversible destruction of the antibiotic.
Antibiotic Resistance Through Altered Transport

To be effective, antibiotics must accumulate to critical levels governed by their affinity for their molecular targets. Furthermore, these targets are frequently intracellular. As a result, antibiotics must efficiently permeate the bacterial cell envelope and achieve sufficiently effective local concentrations. In Gram-positive bacteria, the cell envelope consists of the cell wall and the phospholipid containing cell membrane. In contrast, Gram-negative bacteria deploy an additional outer membrane consisting of an asymmetric LPS/phospholipid bilayer to complement the peptidoglycan and phospholipid cell membrane components of the cell envelope. These architectures provide a substantial barrier to antibiotic access to the cell interior.

Transport-linked resistance to antibiotics can emerge as a result of poor penetration of the bacterial cell envelope or from the energy-dependent purging of antibiotic molecules that have managed to penetrate the envelope through the aegis of efflux proteins. Often, these two mechanisms, entry and efflux, combine to achieve high level resistance to many antibiotics. Like enzyme-based resistance, several of these transport-based resistance genes are encoded on mobile genetic elements; however, all bacteria encode an elaborate collection of transport proteins in their chromosomes, some of which have the potential to be recruited for antibiotic resistance. In particular, Gram-negative bacteria, such as those from the genera Pseudomonas and Burkholderia, are particularly adapted for transport-mediated resistance, and this mechanism contributes significantly to the high level of broad spectrum antibiotic resistance in these organisms.

Antibiotic efflux

Bacterial cells can express a variety of membrane proteins that mediate the energy-dependent efflux of toxic compounds (Table 2). Five structurally distinct classes of efflux proteins are recognized: ABC transporters, resistance-nodulation-division (RND) proteins, multidrug and toxin extrusion (MATE) proteins, small multidrug resistance (SMR) proteins, and major facilitator superfamily proteins (MFS). The latter four of these proteins promote exchange of a cation (H\(^+\) or Na\(^+\)) for the antibiotic, whereas the ABC transporters use ATP hydrolysis to drive ejection of the compound from the cell. All of the protein classes have been associated with antibiotic resistance in various bacterial strains; nonetheless, some general rules have emerged from the past two decades of efflux research. First, with a few exceptions, plasmid- or integron-mediated resistance usually is associated with MFS and SMR proteins that have broad substrate specificity. Second, ABC transporters are analogous to the P-glycoprotein class of drug efflux systems in eukaryotes. They are not as prevalently associated with antibiotic resistance in pathogenic bacteria as the RND class or in Gram-negative and Gram-positive bacteria, whereas the RND class is generally found in Gram-negatives where they are chromosomally encoded. Fourth, sequencing of bacterial genomes has revealed...
that all microbial genomes have multiple predicted antibiotic efflux proteins (e.g., 25 in Staphylococcus aureus COL, 102 in Bacillus anthracis Ames). Several excellent and comprehensive recent reviews cover this field in depth (57–61); therefore, the following description will briefly emphasize the proposed mechanisms rather than the comprehensive details of efflux systems and their individual components.

The MFS proteins are a large superfamily of transporters that are essential to the shuttling of numerous metabolites (sugars, amino acids, and anions) as well as cytotoxic agents such as antibiotics in exchange for cations. They consist of 12-14 membrane-spanning helices and can be found encoded on mobile genetic elements (e.g., QacA, which is clustered in many integrons) or on bacterial chromosomes (e.g., NorA, which is linked to fluoroquinolone resistance in S. aureus). Three-dimensional structures of members of the MFS superfamily have been reported, including the sugar transporters LacY (62) and GlpT (63) and, more recently, the multidrug transporter EmrD from E. coli (64). These structures reveal a collection of helices that form a pore-like structure to enable transport across the membrane. In EmrD, the interior of the pore is mostly hydrophobic, consistent with the substrate specificity of the protein that includes detergents such as sodium dodecyl sulfate. This structure suggests a “rocker-switch” mechanism where the substrate enters the open pore from the cytoplasm or the inner leaflet of the cell membrane, the open pore then undergoes a conformational change to close around the substrate coupled with H⁺ transport, and finally the pore is reopened facing the exterior of the cell where the substrate can diffuse away (Fig. 15).

The RND proteins have emerged as important mediators of multidrug resistance in Gram-negative bacteria, especially in the opportunistic pathogens P. aeruginosa, Stenotrophomonas maltophilia, Acinetobacter baumannii, and Burkholderia cepacia. These resistance modules combine with reduced uptake and a cadre of chromosomally encoded resistance enzymes to make these bacteria virtually impermeable to antibiotics. The groups of Nikaido and Poole have studied the RND efflux systems in detail from E. coli and P. aeruginosa, respectively, providing great insight into the components of individual RND transports, their mechanisms of action, and substrate specificity. Consequently, the AcrAB/TolC system in E. coli and the MexAB/OprM triad in P. aeruginosa are the paradigms of the class. They are tripartite efflux systems consisting of an inner cell membrane transporter (AcrB, MexB), a periplasmic membrane fusion protein (AcrA, MexA), and an outer membrane pore (TolC, OprM) to seamlessly connect the inside of the cell across two membrane barriers to the external environment (Fig. 16). This structure provides an unimpeded conduit for toxic molecules from the cell interior to the exterior. Additionally, antibiotics such as β-lactams and other molecules are able to access the efflux system within the periplasmic space without entering the cell, thereby expanding the spectrum of the efflux system. The crystal structures of AcrB (65, 66), MexA (67), a fragment of AcrA (68), and TolC (69) have been determined. These structures confirm the predicted membrane spanning arrangement of the efflux system and serve to rationalize the broad substrate specificity of the complex as well as illustrate the challenge of overcoming efflux-mediated resistance.

Figure 14  Enzymatic modification of tetracycline. Tetracyclines bind to the ribosome in several areas, but the primary region is in the A site of the small subunit (shown) (A). The antibiotic binds divalent cations such as Mg²⁺, which is essential for ribosome binding. The enzyme TetX catalyzes the mono-hydroxylation of tetracycline at position 11a disrupting the Mg²⁺ binding site resulting in resistance.

Figure 15 Proposed rocker-switch mechanism for MFS-mediated drug efflux. Antibiotic (circle) enters the open pore from the cytosolic face or inner membrane leaflet and is antiported to the cell exterior with an H⁺ ion coupled with conformational change within the protein.

**Reduced uptake of antibiotics**

Although efflux is a daunting obstacle for many antibiotics, it is the balance between influx and efflux that determines whether cells will be sensitive or resistant in the face of an antibiotic challenge. As a result, reduced uptake of antibiotics coupled with activation of efflux pumps is a potent combination that can overcome sensitivity to drugs in many pathogens. Many metabolites and compounds such as antibiotics penetrate cells via transport proteins and, as a result, mutation in these proteins or decrease in their expression can decrease antibiotic uptake. In Gram-negative bacteria, the outer membrane porins are required for entry of many antibiotics such as β-lactams and aminoglycosides, and antibiotic resistance can occur through modulation of these proteins. For example, imipenem resistance...
Bacterial Resistance to Antibiotics

In P. aeruginosa, resistance to antibiotics is frequently associated with mutation in the OprD porin (70).

Other Mechanisms of Antibiotic Resistance

In addition to enzymatic modification or destruction and transport, bacteria can evade antibiotics through a variety of ways, including metabolic bypass, target overexpression or modification, and the production of various protective proteins.

Metabolic bypass: vancomycin resistance

The classic example of metabolic bypass resulting in antibiotic resistance can be found in the glycopeptide antibiotics. Glycopeptides such as vancomycin and teicoplanin are natural product antibiotics that bind to the ubiquitous acyl-D-Ala-D-Ala dipeptide terminus of peptidoglycan (71), which results in sequestration of the substrate for cell wall biosynthetic enzymes including the transpeptidases and glycosyltransferases, resulting in impairment of cell wall synthesis and bacterial growth. Therefore, vancomycin binds to an essential small-molecule metabolite, which is the enzyme substrate, rather than to the protein itself. As a result, simple mutation of a single gene to overcome resistance is not possible.

Vancomycin and other glycopeptides bind to acyl-D-Ala-D-Ala through a series of five hydrogen bonds that includes a key interaction with the amide hydrogen of the D-Ala-D-Ala peptide bond (Fig. 17). The acyl-D-Ala-D-Ala glycopeptide-binding unit is synthesized in stepwise fashion through a series of metabolic steps involving first synthesis of D-Ala, ATP-dependent ligation of two D-Ala molecules to generate the D-Ala-D-Ala dipeptide, and a second ligation where the dipeptide is grafted onto the N-acetyl-muramic acid tripeptide acceptor for incorporation into the growing cell wall (Fig. 18). Vancomycin-resistant bacteria overcome the antibiotic by bypassing the normal cell wall biosynthesis. Instead of producing a cell wall terminating in the D-Ala-D-Ala dipeptide, a peptidoglycan is produced that terminates with the depsipeptide (ester) D-Ala-D-lactate (Fig. 17). This change of NH for O results in loss of a critical H-bond and electronic repulsion between the ester O and the carbonyl of vancomycin. The net effect is a 1000-fold decrease in $K_D$, resulting in vancomycin resistance (72). Incorporation of the D-Ala-D-lactate ester requires three enzymes: VanH, VanA, and VanX. VanH is a D-lactate dehydrogenase generating D-lactate from pyruvate. VanA is an ATP-dependent depsipeptide ligase that generates D-Ala-D-lactate. Finally, VanX is a highly specific D-Ala-D-Ala dipeptidase that clears the cell of D-Ala-D-Ala that continues to be synthesized by the chromosomally encoded D-Ala-D-Ala ligases. These three proteins work in concert to bypass the normal cell wall biosynthetic metabolism and are each essential for resistance. Not surprisingly, they are colocated on resistance islands (73).
Bacterial Resistance to Antibiotics

**Figure 18** Synthesis of the D-Ala-D-Ala peptidoglycan terminus. D-Ala-D-Ala ligases (Ddl) synthesize the dipeptide, which is incorporated into the UDP-MurNAc-tripeptide by the D-Ala-D-Ala adding enzyme (MurF in *E. coli*).

plasmids and transposons that have emerged in strains of enterococci and more recently in *S. aureus*.

In a variant of this strategy, vancomycin resistance can also emerge by incorporation of peptidoglycan terminating in D-Ala-D-Ser. Substitution of D-Ala for D-Ser has steric implications for tight vancomycin-peptidoglycan binding, which also can result in resistance.

**Target modification**

One of the most straightforward mechanisms of antibiotic resistance is mutation of the target to a form that has less affinity for the antibiotic. Spontaneous mutations that provide some benefit to the organism occur roughly $2 \times 10^{-9}$ per replication (reviewed in Reference 73). Exposure to certain classes of antibiotics such as the rifamycins and fluoroquinolones can induce mutation, increasing the opportunity of developing resistance (74). Point mutations are associated with resistance to virtually all antibiotics, but this form of resistance is particularly important in the clinic for the fluoroquinolones, rifamycins such as rifampin, trimethoprim, and the sulfonamides.

Enzyme-mediated target modification can also be an important mechanism of antibiotic resistance. The Erm proteins are 23S rRNA S-adenosylmethionine-dependent methyltransferases that immunize the bacterial ribosome against the macrolide antibiotics such as erythromycin, the lincosamides, and type B streptogramins (75). The Erm proteins, specifically methylate A2058, provide a steric block for all three classes of antibiotics: a remarkable example of potent and strategic resistance parsimony. The *erm* genes are widespread in clinical isolates and can be constitutively expressed or strategically deployed through a complex induction mechanism (76).

By means of similar logic, methylation of the 16S rRNA at position G1405 by Arm and related proteins results in high level aminoglycoside resistance (77).

**Protective proteins**

Expression of various proteins, which can collectively be called protective, can result in antibiotic resistance. These immunity proteins often work in stoichiometric fashion to sequester the compounds, or otherwise protect the cell against the toxic activity of the antibiotics.

Resistance to the peptide antibiotic/anticancer agent bleomycin can occur through the expression of the Blm family of proteins that sequester the antibiotic. Bleomycin includes...
Bacterial Resistance to Antibiotics

Resistance to antibiotics is manifested through a number of different chemical and biophysical mechanisms, each with its own associated biochemical logic. A fundamental component of this logic is the sensitivity of the antibiotic warhead to chemical alteration. Although resistance is inevitable, understanding how resistance can occur, what the sensitive regions of the molecule are, and biochemical strategies that could overcome it such as the identification of specific inhibitors of resistance are essential to delay the emergence of resistance. Recently, it has been shown that penetration of antibiotic resistance in the microbial community at large is much deeper than previously appreciated (16). Understanding the origins and evolution of resistance will also provide drug discoverers with valuable information to circumvent established mechanisms. The concept of overcoming the inevitability of antibiotic resistance with small-molecule inhibitors of resistance mechanisms has been proven to be highly effective in the β-lactam class of antibiotics (90), and this approach should be broadly applicable (91). In fact, this area is one of intense interest, especially as applied to efflux mechanisms (92, 93). The routes forward in this important area of medicine require Chemical Biology approaches to understand antibiotic-target interactions and antibiotic resistance mechanisms. Chemical Biology and other multidisciplinary disciplines are therefore essential to prolong the utility of these essential therapeutic agents.

References

Conclusions

The history of antibiotic use over the past 70 years is invariant: initial deployment to the clinic with littleto background resistance followed by emergence and global spread of resistance, a metal-binding region that complexes Fe\(^{2+}\) resulting in a potent generator of oxygen radicals (warhead) and a DNA intercalating portion (scaffold) that targets the complex to DNA. Bleomycin, therefore, is a remarkable molecule with the ability to produce toxic radicals in an unregulated fashion proximal to DNA. The Blm proteins, such as BlmA from the bleomycin producer Streptomyces verticillus and BlmT found on various resistance transposons such as Tn14,000, are small dimeric proteins (~14,000 Da/molecular), and high resolution crystal structures are available for each protein (78, 79). The structure of the BlmA protein in complex with a Cu(II)-bleomycin complex reveals that each monomer binds one antibiotic molecule and that binding of the second molecule of bleomycin is cooperative (80). The precise mechanism of resistance is likely through sequestration of both the warhead and scaffold portions of the antibiotic, thereby preventing optimal activation of the Fe(II) complex.

Similarly, resistance to the anticancer antibiotic mitomycin C in the producing organism Streptomyces lavendulae, occurs via sequestration of the antibiotic by the binding protein MBD (81, 82). This protein interacts with the mitomycin export system, thus additionally facilitating export of the antibiotic from the cell. The structure of MBD reveals similarity to the bleomycin resistance proteins and, in fact, the protein can also bind bleomycin and confer resistance to this antibiotic (83).

By similar means, resistance to the highly toxic enediyne antibiotics, which are active at ng/mL concentrations, occurs through binding proteins in the producing bacteria. These antibiotics include a conserved core warhead consisting of two acetylenic groups bridged by a carbon–carbon double bond. This warhead generates a diradical after thiol activation resulting in DNA cleavage (84). The class is divided into two structural groups, the 9-membered and 10-membered enediyynes, referring to the size of the warhead-containing ring. The 9-membered enediyynes are stabilized by cooperation and titration by core protective binding proteins. The X-ray crystal structure of one of these complexes, C-1027 with the binding protein CagA, has been reported (85). Resistance to the more chemically stable 10-membered enediyynes (e.g., calicheamicin), however, involves the remarkable expression of the protective protein CalC that undergoes calicheamicin-dependent proteolytic self-sacrifice simultaneously inactivating the antibiotic (86).

Another example of protective protein expression is the tetrapeptide antibiotic, which is active at ng/mL concentrations, occurs through binding proteins in the producing bacteria. The antibiotics include a conserved core warhead consisting of two acetylenic groups bridged by a carbon–carbon double bond. This warhead generates a diradical after thiol activation resulting in DNA cleavage (84). The class is divided into two structural groups, the 9-membered and 10-membered enediyynes, referring to the size of the warhead-containing ring. The 9-membered enediyynes are stabilized by cooperation and titration by core protective binding proteins. The X-ray crystal structure of one of these complexes, C-1027 with the binding protein CagA, has been reported (85). Resistance to the more chemically stable 10-membered enediyynes (e.g., calicheamicin), however, involves the remarkable expression of the protective protein CalC that undergoes calicheamicin-dependent proteolytic self-sacrifice simultaneously inactivating the antibiotic (86).

A rather example of protective protein expression is the tetra-cyclic resistance TetO and TetM proteins and their analogues (87). These proteins structurally resemble the prokaryotic GT-Pase elongation factors such as EF-G and EF-Tu that bind to the ribosome and are essential for translation. TetO/M protection proteins do not replace elongation factors, but they do bind to the ribosome and displace bound tetracyclines in a GTP-dependent manner (88, 89).

Calcium is a universal second messenger that controls many cellular reactions. Considering its pleiotropic role, it seems evident that the cells, to get a specific message in the proper time and manner, need precise and efficient mechanisms to encode and decode Ca\(^{2+}\) signals. Generally, extracellular stimuli are converted in a transient increase in cytosolic Ca\(^{2+}\) concentration, \([\text{Ca}^{2+}]_c\), which, in turn, modulates cell function. In the last two decades, improvements in the development of probes and instrumentation for Ca\(^{2+}\) imaging have led to the discovery that the coordinated action of different players is responsible for a complex spatio-temporal organization of the Ca\(^{2+}\) signal. It is intriguing to observe that cells can encode and discriminate Ca\(^{2+}\) signals not only according to their magnitude but also according to their localization (microdomains) and shape; i.e., cells can discriminate between sustained and oscillatory signals. Even more, in the case of oscillations, messages can be read differently according to the frequency of the oscillatory signals. The mechanisms by which cells decode Ca\(^{2+}\) signals are now explored in numerous laboratories. This article focuses on the autoregulation properties of the Ca\(^{2+}\) signals. It will show that Ca\(^{2+}\) itself is central in the regulation of the Ca\(^{2+}\) signal. It will also show that it can act as a first and second messenger and that it can modulate the activity and the availability of the other players in the signaling operation.

Eukaryotic cells are surrounded by media containing free Ca\(^{2+}\) concentrations that exceed 1 mM, but they manage to maintain a free Ca\(^{2+}\) concentration in the cytoplasm that is four orders of magnitude lower. The very low internal concentration is maintained by the active transport of Ca\(^{2+}\) ions against their concentration gradient by Ca\(^{2+}\) pumps in the plasma membrane, in the endoplasmic/rough endoplasmic reticulum (ER/SR), and in the Golgi membranes. The plasma/membrane Na\(^+/\)Ca\(^{2+}\) exchangers also play a role, particularly in heart and skeletal muscle. The cells invest energy in this process that not only preserves the low \([\text{Ca}^{2+}]_c\), but also generates an intracellular source of Ca\(^{2+}\) within the lumen of intracellular organelles, essentially, the ER/SR and the Golgi apparatus. Generally, extracellular stimuli are converted in a transient increase in the \([\text{Ca}^{2+}]_c\), which, in turn, activates cellular functions. The sources of Ca\(^{2+}\) are both extracellular and intracellular; i.e., Ca\(^{2+}\) channels in the plasma membrane and in the intracellular membranes are critical in the control of cellular Ca\(^{2+}\) homeostasis. To guarantee the specificity of the signal transmission, the cell organizes dynamically the Ca\(^{2+}\) fluctuations in the cytosol by varying the distribution, the type, and the availability of the different Ca\(^{2+}\) transporters, and it increases the spatial and temporal complexity of Ca\(^{2+}\) homeostasis by compartmentalizing the signals into the organelles. The ER was originally considered to be the sole dynamic Ca\(^{2+}\) regulator in the cell, but it has now become clear that the nucleus, the mitochondria, the Golgi apparatus, the endosomes/lysosomes, and the secretory vesicles also play fundamental roles (Fig. 1). Recent methodological developments have revealed that, in living cells, these systems are strictly interconnected. The control of their Ca\(^{2+}\) homeostasis is not only essential in the control of organelle-specific processes, but it is also fundamental in the overall dynamic modulation of the Ca\(^{2+}\) signaling in the cytosol. Many protein components of this signaling cascade have been cloned and characterized: Strikingly, many exist as different isoforms, the number of which is further increased through mechanisms of alternative splicing.
Ca2+ channels (VOCCs) (1), or on ligand binding [in the case of receptor-operated Ca2+ channels (ROCCs) (2)], or on a still poorly understood mechanism linked to the emptying of intracellular Ca2+ stores. VOCCs are found not only in excitable cells such as neurons, skeletal muscle, and heart, but also in nonexcitable cells. Six classes (termed L, N, P, T, R, and Q) have been identified based on physiologic and pharmacologic properties. Structurally, all VOCCs are complexes of five subunits, termed α1, α2, β, γ, and δ, that assemble into large macromolecular complexes and that are encoded by different genes. α1, the largest subunit, contains the conduction pore, the voltage sensor, the gating apparatus, and the sites of channel regulation, e.g., by protein kinases, by drugs, and by toxins. Much of the diversity of Ca2+ channel types originates from the variety of α1 subunits, and at least 10 different genes encoding for different α1 subunits have so far been identified in mammals. ROCCs are activated by the interaction of ligands with plasma membrane receptors. L-glutamate is the most abundant excitatory transmitter in the vertebrate central nervous system. It activates two general classes of receptors, the “ionotropic” receptors, which are ionic channels, and the “metabotropic” receptors, which are coupled to G-proteins, which activate phospholipase C (PLC) and promote intracellular Ca2+ responses. Three forms of ionotropic receptors have been characterized and named after their most widely used agonist: the kainate (KA), the α-amino-3-hydroxy-5-methyl-4-isoxazole propionate (AMPA), and the N-methyl D-aspartate (NMDA) receptors. AMPA and NMDA receptors colocalize at the same postsynaptic membrane, and their close functional interdependence has important roles in the processes of memory storage and learning. A heterogeneous group of channels (most of which belong to the so-called transient receptor potential family, TRPs) are activated by a variety of factors, including mechanical stretch, osmolarity, temperature, second messengers, G-proteins, protein–protein interactions, and so on (3). The molecular nature of an additional group of channels, in this case activated by arachidonic acid, is still undetermined (4). Whatever the nature and gating properties of a channel, it is easily envisaged that upon its opening, a high concentration of Ca2+ will be generated at its mouth, on the inner side of the plasma membrane. In general terms, the peak amplitude and duration of Ca2+ microdomains formed at the internal mouth of a Ca2+ channel and its immediate neighborhood will depend on the following: the conductance of the channel itself, its Ca2+ selectivity, the concentration of Ca2+ in the extracellular medium, the membrane potential, and the nature and amount of the intracellular Ca2+ buffers.

Intracellular Ca2+ Release Mechanisms

The release of Ca2+ from internal stores, usually the ER or its muscle equivalent, the SR, is controlled by Ca2+ itself, or by an expanding group of messengers, such as inositol 1,4,5-trisphosphate (InsP3), cyclic ADP ribose (cADPR), nicotinic acid adenine dinucleotide phosphate (NAADP), and sphingosine-1-phosphate (S1P), that either stimulate or modulate the release channels on the internal stores. The Ca2+ release channels represent the molecular component of the Ca2+ handling machinery of the intracellular stores. They belong to two families, the so-called InsP3 receptors (InsP3Rs) and Ryanodine receptors (RyRs) (5). The heterogeneous distribution of these channels within intracellular compartments is one of the key factors in determining the spatial heterogeneity of the Ca2+ signals and thus the formation of Ca2+ microdomains. The two channel types have been conserved during evolution, as a significant degree of homology characterizes the sequences of the domains next to the C-terminus that span the membrane and contribute to the assembly of the channel proper. Both are...
In cardiac and skeletal muscle, a highly structured morphologic architecture allows the generation of Ca$^{2+}$ microdomains at the surface of the SR; these microdomains are a key component of the trigger for firing the Ca$^{2+}$ signals necessary for cell activation according to the mechanism known as Ca$^{2+}$-induced-Ca$^{2+}$-release (CICR) (6). Indeed, in both cell types, the physiologic stimulatory signal leading to contraction is conveyed by action potentials: A plasma membrane depolarization travels via the opening of voltage-dependent Na$^+$ channels and reaches the cell interior through invaginations (the T tubules) in which VOCCs are located; this process causes the influx of Ca$^{2+}$ that is per se insufficient to induce the physiologic response (the sliding of the acto-myosinic contractile apparatus), but it represents the trigger for the release of Ca$^{2+}$ (particularly in the heart) from the large intracellular Ca$^{2+}$ reservoir (the SR), through the RyRs (7). In skeletal muscle, direct coupling between the two molecules (VOCCs and RyR) is believed to cause the opening of RyRs; thus, the influx of Ca$^{2+}$ through VOCCs plays a facilitatory, but not a necessary, role.

The interaction between the two channels is thought to be the necessary event to cause activation of the RyR isoform of skeletal muscle (RyR1), and then Ca$^{2+}$ release through the RyR1 is amplified by CICR. In heart, no direct physical interaction occurs between the two types of channels, and thus a high [Ca$^{2+}$] in the proximity of the RyR2 (the cardiac RyR isomorph) represents the essential activatory signal (8). Therefore, in heart, Ca$^{2+}$ influx through VOCCs is necessary to trigger SR Ca$^{2+}$ release through the RyR2 via the process of CICR.

In this context, the Ca$^{2+}$ sensitivity of the RyRs, as well as the evaluation of the local Ca$^{2+}$ concentration to which they are exposed, is a key factor in determining the excitability of the muscle fiber and the efficiency and duration of contraction. As a result, a great deal of work has concentrated on identifying the “fundamental” Ca$^{2+}$ signaling. Rapid Ca$^{2+}$ imaging of both cardiac and skeletal muscle has revealed the occurrence of transient, local increases in Ca$^{2+}$ concentration, denominated Ca$^{2+}$ puffs (9) that were attributed to the opening of single RyR channels, or more likely, a cluster of RyRs (10, 11).

The occurrence of elementary signals, generated by the opening of a spatially restricted group of channels (12) and denominated “Ca$^{2+}$ puffs” (13), is also shared by the InsP$_3$-dependent signaling system. Ca$^{2+}$ puffs denote the “Ca$^{2+}$ excitability” of the cell, but the induction of a physiologic response requires the coalescence of these elementary events into a larger rise, which may be limited to a portion of a polarized cell or may diffuse to the whole cell body in a truly global Ca$^{2+}$ signal. The transition from elementary to global events, and its regulatory mechanisms, is thus critical in determining the final cellular outcome of the InsP$_3$-dependent Ca$^{2+}$ signal. Numerous stimuli function through the activation of PLC to generate InsP$_3$. Several isozymes of PLC have been described: all of them specific for phosphatidylinositol (PhIns, PI), a phospholipid that is predominantly present in the inner leaflet of the plasma membrane, and its mono (PhIns-4-P, PIP$_1$) and bis-phosphorylated forms (PhIns-4,5-P$_2$, PIP$_2$). Diacylglycerol (DAG) and phosphorylated inositolis are formed, with 1,4,5 InsP$_3$ being the only one among the numerous inositol phosphate isomers that is capable of releasing Ca$^{2+}$ from intracellular stores by interacting with a specific receptor. Three genes encode the InsP$_3$Rs. They are ubiquitously expressed; type 1 is expressed in particularly high levels in Purkinje neurons in the cerebellum. The differential contribution of InsP$_3$R isoforms to Ca$^{2+}$ signaling is now being explored. Studies on the DT40 chicken lymphoma cell line, in which one or more of the InsP$_3$R genes were systematically eliminated by homologous recombination, have shown that the expression of isoform 2 is necessary for the generation of Ca$^{2+}$ oscillations after cell stimulation (14).

The InsP$_3$R is operated by InsP$_3$, but it is also modulated by Ca$^{2+}$. Low luminal Ca$^{2+}$ has been proposed to stimulate the opening of the Ca$^{2+}$-channel, but the matter is still being debated. The effects of cytosolic Ca$^{2+}$ on the receptor are better documented. Even if they may vary, depending on concentration, cell type, or experimental conditions, the effects of Ca$^{2+}$ are biphasic. They are stimulatory at <300 nM and inhibitory at >300 nM (15, 16).

**Intracellular Ca$^{2+}$-Removing Mechanisms**

During the generation of a Ca$^{2+}$ transient, the “on” reactions are counteracted by “off” reactions, during which time various pumps and exchangers remove Ca$^{2+}$ from the cytoplasm. These mechanisms are essential in maintaining the resting level of Ca$^{2+}$ at approximately 100 nM and in ensuring the Ca$^{2+}$ loading of internal stores. As mentioned, three different molecular components are involved in the “off” reactions: the plasma membrane Ca$^{2+}$-ATPase (PMCA), the Na$^+$/Ca$^{2+}$ exchanger (NCX), and the sarcoplasmic reticulum Ca$^{2+}$-ATPase (SERCA). PMCAs represent the main Ca$^{2+}$-extrusion system of all eukaryotic cells and have high Ca$^{2+}$ affinity. In mammals, four separate genes encode distinct PMCA isoforms. PMCAs and PM CA are ubiquitously expressed, whereas PMCA 2 and PMCA 3 are expressed almost exclusively in the central nervous system. Complex patterns of alternative RNA splicing generate additional isoform variability. Of interest are variants in which the alternative splicing occurs at site C, located in the C-terminal tail of the protein, which involves the region containing the calmodulin-binding domain (see below). The calmodulin (CaM)-binding domain, in the absence of CaM, interacts with two sites next to the active site of the PMCA maintaining the pump in an inhibited state. CaM removes its binding domain from its intramolecular regulatory receptors, freeing the pump from autoinhibition. C site splicing occurs in all isoforms and, in general, causes the inclusion of one (or two) additional exons, inducing a premature truncation of the protein, which now has a shorter regulatory domain (termed C1 or a variant) that differs significantly from that of the variant termed C1 or b (17).

The other plasma membrane Ca$^{2+}$-exporting system, the NCX, is particularly active in excitable cells, e.g., heart, which periodically experiences the need to rapidly expel large amounts of calcium. It has low Ca$^{2+}$ affinity but high Ca$^{2+}$-transporting capacity. Three basic exchanger gene products are known, NCX1, NCX2, and NCX3. The first two products are ubiquitously distributed in tissues, whereas NCX3 is restricted to the brain (18). The SERCA pumps are encoded by three genes and are differently distributed in the animal tissues. SERCA1...
Calcium Signaling: Encoding and Decoding

is largely expressed in fast-twitch skeletal muscle. SERCA2 has two splicing variants: isoform 2b, which is ubiquitously distributed, and isoform 2a, which is dominantly expressed in cardiac muscle. SERCA3 is instead expressed in nonmuscle cells. Recently, the tertiary structure of the SERCA1a pump has been solved, and it has confirmed the predicted architecture containing 10 transmembrane domains (39).

The diverse PMCA, SERCA, and NCX isoforms are expressed in a tissue- and development-specific manner, and their apparent redundancy probably enables the cells to select the combination of reactions that exactly meet their specific Ca$^{2+}$-signaling requirements.

Functional Significance of the Different Modes of Ca$^{2+}$ Signal Transmission

Different cell types use distinct Ca$^{2+}$ signals, as suits best their physiology. In particular, the possibility of local and global Ca$^{2+}$ signaling permits the control of separate processes in the same cell.

Emerging evidence reveals that cells use local Ca$^{2+}$ signals, i.e., spatially confined high Ca$^{2+}$ concentration microdomains, to obtain specific and rapid effects such as the release of the contents of synaptic or secretory vesicles, the activation of ion channels, mitochondrial energy metabolism, and the generation of nuclear specific Ca$^{2+}$ oscillations (20, 21). Confined Ca$^{2+}$ signals at the internal mouth of the channels may thus remain localized and transmit the signal to targets in the immediate vicinity or trigger a chain of autocatalytic Ca$^{2+}$-releasing events that results in the generation and spreading of Ca$^{2+}$ waves across the cell. Ca$^{2+}$ waves have been classified based on the speed of their motion (22). Global Ca$^{2+}$ signals, such as waves and oscillations, are preferentially used when the targets to reach are distributed throughout the cell. Many processes require prolonged stimulation to be activated, such as fertilization, axonal growth of cortical neurons, neuronal cell migration, exocytosis, and gene transcription. Ca$^{2+}$ waves can also spread from one cell to the next, thus coordinating the activity of groups of cells within a tissue. For example, in perfused intact liver, hormones linked to the formation of InsP$_3$ evoke Ca$^{2+}$ transients with an oscillatory pattern, the frequency of which depends on the concentration of the agonist. The spikes spread as wave through the cytoplasm, the nucleus, and also through gap junctions to the entire liver lobule to coordinate the metabolic liver function (23).

Information is also encoded within the frequency of Ca$^{2+}$ oscillations that occur in the cytosol. Oscillations can derive either from fluctuations of the entry of external calcium or of the release from intracellular stores. The former occur primarily in excitable cells, after the periodic opening of plasma membrane Ca$^{2+}$ channels, such as induced, for example, by the rhythmic changes of the plasma membrane potential of the heart or by bursts of action potential in neurons. In nonexcitable cells, the predominant mechanism of [Ca$^{2+}$], elevation is from the activation of plasma membrane receptors coupled to G-proteins and to the phospho-inositol pathway. In these cells, the oscillatory pattern of Ca$^{2+}$ increases is not dependent on the periodic opening and closing of plasma membrane Ca$^{2+}$ channels, but on cycles of Ca$^{2+}$ release and uptake from the intracellular compartment sensitive to InsP$_3$. Recent works suggest at least two possible mechanisms for the generation of oscillatory Ca$^{2+}$ signals: either an oscillatory production of InsP$_3$, or an oscillatory inactivation of InsP$_3$Rs. The two mechanisms appear to operate differentially according to the cell type. The fluctuations in InsP$_3$ may be controlled by Ca$^{2+}$ itself through the regulation of membrane PLC that generates InsP$_3$, from PLC$_{eta}$, or through regulatory proteins, which act directly on G-proteins, thus affecting the downstream InsP$_3$ production. Figure 2 summarizes the different shapes of Ca$^{2+}$ signals and some of their biologic targets.

How are the Ca$^{2+}$ Messages Decoded?

The ability to use Ca$^{2+}$ in different modes helps cells to achieve a multitude of signals varying in amplitude, frequency, kinetics, and localization, as well as to avoid the deleterious effects associated with sustained Ca$^{2+}$ increases. Cells avoid death either by using low amplitude Ca$^{2+}$ signals or, more usually, by delivering the signals as brief transients. It is intriguing to understand how the encoded message could regulate such a large number of different processes. The explanation probably lies in the fact that different "forgers" personalize the message.

After cell stimulation, Ca$^{2+}$ flows into the cells and interacts with different Ca$^{2+}$-binding proteins that function either as Ca$^{2+}$ effectors (i.e., decoding the message) or Ca$^{2+}$ buffers. Proteins able to bind Ca$^{2+}$ with the affinity and specificity required for the regulation of its concentration in the intracellular environment generally belong to the so-called EF-hand family (24). The family contains hundreds of members, of which the most intensively studied is the ubiquitous CaM. CaM (and a number of homologous proteins) consists of two independently folded domains connected by a flexible long helical segment. Each domain contains one pair of EF hands. Upon Ca$^{2+}$ binding, structural rearrangements occur and CaM collapses into a hairpin structure around the binding domains of target proteins. Clearly, the decoding of the Ca$^{2+}$ signal by EF-hand proteins is a sophisticated operation, which is not restricted to the relatively simple process of reversibly binding Ca$^{2+}$ for buffering purposes. In fact, the buffers function to fine-tune the spatial and temporal properties of Ca$^{2+}$ signals. They can alter both the amplitude and the recovery time of individual Ca$^{2+}$ transients. These buffers have different properties and expression patterns. For example, calbindin-D28 (CB) and calrectin (CR) are fast buffers, whereas parvalbumin (PV) has much lower binding kinetics and high affinity for Ca$^{2+}$. The physiologic roles of CB, CR, and PV have been particularly studied in neurons. These studies have been facilitated by the recent generation of mouse strains deficient in these proteins. CR is principally expressed in cerebellar granule cells and their parallel fibres, whereas PV and CB are present throughout the asan, soma, dendrites, and spines
Calcium Signaling: Encoding and Decoding

Figure 2  Scheme of the main cellular events modulated by local (microdomains) and global (waves and oscillations) Ca²⁺ signaling.

of Purkinje cells. PV is additionally found in a subpopulation of inhibitory interneurons, the stellate, and basket cells. Studies on deficient mice, together with in vitro work and the discovery of their unique cell type-specific distribution in the cerebellum suggest that these calcium-binding proteins have evolved as functionally distinct, physiologically relevant modulators of intracellular calcium transients. Analysis of different brain regions suggests that these proteins are involved in regulating calcium pools critical for synaptic plasticity (25). Interestingly, and unexpectedly, PV⁻/⁻ fast-twitch muscles are considerably more resistant to fatigue than the wild-type controls. This effect was attributed mainly to the increased fractional volume of mitochondria in PV⁻/⁻ fast-twitch muscle, where the mitochondria are suggested to functionally replace the slow-onset buffer PV based on similar kinetic properties of Ca²⁺ removal (26).

In addition to limiting the diffusion and the magnitude of Ca²⁺ transients by activating the Ca²⁺ extrusion systems and by buffering them using cytosolic Ca²⁺ buffers, it recently became evident that cells also use the spatial distribution of intracellular organelles, such as mitochondria (for a comprehensive review, see Reference (27)). The control of the ion diffusion throughout the cell has been found to control the shaping of cytosolic Ca²⁺ signals in different cell types. In pancreatic acinar cells, mitochondria strategically located beneath the granular region prevent the spreading of a Ca²⁺ wave from the secretory pole toward the basolateral region by accumulating Ca²⁺; a similar role was reported for mitochondria in rat cortical astrocytes. In addition, the clearing of local [Ca²⁺]c in the proximity of Ca²⁺ release channels plays a role in the modulation of their activity. The first example of this effect was reported in Xeropus oocytes where mitochondria buffer microdomains of [Ca²⁺], regulating the open probability of InsP₃ channels, relieving the inhibitory effect of Ca²⁺. As a consequence, the rate of Ca²⁺ efflux from ER and, in turn, the shape of cytoplasmic Ca²⁺ waves, becomes modulated. A similar role for mitochondria has been described also in mammalian cells where mitochondria suppress [Ca²⁺]c positive (or negative) effects on the InsP₃ or on ryanodine channels or plasma membrane channels. By dissolving these local (Ca²⁺) microdomains, mitochondria buffer the Ca²⁺ that enters T cells via store-operated Ca²⁺ channels. They sequester Ca²⁺ during periods of rapid Ca²⁺ entry and release it slowly after Ca²⁺ entry has ceased. The idea that mitochondria can prolong the period of [Ca²⁺], elevation in response to a transient episode of Ca²⁺ influx by slowly releasing stored Ca²⁺ was already proposed as important for Ca²⁺-dependent processes such as exocytosis and synaptic transmission.

We still have little understanding of how cells actually decode the information contained in the different "shapes" of the Ca²⁺ signaling and, in particular, in the frequency of Ca²⁺ signals. The molecular machines that are responsible for decoding frequency-modulated Ca²⁺ signals include CaM kinase II (CaMKII) and protein kinase C (PKC). CaMKII is a multimer, consisting of 6–12 monomers that could be identical or different. It has a broad tissue distribution, being particularly abundant in the forebrain, where it is supposed to be particularly important in decoding the frequencies of synaptic inputs. CaMKII phospho-tylates and regulates multiple cellular targets that contribute to neurotransmission, neuronal plasticity, cell excitability, gene expression, secretion and cell shape, and, especially, memory formation and storage (28). Evidence that CaMKII could act...
as frequency decoder of Ca\(^{2+}\)-oscillations comes from the work of De Koninck and Schulman (29), who had shown that, after the threshold for kinase activation was reached and some subunits of the enzyme had become autophosphorylated, the response of the kinase to low frequency stimuli increased, presumably because CaMKII autophosphorylation is functionally cooperative.

PKC is a member of a family of Ser/Thr phosphotransferases that is involved in numerous cellular signaling pathways. These enzymes possess two regulatory domains, C1 and C2, that are the targets of different second messengers. Conventional and novel PKCs migrate to the plasma membrane in response to increased levels of DAG, resulting in complete activation of the isoenzymes. Activation is produced by the direct binding of DAG to a motif known as protein kinase C homology-1 (C1) domain. The main role of C2 domains in conventional PKCs is to act as the Ca\(^{2+}\)-activated membrane-targeting domain. In the absence of receptor-mediated lipid-hydrolysis, PKC isoenzymes are, in most cases, cytosolic and autoinhibited by the binding of a pseudo substrate motif to the substrate-binding site. Receptor-mediated generation of DAG and elevation in [Ca\(^{2+}\)]\(_{i}\) result in the membrane recruitment of conventional PKC molecules. Once fully membrane-associated, the pseudo substrate motif is released, allowing substrate binding and phosphorylation. The use of the green fluorescent protein (GFP) has shown that conventional PKC isoenzymes undergo oscillatory plasma membrane associations, which are "phase-locked" with the underlying receptor-mediated oscillations in [Ca\(^{2+}\)]\(_{i}\). Each oscillatory membrane association may lead to a burst of PKC activity, which in turn induces transient bursts in substrate phosphorylation. As Ca\(^{2+}\) returns to the basal level between oscillations, PKC regains the autoinhibited conformation. This pause in PKC activity allows the dephosphorylation of the substrate to dominate (30, 31). Such precise control of PKC activity is crucial to decoding the information contained in [Ca\(^{2+}\)]\(_{i}\) oscillations, and it is worthwhile to note that the other Ca\(^{2+}\)-oscillation decoder (CaMKII) does not fully deactivate between oscillations (29).

Recently, it has been proposed that Ca\(^{2+}\) signals could be decoded also through a pathway involving the Ras GT-Pases (32). In neuronal cells, Ca\(^{2+}\)-microdomains generated through Ca\(^{2+}\)-influx through the NMDA receptors and Ca\(^{2+}\)-influx through the AMPA receptors, the activity of which modulates the conversion between Ras-GTP and Ras-GDP in a Ca\(^{2+}\)-dependent manner. This confined coupling is essential in the physiology of neuronal cells, because the Ras/ERK pathway is important in eliciting two forms of synaptic plasticity, long-term depression (LTD) and long-term potentiation (LTP), both processes that have been proposed to form part of the cellular basis of learning and memory. AMPA-Rs trafficking in the postsynaptic membrane, a process that also controls LTP and LTD, appears to be modulated through the Ras/ERK pathway by CaMKII-mediated phosphorylation (33). Efficient Ca\(^{2+}\)-mediated activation of the Ras/ERK cascade appears to be optimized according to the frequency of the Ca\(^{2+}\) oscillations thanks to the action of two Ca\(^{2+}\)-regulated Ras GAPs, CAPRI and RASAL. These two proteins have been recently identified as sensors of distinct temporal aspects of the Ca\(^{2+}\) signals. Whereas CAPRI detects the intensity of the Ca\(^{2+}\) signal and undergoes transient association with the plasma membrane, RASAL senses the frequency by undergoing synchronous and repetitive oscillatory associations with the plasma membrane (34).

Calcium Controls the Expression of Its Own Transporters

Control of gene expression by Ca\(^{2+}\) was identified in 1985 when it was shown that prolactin gene transcription was stimulated up to 200-fold by the elevation of intracellular Ca\(^{2+}\) in cultured CH3 cells (35). After this observation, the transcription of numerous other genes was also found to be stimulated by Ca\(^{2+}\). According to general consensus, Ca\(^{2+}\) acts through three major pathways (Fig. 3). The first pathway, which is probably the principal one, involves changes in the activity of several Ca\(^{2+}\)-dependent kinases and phosphatases, which in turn change the trans-activating properties of several transcription factors. The best-known proteins involved in this pathway are probably CaM-dependent kinases CaMKIV, CaMKII (36), and the CaM-dependent protein phosphatase calcineurin (37). All of these proteins need CaM to process the Ca\(^{2+}\) signal. They stimulate gene transcription by regulating the phosphorylation state of the transcription factor CREB, and, as a result, the extent of CRE (cAMP Response Element)-dependent transcriptional activation, or by dephosphorylating the transcription factor NF-AT, thus promoting its translocation to the nucleus, respectively.

The regulation of synaptic plasticity in neuronal cells is an important consequence of the activation of this pathway of gene expression, after Ca\(^{2+}\) entry from the extracellular environment. An interesting finding that recently emerged was that Ca\(^{2+}\) itself could control the expression of its own transporters, suggesting that the cell can finely adjust the amount, the type, and the distribution of the Ca\(^{2+}\) transporters according to its specific demands. Ca\(^{2+}\) regulation of the plasma membrane Ca\(^{2+}\) pump isoforms at the transcriptional level was firstly reported by Guerini et al. (38) in cerebellar granule neurons. When neurons were cultured under condition of partial membrane depolarization, which is required for their long term in vitro survival, they underwent a chronic and modest increase of the resting free Ca\(^{2+}\) concentration, which promotes the up-regulation of PMCA2, 3, and 1CII (1a) (that are typical of the adult brain), and the down-regulation of PMCA4CII (4a) (which is absent from adult rat cerebellum). Calcinurin regulates the disappearance of PMCA4a but not the up-regulation of the other PMCA isoforms (39).

Interestingly, a similar pattern of remodeling also occurs for the expression of the other Ca\(^{2+}\) extrusion system of the plasma membrane, the NCX, which has a high level of expression in brain. Three separate genes encode for the three different isoforms of NCX, and, as in the case of PMCA, a number of splice variants are generated at least at the transcriptional level. It has been shown that during the maturation of neurons, the number of NCX variants are generated at least at the transcriptional level.
Calcium Signaling: Encoding and Decoding

Figure 3  Signaling pathways that participate in Ca\(^{2+}\)-regulated gene expression. Two important enzymes (calcineurin, CN, and calmodulin-dependent kinases, CaMK), which by regulating the phosphorylated/dephosphorylated state of the transcription factors CREB and NF-AT, translate the Ca\(^{2+}\) signal into nuclear specific information, are indicated. The transcriptional regulator DREAM, which is an EF-hand Ca\(^{2+}\)-binding protein, and the basic-helix-loop-helix (bHLH) transcription factors, which bind calmodulin (CaM) or S-100 proteins, are also shown. NLS, nuclear localization signal. Ca\(^{2+}\) levels, through the indicated pathways, directly regulate the transcription of the genes for the membrane Ca\(^{2+}\) transporters PMCA, NCX, and InsP\(_3\)R.

of splicing variants of NCX1 decreased but the total amount of NCX1 protein did not change significantly. At variance with this result, the amount of NCX2 protein increased dramatically with time if the cultured neurons were kept in low KCl-containing medium, reflecting the behavior of the isoform in the cerebellum during the first week, but became rapidly down regulated after partial depolarization of the plasma membrane (40). The NCX3 gene was also affected by the depolarizing treatment: its transcription became up regulated when Ca\(^{2+}\) influx is promoted by high KCl treatment. Interestingly, the NCX2 transcript up regulation was dependent on the activation of calcineurin, whereas the effects on the NCX1 and NCX3 genes were instead calcineurin-independent. Further reports have indicated that the Ca\(^{2+}\)-mediated increase in the expression of type 1 InsP\(_3\)R in cerebellar granules (41) and in hippocampal neurons (42) is mediated by Ca\(^{2+}\) influx through L-type channels or NMDA-Rs. The expression of type 1 InsP\(_3\)R appears to be regulated through the activity of calcineurin, which dephosphorylates the NF-AT transcription factor, promoting its translocation to the nucleus and transcription activation. These regulation pathways underline the importance of regulating cell Ca\(^{2+}\) with absolute precision: To promote the survival of the neurons, cytosolic Ca\(^{2+}\) must increase, but only to the relatively modest level that is necessary and no more. Evidently, to better control Ca\(^{2+}\) levels, cells adjust the abundance and the type of the different Ca\(^{2+}\) transporters.

Another important recent development in the transcriptional autoregulation of the Ca\(^{2+}\) message is that linked to the second pathway that Ca\(^{2+}\) uses to control gene expression: Ca\(^{2+}\)-ions bind directly to the transcriptional regulator DREAM (DRE Antagonist Modulator) and change its affinity for the DNA, relieving the repression on the transcription of specific target genes (43). DREAM belongs to the family of neuronal calcium sensors. It contains 4 EF-hands and acts as a transcription silencer for a large number of genes by binding to specific DRE (Downstream Regulatory Element) sites in the 5′ UTR region of the gene promoters. When Ca\(^{2+}\) becomes bound to DREAM, presumably as a result of its increase in the intracellular (intranuclear) environment, the DRE sites release DREAM and transcription resumes. The first discovered target gene for DREAM was that for the human prodynorphin, a protein involved in memory acquisition and pain (43); but an increasing number of genes have now been found to be regulated by this Ca\(^{2+}\)-sensitive transcriptional repressor. Very recently, DREAM has been shown to control the transcription of the gene for NCX3, an isoform of NCX that is important in Ca\(^{2+}\) extrusion.
in neurons (44). Overexpression of a DREAM EF-mutant (EFm- 
DREAM) insensitive to Ca2+ in hippocampus and cerebellum of 
transgenic mice significantly reduced NCX3 mRNA and protein 
levels. Cerelinar granaules from EfMDREAM transgenic mice 
displayed increased levels of cytosolic Ca2+, lost the ability to 
efficiently export Ca2+, and were more vulnerable to increased 
Ca2+ influx after partial opening of VOCCs. However, they 
survived better under conditions of reduced Ca2+ influx, sug-
gesting that DREAM plays a role in the autoregulation of the 
Ca2+ signal in neurons.

Lastly, the third mode that Ca2+ uses to control gene ex-
pression must be mentioned, even if no evidence has yet con-
clusively shown that this mode is employed to control the 
transcription of the Ca2+ transporters. This pathway involves 
the basic-helix-loop-helix (bHLH) transcription factors that, af-
ter Ca2+-dependent interaction with CaM or with the S-100 
proteins, modify the ability to bind to DNA and thus to activate 
transcription (45).

Measuring Ca2+ Concentration

Ca2+ probes (also known as indicators, reporters, or sensors) 
are molecules that form selective and reversible complexes 
with Ca2+ ions. The physicochemical characteristics of the 
Ca2+-free and Ca2+-bound form are sufficiently different to 
enable their relative concentrations to be measured. They can be 
divided in two main categories: synthetic Ca2+ indicators and 
protein-based Ca2+ indicators. In the late 1970s, Roger Tsien 
synthesized the first fluorescent Ca2+ probe for intracellular use. 
Its structure was based on the selective Ca2+-chelator EGTA. 
The portion of the molecule that binds Ca2+ is a carboxylic 
backbone perfectly adapted to the dimension of the ion, which 
confers its specificity. A fluorophore group, associated with 
the carboxylic group, endows the molecule with fluorescent 
properties dependent on the binding of Ca2+ to the carboxylic 
cage. Tsien and co-workers modified the original molecule 
by esterification of the charged carboxylic groups, making it 
permeable through the plasma membrane, it is trapped in the cytoplasm 
thanks to the action of cellular extremates that hydrolyse the 
ester, yielding the active form of the indicator. Thanks to 
the simplicity of use, this type of indicators is enormously 
employed by many researches. Big developments have been 
made to improve their fluorescent signal that, together with the 
improvements of the instrumentation, have contributed to image 
a single cell level the changes in Ca2+ concentration induced 
by physiologic stimuli.

In recent years, the wide diffusion of molecular biology tech-
niques has extensively expanded the number of applications of 
protein probes in cell biology. Two types of protein probes 
currently employed derive from bioluminescent organisms. The 
first is the group of chemi-luminescent proteins, which emit light 
usually in response to changes of a physiologic parameter, such 
as concentration of ATP or Ca2+. Among these proteins, the 
photoprotein aequorin (AEQ) has dominated the Ca2+-signaling 
field. The second group of protein probes is that of fluorescent 
proteins, of which GFP from Aequorea victoria is the “protag-
onist”.

AEQ was largely employed before the introduction of syn-
thetic fluorescent probes, as it was extracted and purified from 
jellyfish and microinjected in giant cells to monitor Ca2+. A 
Ca2+-induced conformational change in the apoprotein leads to 
peroxidation of the coenzyme, which results in the release of 
blue light. The rate of the reaction depends on the Ca2+ con-
centration to which the photoprotein is exposed. The cloning 
of the AEQ cDNA in 1985 (47) opened the possibility to ex-
tend AEQ use to a large variety of cells by transfecting them 
with a plasmid that allows recombinant expression of exoge-
nous protein. But the most important incentive to reconsider 
AEQ to monitor Ca2+ was the possibility to target it to a spe-
cific cell compartment by introducing in its sequence specific 
signal sequences. This approach has allowed the construction 
Ca2+ probes, which, in contrast to fluorescent dyes, are exclu-
sively localized in the intracellular district of interest. The use 
of chimeric AEOs allowed substantial advances in our under-
standing of Ca2+ signaling, such as the interplay between the 
ER and mitochondria (48), the presence of subplasma mem-
brane Ca2+ microdomains (49), and the role of Golgi apparatus 
as an important Ca2+ store (50). Despite its undoubted ad-
vantages, aequorin has a big defect: Although the amount of 
photons that are emitted from a cell population is more than 
adequate to measure Ca2+ concentration, the amount of photons 
that are emitted by a single cell is very low and not sufficient to 
guarantee a good space and time resolution. To overcome this 
deficiency, recombinant Ca2+ probes based on GFP were devel-
oped. Essentially, these indicators can be divided in two main 
groups based on their structure: double barrel probes, such as 
cameleon, made of two different coloured mutants of GFP con-
ected by a Ca2+-sensitive linker and single barrel probes, such 
as campanor and pericams, based on a single GFP engineered 
to bear a Ca2+-dependent inserted sequence. Generally, Cam 
is used as a molecular switch, which changes its conformation on 
the binding of Ca2+. The first two GFP-based fluorescent Ca2+ 
indicators were developed in 1997 (51, 52). Both probes are 
based on a similar strategy: the change of Fluorescence Reso-
nance Energy Transfer (FRET) between the two GFP mutants 
that is caused by the interaction between Ca2+-activated CaM 
and the targeted peptide. Although the cameleons were greatly 
improved over the original design, they still displayed insuffi-
cient signal-to-noise ratio when targeted to the organelles. To 
further increase the dynamic range of cameleons, the second 
generation probes (campanor and pericams) have been devel-
oped. In this construct, the GFP β barrel has been cut open and 
the original N- and C-termini linked together to create new ter-
imini located close to each other. The circular permuted (cp) 
GFP retains the ability to form a chromophore, but the permu-
tation renders the chromophore more accessible to changes in 
the pH of the surrounding ambient. As a result, the variation 
around the chromophore changes its ionization state, the 
fluorescence of all cpGFP is highly pH sensitive. This property 
has been exploited to detect Ca2+ by fusing Cam to cpGFP. In 
this way, the binding of Ca2+ mimics alkalization or acidifica-
tion, and so results in the increase or decrease of chromophore 
fluorescence. Further developments have been made to improve
the Ca\(^{2+}\) sensors and, in particular, CaM has been substituted by troponin C (53) or by an artificial Ca\(^{2+}\)-binding module to reduce the interaction with endogenous proteins (54), but the "perfect" Ca\(^{2+}\) probe is still missing.

Conclusion

More than 40 years of investigations of Ca\(^{2+}\) transport and Ca\(^{2+}\) actions have resulted in the well-defined concepts of intracellular Ca\(^{2+}\) homeostasis and Ca\(^{2+}\) signaling. The molecular mechanisms of Ca\(^{2+}\) transport between cells and extracellular space as well as within cells are clearly defined. We also know that Ca\(^{2+}\) signaling is extremely compartmentalized and that local and transient gradients could be responsible for spatial signal encoding. The study of the mechanisms of encoding/decoding the Ca\(^{2+}\) signal is fundamental to understanding the Ca\(^{2+}\) signaling pathways carried out in cultured cells or in tissue slices has clearly contributed to the progression in this field. Now, it will be nice when the recent technological developments drive the analysis toward in vivo cellular imaging, where the effects of physiology and pathologic stimuli could be investigated on the whole living organisms.

Chemical Molecules that Regulate Transcription and Facilitate Cell-to-Cell Communication

Arthur Wuster and M. Madan Babu, MRC Laboratory of Molecular Biology, Cambridge, United Kingdom

doi: 10.1002/9780470048672.wecb501

In this article we review cell-to-cell communication in three groups of organisms: bacteria, fungi, and the amoeba Dictyostelium. In particular, we concentrate on cell-density-dependent quorum sensing, which seems to have evolved independently on several occasions. The biologic and chemical properties of select systems are outlined, and the way they affect transcription, often via cross-genome interactions, is described for each of the three groups. Furthermore, we give a short overview of the methods that can be used to study quorum sensing. We also outline the general properties of quorum sensing systems, such as positive feedback and its link to starvation-dependent pathways.

Cell-to-cell signaling is a prerequisite for the development of multicellular organisms, such as animals and plants, but has also evolved in groups that would not usually be described as multicellular, such as bacteria and unicellular fungi. In this article we review and compare cell-to-cell signaling in several representative organisms, which are normally unicellular and never or only transiently aggregate to form multicellular bodies.

Quorum sensing is a process of cell-to-cell communication by which individual cells regulate their phenotype in response to the extracellular concentration of pheromones. This regulation is achieved by the secretion of pheromones into the environment that bind sensory proteins and directly or indirectly affect transcription and translation. The binding threshold is assumed to be reached once the growing population, and hence the secreted pheromone, reaches a certain density. In what follows, we will use the term quorum sensing system to mean a cell-to-cell communication system in unicellular organisms, which functions via the secretion of pheromones into the environment and their subsequent binding to sensor proteins. The term pheromone as we use it here refers to any chemical molecule that is excreted by one organism and changes the behavior of another one. It is not necessary that the pheromone synthesis or detection machinery has evolved for this purpose, although this is often the case. Different systems can be distinguished by the different types of pheromones they use, which are normally associated with different types of signal synthesis, import and export, and reception and response machinery.

In this article, we will concentrate on cell-to-cell communication in the form of quorum sensing in two unicellular groups, bacteria and yeast. Additionally, we will consider intercellular signaling in one species that is at the boundary between unicellularity and multicellularity, Dictyostelium discoideum. To illustrate the diverse mechanisms of cell-to-cell communication, we will discuss their biologic function, on the one hand, and the molecular details of pheromone synthesis, signal transduction, and transcription regulation in each of these groups, on the other hand.

The study of cell-to-cell communication and its effects on transcription in unicellular organisms promises a variety of practical applications. One of them is the possibility of interfering with intercellular communication systems in pathogenic microbes, which is a process also referred to as quorum quenching. A short mention of this topic and a more general attempt to integrate cell-to-cell communication in unicellular organisms with other pathways and processes, such as starvation, will be given toward the end of this article.

Although this article can be read by itself, we strongly recommend the reader consult the supplementary material on http://www.mrc-lmb.cam.ac.uk/genomes/awuster/wecb/ for links to additional literature and other relevant information.
Cell-to-Cell Communication in Bacteria

Quorum sensing involves dedicated cellular systems for the production and detection of pheromones, sometimes called quorumones. In bacterial species that employ quorum sensing, each cell secretes a basal amount of pheromones at low cell density. As cell density increases, pheromone concentration also increases, provided that the cells are not too far apart. Pheromones bind to specific receptors once their concentration exceeds a certain threshold, which in turn produces the physiological response. It has been shown that in addition to population density, diffusion barriers can be sensed in the same way. For example, Staphylococcus aureus can induce quorum sensing-dependent genes when confined in a host endosynome (1). It has even been proposed that most pathways attributed to quorum sensing in fact are diffusion-sensing pathways (2), although evidence for this is relatively scarce. In bacteria, quorum sensing-regulated phenotypes include bioluminescence, antibiotic and exoenzyme production, biofilm formation, and growth inhibition (3). Types of pheromones discussed in this section are acyl homoserine lactones (AHLs), AI-2 molecules, and modified oligopeptides. AHLs mostly affect transcription via a one-component signal transduction system, where the pheromone-binding protein domain is fused to a DNA-binding domain. Peptide pheromones and AI-2, on the other hand, often affect transcription via two-component signal transduction systems (TCSs) composed of a histidine kinase and a response regulator domain. Peptide pheromones and AI-2 in some instances, the AI-2 signal transduction cascade can also be composed of more than two components. The structure of the pheromones as well as their cognate system components are listed in Table 1 (columns 1–3).

Acyl homoserine lactones

Quorum sensing via acyl homoserine lactones is the best characterized bacterial cell-to-cell communication system. AHLs are often referred to as autoinducer-1 (AI-1)-type molecules. The term autoinducer has been chosen because synthesis of AHLs is regulated by positive feedback (Fig. 1), as has been described in the bacterium Vibrio harveyi (5). AHLs are composed of a homoserine lactone ring with an attached fatty acid chain, which can vary in length between 4 and 18 carbons and may or may not have a keto-group in position 3 (6, 7). For example, in V. harveyi, the AHL synthase LuxI produces C12 homoserine lactone with a keto-group on the third of six carbons, but in Agrobacterium tumefaciens, the LuxI homologue TraI produces the C12 molecule with a keto-group on the third of eight carbons. In most studied systems, AHLs are synthesized from S-adenosyl methionine (SAM) and fatty acid carrier proteins by LuxI and its homologues. However, alternative AHL synthases that are not homologous to LuxI exist. These synthases include LuxI in V. harveyi and HhIs in Pseudomonas fluorescens. In many species, more than one AHL is synthesized by different LuxI homologues. For example, in Rhizobium leguminosarum, six different AHLs synthesized by four different LuxI homologues have been identified (3). The structure of the LuxI homologue in P. aeruginosa has been resolved, and a detailed mechanism of its function has been proposed (8).

Most AHLs cross membranes by diffusion and bind LuxR-like response regulators. LuxR-like response regulators are sensors and transcription factors that at the same time (9), which makes the system a very simple one (Fig. 2a). Signal transduction systems in which the signal binding domain and the transcription regulating DNA binding domain are fused are referred to as one-component signal transduction systems. They are the most common type of bacterial signal transduction system (4, 10, 11).

The N-terminal signal binding domain of LuxR-like proteins has a α-helical αC domain. This occurrence is particularly interesting as GAF domains are usually found in signaling and sensor proteins (12). The structure of the A. tumefaciens LuxR homologue TraR (3) shows that at binding AHL is deeply embedded in the protein. Contact with some conserved hydrophobic and aromatic residues is established via several hydrogen bonds directly or via water. AHL binding is high affinity, which means that bacteria can sense relatively small pheromone concentrations. The specificity of the LuxR-like protein for AHL is determined by the acyl binding pocket of the LuxR homologue (14), as AHLs differ only in their acyl chains. The C-terminal domain belongs to the DNA and RNA binding helix-turn-helix fold. LuxR-like proteins use this domain to bind their cognate DNA motifs, such as the palindromic Lux box in the case of V. harveyi in which it activates transcription of the luxCDABE operon. Because this operon encodes the AHL synthase LuxI, AHL synthesis is subject to positive feedback (Fig. 1). However, in other species, LuxR protein orthologues with AHL bound can act as transcriptional repressors, such as the case for P. aeruginosa RhlR and LasR, which have been shown by microarray analysis (15, 16) to negatively regulate multiple genes.

Many, but not all, LuxR homologues dimerize at the ligand binding the N-terminal domain. An example of this dimerization is the A. tumefaciens LuxR homologue TraR. Furthermore, it is likely that the conformational changes caused by ligand binding modify the DNA-binding abilities of the protein (10). Modulated DNA affinity of TraR has been observed. It is also possible that ligand binding affects the LuxR protein ability to interact with RNA polymerase. Furthermore, AHL binding to LuxR has been shown to stabilize it, and in its absence, degradation is more likely (6).

Because of the positive feedback effect AHLs have on regulating the transcription of their own synthases, concentrations of AHLs can vary enormously between lower density and higher density cultures, such as biofilms. P. aeruginosa 3OC12 homoserine lactone (with a keto-group on the third of the 12 carbons of the acyl chain) has been measured to have a concentration of 2–10 µM in a standard lab culture and of up to 600 µM in the vicinity of an in vitro biofilm (17). However, experimental sensitivity and issues with AHL stability might have influenced the above results.

Although the basic AHL quorum sensing system only consists of two proteins—LuxI and LuxR—a variety of proteins modulates it. These proteins include the AIA AHL lactonase of Bacillus thuringiensis, which inactivates AHL by hydrolyzing...

**Synthase**
- **Vibrio fischeri**: LuxI, synthesis from S-adenosyl methionine (SAM) and fatty acid carrier protein.
- **Staphylococcus aureus**: Prepeptide modified by AgrB, which adds thiolactone ring.
- **Vibrio harveyi**: LuxS, synthesis from 4,5-dihydroxy-2,3-pentadione (DPD).
- **Dictyostelium discoideum**: Steely enzyme; subsequent chlorination and O-methylation.
- **Saccharomyces cerevisiae**: Aro9p, Aro10p.

**Transporters (exporters and importers)**
- **Vibrio fischeri**: no transporter—AHL can diffuse through membranes.
- **Staphylococcus aureus**: ABC exporter.
- **Vibrio harveyi**: no exporter for AI-2. no importer in *V. harveyi*, but importer is present in *Escherichia coli* and *Salmonella* (Lsr ABC-type transporter).
- **Dictyostelium discoideum**: no transporter—DIF-1 can diffuse through membranes.
- **Saccharomyces cerevisiae**: no transporter—aromatic alcohols can diffuse through membranes.

**Sensor**
- **Vibrio fischeri**: LuxR, AgrC transmembrane sensor kinase binds extracellular AIP, and phosphorylates cytoplasmic AgrA.
- **Staphylococcus aureus**: unknown.
- **Vibrio harveyi**: ABC-type transporter.
- **Dictyostelium discoideum**: LuxO transmembrane sensor kinase binds periplasmic complex LuxP-AI-2, and phosphorylates cytoplasmic LuxU.
- **Saccharomyces cerevisiae**: signal passed on to the protein kinase Tpk2p and subsequently to Flo8p.

**Transcription regulator**
- **Vibrio fischeri**: AgrA.
- **Staphylococcus aureus**: LuxO.
- **Vibrio harveyi**: DimAB.
- **Dictyostelium discoideum**: Flo8p.

For columns 1–3, also see Fig. 1.
**Chemical Molecules that Regulate Transcription and Facilitate Cell-to-Cell Communication**

The homoserine lactone ring. It is an instance of quorum quenching, more examples of which will be given later. Other LuxR homologues, such as *E. coli* SdiA, recognize more than one AHL (6, 7), which might be because SdiA is probably used to detect AHL produced by other species, as no LuxR homologue has been detected in *E. coli*.

**Autoinducer-2**

An overlap of AHL signaling exists with other quorum sensing systems, such as observed in *V. harveyi*. Apart from an AHL system, *V. harveyi* has a parallel system whose signaling molecules are referred to as autoinducer-2 (AI-2). In *V. harveyi*, AI-2 is a furanosyl borate diester, whose precursor is 4,5-dihydroxy-2,3-pentanedione (DPD). DPD is synthesized by LuxS from S-adenosyl methionine (SAM). Thus, SAM is a precursor in both AHL synthesis and AI-2 synthesis. It is assumed that DPD spontaneously rearranges into AI-2 when borate is available (18). In other species this rearrangement does not occur, and AI-2 has a different structure. The homologues of the DPD synthase LuxS are distributed widely among bacteria, but it is not clear whether they all produce furanosyl borate diesters. For example, LuxS in *S. aureus* was not shown to have any involvement in quorum sensing (19), because LuxS is not devoted solely to AI-2 production but also has a function in the methionine metabolic pathway.

In *V. harveyi*, in the absence of the AI-2 pheromone, the membrane-bound kinase LuxQ undergoes autophosphorylation on a conserved histidine residue (20, 21). The phosphoryl group is then transferred from the histidine of LuxQ to an aspartate of the response regulator LuxU. Phospho-LuxU in turn phosphates LuxO. Phospho-LuxO together with the sigma factor σ^73 then activates transcription of a set of small RNAs (Fig. 3c). These small RNAs, together with the RNA chaperone Hfq, contribute to the degradation of the mRNA of the LuxR transcription factor. LuxR is therefore the ultimate effector of the system in the presence of AI-2 in *V. harveyi*. It is important to distinguish this LuxR from the nonhomologous LuxR protein that binds AI-2 in *V. fisheri* as discussed in the previous section.

In the presence of the AI-2 pheromone, AI-2 is bound by LuxP (Fig. 2c), which is a periplasmic binding protein. LuxP–AI-2 binding to the LuxQ kinase triggers a dephosphorylation cascade by turning the kinases into phosphatases. LuxQ dephosphorylates LuxU, and LuxU dephosphorylates LuxO. The result is that the mRNA of the transcription factor LuxR is no longer degraded by sRNAs, and it can regulate its target genes (22). Interestingly, LuxU can also be phosphorylated by two other mechanisms. The first mechanism involves 3OC_4 homoserine lactone that binds to the LuxS sensor kinase, which in turn dephosphorylates LuxU. The second mechanism acts via the unidentified autoinducer CAI-1. Thus, AI-2, 3OC_4 homoserine lactone, and CAI-1 funnel their signals into one common system. Furthermore, sensing of the AI-2, 3OC_4 homoserine lactone by a membrane-bound kinase in *V. harveyi* shows that AHLs can also be sensed by pathways that are dissimilar to the one-component pathway outlined in the previous section. AI-2s are found only in Gram-negative bacteria, whereas AI-2 regulates phenotypes in genera as diverse as the firmicute *B. subtilis* and the γ-proteobacterium *V. harveyi*. As a result, AI-2 has been proposed to be involved in interspecies communication (23). Homologues of LuxQ have only been found in *Vibrio* species. Therefore, it can be assumed that sensing of AI-2 occurs in a different way in other species. For example, in *E. coli* and *Salmonella typhimurium*, AI-2 is imported into

---

**Figure 1** Three bacterial quorum sensing systems (also see Table 1, columns 1–3). The gray ovals represent cells; the small circles are the quorum sensing molecules (AHL, brown; AP, light blue; furanosyl borate diester, violet). Receiver and signal transduction molecules in blue, DNA binding response regulators in green, transcriptional interactions, green arrows; phosphorylation/dephosphorylation cascades, blue arrows; metabolic pathways, black arrows. Sender and receiver cells are only shown separately to keep the figure simple; in reality most cells in a population will receive and send signals at the same time. (a) The *Vibrio fisheri* AHL system; SAM: S-adenosyl methionine; (b) the *Staphylococcus aureus* AI-2 system; (c) the *Vibrio harveyi* furanosyl borate diester system; SAM: S-adenosyl-L-homocysteine; MTAN: methylthioadenosine/S-adenosylhomocysteine hydrolase; DPD: dihydroxy pentadione. Interaction with other quorum sensing systems (CAI-1, 3OC_4 homoserine lactone; also see main text) not shown.
Chemical Molecules that Regulate Transcription and Facilitate Cell-to-Cell Communication

Figure 2 Representative domain organization and structure of some proteins involved in cell-to-cell communication. (a) The AHL binding transcription factor TraR; (b) EsaI, a LuxI homologue and involved in AHL synthesis; (c) LuxP, a periplasmic protein binding AI-2; (d) LuxS, a protein involved in AI-2 synthesis; (e) the quorum quenching enzyme AiiA.

the cytoplasm by an ATP binding cassette (ABC) transporter. This transporter recognizes the periplasmic protein LsrB, which has the same periplasmic binding fold as LuxP. A-I-2 is then phosphorylated by the cytoplasmic kinase LsrK. It has been suggested that phospho-AI-2 subsequently interacts with the transcription factor LsrR (24).

Processed oligopeptides

Many Gram-positive bacteria use processed oligopeptides as pheromones. The precursor peptides are typically between 40 and 65 amino acid residues in length. These pre-peptides are processed (cleaved) in all known cases, and the resulting peptide pheromones are typically 5 to 34 residues in length. In many cases the peptides are also modified. The minimum components for peptide communication, apart from the peptide signal itself, are a membrane-bound histidine kinase and a response regulator with an aspartate phosphorylation residue. These components constitute a two-component signal transduction system, as opposed to the one-component system observed in AHL-based communication.

Peptide communication systems include the competence stimulating factor (CSF) of B. subtilis, which is a pentapeptide (sequence: ERGMT) derived from the 5 carboxy-terminal amino acids of the 40-amino-acid peptide encoded by phrC (25). Other systems include the lantibiotic nisin in Lactococcus lactis, which positively regulates its own expression. Staphylococcus epidermidis has a similar system to the lantibiotic epidermin (26). A peptide pheromone discovered in S. aureus is the autoinducing peptide (AIP), which is derived from the precursor AgrD to which a thiolactone ring is added between the carboxyl residue and a Cysteine residue at position 5 (Table 1, column 2) by AgrB. The AIP is sensed by the AgrC sensor kinase, which may dimerize at signal binding. The signal is then passed on to the AgrA response regulator, which activates transcription of the agr operon (6, 27), therefore again leading to autoinduction. Both AgrD and ComX, another peptide pheromone precursor found in B. subtilis, have an amphipathic motif in their N-terminal region, which might serve the purpose of recruiting the peptide to the membrane where it can be processed (28). This recruitment is often done by a dedicated ATP binding cassette (ABC) transporter, which in some cases recognizes a so-called GG leader sequence (consensus sequence LSxxELxxixGG) to the N-terminus of the region that encodes the actual signal (29).

Peptide signals might be more flexible than the small molecules discussed, as they do not require a specialized synthase and can change to adapt to ecological niches by simple codon mutation (30). The observation that some genes encoding peptide signals are more variable than other genes might be an indication that this actually happens. Furthermore, peptides might also be more flexible in the sense that they could be modulated by the external environment of a cell, therefore serving
some kind of sensor function in addition to their function as communication molecules. It can be caused by the external environment (for example, pH, temperature, salinity, the presence of certain chemicals or enzymes including proteases) modifying the communication peptides, therefore changing their ability to change the activity of the sensor histidine kinase and the subsequent signaling cascade (30).

Other systems

Other bacterial quorum sensing systems include the P. aeruginosa quinolone signal (PQS; 2-heptyl-3-hydroxy-4-quinolone) synthesized by PqsH, which is hydrophilic and is exported out of the cell by a vesicular transport system analogous to the ones used by eukaryotes. It seems that PQS is directly facilitating vesicle formation, as pqsH mutants do not produce vesicles. However, the phenotype can be rescued by the addition of exogenous PQS. The advantages of vesicle formation in P. aeruginosa might include the high concentration of vesicle contents delivered, as well as a certain resistance to quorum quenching signal degrading substances (31). The PQS genes have also been found in Burkholderia, although the production of PQS in these species could not be confirmed.

In Streptomyces γ-butyrolactone, a molecule structurally resembling AHLs has been shown to be a quorum sensing signal (32). Interestingly, in the genome of the Rhodococcus strain, RHA1 homologues for protein domains of both the γ-butyrolactone synthase and the receptor can be found, which suggests that γ-butyrolactone might play a role in this organism too. This suggestion is in agreement with close genomic proximity of the synthase genes and the response regulator genes (32).

Fruiting body formation in the bacterium Myxococcus xanthus is facilitated by the diffusible A-signal, which seems to consist of six different amino acids generated by extracellular proteolysis, and the contact-dependent C-signal. The C-signal is a cell-surface protein (32). Contact-dependent communication has also been observed in E. coli, where it is facilitated by CdaA and CdbB and leads to growth inhibition (33). Potential CdaAB homologues have been identified in a wide range of bacteria.

The list discussed here is by no means complete (for a comprehensive list, see Reference (34)), and it is reasonable to expect that even more bacterial quorum sensing systems await discovery, especially when considering the vast amounts of microbial diversity made available by metagenomics projects.

Quorum quenching and cross-genome interactions

In the human pathogen P. aeruginosa it has been shown that disrupting its quorum-sensing system diminishes virulence (35). Quorum quenching often takes the form of enzymes degrading the pheromones. Two different sorts of enzymes doing this for AHLs have been described: AHLases [e.g., AiiA in B. thuringiensis (Fig. 2e)] hydrolyze the lactone ring, resulting in acyl homoserine, but AHL-acylases (e.g., AiiD) break the amide bond, cleaving homoserine lactone from the acyl side chain (36, 37). Quorum signals can also be quenched by organisms that do not produce the signals, presumably to gain an advantage over communicating bacterial species in the same ecological niche. For example, Rhodococcus can degrade AHL signals without having any known ability to produce them (38).

On the one hand, closely related bacterial strains can produce surprisingly diverse quorum sensing molecules. For example, in the AIP system, the gene regions encoding the AIP precursor AgrD are extremely variable between strains (30). The purpose of this is most likely to avoid quorum sensing interference between strains living in the same niche. On the other hand, identical quorum sensing molecules are used by a wide variety of bacterial species, such as seems to be the case for AI-2. In fact, quorum sensing molecules can have effects outside the eubacterial kingdom, interfering with transcription in eukaryotes. One reason why quorum sensing molecules might have an influence on eukaryotic gene expression might be in order to enable the eukaryote to respond to bacterial infection in a more timely fashion by being able to sense bacterial presence sooner than would normally be possible. A further possibility is that interference with eukaryotic transcription is in the interest of the bacteria, causing the host to express genes that create a more favorable environment. This interference is of particular relevance for pathogenic bacteria, such as P. aeruginosa, a pathogen of humans that infects all sorts of organs, including the lungs of cystic fibrosis (CF) patients. In the mouse model for CF, it has been shown that the P. aeruginosa 3OC12 homoserine lactone induces and represses the expression of several mouse genes, including the chemokine interleukin-8 (IL-8). IL-8 causes the migration of neutrophils to the site of infection. If these neutrophils become activated, this can then lead to tissue damage. Although the exact molecular mechanism of how AHLs can regulate eukaryotic transcription is not yet known, at least four possibilities exist: 1) AHLs have been shown to be able to cross mammalian cell membranes, which means that inside the cell they could bind specialized receptor molecules, although no such molecules have been identified yet, 2) The AHLs could regulate the function of enzymes in a nonspecific manner and therefore modulate metabolic pathways, 3) The AHLs could directly act as nonspecific substrates in metabolic pathways, 4) The AHLs could bind membrane-associated receptors without entering the cell and possibly could disrupt host signaling (37).

Another way in which quorum sensing can be disrupted is by pheromone analogs that have similar structures and functions as agonists or antagonists to the actual molecules. In Staphylococcus, where quorum sensing is also mediated by peptides, different strains use slightly different, but homologous, peptides. These peptides tend to interfere with each other and inhibit the quorum sensing cascades of other strains (23). Eukaryotes can use a similar approach by synthesizing molecules that mimic AHLs as has been demonstrated in plants (39). The advantage of this approach might be that in this way pathogenic bacteria are exposed to a high level of pheromones earlier in the infectious process than they would normally be, therefore “confusing” them by suggesting a higher population density than is actually the case. This situation can cause the premature expression of virulence genes, which gives the host immune system more time to respond (37).
Cell-to-Cell Communication in Yeast

In yeasts, several workers report on putative quorum sensing-like mechanisms. In all reported cases, the major phenotype affected by quorum sensing is the transition between the filamentous form and the solitary yeast form. For example, Histo-plasma capsulatum is a parasitic yeast that can exist either in its filamentous form in soil or in its yeast form as a parasite of humans. Once it enters the host, its morphology switches to the yeast form that synthesizes cell-wall polysaccharides, such as α-(1,3)-glucan. It has been shown that the glucan concentration increases in a cell-density-dependent fashion. A culture grown in fresh medium to which filtrate from a dense culture is added will produce glucan, which suggests the existence of a factor that promotes glucan incorporation into the cell wall (see the section “Tools and Techniques” for more details on this approach). Very similar results have been reported for the causative agent of the Dutch Elm disease, Ceratocystis ulmi.

Farnesol

The existence of a couple of different quorum sensing molecules has been reported for the human pathogen Candida albicans. At low densities, the cells develop germ tubes (filamentous protrusions), which are not observed normally at high cell densities, which suggests that the switch between unicellular yeast and filamentous form depends on cell density. A molecule that blocks the formation of these germ tubes at high cell densities has been identified as farnesol, which has only been shown to affect transcription. The product of the aromatic alcohol quorum sensing system of C. albicans is tyrosol (42). As opposed to farnesol, it promotes cell growth and the development of germ tubes at low cell densities. Expression profiling of cultures under conditions of reduced tyrosol concentration showed reduced expression of proteins involved in DNA synthesis and cell cycle regulation (43). Other putative C. albicans quorum sensing molecules include the substance MARS of unknown identity and, with diminuitive effect, farsenoic acid (41).

Aromatic Alcohol Derivatives

A more detailed picture of density dependent cell-to-cell communication has been uncovered for Saccharomyces cerevisiae (44). In this fungus, phenylethanol (a phenylalanine aromatic alcohol derivative) and tryptophol (a tryptophan aromatic alcohol derivative) have been implicated in quorum sensing, and a model of how they act on their target genes has been proposed (Table 1, column 5). As in the other examples of yeast quorum sensing discussed above, these molecules regulate the transition to the filamentous form. They synergistically affect the upregulation of FLO11 via the cAMP-dependent kinase Tpk2p (a PKA subunit) and the transcription factor Flo10p. Flo10p, the product of FLO10, is the GPI-anchored cell-surface flocculin protein and is essential for filamentous growth. S. cerevisiae strains with deletions of either TPK2 or FLO10 do not form filaments in response to aromatic alcohols (44).

As in bacterial quorum sensing, the production of these two aromatic alcohols is cell-density dependent. Another similarity to bacterial quorum sensing is the autocatalytic fashion of phenomone production. Arotol is an aromatic aminotransferase and catalyzes the first step of tryptophan, phenylalanine, and tyrosine catabolism. The expression of the genes ARO9 and ARO10 is induced by tryptophol via the Aro80p transcription factor. Both ARO9 and ARO10 are required to synthesize tryptophol from tryptophan. It has been speculated that Aro10p is also involved in the aromatic amino acid catabolic pathway (45). As tryptophol induces the enzymes required for its own synthesis, it results in a positive feedback loop. Therefore, cells at high densities produce more aromatic alcohols per cell than cells at low density.

Together with C. albicans and many other yeast species, S. cerevisiae switches to the filamentous form when starved of nitrogen. The signal conferring information about nitrogen shortage has not been characterized in detail yet. Its message is transmitted via a MAPK–PKA pathway and results in an increase in the transcription of filamentation genes. Overlaps of tryptophol/phenylethanol communication with the nitrogen sensing pathway exist: Ammonia (nitrogen rich condition) represses filamentous growth as well as the expression of the above-mentioned ARO9 and ARO10 genes. However, elements of the MAPK–PKA pathway do not seem to be affected by aromatic alcohol communication.

Microarray data show that aromatic alcohols upregulate the expression of around 150 genes by twofold or more. These genes have diverse functions, but it is remarkable that 70% of them were shown independently to be upregulated upon entry into stationary phase. In contrast to S. cerevisiae, C. albicans filamentation is not stimulated by tryptophol or phenylethanol, although high concentrations of tyrosol were shown to slightly stimulate biofilm formation. This result shows that the function of the aromatic alcohol quorum sensing system of S. cerevisiae is not conserved in C. albicans (44).

Cell-to-Cell Communication in Dictyostelium

D. discoideum is a protozoon that is closely related to opisthokonts, the group comprising animals and fungi. The Dictyostelium amoebae are interesting from the point of view of cell-to-cell communication: not only starvation-dependent signaling but also a complex network of developmental intercellular signaling is observed (46).
Starvation Response-Related Signaling

It is a well-reviewed fact (for a review see Reference 47) that in Dictyostelium development triggers a behavior that causes aggregation of the single amoeba. The signal controlling this behavior is cyclic AMP (cAMP). Genes involved in cAMP signaling include the receptor for extracellular cAMP (CAR1) and the cAMP synthase, adenylyl cyclase (ACA). Interestingly, expression of these genes increases even before starvation sets in toward the end of the exponential growth phase. The amoeba can discern that genes required for the starvation response should be expressed by sensing their local population density. A high population density means that more nutrients are consumed and that future starvation is more likely. The amoeba can sense population density in a similar way to quorum sensing in bacteria. Glycoproteins, termed prestarvation factors or PSFs, are secreted into the environment at a basal level. Once their concentration exceeds a certain level, the genes required for cAMP signaling are upregulated (48). The exact mode of function of the two PSFs identified so far has yet to be determined (49).

Signaling during the developmental cycle

Once the amoebae have gathered in response to cAMP signaling, they form a multicellular structure surrounded by an extracellular matrix. This structure has many characteristics of development, such as differential cell sorting, pattern formation, or cell-type regulation. Although these characteristics can also be observed in animals, in Dictyostelium, multicellularity seems to have evolved independently (50). To reproduce, the cells of the Dictyostelium slug differentiate into two basic cell types, known as prespore and prestalk cells. The prespore cells are relatively homogenous, whereas there are several prestalk cell subtypes. The prestalk cell subtypes can be distinguished by using the promoters of the extracellular matrix genes ecmA and ecmB. By using these genes to control the expression of reporter genes, it is possible to differentiate between prespore and prestalk cells.

The recent sequencing of the Dictyostelium genome has shown that it shares many genes with higher eukaryotes, such as animals, which are not found in fungi. Because fungi are more closely related to animals than to Dictyostelium, this suggests loss of these genes in fungi. An example of a category of such genes is the transmembrane G-protein-coupled receptors (the cAMP receptor-like family). Three families of G-protein-coupled receptors that were thought to be unique to animals prior to the sequencing of the Dictyostelium genome are the frizzled/smoothed, secretin, and metabotropic glutamate/ GABAB families (50). Another finding resulting from the sequencing of the Dictyostelium genome is the relative abundance of genes encoding polyketide synthases (51). Polyketide synthases are needed for the synthesis of many molecules involved in developmental signaling in Dictyostelium, some of which will be discussed here.

Differentiation inducing factors (DIFs; see Table 1, column 4) are polyketide-derived signaling molecules critical for orchestration of cellular differentiation. DIF-1, a chlorinated hexanaphene (1,3,5-dichloro-2,6-dihydroxy-4-methoxyphenyl hexan-1-one), has been proposed to induce formation of prestalk cells by activating the expression of prestalk specific genes such as ecmA mentioned above. DIF-1 concentration is regulated by negative feedback, wherein DIF-1 activates the DIF-1 dechlorinase, which in turn inactivates it.

However, DIF-1 clearly cannot be the only factor involved in prestalk development as mutants blocked in the final step of DIF-1 biosynthesis, which is catalyzed normally by an O-methyltransferase, still produce pink cells and develop aberrant fruiting bodies. The way in which DIF-1 regulates the expression of its target genes might be via DimA and DimB, which are DNA binding basic leucine zipper proteins that migrate to the nucleus on exposure to DIF-1. The inability of mutants with a dim deletion to express ecmA in response to DIF-1 is consistent with the idea that DimA and DimB are DIF-1-activated transcription factors (46).

DIF biosynthesis has been investigated recently (52), and the protein Steely has been described as a key enzyme. Steely consists of six fatty acid synthase (FAS) catalytic domains and a C-terminal polyketide synthase (PKS). The N-terminal acyl products of steely are transferred to the C-terminal PKS active sites, which then catalyze polyketide extension and cyclisation. The result is a chloropropenophene, which is chlorinated subsequently and finally methylated.

Recent research (51) has shown that two putative DIF-1 precursors, 1,3,5,6-tetrachloro-2,4,6-trihydroxyphenyl hexan-1-one and 1,3-chloro-2,4,6-trihydroxyphenyl hexan-1-one, are also inducers of stalk development. This indicates that the dimethyl and desmethyl-monochloro analogs of DIF-1 are sufficient for stalk formation, which does not exclude the possibility that the methyl forms serve a different purpose. A third stalk-inducing compound identified in the same study was 4-methyl-5-pentylbenzene-1,3-diol.

From current data, it can be assumed that signaling complexity in Dictyostelium development is higher than previously thought (51), which is also reinforced by the insight that development requires highly selective signaling systems (50). The description of the systems given here, including the PSF system and the DIF systems, is therefore far from exhaustive.

Tool and Techniques

Chemical

The identification of cell-to-cell communication molecules is a nontrivial task. At an abstract level, a simple assay that allows for ascertaining if a certain phenotype is influenced by quorum sensing is to grow cells in culture in stationary phase for some time. During that period, potential phenomones can accumulate. The cells are then filtered and/or centrifuged out of the growth medium and the remainder is purified. If the addition of this conditioned medium to fresh exponentially growing cells induces the phenotype in question, one possible explanation is that quorum sensing molecules affecting the phenotype
were present in the filtrate. High-resolution liquid chromatography/mass spectrometry (LC/MS) and nuclear magnetic resonance (NMR) spectroscopy can aid in the identification of the actual quorum sensing molecules by enabling the researcher to compare the spectra of synthetic molecules to molecules purified from the conditioned medium.

Genetic

Genetic techniques to investigate quorum sensing include the disruption of the genes in a pathway that produces quorum sensing molecules, knockout of sensor and response regulator genes, addition of purified or synthetic quorum sensing molecules, or addition of quorum quenchers. The identity of synthetic and actual (purified) communication molecules can be verified by adding synthetic molecules to a mutant culture that cannot produce its own signals. If the phenotypic effects are the same, this indicates that the synthetic and purified molecule share the same structure. It can, however, also happen that chemically analogous molecules elicit similar effects. For example, the quorum sensing homoserine lactone 3OC12 as produced by the bacterium P. aeruginosa has been shown to mimic the effects of farnesol in S. cerevisiae, probably because it is somewhat similar in its side chain structure.

Computational

Quorum sensing can also be studied from a different viewpoint, for example, by computational methods. The structure of many quorum sensing molecules as well as of their cognate synthases and receptor molecules has been solved by X-ray diffraction analysis or NMR. A list of PDB entries associated with quorum sensing is available from the supplementary materials section on http://www.mrc-lmb.cam.ac.uk/genomes/awuster/wecb/. and some structures are shown in Fig. 2. These structures provide invaluable insights in determining the molecular mechanisms of quorum sensing. Similarly gene expression microarray datasets under quorum sensing conditions are available publicly. Integrating structural and gene expression data with the abundantly available genome sequence data will therefore be of great value for the discovery of new quorum sensing systems as well as for the integration of quorum sensing with intracellular signaling pathways.

Discussion and Concluding Remarks

A Link Between Quorum Sensing and Starvation

It is easy to see that in a growing population limited resources will become scarce sooner or later, which suggests that there is a fundamental link among population density, growth, and starvation. One such link has been uncovered in P. aeruginosa, where an AHL induces the transcription of the gene encoding σ53, a sigma factor that is active maximally under conditions of starvation (53). In yeast, the link has been demonstrated in S. cerevisiae with ammonia—a often a limiting resource for growth— inhibiting the expression of ARO9 and ARO10, two enzymes involved in the production of the aromatic alcohols functioning as quorum sensing pheromones. In Dictyostelium, the pre-starvation factors regulate changes in gene expression in a cell-density-dependent manner toward the end of the exponential phase during the vegetative cycle to be prepared for the secretion of cAMP, which is the starvation signal and leads to the aggregation of cells.

Positive Feedback

Positive feedback is another theme common to quorum sensing systems. The purpose of positive feedback during quorum sensing is presumably to speed up the response time, or to give a more pronounced response. In many of the discussed cases, positive feedback takes the form of quorum sensing molecules increasing the expression of their own syntheses, such as in yeast, where the aromatic alcohols, via the transcription factor ARO80p, promote the expression of ARO9 and ARO10. Similarly, in the bacterial LuxI/LuxR system, the AHLs synthesized by LuxI promote their own synthesis when bound to LuxR by positively regulating the expression of luxICDABE operon. One result that can be anticipated from this is that cells at high densities secrete more autoinducer per cell than cells at low densities.

Interest in cell-to-cell communication in unicellular organisms is still increasing, which might also be because of two important realizations, the first one of which is the relevance of quorum sensing to many disease-related processes, for which P. aeruginosa with its multiple and interacting systems has become a model organism. Furthermore, interaction between eukaryotic hosts and microbial pathogens via quorum sensing molecules might prove to be of high importance for furthering our understanding of bacterial infectious diseases. The second realization is that quorum sensing is not limited to a few species but that it seems to be a next-to-universal mechanism in unicellular organisms, with a multitude of quorum sensing systems likely to be awaiting discovery.

Intercellular Signaling
Quorum Sensing
Transcription Factors
Lipid molecules can act as extracellular signals. They form a large and expanding class of influences on cellular and organismal homeostasis, which affect all organ systems and participate in many disease processes. Prominent members of this class include eicosanoids (e.g., leukotrienes or prostanoids like prostaglandins, protacyclins, and thromboxane), lysophospholipids (e.g., lysophosphatidic acid and sphingosine 1-phosphate), endocannabinoids (e.g., anandamide and 2-arachidonoylglycerol), ether lipids (e.g., platelet activating factor), and free fatty acids. These signals are in a dynamic steady state with structural phospholipids that make up the lipid membrane bilayer of all cells. Both distinct and shared enzymologies are involved in lipid signal biosynthesis and degradation. A dominant mechanistic theme for all bona fide extracellular lipid signals is their use of cognate 7-transmembrane domain G protein-coupled receptors. Activation of these receptors causes myriad physiologic and pathophysiologic effects that encompass most aspects of cell biology and physiology. Studies on extracellular lipid signals have led to both mechanistic understanding and successful creation of useful medicines.

Extracellular lipid signals are small fat molecules that produce myriad cell signaling effects upon exposure to the extracellular surface of cells. The dominant mechanism for these effects is the activation of specific cognate cell surface receptors, called G protein-coupled receptors (GPCRs), which are characterized by a predicted 7-transmembrane-spanning structure and which activate most known, intracellular heterotrimeric G proteins. These G proteins in turn activate a wide range of downstream signaling pathways, with the actual physiologic responses dependent on receptor expression patterns and involved cell types. All of these lipid mediators are linked, directly or indirectly, to membrane phospholipids that can be thought of as a dynamic repository of signaling lipid precursors. A diverse, yet often overlapping, enzymatic machinery exists for both the biosynthesis and the degradation of these signals. Compared with peptidergic factors, the lipid mediators are often one tenth or less in mass, and they have brief half-lives, although binding to carrier proteins can substantially increase their stability. Historically, the understanding of these factors emerged in two phases. The first phase, which began about 70 years ago and continues today, was the important biochemical identification of lipids that showed bioactive properties in animals, and could be chemically isolated and structurally analyzed. This phase was marked by many mechanistic hypotheses to explain the observed bioactivities, including receptor hypotheses. Tools for the identification of lipid components include classic thin layer chromatography, liquid chromatography, mass spectroscopy, as well as the use of bioassays and isotope labeling.

The second phase began with the advent of molecular cloning of cell-surface lipid receptors that commenced in the late 1980s/early 1990s and that allowed rigorous assessment of the existence, pharmacology, and functional roles for extracellular lipid signaling. It included the use of genetics to create mouse mutants that allowed additional analyses of both receptor identity and essential physiologic or pathophysiologic roles. Most receptor-ligand interactions occur at nanomolar affinities, with the exception of free fatty acids that interact at micromolar concentrations. A mainstay of these studies is the use of modern cell and molecular biology leading to the creation of mutant cell lines and animals. A standard in all fields is the use of receptor overexpression or heterologous expression, particularly combined with the use of receptor-null cells and tissues created by targeted deletion of one or more of the receptors in question. Interestingly, deleting individual lipid receptors produces a variety of phenotypes, which demonstrates both the possible redundancy of some receptors as well as the unique functions that cannot be rescued by the large number of lipid GPCRs. These reagents have led to the development of specific chemical agonists and antagonists, including some that have become therapeutic drugs. Intracellular roles for some of these mediators have been documented; however, this aspect of lipid signaling...
will not be considered further in this article. Major extracellular lipid signals are considered next, in alphabetical order. Representing literally tens of thousands of primary references over the past 70 years, the reference list is necessarily incomplete, and the reader is referred to the recent primary literature for more in-depth data and discussion in this rapidly evolving and expanding field.

Eicosanoids

Eicosanoids, also referred to as eicosanoids, are so named because of the 20-carbon constituency that identifies this class of oxygenated lipid molecules. A primary synthetic pathway for these molecules involves the phospholipase-mediated cleavage of a membrane phospholipid to produce arachidonic acid [(all-2, conjugated linoleic acid)] and eicosapentaenoic acid (EPA). From this biologically essential intermediate fatty acid, two major subclasses of eicosanoids can be produced: 1) leukotrienes, via the action of lipooxygenases, and 2) prostanoids, via the action of cyclooxygenases (COX-1 and COX-2). Examples of chemical structures for a leukotriene (Fig. 1a) and three types of prostanoids (Fig. 1b-d) underscore their shared arachidonate origin.

Leukotrienes

Leukotrienes were identified in the 1930s as a bioactive substance released by smooth muscle in the lung after an antigenic challenge. Their current name reflects their well-recognized role in leukocyte (white blood cell) activities and the three prominent adjacent double-bonds in their chemical structure (Fig. 1a). There are multiple leukotriene species, including leukotriene (LT) A4, B4, C4, D4, and E4. The C, D, and E4 species are named cysteinyl leukotrienes because of the presence of the amino acid cysteine in their structure or slow-reacting substance for a leukotriene (Fig. 3a) and three types of prostanoids (Fig. 3b-d) underscore their shared arachidonate origin.

Prostanoids

These lipid factors were first identified in the 1930s as bioactive components of semen. Their name is derived from the original belief that they were secreted from the prostate gland. Their unique chemical structures are characterized by a trans double bond at C13-14, a hydroxyl group at C15, and a cyclic carbon ring (Fig. 3b-d). Three subclasses of prostanoids are defined by their cyclic ring configuration: 1) the well-known prostaglandins, which have a cyclopentane ring (Fig. 3b), 2) prostacyclins that contain a six-residue ring (Fig. 3c), and 3) thromboxanes that contain a six-residue ring (Fig. 3d). Naturally occurring prostaglandins include PGD2, PGE2, PGI2, and PGH2, of which the latter is a common precursor in the synthetic pathways of many prostanoids. PGF2a and TXA2 are the most common naturally occurring prostacyclin and thromboxane forms, respectively. Like leukotrienes, prostanoids are important lipid mediators in the inflammatory response and are not synthesized unless their source cells are activated (3). Because of their short half-life, these lipids are primarily paracrine and autocrine extracellular effectors, which signal through at least nine cognate GPCRs (6). Alternatively spliced isoforms of these receptors also exist, with varying affinities for individual prostanoids. Signaling through prostanoid GPCRs encompass at least three classes of heterotrimetric G proteins: Gs (receptors DP, IP, EP1, EP4), Gr, and Gq (receptor EP3) (7).

Prostanoids are most prominently recognized as proinflammatory factors that are vasoactive, cause blood coagulation, and produce associated symptoms of fever and pain (8). With the development of mouse receptor-null mutants, an increasingly wide range of biologic effects mediated by prostanoids is beginning to be appreciated (8). Complex physiologies associated with the numerous receptors are still being determined and point to kidney, cardiovascular, gastrointestinal, and reproductive system functions (6). Inhibitors of the rate-limiting enzyme in prostanoid synthesis, COX1 and COX2, have been the basis for nonsteroidal anti-inflammatory drugs, most prominently the nonselective COX inhibitors such as aspirin, ibuprofen, and naproxen, as well as the selective COX-2 inhibitors celecoxib (Celebrex; Pfizer, New York, NY) and the recently withdrawn drug, rofecoxib (Viscera; Merck).

Lipoxins

A third class of eicosanoids, the lipoxins (LX), has recently been defined based on its unique anti-inflammatory signaling. LXs derive their name from their generation via lipooxygenase interactions, requiring at least two lipooxygenases in their biosynthesis. Unlike the LTs and prostanoids, which are proinflammatory, LXs reduce inflammation through multiple pathways, including binding LX-specific GPCRs (e.g., LXA4), inhibiting LT-mediated inflammation through competitive inhibition of cysteine leukotriene receptors, and directly interacting with intracellular targets, e.g., transcription factors (10). Recently, the carbon-15 R epimers of LXs, termed aspirin-triggered lipoxins (ATLs), have been identified as a novel component in the anti-inflammatory mechanism of action for aspirin (10). Production of LXs has been observed in many human tissues, and reduced production is implicated in several inflammatory related...

Endocannabinoids

The psychotropic properties of the plant-derived chemical compounds in marijuana, most prominently Δ9-THC (delta-9-tetrahydrocannabinol), have been known since the mid-1960s. The mechanism through which these exogenous compounds act was a subject of controversy until the early 1990s when the first cannabinoid receptors, referred to as CB1 and CB2, were cloned (discussed below). This quickly led to the identification of endogenous cannabinoid receptor ligands, "endocannabinoids," which fall into two major classes: the N-acyl ethanolamines (NAEs) and monoacylglycerols (MAGs). The NAE, "anandamide" or N-arachidonoylethanolamide (Fig. 2a), is a high affinity agonist for both CB1 and CB2 and can produce all of the known neurobehavioral effects of marijuana. Anandamide is synthesized through a two-step process from the membrane phospholipid, phosphoethanolamine, and is created in a one-to-one ratio with phosphatidic acid, which is another important lipid signal (12). The second major endocannabinoid is 2-arachidonoylglycerol (2-AG), a MAG with lower affinity for both cannabinoid receptors and many distinct physiologic effects. It has an esterfied arachidonic acid acyl chain in the sn-2 position of the glycerol backbone (Fig. 2b); thus, 2-AG can also be a precursor for some prostanoids (13). Many enzymes are involved in the biosynthesis and catabolism of endocannabinoids, regulating their diverse physiologic functions (14). One important catabolic enzyme is the fatty acid amide hydroxylase (FAAH) and inhibitors of FAAH are currently being investigated for their analgesic properties (15).

The cannabinoid receptors are GPCRs that are known to couple to Gi/o, although other coupling may exist in different cell types (16, 17). CB1 and CB2 have distinct expression profiles, with the former primarily expressed in the nervous system and the latter expressed in immune cells and in intestine (18). Within the central nervous system (CNS), CB1 receptors are widely expressed, particularly in the basal ganglia, the hypothalamus, and limbic areas, which suggests roles in mood, endocrine regulation, and memory (19). Indeed, genetic deletion of CB1 in mice is associated with enhanced short-term memory and weight loss (20). CB1 is also expressed in the male and female reproductive systems, although the role of cannabinoid signaling in reproduction is still unknown.

Diseases, such as arthritis, atherosclerosis, liver disease, cystic fibrosis, and periodontitis (11).

Endocannabinoids

Figure 2 Endocannabinoid chemical structures: (a) anandamide and (b) 2-arachidonoylglycerol. Chemical formulas and molecular weights (g/mol) are given.

Cannabinoid receptors have been of great therapeutic interest in a variety of conditions, in particular obesity and neuropathic pain (21). Several medicines targeting these receptors are now on the market, including nabilone (Cesamet; Valeant Pharmaceuticals International, Costa Mesa, CA), dranabinol (Marinol; Unimed Pharmaceuticals, Deerfield, IL), and the recently released rimonabant (Acomplia; Sanofi-Aventis, Bridgewater, NJ), a selective CB1 antagonist for obesity management.

Ether Lipids

Platelet-activating factor (PAF, 1-O-alkyl-2-acetyl-sn-glycero-3-phosphocholine) was the first extracellular lipid signal for which a cloned receptor was identified (22). A hallmark of the molecule is an alkyl ether at the sn-1 position of the glycerolphosphate backbone (Fig. 3), in contrast with ester-linked molecules such as the lysophospholipids. In addition, the inactivation for PAF by platelet activating factor acetylhydrolase (PAFAH, a specialized phospholipase A2) is highly specific for the short-chain acyl group off the sn-2 carbon (23). PAF is the best characterized of the ether lipid signaling molecules, with potent activity on platelets and other immune cells, as its name implies (3). However, since its initial characterization in the immune system, a broad range of additional physiologic or pathophysiologic processes have been linked to this lipid molecule, including reproduction, neural migration, and blood circulation (24). Its receptor is a GPCR linked to numerous intracellular signaling pathways. Although the PAF receptor has widespread expression in many tissues, the subtle phenotype of the null-mutant mouse suggests the involvement of compensatory signaling mechanisms that involve other as yet unidentified receptors or redundancy of signaling mechanisms. In-depth studies using both transgenic and receptor-null models have demonstrated influences on allergic response, inflammation, infection, as well as osteoporosis (25), reproduction, wound healing, and subtle CNS functions (26).

Free Fatty Acids (FFAs)

The most recent class of molecules to be characterized as extracellular lipid signals are free fatty acids (Fig. 4). Fatty acids are essential residues of biologic phospholipids, and they can exist in numerous permutations of length and saturation. FFAs are “free” in that they are not linked to other molecules such as the glycerolphosphate backbone found in cell membranes and have important roles in both energy production and cell signaling. They can be produced through several metabolic processes such as cleavage of membrane phospholipids by several different phospholipases (e.g., phospholipase A). Both short-chain and long-chain FFAs of varying carbon lengths and saturation have demonstrated biologic activity consistent with being lipid signals. Supporting this interpretation, recent receptor de-orphaning research has identified a set of four

Extracellular Lipid Signals

Figure 4 Examples of short-chain and long-chain free fatty acids are shown: (a) 4-carbon butyric acid and (b) 16-carbon palmitic acid. Chemical names, formulas, and molecular weights (g/mol) are given.

GPCRs—GPR40, 41, 43, and 120—that mediate a response to a range of FFA forms (27–29). These GPCRs couple to Gq/11 resulting in an increase in intracellular calcium (coupling has not been reported for GPR120, although it can alter calcium levels consistent with a Gq/11 coupling). An important distinction to be made between FFAs and other extracellular lipid signals is that, unlike the other receptor–ligand interactions considered in this entry, these FFA receptors respond only to microM concentrations, and do so with a relative lack of selectivity for specific FFA forms. This raises the possibility that other endogenous ligands with higher affinities might exist, although this remains to be determined.

The FFA receptors serve as sensors for levels of FFAs that allow homeostatic metabolic mechanisms to be activated. Expression is primarily in the pancreas and gut (GPR40, -41, -120), which is consistent with a role in metabolic functions. For example, GPR120 increases circulating blood insulin levels indirectly through the release of glucagon-like peptide 1 (GLP1) (27). Other receptor expression patterns in adipose tissue (GPR41), brain (GPR40), and lymphocytes (GPR43) have also been reported (28, 29). However, their functional significance is not yet known. Data from receptor-null mutants have not yet been reported.

Lysophospholipids

Representing one the simplest forms of phospholipids, these molecules are characterized by a phosphate headgroup attached to a glycerol or sphingoid 3 carbon backbone with acyl chains that can vary with respect to length and saturation. The two best-studied forms of lysophospholipids are lysophosphatidic acid (LPA) and sphingosine 1-phosphate (S1P) (Fig. 5). Bioactive forms of LPA are numerous and include 1-oleyl LPA (18 carbons, 1 double bond acyl chain at the sn-1 position), as well as forms with acyl chains at the sn-2 position. LPA can be produced by the action of PLA2 on phosphatidic acid, as well as through the action of autotaxin, a lysophospholipase D enzyme that produces LPA from LPC (30). By contrast, S1P is produced by the action of sphingosine kinase 1 or 2 on sphingosine resulting in the phosphorylated bioactive lipid (31). Lysophospholipids can be degraded by multiple lipid phospholipases, lipid phosphate phosphatases, and/or lyases. Other lysophospholipids, such as lysophosphatidylcholine (LPC), lysophosphatidylethanolamine (LPE), lysophosphatidylserine (LPS), and sphingosylphosphorylcholine (SPC), may have biological activity as extracellular signaling lipids; however, bona fide signaling via defined receptors remains unclear. Many cell types can produce most forms of lysophospholipids, but it is often not possible to distinguish the signaling pools versus structural or other nonsignaling pools of these lipids within a cell.

To date, five GPCRs have been identified for LPA and five for S1P: LPA1–5 and S1P1–5. Although most of these receptors share a high degree of homology within and even between ligand classes, lower homology receptors for both classes have been identified, particularly two recently reported LPA receptors, LPA4 and LPA5 (32–34). A wide range of G proteins are activated by these receptors, including Gi/o, Gq/11, G12/13, and Gs. As a group, these receptors show widespread expression during development and postnatal life, and they have been documented across phylogeny, from humans through fish. Clear cellular effects include cell survival, actin cytoskeletal alteration and cell shape changes, proliferation, electrophysiological changes, and transcriptional activation, among others (35). These effects in turn contribute to a rich and complex physiology and pathophysiology that has been prominently revealed by receptor-null animals, as well as other approaches (36). Loss of LPA receptors can affect normal development, craniofacial formation, bleeding, CNS development and function, initiation of neuropathic pain, and normal fertility via uterine implantation. S1P receptor deletion can affect embryonic survival (S1P1), vascular formation, immunologic lymphocyte egress, cardiovascular function, and fertility (37).
Lipoxins and aspirin-triggered 15-epi-lipoxins are the biologic and therapeutic importance of these extracellular lipid signals.

Hormone Signaling
Ross V. Weatherman, Department of Medicinal Chemistry and Molecular Pharmacology and the Purdue Cancer Center, Purdue University, West Lafayette, Indiana
doi: 10.1002/9780470048672.wecb229

Hormone signaling has always been a field that has required working at the chemistry–biology interface. The development of new chemical tools plays a major role in understanding the molecular mechanisms of hormone signaling and the physiologic outcomes of hormone receptor action. This article will outline the relevance of molecular endocrinology to the field of chemistry and the use of chemical approaches to solving problems in hormone research. The basic biologic outline of a hormone signaling system and the different classes of hormone molecules and their receptors will be discussed. In addition, several research areas in which new chemical tools have been playing key roles will be described in more detail, including the discovery of ligands for orphan hormone receptors, the development of non-natural hormone receptor mimics, and the use of selective hormone receptor modulators to understand the role of specific hormone receptor signaling pathways. Hormone signaling systems that will be discussed include the thyronamines and trace amine receptor, the liver X and farnesol X receptors, small molecules capable of binding to peptide hormone receptors, the melanocortin receptor family, the estrogen receptor, and chemically orthogonal hormone receptor–ligand pairs. Major challenges facing the field as well as some different experimental methods used to study hormone signaling will also be discussed.

At a fundamental level, multicellular life would not be possible if it were not for the ability of different cells to communicate and coordinate using a language based on biomolecular interactions. From the simplest two-component signaling systems found in primitive multicellular colonies to the complicated networks of overlapping signaling cascades found in higher vertebrates, hormone signaling is dependent on the production, diffusion, and recognition of small molecules and peptides. As such, hormone signaling has always been a productive area of study for people working at the chemistry–biology interface. Chemistry has played an important role in elucidating the molecular mechanisms and consequences of hormone signaling and will continue to be a vital tool in tackling the complicated new challenges that face the field. This advanced review will introduce some key features of hormone signaling that are relevant to the chemist: why a chemist should care about hormone signaling, some basic features of hormone signaling systems, and the archetypal classes of hormones and hormone receptors.

The Basic Biology of Hormone Signaling

A hormone, simply defined, is a chemical messenger that relays signals from one cell to another. With such a broad definition, almost any biomolecule could be a hormone in certain contexts, but this article will focus on classically recognized endocrine and paracrine hormones that typically are produced in specific groups of cells in one organ and target nearby cells (paracrine) or cells or tissues in distant organs (endocrine). Even with a focus just on these classes of hormones, the biology of hormone signaling is too vast to be covered by writing a large textbook let alone a small review article. As a result, this section will concentrate on issues relevant to the point of view of the chemist: why a chemist should care about hormone signaling, some basic features of hormone signaling systems, and the archetypal classes of hormones and hormone receptors.

Why chemists should care about hormone signaling

In a schematic of a typical hormone signaling pathway, one often sees a jumble of arrows pointing to various geometric shapes...
Hormone Signaling

Hormones also play a key role in the development and treatment of many hormone receptors (1–5). As will be discussed, the development of radiolabeling techniques and molecular biology led to the isolation and characterization of many hormones, and the development of radiolabeling techniques and molecular biology led to the isolation and characterization of many hormone receptors (1–5). As will be discussed, the development of new compounds with selective modulation of specific hormone signaling pathways has greatly increased our knowledge of the molecular underpinnings of hormone action (10–12).

Hormones also play a key role in the development and treatment of a large number of diseases ranging from breast and prostate cancer to diabetes and obesity (13, 14). A significant percentage of people in the United States target hormone signaling, including drugs used to treat inflammation, diabetes, hypertension, hypothyroidism, and other hormone-related indications (13–15).

Basic features of hormone signaling

At its most basic level, hormone signaling must involve a hormone and some sort of target. In most cases the target is a receptor protein, although some hormones have been proposed to function also by non-receptor-mediated mechanisms such as altering the local redox environment of a particular cell (16, 17). Basic hormone signaling follows a simple signaling loop (see Fig. 1). Every component of a hormone signaling loop can be affected through the use of chemical tools. In an endocrine or paracrine signaling system, two different cells exist: one making the hormone and one possessing the receptor and carrying out the biologic response. In the hormone-producing cell, typically some sort of stimulus exists to initiate production of the hormone, usually some sort of change in the concentration of a marker sensed by the cell or perhaps another hormone. The hormone is then produced either by biosynthetic enzymes or by release from storage vesicles inside the cell. The hormone then must be secreted out of the cell and transported to the target cell. This secretion and transport either can be a passive process or can involve other proteins. After reaching the target cell, the hormone can bind to the receptor, if it is extracellular, or it can be taken into the cell by either passive or active transport and bind to intracellular receptors. Once bound to the receptor, the signal must be transduced into a biologic response.

As mentioned, it is possible to modulate each of these processes using chemical tools and to affect the whole signaling loop. Sometimes this modulation can be intentional, such as the use of aromatase inhibitors to halt the production of estrogens and block estrogen signaling (18), or it can be unintentional, as is often the case with hormone receptor antagonists also blocking negative feedback inhibition and causing overproduction of the natural hormone (19). As such, it is important for any chemist who wishes to apply chemical tools to the study of hormone signaling in whole organism models, as in the case of new therapeutics, to consider hormone signaling as a system with many different components.

Classes of hormones and hormone receptors

Generally, hormones can be organized into three families: the peptide hormones, the steroid hormones, and a very loosely organized class of hormones derived from the modification of amino acids and lipids (see Fig. 2). The structure of the hormone dictates in many ways the nature of the hormone receptor. The peptide hormones can vary widely in length and amino acid composition, but they are generally too hydrophilic to cross the plasma membrane. As a result, most hormone receptors for peptide hormones are membrane receptors such as G-protein coupled receptors (GPCRs), receptor tyrosine kinases, and ion channels. As will be discussed, a key problem in the area of peptide hormone research is how to improve the physical properties of therapeutics by targeting peptide hormone receptors using peptidomimetics. The steroid hormone family is sufficiently hydrophobic to cross the membrane receptors, so its
Hormone Signaling

Figure 2
Examples of the different basic structural classes of hormones.

Receptors tend to be intracellular nuclear receptors, although extracellular receptors for steroid hormones have been proposed (20). The third family of hormones covers all remaining small molecules and, as such, targets several different extracellular receptors or intracellular receptors depending on the particular hormone. One class of hormones synthesized from amino acids includes biogenic amines such as dopamine, serotonin, histamine, and epinephrine. Although most of these biogenic amines are more closely identified as neurotransmitters, the biogenic amines are present in physiologically relevant concentrations in circulation and have receptors located in several tissues in the cardiovascular, digestive, and immune systems (21–24). Molecules well known to chemical biologists for other roles, such as adenosine and ATP, also are known to have hormone signaling functions (25). Also several hormone receptors exist for which no hormone has ever been discovered. These so-called “orphan” receptors are numerous, and discovering ligands to match these orphan receptors is one important area of hormone research that requires chemical tools.

Chemical Applications in the Study of Hormone Signaling

As stated, major leaps forward in the study of hormone signaling have often coincided with the development of new chemical tools. As such, an exhaustive history of these tools is far beyond the scope of this article. Instead, the article will focus on a few studies in which newly developed chemical tools have had an important impact on the understanding of different hormone signaling systems. The types of approaches used in these studies can be applied to several different types of hormone signaling systems and hopefully will serve as examples of the potential of studying hormone signaling at the chemistry-biology interface.

Discovering new ligands for orphan hormone receptors

One of the consequences of the Human Genome Project has been the identification of genes that encode proteins with no known function. Some of these proteins share sequence homology with known hormone receptors, which strongly suggests that these new receptors should have ligand partners. These “orphan” receptors exist in every major family subtype but they seem to be especially common in the GPCR and nuclear receptor families (26, 27). Although it is likely that some of these hormone receptors will not have a ligand, undoubtedly other orphan receptors exist that do have a hormone that has not yet been discovered. Finding methods to match ligands to orphan receptors would have a huge impact in discovering new drug targets and remains a major challenge in the field of molecular endocrinology. Several approaches are currently being used to attempt to accomplish this task. These methods include in vitro screening of large libraries of compounds, transgenic mouse models, structure-based screening methods, and bioinformatics; they have been applied most often to orphan members of the GPCR and nuclear receptor families (27, 28). Although some successes have been reported, it is important to remember that any potential ligand found during in vitro studies must also be...
Hormone Signaling

Present at sufficient concentrations in vivo for a sufficiently long enough period of time to qualify as an endogenous ligand.

Another strategy to discovering ligand matches for orphan receptors is to start with metabolites of known hormones, assuming that only a limited number of hormone structures exists that an organism can synthesize. This approach was used with great success in finding hormone ligands for the orphan nuclear receptors liver X receptor (LXR) and farnesoid X receptor (FXR). Based on expression patterns of the receptor in different tissues, Manglesdorf et al. hypothesized that LXR and FXR played some sort of role in cholesterol and bile acid metabolism. Through a combination of tissue extracts and screening and organic synthesis, they discovered that LXR could be regulated by sterols such as 24(S)-hydroxycholesterol and that FXR could be modulated by bile acids such as chenodeoxycholic acid at physiologically relevant concentrations (29, 30). The matching of ligands with these two receptors has had a huge impact in the field of lipid metabolism and has led to the development of potentially promising therapeutic candidates.

Another example of using hormone metabolites to discover new hormone signaling pathways is the case of a metabolite of thyroid hormone. Scanlan et al. noted the similarities between 3,3',5-triiodothyronine (T3), the highest affinity endogenous ligand for the thyroid hormone receptor, and various biogenic phenethylamines such as dopamine if T3 were to be enzymatically deacetylated to a thyronamine (see Fig. 3). Several different thyronamines were synthesized with different degrees of iodination and screened against GPCRs thought to bind to biogenic amines. One of these compounds, 3-iodothyronamine, was found with high affinity to an isoform of the trace amine receptor (TAAR1), an orphan GPCR with no previously identified endogenous ligand (31). Additional biologic characterization of this interaction showed that the ligand was found endogenously in rat and guinea pig brain and that when the compound was administered to mice it caused rapid slowing of heartbeat and an almost 8-degree drop in body temperature. The effects were reversible over time with no deleterious long-term effects on the mice. Interestingly, the effects of 3-iodothyronamine on the organism were opposite to those of T3. The thyroid hormone receptor is a member of the nuclear receptor superfamily and exerts most of its effects at the transcriptional level where it causes an increase in body temperature and heart rate. It seems like T3 and its iodothyronamine metabolite act in concert to maintain a balance in homeostasis as it relates to body temperature and heart rate—two of the most fundamental processes of an organism. Higher potency analogs have also been synthesized to explore this whole new area of hormone signaling research that was made possible by new chemical tools (32).

Non-natural hormone mimetics

In contrast to the case of orphan receptors without an endogenous ligand, many hormone receptors have well-characterized endogenous ligands. Even with well-characterized hormones, however, a strong need remains for synthetic analogs for these hormones that have different structures than their endogenous counterparts. Many reasons exist for needing synthetic analogs, including the possibility of designing a hormone antagonist that can be used as a tool to block hormone signaling. A rather reason that is especially relevant to peptide hormones is the need to change the physical properties of the hormone. Although several peptide hormones are used therapeutically, such as insulin and oxytocin, peptides generally are not orally bioavailable and usually are administered parenterally (33). The ideal hormone mimic would be orally available and would show increased half-life in the circulation.

Most successes in designing non-natural hormone mimics have come from nonpeptide hormone families. Nonsteroidal ligands exist for almost all steroid hormone receptors, and many are used therapeutically (34, 35). The same is true for hormones based on amino acids and lipids. The one hormone class where mimicry has been difficult to achieve is the peptide hormone class. Several strategies have been employed using peptide scaffolds to alter the physical properties of peptide hormones, including truncation, cyclization, and substitution with non-natural amino acids (36). These sorts of strategies have been greatly aided by the development of rapid peptide synthesis and screening techniques such as phage display (37). Many attempts have been made to create nonpeptide mimics of peptide hormones. It is a well-known problem that protein–protein interfaces are difficult interactions to mimic or block with a small molecule (38), but some notable successes exist in the field of hormone signaling (39, 40). A small molecule capable of mimicking the biologic activity of granulocyte colony stimulating factor (G-CSF) can induce the oligomerization of the hormone receptor in a manner similar to the endogenous peptide hormone (41). Also, small-molecule mimics have been discovered for the insulin receptor (42), fibrinolysis growth factor (43), and interleukin 2 (44). Although these mimics all seem to possess the functional equivalence of the endogenous hormones, it is still possible that these small molecules achieve their biologic effects by mechanisms other than direct binding to the hormone-binding site on the receptor.

Synthetic hormone signaling systems

In some cases, a particular application may call for some sort of hormone-regulated control that is not present, as in the case of selective transcriptional modulation of a specific transgene or signal transduction event. Several research groups have developed approaches to this problem by engineering a synthetic hormone signaling system that is orthogonal to all endogenous hormone pathways. If an effector is also placed under the regulation of this orthogonal receptor, then the response can be modulated by the addition of the matching ligand. The approaches have varied from using hormone receptors from other species to engineering receptors and ligands via a "bump-hole" approach. These approaches have been used to generate orthogonal versions of estrogen and the thyroid hormone receptor and can be used to explore the functions of a specific receptor (45–48). These synthetic hormone signaling systems have also been used to regulate transcription of specific transgenes as well as to control other hormone receptor families such as GPCRs, as was the case with the adenosine A2A receptor (49).
Selective hormone receptor modulation

Sometimes, simple mimicry of the hormone is not enough. One major reason that hormone signaling has been such a fruitful area of research is that many of these hormones have multiple effects. Endocrine hormones are systemically circulated, so it is not surprising that they can modulate receptors in many different tissues. Although this finding means that a hormone can have many different functions worthy of study, it also means that looking at the role or mechanism of one specific response is more difficult because of possible interference from other signaling events elicited by that hormone. This interference can have significant therapeutic ramifications if the other signaling events cause deleterious side effects. Several examples exist in endocrinology where selective modulation of hormone signaling is desired and where one of the most effective ways to achieve selective modulation is to use a selective ligand. The term “selective” can have different meanings when it comes to hormone signaling. This section will look at two different examples of selectivity: receptor isoform selectivity and “response” selectivity.

One key feature of many hormone signaling systems is that often multiple receptors can bind the same hormone. The same hormone can sometimes bind totally different receptors, as in the case with estradiol binding to the estrogen receptor, a member of the nuclear receptor superfamily, and to GPR30, a GPCR (50). Typically, however, the same hormone binds to variants of a single hormone receptor, either isoforms created by alternative splicing or subtypes actually encoded by different genes. Even though these variants may bind to the same hormone and have similar structural features, they can have significantly different functions. They may be expressed in different tissues or expressed at different times in the development of an organism and thus can regulate significantly different signal transduction pathways from other variants of the same receptor. To determine the function of individual variants in a biologic system, it is necessary to uniquely activate the variant of interest. Although genetic approaches that use knockout animal models have been necessary to uniquely activate the variant of interest, it is often multiple receptors can bind the same hormone, either isoforms created by alternative splicing or subtypes actually encoded by different genes.

Numerous examples exist where variant-selective ligands have been used to dissect complex hormone signaling pathways, but one of the best examples of the use of selective ligands to uncover the function of very disparate receptor variants is the case of the melanocortin receptor. The melanocortin receptor family is a group of five receptor subtypes that belong to the GPCR superfamily and bind to several similar peptide hormones, α, and γ-melanocyte stimulating hormones (MSHs) (51). The receptors are expressed at different amounts in a wide variety of tissues and seem to have roles in obesity, inflammation, and cardiovascular function, as well as the more expected role of controlling skin pigmentation. To better understand what specific receptor subtypes are doing, as well as to explore the potential of using melanocortin receptors as drug targets, several attempts have been made to design and synthesize selective receptor modulators. The different receptor subtypes have different binding preferences for the various hormones, which suggests that it might be possible to differentiate the receptor subtypes on the basis of ligand-binding affinity. Several selective ligands have been reported, although few of them are specific for just one subtype. Enough selectivity has been achieved, however, to start to understand the roles that some receptor subtypes are playing in the melanocortin hormone signaling system.

Because the melanocortin receptor subtypes are peptide hormone receptors, great effort has gone into using various peptide synthesis and screening methods to uncover selective ligands (52). This work has led to the development of several compounds with different patterns of selectivity toward the different receptor subtypes. One of the first reported selective compounds, a peptide termed MTII, showed selectivity for both the MC3R and the MC4R subtypes (53); it was an anti-inflammatory agent in a rodent model and could block overeating in an animal obesity model, which suggests that the peptide may play a role in both energy homeostasis and inflammation (54, 55). In addition, another peptide, labeled SHU9119, acted as an antagonist at the MC1R and MC5R subtypes, and was able to block the anti-inflammatory and anti-obesity effects of MTII. Selective nonpeptide ligands have also been developed for the MC1R subtype, which prevented inflammation in acute inflammatory mouse models (56), as well as for the MC4R subtype, which seemed to affect sexual function (see Fig. 4) (57). Although the various compounds are not quite selective enough to precisely determine what each melanocortin receptor subtype is doing, the development of selective chemical tools has greatly increased understanding of this complex hormone signaling network.

In some cases, it seems that different responses to a given hormone can come from just one receptor subtype. In such cases, the hormone is binding to the same receptor variant, but the response is different depending on the cell or tissue context. This has been reported for several hormone receptors, but the classic example is the estrogen receptor (ER) (58). Estrogens have a variety of responses in different tissues ranging...
developed and can help dissect this challenging problem. Selective estrogen receptor modulators (SERMs), have been chemical tools that show patterns of selective modulation, called responses depending on the cell context. Fortunately, several to the same compound but have totally different signaling challenges is to understand how the receptor can bind identically from binding to a single receptor subtype—ER alpha (59). The ER subtype ER beta, several tissue-dependent responses result from binding to a single receptor subtypes—ER alpha (59). The challenge is to understand how the receptor can bind identically to the same compound but have totally different signaling responses depending on the cell context. Fortunately, several chemical tools that show patterns of selective modulation, called selective estrogen receptor modulators (SERMs), have been developed and can help dissect this challenging problem. Some of the most widely used SERMs have already been clinically validated: tamoxifen, the most widely used drug to treat and prevent hormone-responsive breast cancer, and raloxifene, used for the prevention of osteoporosis and being considered as a breast cancer preventive (60). Both compounds act as anti-estrogens in the breast and block estrogen-induced proliferation but act as estrogens in the bone where they prevent osteoporosis. In the uterus, they have different activities: tamoxifen is estrogenic and induces proliferation in the uterus, whereas raloxifene blocks proliferation (61). Other compounds have different patterns of responses in different tissues, and all seem to be able to bind to the estrogen receptor with high affinity. So key questions remain: How can one receptor have so many different responses that are dependent on cell context? How can it be controlled? The combination of chemical tools and structural biology are beginning to provide the answers to these important questions. When comparing mechanisms to explain estrogenic responses versus anti-estrogenic responses, the structures of the ligand-binding domain of the estrogen receptor bound to estradiol, tamoxifen, or raloxifene were compared (see Fig. 5) (62). The SERMs tamoxifen and raloxifene cause a major perturbation in one alpha helix of the domain. The cleft created by that helix when an estrogen binds is recognized by a coactivating protein that allows further buildup of a complex that activates transcription at a particular promoter. The cleft is obstructed when tamoxifen or raloxifene binds to the ligand domain; this binding leads to an interaction with a copressor protein that, in turn, promotes the buildup of a complex that represses transcription. This mode of antagonism has become a common feature in drug design for nuclear receptors (10).

Although this structural comparison only reveals possible mechanisms by which estradiol can differ from tamoxifen and raloxifene, it also suggests that a single receptor can have several different biologic responses caused by different downstream effectors that interact with different parts of the receptor. Differential expression of those effectors can then dictate different responses to the same drug in different cells and tissues. Even though the tamoxifen and raloxifene structures are similar, the crystal structures contain only one domain of a three-domain receptor, the other domains could be playing a role in transducing slight changes in conformation of the ligand-binding domain into more significant changes in the overall receptor conformation. It is also known that the estrogen receptor modulates many different pathways, including the activity of different transcription factors (63). Some success has been reported at developing inhibitors to block interactions between ER and downstream effectors (64). Finding more chemical approaches like these to identify ligand-selective effectors as well as developing new chemical tools that can find new downstream estrogen signaling pathways are key areas where chemical biology will play a key role in untangling a complicated and therapeutically important hormone signaling network.

Chemical Tools and Techniques

For a field as broad as hormone signaling, the key chemical tools and techniques used in the field could include almost anything. The important thing to remember about studying the chemical biology of hormone signaling is that relying on only in vitro data usually will give you only a small part of the story. Ultimately, cell-based and preferably animal-based studies should be conducted to test any tools that might be developed. In general, several techniques are shared by most hormone signaling studies, but each hormone and hormone receptor will have unique assays. Very brief descriptions of these techniques will follow. Most of the assays described are very generalized and not described by single reference sources. The most useful source for many of these assays will be medicinal chemistry papers that describe a hormone receptor modulating compound from synthesis to animal testing, but another good source for protocols are the retailers of commercially available assay kits and can be easily found online.

Receptor-ligand binding assays

In almost all cases hormone signaling involves the binding of receptors and ligands, and the development of any chemical tool will need to include some assay to measure binding affinity. Typically, in vitro binding assays with either radiola beled or fluorescently labeled ligand and purified receptor are used, although sometimes membrane extracts have to be used for membrane-localized receptors (65–68). Several of these assays have been developed, are available commercially, and are amenable to high-throughput screening. It is important to calculate binding affinity with dose response curves using nonlinear regression analysis whenever possible. Several affordable software packages are available to do this sort of statistical analysis.
Hormone Signaling

Figure 5 A representation of the estrogen receptor alpha ligand-binding domain bound to estradiol, 4-hydroxytamoxifen, or raloxifene. Key helix 12 is highlighted in white. The hatched area indicates the coactivator-binding cleft formed upon estradiol binding, which is blocked by helix 12 upon 4-hydroxytamoxifen or raloxifene binding.

One caveat to these types of binding assays is that receptor binding affinity in vitro does not always correlate well to binding affinity in cells.

Reporter assays

Most hormone signaling studies will also need some assay to measure the cellular effects of the ligand being developed. These studies usually are performed in cultured cells and can range from transcriptional reporter assays using luciferase reporter plasmids (69) to enzymatic assays for the activation of various kinases and cyclases (70, 71) to cellular sensor assays looking for changes in the concentration of markers such as intracellular calcium (72). In these assays the cells are typically dosed with a compound for a certain period of time in multwell culture plates, then the cells are lysed, and the reporter is measured using some sort of spectrophotometric technique. Also whole-cell and whole-animal imaging techniques are beginning to be used to perform more complex reporter assays (73).

Mutagenic scanning methodologies

One key question that should be addressed when searching for a new hormone receptor or hormone receptor subtype is as follows: Which amino acids are involved in hormone binding? Homology modeling with similar receptors has been extremely useful in identifying potential ligand binding sites in orphan nuclear receptors, but one of the most useful techniques for peptide hormone receptors is scanning mutagenesis. In this technique, amino acids in a protein can be systematically replaced with other amino acids, typically alanine, and receptor binding can be assessed. The mutagenesis can be performed using several different approaches, but some sort of high-throughput screening of receptor binding or activity must be used in order to achieve thorough coverage (74). Mutagenesis has been used extensively to study the interaction between the human growth hormone and its receptor (75, 76). It has also been used with peptide hormones such as insulin and vasopressin (77, 78), as well as nonpeptide hormone receptors such as the vitamin D receptor (79).

Proteomics, genomics, and systems biology

Proteomic and genomic technology are other tools derived by chemists that are having a dramatic effect on the study of hormone signaling. Many questions regarding downstream effectors of a specific hormone receptor in a specific cell type can be answered using proteomic techniques to identify uniquely expressed proteins in specific tissues (80). If the hormone receptor modulates transcription, genomics can be very valuable in determining the subsets of genes affected by the receptor in a given tissue (81). In addition, the emerging field of systems biology should make significant contributions to the molecular study of hormone signaling at the organism level (82).

Major Challenges and Future Direction

Hormone signaling was one of the original fields of study that required working at the chemistry–biology interface, and it will continue to need people trained in multidisciplinary work to unravel many big questions facing the field. The topics described...
above—matching ligands to orphan receptors, finding unnatural mimics of hormones, and improving and understanding selective receptor modulation—will continue to remain major challenges in the field and to require the development of new chemical tools. The other major challenges are the development of real-time techniques for detecting the biological responses to hormones and hormone mimics, as well as the development of compounds and techniques to dissect the roles of multiple hormone signaling systems in a particular physiological response. It is becoming abundantly clear that most hormone receptors crosstalk with other receptors from the same hormone family as well as with other hormone families. For instance, the crosstalk between growth factor receptor signaling and estrogen receptor signaling is believed to play a major role in the development of several kinds of antiestrogen resistance in breast cancer (83). Major health problems facing western populations, such as obesity, are also endocrine disorders and will involve several different hormone receptor systems (84). These tough problems require people trained in the chemical sciences to develop the tools necessary to solve them. If the past is any guide, it is likely that a new chemical tool will be behind every great push forward in our understanding of the molecular mechanisms of hormone signaling.

doi: 10.1002/9780470048672.wecb447

Phosphatidylinositol phosphates are cellular signaling molecules that came to prominence in the mid-1980s, after inositol trisphosphate was discovered as a key intracellular second messenger generated from phosphatidylinositol 4,5-bisphosphate in response to stimulation of a wide range of extra-cellular receptors. Since then, many novel inositol phosphates and phospholipids have been discovered, and their cellular functions have been studied. The roles of these molecules encompass regulation of many processes indispensable to organism homeostasis. On the cellular level, the processes include regulation of cell growth and differentiation, cell motility and invasiveness, vesicular trafficking, protein targeting to specific cell compartments. This review focuses on biosynthesis and biological roles of phosphatidylinositol phospholipids.

One of the most significant discoveries of the last two decades was the finding that multiple cellular signal transduction pathways are mediated by inositol phospholipids (PIPs) and that inositol phosphates are intracellular second messengers.1 Because of the sheer complexity, studies of the signaling function of these molecules remain an important field of biomedical research. Once deemed obscure minor components of biological membranes, inositol phospholipids are now known to be involved in the transduction of the vast array of extracellular signals, which include neurotransmitters, growth hormones, and photons (1, 2). Because of the broad scope of these signaling events, several thousand research publications related to inositol phospholipids are published every year (3). Much of this activity is enabled by the availability of phosphoinositides because of the success in developing synthetic methodologies that lead to these compounds during the last 20 years (4, 5).

Structure of Inositol Phospholipids

Overall, nine major inositol phospholipids (1-9) (Fig. 1) have been identified in cellular signaling pathways, and more are likely to be discovered. Of two possible enantiomers of the unsymmetrically substituted inositol residue, only the molecules in which the phosphatidate residue is attached to the D-1 position of myo-inositol are active physiologically (6, 7). Most naturally occurring PIPs that participate in signal transduction pathways in mammalian cells feature inositol ring phosphorylated at the 3-, 4-, and/or 5-positions. The addition or removal of the phosphate residue at the inositol ring is a simple biochemical process, yet given the large number of possible hydroxylation sites, it generates molecules that are characterized by a different net charge and feature distinct geometric distribution of the individual negative charges. In addition, the net negative charge of these molecules can be modulated easily by slight differences in pH of a local environment. Rapid generation of such a molecular array and facile interconversions between its members may be the basis for the omnipresence of inositol phospholipids in the signaling phenomena. The molecules that are nonphosphorylated at any of the 3-, 4- and 5-positions can also be glycosylated at the 6-position (GPI) (8). These phosphatidylinositols serve a multitude of other functions such as protein and protozoan VSG anchoring (9), and serving as precursors for the putative insulin mediators (10).

Regarding the lipid composition of phosphatidylinositols, the mammalian PIPs carry stearic and arachidonic acid esters at the glycerol sn-1 and sn-2-positions, respectively (11). The composition of inositol phospholipids isolated from plants varies from those present in mammalian tissues because they contain linoleoyl residue at the sn-2-position and palmitoyl residue at the sn-1-position.

As of 05/2007, the Chemical Abstract Service database included ca. 140,000 entries containing the "inositol" keyword.
In principle, only three members of the PIPn family, including phosphatidylinositol 4-phosphate ([PI(4)P], and 4,5-bisphosphate ([PI(4,5)P2]), are available in sufficient quantities by isolation from natural sources. Other phosphoinositides, although they play important roles in cell physiology, are formed transiently or are present in biological sources at very low concentrations, which makes preparative isolation of these compounds unfeasible. To date, all known naturally occurring phosphoinositides, with the exception of putative prostaglandyl inositol phosphate ([PI(3,4,5)P3]), have been synthesized, with some methodology published from the Department of Medicinal Chemistry and Pharmacognosy laboratory at the University of Illinois (14). Because of the synthetic expedience, most available synthetic inositol phospholipids are supplied as unnatural analogs that contain the saturated fatty acid chains, with either a long (dipalmityl) or shorter chains (dioctanoyl or diohexanoyl). These saturated analogs are not only easier to synthesize, but also are more stable chemically because they do not undergo peroxidation reactions common to unsaturated fatty acids. In addition, synthetic methods have been developed toward phosphatidylinositol analogs that carry fluorescent, biotin, and photoaffinity residues to identify the various phosphoinositide binding proteins and to study spatiotemporal aspects of inositol signaling pathways (15, 16).

Principal Biosynthetic and Metabolic Pathways

In plants, inositol is biosynthesized from glucose 1-phosphate via inosose 1-phosphate, which is reduced into 1D-inositol 3-phosphate (INO1 pathway). After dephosphorylation by inositol phosphate monophosphatase, myo-inositol is fed into biosynthesis of inositol phospholipids via a Kennedy-like sequence. In mammalian organisms, inositol is acquired from the diet and is also biosynthesized via INO1. The latter pathway, rather than the inositol phosphate phosphatase, seems to be a more promising target of antipsychotic drugs (17, 18). This compound is biosynthesized from myo-inositol and CDP-diacylglycerol by phosphatidylinositol synthase localized in the endoplasmic reticulum (19). The PI metabolism involves sequential phosphorylations at the 3 (20), 4- (21), and 5-positions (22) to provide compounds (2-8). In addition, PI is subject to degradation by phospholipases C and phospholipases A2. Although most mammalian phospholipases C prefer PI-4,5-P2 and PI-4-P (23), isolated reports of PI-specific phospholipases in mammalian tissues exist (24). In contrast to mammalian PI-PLC, the bacterial enzymes display strict specificity for unphosphorylated PI (25). Generally, PI, that bear a phosphate group at the inositol 3-position are regarded as resistant to cleavage by all PLC isozymes (26). PI seems also refractive to hydrolysis by two major isozymes of mammalian PLOD (27). PI is also subject to the decarboxylation reaction by sequential action of phospholipase A and lysophospholipase that generate glycerophosphoinositols (28), which was recently shown to inhibit invasion of cancer cells (29).

Phosphatidylinositol 3-phosphate

Phosphatidylinositol 3-phosphate ([PI(3)P]) is the second most abundant inositol phospholipid in biological membranes. It is a product of phosphorylation by four different species of PI 4-kinases (21), and it is a precursor to PI-4,5-P2 and PI-3,4,5-P3. These kinases are the two inositol lipids whose biological roles are understood best. The biological function of PI-4-P is not well known; however, the studies in yeast indicate its role extends beyond the substrate for PI 5-kinase (21), such as regulation of vesicular trafficking and protein secretion from Golgi. PI-4-P is removed by the subsequent phosphorylation to PI-4,5-P2 or dephosphorylation to PI by ER-localized phosphatase (21).

Phosphatidylinositol 5-phosphate

Phosphatidylinositol 5-phosphate ([PI(5)P]) is formed by the hydrolysis of 3-phosphate from PI-3,5-P2 by myotubulin,

Inositol Phospholipids: Biosynthesis and Biological Functions of...
Figure 2  Principal metabolic pathways of inositol phospholipids.
M TM 1 (33). This molecule can be removed either by phospho-
rylation into PI-4,5-P2 by phosphorylation with the ρ-form of
PI-4K (34) or by dephosphorylation of PI-5-P by the novel form
of Pten-like proteins with selectivity toward phosphatidyli-
nositol phosphates at the 5-position (35). Recent studies
suggest a role for PI-5-P in a variety of cellular events, such
as tumor suppression, response to bacterial invasion (35), and
control of osmotic pressure (36). This phosphophosphid has been
shown recently to function as a second messenger that binds
to an Arabidopsis homolog of trithorax, which suggests that it
may have a regulatory function that connects lipid signaling
with nuclear functions (37).

Phosphatidylinositol 3,5-bisphosphate

Phosphatidylinositol 3,5-bisphosphate (PI-3,5-P2, 6) is the low
abundance, newest member of PIPn family (33). It is involved
in mediation of several cellular processes such as vascular
homeostasis, membrane trafficking, and vesicular protein sorting
(36, 38). The recently discovered PI-3,5-P2 effectors include a
family of β-propeller, epsin, and CHMP protein families (39).
The importance of PI-3,5-P2 in human physiology is demon-
strated by its role in insulin signaling, myotubular myopathy,
and corneal dystrophy (38).

Phosphatidylinositol 3,4-bisphosphate

Phosphatidylinositol 3,4-bisphosphate (PI-3,4-P2, 5) is biosyn-
thesized by phosphorylation of PI-4-P at the 3-position (26), by
dephosphorylation of PI-3,4,5-P3 at the 5-position by the SHIP
phosphatase (39, 40), and by phosphorylation of PI-3-P by the
Type II 4-kinase (41). The significance of this lipid is under-
standing the association between SHIP2 gene polymorphism
and type 2 diabetes mellitus (39). Therefore, SHIP2 constitutes
an important target for treatment of both type 2 diabetes and
obesity (40).

Phosphatidylinositol 4,5-bisphosphate

Phosphatidylinositol 4,5-bisphosphate (PI-4,5-P2, 7) is the third
most abundant inositol phospholipid in biological membranes.
The predominant biosynthetic pathway is via phosphoryla-
tion of PI-4-P by a 5-kinase (3h). This inositol lipid is best
known for participating in receptor-mediated cleavage by mam-
alian phospholipases C-β, γ, δ, and ε to produce inositol
1,4,5-trisphosphate second messenger (41, 42), and for initiating
extremely complex metabolic pathways of inositol phosphates,
which include formation of several new second messengers,
such as inositol 1,3,4,5-tetrakisphosphate, 1,3,4-trisphosphate,
and 3,4,5,6-tetrakisphosphate (3e, 43). The biological role
of PI-4,5-P2 is much larger because it is a substrate for Type
I 3-kinases that ultimately provide PI-3,4,5-P3 as an-
other important signaling molecule (44). In addition, PI-4,5-P2
is recognized specifically by pleckstrin homology domains
of many important proteins, which include several enzymes
(e.g., phospholipase D (45)), which provides an interesting
crosslink between the PLC and PLD lipolytic activities. A nother
example of the interrelationship between phospholipases is the
regulation of Ca2+ by PI-4,5-P2 (46). Furthermore, associa-
tion of certain transmembrane receptors with PI-4,5-P2 affects
their functional activity (e.g., interaction of vanilloid receptor
with PIP2 is necessary for receptor desensitization (47)). There-
fore, PI-4,5-P2 plays an important role in both human health
and disease (48).

Phosphatidylinositol 3,4,5-trisphosphate

Phosphatidylinositol 3,4,5-trisphosphate (PI-3,4,5-P3, 8) is the
most phosphorylated inositol phospholipid, and it is one whose
function is related to cell growth, survival, and differentiation
(49, 50). The proper physiological levels of PI-3,4,5-P3 are
maintained in a major part by phosphorylation of PI-4,5-P2
by the Type I phosphatidylinositol 3-kinases and by hydrolysis
of two 3-phosphoinositide phosphatases: PTEN and SHIP2 (20).
The latter activities lead to the regeneration of PI-4,5-P2 and to
formation of another second messenger, PI-3,4,5-P3, respectivelv
(39, 40). Strong evidence suggests that PI-3,4,5-P3 is an impor-
tant player of signaling pathways in the nucleus. Recent results
also indicate that nuclear translocation of cell surface receptors
could activate nuclear PI-3K, which suggests a new pathway
of signal transduction (51). The most important cellular func-
tion of PI-3P at the moment seems to be its strong interaction
with the PH domain of protein kinase A(κ). Binding of PIP3
causes translocation of Akt to the plasma membrane where it
becomes phosphorylated and activated (50). The activated Akt
then phosphophates downstream cellular proteins that promote
cell proliferation and survival, which results ultimately in tu-
morigenesis. Therefore, the proper concentration of PI-3,4,5-P3
is pivotal to cell homeostasis, and its elevated levels promote
tumor formation (50).

Phosphoinositide-Binding Protein Domains

A major advance in understanding signaling roles of phos-
phatidylinositols has been the discovery of several highly con-
served protein domains whose function is to bind head groups of
specific phosphatidylinositol phosphates. Such “cut and paste”
modules are attached to a diverse array of multidomain pro-
teins, and they enable recruitment of such proteins to spe-
cific regions in cells via binding to plasma or to intracellular
membranes enriched with such phosphoinositides (52, 53).
As a result, phosphoinositides can act as signal mediators in a
spatially- and temporally-defined manner, and they can control
various intracellular events such as cytoskeletal rearrangement
and membrane trafficking. The pleckstrin homology (PH) do-
main was the first identified phosphoinositide-binding domain.
It contains the largest number of members and is associated with
the formation of signaling complexes on the plasma membrane.
Recent studies identified other novel phosphoinositide-binding
domains such as FYVE, Phox homology (PX), and epsin
N-terminal homology (ENTH), which attest even more to the
functional versatility of phosphoinositides (54). The number of
known domains or modules that bind phosphoinositides has
increased dramatically over the past few years. Struc-
tural analysis of interactions of inositol phospholipids with
phosphoinositide-binding domains has provided significant insight into the mechanism of membrane recruitment by the different cellular phosphoinositides. Thus, the domains that target only the rare (3-phosphorylated) phosphoinositides must bind with high affinity and specificity. In the case of certain PH domains (which bind PI-3,4,5-P3 and/or PI-3,4-P2), this binding is achieved exclusively by headgroup interactions. In contrast, the PI-3P-targeting PX and FYVE domains require the same stringent affinity and specificity and tend to be more diverse in structure. The mode of phosphoinositide binding by different domains also seems to reflect their distinct functions. For example, PX domains that serve as simple targeting domains recognize only the phosphoinositide headgroup. By contrast, certain other domains, notably the epsin targeting domains recognize only the phosphoinositide headgroup interactions. In contrast, the phosphoinositide binding domains is listed in Table 1.

In summary, transmembrane and intracellular signaling with phosphoinositides is a dynamically expanding field. The progress in this area is critical to understanding the intricate spatiotemporal effects of generation of these small molecular mediators in response to extracellular signals on the functional roles of intracellular proteins.

Inositol Phospholipids: Biosynthesis and Biological Functions

Inositol Polyphosphates

Adam C. Resnick, Division of Neurosurgery at the Children’s Hospital of Philadelphia, Department of Neurosurgery at the University of Pennsylvania School of Medicine, Philadelphia, Pennsylvania
Adolfo Saiardi, Medical Research Council (MRC) Cell Biology Unit and Laboratory for Molecular Cell Biology, Department of Biochemistry and Molecular Biology, University College London, London, United Kingdom
doi: 10.1002/9780470048672.wecb252

Inositol polyphosphates comprise a large family of water-soluble molecules derived from the combinatorial phosphorylation of the six hydroxyls of myo-inositol. Second messenger roles for inositol polyphosphates in Ca2+ mobilization were first identified for what is now the best characterized family member, inositol 1,4,5-trisphosphate (InsP3). Additional anabolic and catabolic metabolism of InsP3 results in the formation of a large, diverse family of higher inositol polyphosphates whose signaling roles and biologic functionality remain largely undefined. However, the recent cloning and identification of the kinases and phosphatases involved in the combinatorial modification of inositol polyphosphates has served to further define and characterize this complex metabolic network and to identify its preeminence in nearly all aspects of cell biology. Conserved from yeast to humans, inositol polyphosphates regulate a wide array of processes, including ion-channel conductance, membrane dynamics, transcription, nucleic acid metabolism, and protein phosphorylation.

The scientific study of inositol polyphosphates began in 1850 with the isolation of a crystalline “sugar” from heart muscle extracts (1). The substance was named “inosit” from the Greek root inos for muscle, fiber, or sinew. The later identification of this optically inactive inositol (the “ol” suffix added in French and English) as one of nine possible cyclohexanehexol isomers necessitated the use of prefix designations for the specific stereoisomeric configurations of the secondary hydroxyl groups about the six-carbon ring (cis-, epi-, allo-, muco-, neo-, scyllo- (+)-chiro,-(-)-chiro, and myo-) (Fig. 1). Although several, if not all, inositol isomers occur in nature, myo-inositol (myo, once again derived from the Greek word for muscle) is the biologically relevant stereoisomer in most species and functions as the structural building block for the inositol polyphosphates. Viewed in its favored chair conformation, myo-inositol possesses five equatorial groups and one axial hydroxyl group. The modern D-numbering system for inositol is by convention counterclockwise as viewed from above and assigns the axial hydroxyl group to C2. This conformation is best illustrated by Agranoff’s turtle (2) in which the six hydroxyls are envisaged as the appendages (1-, 3-, 4-, 6-hydroxyl), head (2-hydroxyl), and tail (5-hydroxyl) of a friendly turtle. It is worth noting that among the stereoisomers of inositol, myo-inositol is unique in containing a single axial OH group (Fig. 1). This results in an achiral molecule with a plane of symmetry through C2–C5 (head to tail) and two pairs of enantiomorphic hydroxyls (C1–C3 and C4–C6, the turtle’s arms and legs, respectively). Presumably, it is the chemical uniqueness of this configuration that resulted in nature’s selection of the myo isomer over others for enzymatic modification and biologic significance.

Myo-inositol’s most basic function, like other polyols (such as sorbitol), is as an osmolyte whose increased cellular concentration reflects responses to hyperosmolarity. However, inositol’s full biologic potential is only realized via chemical modification. Although inositol participates in several varied enzymatic reactions, it is the combinatorial substitution of phosphate moieties to the six hydroxyls that impart preeminent metabolic and functional significance to this deceptively simple molecule. Mathematically, 63 such combinations are possible; this number, however, is an underestimate as di- and triphosphates (also known as pyrophosphate) moieties also exist. To date, over 30 different inositol polyphosphates have been observed across euarchdolic evolution resulting in a fairly crowded metabolic map. Complicating matters, the cellular biosynthesis of inositol polyphosphates—composed of only myo-inositol and phosphates and therefore water-soluble—is not achieved by the mere sequential phosphorylation and/or dephosphorylation of the myo-inositol ring (although there are exceptions in...
Inositol Polyphosphates

(a) Myo-inositol and its polyphosphate derivatives. Although nine stereoisomeric configurations of inositol are possible, the turtle-like myo-inositol with its single axial hydroxyl is the most biologically relevant. Also depicted are the scyllo- and neo-inositols with zero and two axial hydroxyls, respectively. The modern D-numbering system for inositols is counterclockwise viewed from above and assigns the axial hydroxyl group to C2 of myo-inositol. (b) Inositol polyphosphates. Depicted are representatives of phosphorylated derivatives of myo-inositol, including Ins(1,4,5)P3, the calcium releasing factor; InsP6, the naturally most abundant fully phosphorylated inositol polyphosphate; and InsP7, an inositol diphosphate (pyrophosphate).

Receptor-Stimulated Inositol Metabolism and the “Inositol Cycle”

The birth of receptor-stimulated inositol polyphosphate metabolism and its role in cell signaling was the observation in the early 1950s of acetylcholine-stimulated 32P incorporation into inositol lipids (termed the “PI response”) (3). However, it would take more than two decades for the mechanisms and significance of this response to come to light. Key to the eventual elucidation of the “PI response” was the realization that receptor stimulation leads to the activation of phosphoinositol-lipid-specific phospholipase C (PLC). Upon activation, PLC hydrolyzes the glycerol-phosphate bond in PtdIns(4,5)P2 causing the release of water-soluble inositol 1,4,5-trisphosphate (InsP3 or Ins(1,4,5)P3) and the lipid diacylglycerol (DAG). After receptor-mediated catabolism, a regenerative cycle undertakes to restore PtdIns(4,5)P2 to the plasma membrane. Released DAG acts as the now familiar activator of PKC, but subsequently it reenters the inositol metabolism pathway as CMP-phosphatidic acid (CMP-PtdOH, alternatively named CDP-DAG). Synthesis of CMP-PtdOH proceeds via the phosphorylation of DAG by DAG kinase and conjugation to a cytidine nucleotide. Inositol lipid synthesis initiates as the phosphatidic acid (PA) moiety of CMP-PtdOH is enzymatically donated to the C1-hydroxyl of myo-inositol forming PtdIns. Sequential phosphorylation of PtdIns to PtdIns(4)P and PtdIns(4,5)P2 completes the “inositol cycle” and regenerates the substrate for receptor-activated PLC hydrolysis ([Fig. 2]).
Figure 2  The "inositol cycle." A simplified representation of the regenerative metabolism responsible for the synthesis of InsP₃. Generation of InsP₃ and DAG upon PLC-mediated hydrolysis of PtdIns(4,5)P₂ is followed by sequential dephosphorylation of InsP₃ and DAG’s modification to CDP-DAG. The enzymatic attachment of CDP-DAG to inositol regenerates the lipid precursors that ultimately replenish PtdIns(4,5)P₂.
Inositol Polyphosphates

PtdIns synthesis is often dephosphorylated Ins(1,4,5)P3. Alteration of an "inositol cycle" is concomitantly dependent on the continuous supply of free inositol. The source of myo-inositol for PtdIns synthesis is often dephosphorylated Ins(1,4,5)P3. Alternatively, cells take up extracellular inositol or synthesize inositol de novo.

Myo-inositol uptake and synthesis

Sodium- or proton-coupled myo-inositol transporters provide the most direct route for the initiation of inositol polyphosphate metabolism (affording the inositide researcher a simple avenue for the analysis of inositol polyphosphate dynamics using radiolabeled inositol). To date three different mammalian cotransporters have been identified (SMIT 1 and 2 are Na+-coupled, whereas HMIT uses a proton gradient). Although transporters are widely transcribed in many animal tissues, access to extracellular inositol varies among organs. In the absence or low levels of extracellular inositol, de novo synthesis of free myo-inositol is transcriptionally induced; this seems to be a universal capacity of cells conserved from bacteria to humans. Synthesis is initiated via the cyclization of glucose-6-phosphate by 1D-myo-inositol-3-phosphate synthase (MIPS) and the formation of inositol-3-phosphate (Ins(3)P). Dephosphorylation of Ins(3)P by inositol monophosphatase (IMP) yields the free inositol that can then be incorporated into inositol lipids (PtdIns).

In addition to its role in the de novo synthesis, IMP also functions to dephosphorylate downstream hydrolytic products of InsP1, Ins(1)P, and Ins(4)P. As such, IMP is situated at a metabolic intersection of de novo synthesis and the regeneration of myo-inositol, functioning as a gateway for the completion and maintenance of the "inositol cycle."

InsP1, and InsP2, lithium, and the inositol depletion hypothesis

By and large the inositol monophosphates and bisphosphates are thought to lack messenger functions and are most often conceived as catabolic products of the regenerative portion of the inositol cycle or as components of the "off" switch of inositol polyphosphate signaling. Sequential dephosphorylation of Ins(1,4,5)P3 in most eukaryotes proceeds with the concomitant dependence on the continuous supply of free inositol. The source of myo-inositol for PtdIns synthesis is often dephosphorylated Ins(1,4,5)P3. Alternatively, cells take up extracellular inositol or synthesize inositol de novo.

The use of lithium to treat manic-depressive illness dates back to 1949 (4). J.F.J. Cade, while working at a psychiatric hospital, was using guinea pigs to evaluate the effects/toxicity of injections of urine collected from psychiatric patients, testing the hypothesis that a "toxin" may be responsible for the patients' illnesses. In the course of these and other related experiments, he began using the lithium salt of uric acid—chosen merely for its high solubility—and noted a marked depressive effect on the animals' behavior after injection, which he later attributed to the lithium rather than to the uric acid. These experiments were followed by the successful clinical use of lithium in patients suffering from mania and bipolar disorders (4).

Studies in the early and mid-1970s evaluating the effects of lithium administration on inositol levels in rat brains identified a dramatic decrease in the free inositol levels accompanied by a concomitant increase in inositol monophosphates and suggested IMP as the plausible pharmacologic target mediating the therapeutic actions of lithium (5). Subsequent detailed biochemical studies of IMP's inhibition by lithium demonstrated its uncompetitive inhibition by therapeutically relevant concentrations of the ion (6). Surprisingly little attention was paid to the early studies of lithium's effects on inositol metabolism, and it was not until the formulation of the "inositol depletion hypothesis" by Berridge et al. that inositol's mechanism of action and role in aberrant neuronal signaling came to the forefront of the psychopharmacology of lithium's actions in the brain (7).

Stated explicitly, the proposal put forth by Berridge et al. suggests that the cells of the central nervous system (CNS) are uniquely sensitive to the inhibitory effects of lithium on IMP as a result of their limited access to extracellular inositol because of its poor penetration of the blood-brain barrier. Thus, the brain is extensively dependent on IMP's role in de novo inositol synthesis and IMP's functionality in the recycling of inositol monophosphates. Lithium's inhibition of IMP results in the slowing down of the "inositol cycle" and depletes the inositol pool necessary for the production of Ins(1,4,5)P3 in response to receptor stimulation. The corollary of this hypothesis is that, in part, it is the overstimulation of inositol metabolism in the brains of manic-depressive patients that is responsible for the disease's manifestation. In the nearly 20 years since the formulation of the "inositol depletion hypothesis," additional substrates for lithium's actions have been identified, including both the upstream Ins(1,4)P2;Ins(1,3,4)P3, 1-phosphatase as well as the serine/threonine kinase glycogen synthase kinase-3 (GSK-3), whose regulation seems to be independent of inositol metabolism, which suggests lithium's effects on the CNS are more complicated than first envisioned. Nevertheless, it was in fact Berridge et al.'s use of lithium in examining the "PI response" that paved the way for the identification of Ins(1,4,5)P3 as the now well-known calcium-mobilizing second messenger.
Inositol Polyphosphates: Form and Function

Ins(1,4,5)P₃ and Ca²⁺

The identification of Ins(1,4,5)P₃ and its biologic function and significance in the PI3K pathway continually eluded investigators until a conceptual connection between calcium dynamics and receptor-stimulated phosphoinositol turnover was proposed by M ichel (18). Working with blowfly salivary glands, Berridge and Finch demonstrated the cellu lar capacity to rescue calcium release upon cell-surface receptor activation to Ca²⁺ release from intracellular stores. Using permeabilized cells, Streb et al. conclusively demonstrated that application of exogenous InsP₃ mobilized Ca²⁺ from the endoplasmic reticulum (10). A search for the InsP₃ receptor ensued and culminated in the cloning, purification, and reconstitution of the receptor as well as the demonstration that the protein itself is an InsP₃-gated Ca²⁺ channel (11, 12). Calcium dynamics and the regulation of the InsP₃ receptor are still very active research areas. However, by the end of 1980s, a functional and elegant paradigm for soluble inositol metabolism was established.

Ins(1,3,4,5)P₄:C₃-hydroxyl phosphorylation

It was the unexpected identification of an alternative isomer of InsP₃, Ins(1,3,4,5)P₄, derived from the dephosphorylation of Ins(1,3,4,5)P₄ that revealed that there was clearly more to inositol polyphosphate metabolism than circumscribed by the “inositol cycle” (13). Indeed within a few years’ span in the mid-to-late 1980s, the discovery of the C₃-hydroxyl phosphorylation of the inositol ring ushered in an era of “proliferation” for the inositides, within both the lipid and water-soluble arenas of their metabolism. During this time, an inositol lipid 3-kinase activity was found associated with viral Src and the middle-T antigen of the polyoma virus (14). Phosphoinositide-3 kinase (PI3K) produces PtdIns(3,4,5)P₃ from PtdIns(4,5)P₂ upon cell-surface receptor activation and thus they remain relegated to the “lipid switch” for inositol polyphosphate metabolism and function. However, by the end of 1980s, a functional and elegant paradigm for soluble inositol metabolism was established.

Ins(1,3,4,5)P₄ and Ca²⁺

The identification of Ins(1,4,5)P₃ and its biologic function and significance in the PI3K pathway continually eluded investigators until a conceptual connection between calcium dynamics and receptor-stimulated phosphoinositol turnover was proposed by Michel (18). Working with blowfly salivary glands, Berridge and Finch demonstrated the cellular capacity to rescue calcium release upon cell-surface receptor activation to Ca²⁺ release from intracellular stores. Using permeabilized cells, Streb et al. conclusively demonstrated that application of exogenous InsP₃ mobilized Ca²⁺ from the endoplasmic reticulum (10). A search for the InsP₃ receptor ensued and culminated in the cloning, purification, and reconstitution of the receptor as well as the demonstration that the protein itself is an InsP₃-gated Ca²⁺ channel (11, 12). Calcium dynamics and the regulation of the InsP₃ receptor are still very active research areas. However, by the end of 1980s, a functional and elegant paradigm for soluble inositol metabolism was established.

Ins(1,3,4,5)P₄ and Ca²⁺

The identification of Ins(1,4,5)P₃ and its biologic function and significance in the PI3K pathway continually eluded investigators until a conceptual connection between calcium dynamics and receptor-stimulated phosphoinositol turnover was proposed by Michel (18). Working with blowfly salivary glands, Berridge and Finch demonstrated the cellular capacity to rescue calcium release upon cell-surface receptor activation to Ca²⁺ release from intracellular stores. Using permeabilized cells, Streb et al. conclusively demonstrated that application of exogenous InsP₃ mobilized Ca²⁺ from the endoplasmic reticulum (10). A search for the InsP₃ receptor ensued and culminated in the cloning, purification, and reconstitution of the receptor as well as the demonstration that the protein itself is an InsP₃-gated Ca²⁺ channel (11, 12). Calcium dynamics and the regulation of the InsP₃ receptor are still very active research areas. However, by the end of 1980s, a functional and elegant paradigm for soluble inositol metabolism was established.
Inositol Polyphosphates

Ins(3,4,5,6)P₄ - Ca²⁺-activated chloride (Cl⁻) channel regulation

Two separate biosynthetic routes have been proposed for the production of Ins(3,4,5,6)P₄. The "correctness" of both pathways, whether they coexist or merely display species differences, is still a matter of debate. Regardless, both depend on the initial C₃-hydroxyl phosphorylation of Ins(1,4,5)P₃. The first pathway, currently only supported by experiments in avian erythrocytes, depends on several sequential dephosphorylation and phosphorylation reactions that isomerically interconvert between InsP₇ and InsP₅. This pathway can be summarized as follows: Ins(1,3,4,5,6)P₅ → Ins(1,3,4,5)P₄ → Ins(1,3,4,5,6)P₆ (18). A second proposed pathway, which is prevalent in mammalian cells, proceeds via the C₁-hydroxyl dephosphorylation of Ins(1,3,4,5,6)P₅. Surprisingly, despite its use of Ins(1,3,4,5,6)P₅ as a precursor for the formation of Ins(3,4,5,6)P₄, this latter pathway, like the first, also seems to depend on the dephosphorylation of Ins(1,3,4,5)P₃. In a theme of competitive protection that is likely repeated often in inositol metabolism, the generation of Ins(1,3,4,5)P₃ after PLC activation results in the protection of the cellular pools of Ins(3,4,5,6)P₄ by competing as a substrate for a dual specificity kinase that phosphorylates Ins(1,3,4,5,6)P₅ back to Ins(1,3,4,5,6)P₆. Ins(1,3,4,5,6)P₇ 5,6-Ins(3,4,5,6)P₄ 1-kinase (also named ITPK1) is one of several inositol polyphosphate kinases displaying substrate promiscuousity, an enzymatically conservative yet metabolically proliferative measure on behalf of evolution that also affords the potential of competitive "crosstalk." Startlingly, the 1- Ins(1,3,4,5,6)P₅ phosphatase responsible for Ins(1,3,4,5,6)P₅ production turns out to be the very same ITPK1. Thus, ITPK1 functions as a reversible kinase capable of the interconversion of Ins(1,3,4,5,6)P₅ and Ins(3,4,5,6)P₄ (19). The balance of phosphatase/kinase activities seems to be regulated by Ins(1,3,4,5)P₃ such that Ins(1,3,4,5)P₃ stimulates the phosphatase reaction. Reflecting the regulatory "crosstalk" involved in its production, Ins(3,4,5,6)P₄ accumulation in response to persistent PLC activation occurs relatively slowly but persists long after other inositol metabolites have returned to their prestimulated levels, a feature likely important in its regulation of Ca²⁺-activated Cl⁻ channels. Cl⁻ secretion via Ca²⁺-activated channels serves to physiologically regulate epithelial salt and fluid secretion in the gastrointestinal tract, exocrine glands, and lungs of animals. A putative role for a PLC-dependent factor in the negative regulation of Cl⁻ secretion was suggested by experiments in which a Ca²⁺-mediated activation of Cl⁻ secretion upon receptor activation of PLC were followed by a period refractory to the stimulating effects of Ca²⁺. Correlating channel activation and deactivation with cellular levels of downstream PLC-dependent inositol polyphosphates, Sheets and associates identified Ins(3,4,5,6)P₄ as the likely mediator of the inhibition of Cl⁻ conductance and went on to show that a cell-permeant analog of Ins(3,4,5,6)P₄ decreased Ca²⁺-dependent Cl⁻ secretion (20). The apical distribution of ITPK1 in polarized epithelial cells localizes Ins(3,4,5,6)P₄ near its presumed site of action. However, the precise mechanism or target of inhibition has remained elusive. Although much of the delineation of the physiologic importance of Ins(3,4,5,6)P₄ has been derived from the study of epithelial cells, Ca²⁺-activated Cl⁻ channels occur in most cell types raising the potential of Ins(3,4,5,6)P₄-mediated regulation of diverse cellular processes ranging from neurotransmission to smooth-muscle contraction (21).

As indicated, the regulation of Ca²⁺ and/or Ca²⁺-dependent processes by Ins(1,4,5)P₃, Ins(1,3,4,5)P₄, and Ins(3,4,5,6)P₄ likely represents a recent addition to the repertoire of inositol polyphosphate functionality. Soon after the discovery of C₃-hydroxyl phosphorylated inositol polyphosphates came the realization that more phosphorylated inositol species were indeed conserved ubiquitous inositol metabolites predominating the metazoan emergence of InsP₃-receptor-mediated Ca²⁺ signaling. These highly phosphorylated species included inositol hexakisphosphate (Ins(1,2,3,4,5,6)P₆), known at the time to occur in avian erythrocytes, and the fully phosphorylated inositol hexakisphosphate (Ins(1,2,3,4,5,6,7)P₇, also called phytic acid or InsP₇), thought to be predominantly relegated to the plant kingdom. Although the biosynthetic pathways of highly phosphorylated inositol polyphosphates have yet to be fully elucidated, over the last decade significant strides have been made in their metabolic and functional characterization, including the identification of inositol polyphosphate kinases ancestral to the Ca²⁺-dependent Ins(1,4,5,6)P₃ 3-kinases. In large part these advances are the byproducts of the genetic tractability of one of the simplest model organisms, the budding yeast Saccharomyces cerevisiae.

Ins(1,4,5,6,7)P₆ and Ins(1,3,4,5,6,7)P₆: transcriptional regulation

In the budding yeast, inositol polyphosphate synthase's proceeds via what is likely to be one of the earliest incarnations of a PLC-dependent pathway for higher inositol polyphosphate metabolism in eukaryotes. Early biochemical studies in yeast (and plants) failed to identify a calcium-sensitive Ins(1,4,5)P₃ 3-kinase activity analogous to that found in mammalian cells. Instead, these studies identified C₁-hydroxyl phosphorylation of Ins(1,4,5)P₃ and formation of Ins(1,4,5,6)P₄ as the most likely first anabolic step in the production of higher inositol polyphosphates (22). Additional biochemical studies identified the sequential phosphorylation of Ins(1,4,5,6)P₄ to Ins(1,3,4,5,6,7)P₇ followed by Ins(1,2,3,4,5,6,7)P₇ (23). These findings were interpreted as proof of the existence of disparate pathways in yeast and mammals for the metabolism and functionality of Ins(1,4,5)P₃. In contrast, the eventual cloning of the yeast Ins(1,4,5)P₃ kinase activity found that mammalian and yeast inositol metabolism were more closely related than initially suspected.

Biochemical and genetic characterization of the yeast Ins(1,4,5,6)P₃ kinase revealed it to be a dual-specificity Ins(1,4,5)P₃, 3/6-kinase, rapidly converting Ins(1,4,5)P₃ to Ins(1,3,4,5,6)P₄ via the intermediate production of Ins(1,4,5,6)P₃. Sequence comparisons of the yeast Ins(1,4,5,6)P₃ 3/6-kinase with the mammalian Ins(1,4,5,6)P₃ 3-kinases demonstrated them to be part of a closely related family and suggested the Ins(1,4,5)P₃ 3-kinases were merely a recent evolutionary modification and specialization of this catalytically versatile kinase family (14). The cloning
and characterization of the yeast Ins(1,4,5)P3 3/6-kinase was accomplished contemporaneously by two independent groups (24, 25). Noting its catalytic versatility, the Snyder group dubbed the enzyme inositol polyphosphate multikinase (IPMK), whereas the York group chose inositol polyphosphate kinase 2 (Ipk2) as it was one of two simultaneously identified kinases necessary for the synthesis of InsP6 (26). However, yeast IPMK Ipk2 was in fact identical with the previously characterized Arg82, which was a protein with a history of nearly two decades of research that had clearly identified it as a nuclear, transcriptional regulator. Studies of yeast deficient for Arg82 identified it as a required factor for the transcriptional regulation of genes comprising arginine anabolic and catabolic metabolism. Transcriptional regulation of these arginine-sensitive pathways permits yeast to use alternative nitrogen sources such as arginine or ornithine when the preferred sources of ammonia or glutamate are limiting. In the absence of Arg82, yeast fail to grow on media with arginine or ornithine as the sole nitrogen source (27). The identification of yeast IPMK/Ipk2 as Arg82 (henceforth called IPMK) prompted the evaluation of the role its kinase activities may play in regulating these arginine-sensitive transcriptional responses. Monitoring growth phenotypes of various inositol polyphosphate mutants in media containing arginine or ornithine as the sole nitrogen source, York and associates identified the necessity of Pcl1 and IPMK but not downstream inositol polyphosphate kinases for growth on selective media (25). These results supported the conclusion that it is the production of Ins(1,4,5)P6 and/or Ins(1,3,4,5,6)P5 that is required for the regulation of arginine-dependent gene expression. Although determinants of IPMK may play a role in its functional contribution to arginine-sensitive transcription (28), additional experiments using IPMK orthologs found in the fly and plant that lack previously identified yeast regulatory sequences suggest IPMK (1,4,5)P6 and/or Ins(1,3,4,5,6)P5 roles are themselves sufficient for modulating arginine-dependent transcription; however, the molecular mechanism remains unknown (29, 30). Roles for Ins(1,4,5)P6 and/or Ins(1,3,4,5,6)P5 in transcriptional regulation have been supported by subsequent genetic screens in yeast that identified the requirement of Ins(1,4,5)P6 and/or Ins(1,3,4,5,6)P5 in phosphate-responsive regulation of chromatin remodeling and transcription (31). The ipmk null yeast are defective in the induction of the PHO5 gene in response to phosphate limitation. Remodeling of the PHO5 promoter chromatin is impaired in ipmk mutant yeast as a result of defects in the recruitment of ATP-dependent chromatin-remodeling complexes. Specific roles for either Ins(1,4,5)P6 or Ins(1,3,4,5,6)P5 were once again suggested as chromatin remodeling defects were also evident in pcl1 mutant yeast, but not in yeast deficient in downstream inositol polyphosphate kinases (33). A mechanism for Ins(1,4,5,6)P5 mediating repression of chromatin remodeling was suggested by in vitro nucleosome mobilization assays in which Ins(1,4,5,6)P5 and Ins(1,3,4,5,6)P5 were found to have direct stimulatory effects on chromatin remodeling complexes (32). However, these latter studies have been faulted for the use of nonphysiologic concentrations of the inositol phosphates, which suggests additional characterization of the process is necessary. The identification in yeast of a concise anabolic pathway for higher inositol polyphosphates in the nucleus suggests primordial roles for their metabolism consistent with earlier suppositions on the nuclear origin of lipid inositol metabolism (33). Indeed, IPMK not only functions as an inositol polyphosphate kinase, but it is also a nuclear lipid inositol PI3K kinase that predates the evolutionary emergence of the unrelated viral-Src- and middle-T-antigen associated kinases (discussed above). Like its water-soluble inositol polyphosphate activities, IPMK-mediated synthesis of nuclear PtdIns(3,4,5)P2 has also been linked to transcriptional regulation in yeast (34). Whether transcriptional regulatory roles for Ins(1,4,5,6)P5/Ins(1,3,4,5,6)P5 (or PtdIns(3,4,5)P2) are evident in higher eukaryotes remains unknown, although roles in nuclear processes are likely, as nuclear IPMK paralogs have been identified across evolution, including mammals. Characterization of mammalian IPMK showed it had retained its catalytic versatility and was capable of sequential phosphorylation of Ins(1,4,5)P3 to Ins(1,3,4,5,6)P5 (35); however, like the Ins(1,4,5)P3 3-kinase mammalian IPMK prefers to initiate this metabolism via C3-hydroxyl phosphorylation. Additional studies have extended IPMK’s catalytic repertoire and have suggested that in mammalian systems, IPMK serves to synthesize Ins(1,3,4,5,6)P5 via the C5-hydroxyl phosphorylation of Ins(1,3,4,6)P4, the product of Ins(1,3,4,5)P5 phosphorylation by ITPK1 (discussed above) (36). Thus, in mammals, two pathways may exist for the production of Ins(1,3,4,5,6)P5. One pathway is analogous to that found in yeast, mediating exclusively via IPMK, but the second follows a more circuitous route initiated by Ins(1,4,5)P3 3-kinase and ultimately is still dependent on IPMK. This latter pathway can be summarized as follows: Ins(1,4,5)P3 \( \rightarrow \) Ins(1,3,4,5)P4 \( \rightarrow \) Ins(1,3,4)P3 \( \rightarrow \) Ins(1,3,4,5,6)P5 \( \rightarrow \) Ins(1,3,4,5,6)P5. Whether both routes do indeed exist in mammals or whether one pathway predominates is still a matter of some debate. Perhaps the occurrence of both pathways simply reflects cytoplasmic versus nuclear signaling. Whichever the route, production of Ins(1,3,4,5,6)P5 and its more phospho-derivative relatives seems to be of preeminent importance for mammalian systems as deletion of IPMK in mice results in early embryonic lethality and severe developmental defects (37). Ins(1,2,3,4,5,6)P6: from chelator to cofactor Production of Ins(1,3,4,5,6)P5 is the penultimate step in the synthesis of the most abundant inositol phosphate on earth, Ins(1,2,3,4,5,6)P6. Its synthesis is achieved via the phosphorylation of Ins(1,3,4,5,6)P5’s lone remaining axial hydroxyl by an Ins(1,3,4,5,6)P5 2-kinase (IPK2) (28). InsP6’s quantitative dominance on earth is owed largely to its use by plants for phosphate storage in seeds. Although it was the first inositol polyphosphate discovered, it was not until the development and application of high-pressure liquid chromatography (HPLC) in the analysis of inositol polyphosphates that its prevalence in animal cells was appreciated. With intracellular concentration in mammalian cells ranging between 10 and 100 μM, it is the most...
abundant inositol polyphosphate species, often exceeding most others by an order of magnitude or more. Even higher concentra-
tions have been observed in the slime mold Dictyostelium discoideum, which possesses unique metabolic pathways for
inositol polyphosphate synthesis independent of inositol lipids and their hydrolysis by PLC. In fact, in D. discoideum (and in
some plants), higher inositol polyphosphate synthesis can pro-
cceed via the direct sequential phosphorylation of InsP3(3P) after
cyclization of glucose-6-phosphate. In these unusual organisms
InsP4 concentrations can reach as high as 700 µM. Because of
its high charge density, InsP4 is a strong chelator that read-
ily forms insoluble salts with polyvalent cations resulting in its
precipitation at higher concentrations. Under cellular ionic con-
dition found in animal cells, soluble InsP4 concentrations are
limited to ~50 µM (likely in the form a neutral, stable pentam-
agranium salt). Thus, it is likely that much of cellular InsP4 is
actually found in a “bound state.”

Several proteins have been identified to bind InsP6. As
InsP6 interacts strongly with positively charged residues, cau-
tion has been urged in interpreting in vitro binding exper-
iments. Nevertheless, physiologic roles for InsP6 have been
suggested in several processes throughout the cell. In the cy-
toplasm, InsP6 binds tightly to clathrin assembly proteins neg-
avely regulating the assembly of clathrin-coated vesicles and
receptor-mediated endocytosis at the plasma membrane (38). Nu-
clear roles for InsP6 have also been suggested. In mammals,
DNA double-strand breaks can be repaired by nonhomologous
end-joining (NHEJ) requiring the activity of DNA-dependent
DNA-PK. In vitro studies demonstrated the stimulation of DNA-PK dependent NHEJ activity by InsP6 and
identified the Ku70/80 subunits of DNA-PK as direct InsP6 tar-
gets (39). Recently, a crystallographic study unexpectedly found
InsP6 bound within the enzymatic core of an RNA editing
enzyme (ADAR2) belonging to a class of adenosine deami-
nases and further demonstrated its requirement as a cofactor for
this class of enzymes (40). Consistent with a conserved role
in processes involving nucleic acids, a yeast genetic screen for
required factors involved in mRNA export unabiguously iden-
tified Pcl1, IPMK, and Ipk1 and their sequential enzymatic roles
in InsP6 synthesis (26). Finally, like the IPMK mouse knock-
out, IPK1 knockout mice also display early embryonic lethality
demonstrating a critical role for higher inositol polyphosphate
synthesis in mammalian development (41).

In contrast to the rapid changes upon receptor activation
in intracellular concentrations of lower inositol polyphosphates
(e.g., Ins(1,4,5)(P3), InsP3, and InsP4) concentrations seem immute.
This finding, along with observations of the sluggish incorporation
of radiolabeled inositol into InsP6, prompted interpretations of
slow turnover rates for InsP6 in vivo. However, the identification of
InsP6 as a precursor to even more phosphorylated inositol
polyphosphates overturned these misconceptions and revealed
the true dynamic nature of cellular InsP6.

**PP-InsP6 and PP2-InsP6: signaling and protein phosphorylation**

That more than six phosphates can fit onto an inositi-
ol ring was first discovered in D. discoideum (42) and
fluoride-treated pancreatoma cells (43). Subsequent stud-
ies confirmed the widespread evolutionary diversity of the
diphosphate-containing inositols. These “high energy”
molecules contain the fully phosphorylated inositol ring of
InsP6 with additional pyrophosphate moieties on either one
or two α-phosphates. The best characterized diphosphorylated
inositol polyphosphates are the diphosphoinositol pentakisphos-
sphate (InsP5, PP-InsP5) and bis-diphosphoinositol tetrakisphos-
sphate (InsP6, PP2-InsP6) species. In most cell types, these
species are present in submicromolar concentrations, repre-
senting 1-5% of total InsP6 levels. Remarkably, in mam-
alian cells, up to 50% of InsP6 cycles through the more
phosphorylated diphosphates every hour (43). Once again the
slime mold represents the extreme of higher inositol polyphos-
phates metabolism with diphosphates species reaching concen-
trations of 200 µM. Nuclear magnetic resonance spectroscopy
analysis of inositol diphosphates in D. discoideum showed a
single InsP6 isomer present in the cytoplasmic fraction of CS and
C6 (3,6-(PP2)-InsP6) and the two respective InsP5 isomers,
5-PP-InsP5 and 6-PP-InsP5. So far, in mammalian cells, only
a single InsP6 isomer has been detected and demonstrated to be
the CS- and PP2-InsP6 species. The standard free energy of
hydrolysis of the pyrophosphate bond in InsP6 (the nonphysi-
ologic l-PP-InsP6) has been estimated at 6.6 kcal/mol, higher
than that of adenosine-5′-diphosphate (ADP) (6.4 kcal/mol) and
only slightly lower than that of ATP (7.3 kcal/mol). These val-
ues are likely to be quite higher for InsP6 isomers with vicinal
pyrophosphates as a result of steric constraints and strong elec-
 trostatic repulsion. In addition to InsP6-derived diphosphates, in-
ositol species derived from the pyrophosphorylation of InsP6 and
InsP5 have also been observed while triphosphate-containing
InsP6 species have not been ruled out, implying an overall
more diverse ensemble of high energy inositols than first sus-
pected (44).

The enzymatic capacity for the synthesis of diphosphory-
lated inositols has so far been attributed to a single class of
InsP6-kinases conserved across the evolutionary spectrum.
Indeed the InsP6-kinases, along with IPMK and Ins1,4,5P3
3-kinases, define a single, highly related, conserved family with
representative members identified in every eukaryotic genome
studied thus far. Surprisingly, studies examining the occurrence
of this kinase family in some of the “earliest” eukaryotes suggest
InsP6-kinases may be founding representatives as exemplified in
the Giardia genome, which contains a single InsP6-kinase (45).
Along with IPMK and Ipk1, the IPK3-kinase (denoted Kcs1 in
yeast) completes the list of identified inositol polyphosphate ki-
nases in the yeast genome. InsP6-kinase can mediate the produc-
tion of both InsP6 and InsP5 as well as diphosphate derivatives of
InsP5 and InsP6 (46, 47). However deletion studies in yeast
(as well as the absence of a clear paralog in plants, although
they contain IPMK) suggest additional enzymes—including an
InsP6-kinase capable of inositol pyrophosphorylation may ex-
ist (48, 49). It is worth noting that at least in vitro mammalian
and yeast IPMK have also been shown to generate inositol
diphosphates (35).

As yeast contains only a single InsP6-kinase (mammals
contain three isoforms), much of what we know regarding
the functional roles of inositol diphosphates is the result of
loss-of-function studies in the kas1 yeast mutant. Expanding on roles suggested for InsP6 in vesicle formation and endocytosis, in yeast, InsP3, InsP7, and InsP8 seem to regulate vesicular trafficking. Loss of Kas1 results in altered vacuolar morphology with the appearance of smaller fragmented vacuoles and the accumulation of membranous, vesicular structures as a result of aberrant endosomal processing (50). Inositol diphosphates also likely complement the transcriptional regulatory roles of InsP6–InsP8 in phosphate metabolism. InsP6-kinase was in fact identified as a cDNA stimulating inorganic phosphate uptake into Xenopus eggs (51). Furthermore, yeast deficient in inositol diphosphate synthase’s lack polyphosphate synthesis/storage (52). Recently, a remarkable role for inositol diphosphates in telomere length maintenance was revealed by studying ipk1-deficient yeast (49, 53). Telomeres consist of chromosomal caps of long, repetitive DNA sequences that prevent nucleolytic degradation and protect more internal coding sequences from chromosomal shortening associated with cell division. In the absence of InsP6, InsP7-kinase can use InsP6, which accumulates in yeast in the absence of ipk1. As a result, in ipk1-deficient yeast, the products of InsP6 pyrophosphorylation, PP-InsP7, and (PP)2-InsP8 also accumulate to levels not observed in wild-type yeast and in fact exceed concentrations normally observed for InsP7 [PP-InsP7] and InsP8 [(PP)2-InsP8]. When compared with wild-type yeast, ipk1-deficient yeast displays shortened telomere length, whereas yeast deficient in InsP6-kinase activity display increased telomere length, which suggests inositol diphosphates (increased in ipk1-deficient yeast and absent in kas1-deficient yeast) negatively regulate telomere extension. Although the mechanism for these effects remains unknown, inositol diphosphates may target the regulatory actions of phosphatidylinositol 3-kinase-related kinases (protein kinases of evolutionary relatives to PI3Ks) known to be involved in telomere length maintenance (44). While the functional significance for inositol diphosphates observed in yeast is likely to be conserved in mammalian cells, the roles for InsP6, InsP7, and InsP8 in mammalian physiology are more difficult to study because of the presence of three isoforms of InsP6-kinase with distinct subcellular distributions. In mammals, several lines of evidence suggest inositol diphosphates regulate cell death/apoptosis (54) and are dynamically regulated in response to environmental stress (48). As is the case for other inositol polyphosphates, binding allosteric mechanisms for inositol diphosphates’ functional identity have also been proposed, although it must be noted that binding partners must demonstrate significant specificity to allow for meaningful regulation by InsP6–InsP8 within the cellular context of the much more abundant InsP6. In D. discoideum, where the levels of InsP6/InsP8 rival those of InsP6, evidence for the specific regulation by inositol diphosphates of PH-domain lipid binding (analogous to that suggested for InsP1,2,4,5,PK discussed above) has revealed a role in both InsP6 and InsP8-dependent chemotaxis (55). However, the high energy potential of the β-phosphates in inositol diphosphates suggests unique functionality for this class of inositol polyphosphates beyond allosteric competition. Indeed, early characterization of InsP6-kinase demonstrated its capacity for ATP formation in the reverse by transferring a β-phosphate from InsP6 to ADP (56). More recently, Snyder and associates have demonstrated the occurrence of likely more functionally significant acceptors of the high energy β-phosphates than ADP: proteins (57). InsP6 seems to physiologically phosphorylate a variety of protein targets, although its activity seems restricted to eukaryotes. Identification of specific targets in yeast suggested a phosphorylation consensus sequence consisting of an acidic, polyserine stretch interspersed with aspartate or glutamate residues. Such stretches proved to be excellent CK2 (formerly casein kinase-2) substrates. However, careful characterization of the process has demonstrated InsP6-mediated phosphorylation to be quite distinct from ATP/kinase-mediated phosphorylation. In contrast to ATP, InsP6 does not require separate protein kinases but directly phosphorylates its targets in a nonenzymatic and temperature-dependent reaction. Nevertheless, protein kinases such as CK2 are indeed critical for the process but function only to “prime” targets. The significance of kinase-mediated pre-phosphorylation/priming and its requirement for InsP6-mediated nonenzymatic phosphorylation has only recently been elucidated. Biochemical characterization of phosphorylated substrates suggests the chemical nature of InsP6-phosphorylated serines is quite distinct from canonical phospho-serines. In a dramatic twist to protein phosphorylation, InsP6-mediated phosphorylation is in fact serine pyrophosphorylation (R. Bhandari and S.H. Snyder, personal communication). Although the physiologic roles of this novel posttranslational modification need to be evaluated, serine pyrophosphorylation likely expands on the already well-defined roles of canonical protein phosphorylation in modifying protein conformation, regulating catalytic activity, determining protein localization, or altering protein–protein interactions. Experiments assessing these possibilities are currently underway.

Perspective

As the most recently identified members of the inositol polyphosphate family, inositol diphosphates have already complex and universal signaling network. Although they have been known for more than 20 years since the discovery of Ins(1,4,5)P3 as a second messenger, much of the functional and cell signaling roles of most inositol polyphosphates remains poorly understood. Nevertheless it is clear that inositol polyphosphates serve to dynamically organize, regulate, and orchestrate nearly all aspects of cell biology (Fig. 3). Full elucidation of their complex metabolism and roles will likely necessitate the development of better and less laborious analytic methods for the evaluation/identification of their dynamic regulation as well as methods to track their subcellular localization. Although such tools (as well as pharmacologic inhibitors) exist for their lipid counterparts, the inositol polyphosphates have lagged behind, in part because of their greater complexity. Nevertheless, the molecular identification and cloning of the inositol polyphosphate kinases (and phosphatases) achieved in the last decade has allowed for the generation of new experimental/genetic models. Although preliminary characterizations of these have confirmed inositol polyphosphates’ preeminent importance in cell biology
and physiology, they have also revealed how much more we have yet to learn.

Although every effort was made to cite relevant original research, unavoidable omissions because of space constraints exist, for this, the authors apologize. More complete descriptions and referencing of original sources can be found under “Further Reading.”

Integrin Signaling, Bidirectional-Signaling of
Xiaoyang Wu and Jun-Lin Guan, Cornell University, Ithaca, New York
doi: 10.1002/9780470048672.wecb253

Integrins are a large family of heterodimeric receptors that mediate the adhesive behavior of cells. Most integrins bind to extracellular matrix (ECM) molecules, and they transmit signals that are critical in growth, development, tissue homeostasis, and host defense. A central feature of these receptors is their ability to transduce bidirectional signals into and out of the cell. In this article, we will give an overview of our current understanding of the structure and cellular signaling functions of integrins.

An amazing feature of life is that cells, the tiny units of an organism, can develop such elaborate molecular systems to sense all kinds of environmental information and translate it into various cellular responses to survive. The extracellular matrix (ECM) is composed of a complex mixture of polysaccharides and large fibrous proteins such as fibronectin, collagen, and laminin. ECM serves as a key environmental cue for cells in multicellular organisms, because many fundamental cellular processes, including proliferation, survival, migration, and differentiation, are regulated by the cells’ adherence to the ECM and the composition of the ECM (1, 2). In the 1980s, integrins were recognized as the major metazoan receptors for the ECM (3). Ever since, intensive efforts have been made to unravel its complex functions as an important signal transducer. Importantly, the underlying structure–activity relationships have also started to be elucidated by resolving the high resolution three-dimensional (3-D) structure of integrins. It is now widely appreciated that integrins serve as a pivotal module to mediate a bidirectional signal transduction, namely outside-in and inside-out signaling pathways (4). Upon engagement of ECM ligands, integrins make transmembrane connections to cytoskeleton and regulate many intracellular responses through the outside-in signaling. Conversely, intracellular signaling pathways can modulate integrin-mediated cell adhesion to ECM via the inside-out signaling. In this article, we summarize recent progress in this area by discussing the bidirectional signaling of integrins.

Integrin Family (An Overview)

A functional integrin is a heterodimeric protein complex consisting of an α and β subunit. So far, the mammalian integrin family consists of 8 β subunits and 18 α subunits, which are known to assemble into 24 distinct integrins (Fig. 1). The different combination of subunits accounts for heterodimer specificity, with certain integrins showing preference for particular ECM molecules (4–6). Each subunit has a large extracellular domain, a single transmembrane (TM) segment, and a short cytoplasmic tail (with the exception of β4). The N-terminal portion of the α and β subunits associate to form the headpiece, which contains the ligand-binding site, whereas the C-terminal segments traverse the plasma membrane and mediate interaction of the integrin with the cytoskeleton and other signaling molecules. Hence, the exterior and interior of a cell are physically linked by integrins, which allows the bidirectional transmission of mechanical and biochemical signals across the plasma membrane, and leads to a cooperative regulation of cellular functions, including adhesion, migration, growth, survival, and differentiation.
Most integrins bind to ECM components. The ECM is a complex network of polysaccharides and proteins with high molecular weight, such as laminins, collagens, vitronectin, and fibronectin, and with the basement membrane. It has also been demonstrated that the ECM sequesters growth factors and plays a critical role in the differentiation and growth of various cell types. Integrins containing the $\alpha_2$, $\alpha_5$, $\alpha_6$, or $\alpha_{10}$ subunits recognize the RGD (Arg-Gly-Asp) motif of ECM components, namely fibronectin and vitronectin (4–6). Although laminins and collagens also contain the same RGD sequences, they are normally cryptic and inaccessible to the integrin receptors. Instead, these ECM proteins are recognized by integrins containing the $\alpha_2$, $\alpha_5$, and $\alpha_{10}$ subunits (laminin-binding receptors) or the $\alpha_1$, $\alpha_2$, $\alpha_3$, and $\alpha_{13}$ subunits (collagen-binding receptors).

In addition to serving as ECM receptors, some integrins (e.g., integrins of hematopoietic cells) can bind to counter-receptors on other cells, such as intercellular adhesion molecules (ICAMs) and the vascular cell adhesion molecule-1 (VCAM-1) (7). Integrins of hematopoietic cells also recognize plasma proteins that are deposited at sites of injury (e.g., fibrinogen or von Willebrand factor) and complement factors. Other ligands of integrins include inhibitors of platelet aggregation that are secreted by endothelial cells, such as intercellular adhesion molecules (ICAMs) and the vascular cell adhesion molecule-1 (VCAM-1) (7).

Integrin Regulation of Outside-In Signaling

Integrins recognize positional cues encoded by the ECM and convert them into biochemical signals that control a wide spectrum of cellular behaviors. ECM binding to integrins leads to integrin clustering and recruitment of actin filaments and signaling molecules to the cytoplasmic domain of integrins (4). These specialized, cell adhesion organelles and signaling centers are named focal complexes (nascent adhesion structures) or focal adhesions (FA; fully formed, mature adhesion structures). It has been demonstrated that more than 20 different important signaling proteins are recruited to the ECM-integrin-binding site. Because of the length limit of this article, we will only focus on the role of the MAPK (mitogen-activated protein kinase) pathway, FAK, ILK, and Rho family small G proteins in mediating the outside-in signaling of integrin (summarized in Fig. 2).

MAPK Pathway

Activation of the MAPK pathway provides a common route leading to transcriptional regulation of genes that are crucial for cell-cycle progression and differentiation (10). In a classic model, activation of Ras via growth factor receptors (GRFs) leads to sequential stimulation of the protein kinases Raf, MEK, and, finally, the MAP kinases Erk1 and Erk2. It is now well established that, in addition to growth factors, many normal cells require adhesion to the ECM to proliferate (11). Without cell adhesion to ECM, soluble mitogens alone cause a transient and relatively modest activation of Erk. On the other hand, integrin-mediated adhesion also causes a weak activation of Erk in cells deprived of growth factors. Transient activation of Erk is not sufficient to promote transcription of Cyclin D, but it induces transcription of the CDK inhibitor p21 (12).

Several signaling proteins involved in this pathway have been found in focal adhesion complexes. Based on current understanding, integrin signaling activates ERK through two major mechanisms: the SFK (Src Family Kinase)/FAK pathway, which is activated by most, perhaps all, integrins (will be discussed in detail later); and the SFK/Shc pathway (15), which is activated by a subset of integrins through the transmembrane segment of their $\alpha$ subunits. Both pathways are required for efficient joint integrin/GFR signaling to ERK, as supported by the effect of mutations that inhibit either one of the two pathways (16–18). The $\alpha$-subunit-dependent SFK/Shc signaling is necessary and sufficient for activation of ERK in several cell types (18, 19). Shc is an adapter protein containing SH2 and a phosphotyrosine binding (PTB) domain, which links tyrosine-phosphorylated signaling molecules to Ras (15). Upon binding to activated receptors, Shc is phosphorylated on tyrosine, which serves as a binding site to the G-b2mSOS complex. This process leads to the juxtaposition of the GTP exchange factor domain of mSOS to Ras, and it subsequently activates Ras. In addition, recent results indicate that Shc is also a potent PI3K/Akt activator (20).

In hematopoietic cells, phosphorylated Shc recruits p85b2 through Grb2. Gab2 in turn recruits the regulatory subunit of PI3K, which leads to PI3K activation.

In addition to the Shc-mediated response, some integrins may directly cooperate with GFRs. For example, the $\alpha_5\beta_3$ integrin receptor has been found to uniquely associate with insulin receptor substrate 1 (IRS-1), which is a cytoplasmic signaling transducer of the insulin and insulin-like growth factor receptors (IGFRs) (21). IRS-1 is tyrosine phosphorylated by the activated IGFR and subsequently binds to a variety of signaling molecules. In cells that have adhered to ECM, such as vitronectin through the $\alpha_5\beta_3$ integrin, a subset of IRS-1 binds to the integrin. This interaction substantially enhances the growth-stimulating function of insulin and IGF. In another example, a 190-kDa protein that is tyrosine phosphorylated as a result of PDGF receptor activation also binds to $\alpha_5\beta_3$ receptor, which suggests that there could be cooperation between this integrin and the PDGF signaling pathway (22).

Previous studies have also shown that engagement of $\alpha_5\beta_3$ integrin can induce tyrosine phosphorylation of EGFR (epidermal growth factor
Integrin Signaling, Bidirectional-Signaling of

Integrin receptors relay signals from ECM to regulate a wide spectrum of cellular processes, including migration, cell cycle, survival, and cell differentiation. (Please see text for details of the outside-in signaling of integrins.)

Integrin-mediated adhesion not only activates ERK but also JNK (25–27). JNK is another member of the MAPK family, which is activated by stress stimuli, such as UV-radiation, hyperosmolar conditions, and inflammatory cytokines (28). After activation, JNK translocates into the nucleus and phosphorylates the transcription factor c-Jun, thereby activating c-Jun-dependent transcription (29). c-Jun activation plays an indispensable role in initiation of DNA synthesis (30). Thus, cells derived from mice lacking JNK1 and JNK2 or c-Jun display defective proliferation (31, 32). Integrins can activate signaling to JNK in the absence of a significant contribution from GFRs. α6β4 can activate JNK through Shc and a downstream pathway involving Ras, PI3-K, and Rac (25), whereas β1 and αv integrins signal to JNK through the FAK/Cas/Rac pathway (27, 33). In addition, the β2 integrins are associated with JAB1, a coactivator of c-Jun. Upon their association, a subset of JAB1 moves to the nucleus and transactivates c-Jun-dependent transcription (34). The existence of multiple mechanisms of integrin-dependent regulation of c-Jun further highlights the importance of this pathway in integrin signaling.

FAK

Early studies on integrin-mediated cell adhesion and signaling demonstrated that cell adhesion to the ECM was accompanied by integrin aggregation, and that this clustering could trigger increased tyrosine phosphorylation of various intracellular proteins (35). As integrins lack intrinsic tyrosine kinase activity, proteins in the integrin/ECM-binding site (focal adhesions) were dissected carefully to identify potential tyrosine kinases that could mediate this signaling event. Interestingly, a predominant protein in focal adhesions, which was shown to undergo rapid tyrosine phosphorylation after integrin ligation and clustering, is a 120-kDa nonreceptor tyrosine kinase known as FAK (25, 36, 37). FAK lacks SH2 and SH3 domains, but contains an N-terminal FERM domain, a central kinase domain, and a C-terminal focal adhesion targeting (FA T) domain (38, 39). Direct association of FAK and integrin cytoplasmic tails has been demonstrated (40). However, the role of this direct interaction remains unclear. The integrin-binding site in FAK was mapped to the region N-terminal to the central kinase domain; however, this region is not required for localization of FAK to focal adhesions. Instead, the C-terminal FAT domain of FAK (43) and also interacts with vinculin and thereby paxillin (42). Thus, the recruitment of FAK to activated integrin clusters could be indirect.

A tempting model has been proposed that, upon recruitment to focal adhesion complexes, FAK undergoes conformational change and interacts through its amino terminal domain with the integrin cytoplasmic tail (43–45). The amino terminal domain of
FAK could fold back onto the kinase domain and play a negative autoregulatory role. Thus, this conformational change may be a prerequisite for FAK’s catalytic activity. The phosphorylation of FAK then initiates a cascade of phosphorylation events and new protein–protein interactions. Phosphoryrosine 397 serves as a binding site for Src family kinases via the SH-2 domain (46–48). Conversely, it has also been shown that tyrosine 925, which creates a binding site for the Grb2–mSOS complex, resulting in activation of MAPK (50, 53).

The two major substrates of SFKs at focal adhesions are p130CAS and paxillin. CAS associates with FAK through the SH3 domain of CAS and the proline-rich motif at FAK C terminus (52). CAS contains a C-terminal proline-rich segment, through which it interacts with the SH3 domain of Src and likely other SFKs, and a large substrate domain, which contains several phosphoryrosine sites mediating the interaction with adaptor proteins, such as Crk and Nck (53). Crk associates with DOCK180 in many cells (54). DOCK180 is the mammalian counterpart of C. elegans gene, ced-5, which is involved in the regulation of phagocytosis and cell migration in nematode (55). Overexpression of DOCK180, along with CAS and Crk, can stimulate membrane ruffling, which is a hallmark of Rac activation. Crk also binds to the GTP exchange factor (GEF) C3G, which activates the Ras-related small G protein Rap1 (56, 57). Rap1 in turn reinforces integrin adhesion to the ECM by an inside-out activation mechanism (58–60). Additionally, because B-Raf is a target of Rap1 and, like other Raf isoforms, promotes signaling to Erk, C3G/Cas signaling at focal adhesions results in activation of Erk in cells that express B-Raf (16).

Paxillin is phosphorylated by SFKs at Tyr 31 and 118 and can recruit Crk as CAS (61). Furthermore, paxillin can associate with Csk, which suppresses SFKs (62), and PTP-PEST (63), which can dephosphorylate CAS (64). Thus, paxillin could potentially participate in a negative feedback loop. Paxillin also associates with p120CA as GAP (GTPase-activating protein) and prevents it from binding to and suppressing p190RhoGAP (65). Therefore, paxillin may inhibit Rho activity during the initial phase of cell adhesion. Furthermore, paxillin is associated with a complex containing the adaptor Pkl, the GEF Pia/Coid, and the Cdc42/Rac target-effector PAK, and it may play a role in linking Cdc42 and Rac to PAK and its downstream targets, such as LIMK and MLCK (66, 67). Lastly, paxillin can recruit the Abl tyrosine kinase from the nucleus to focal adhesions upon integrin ligation (68). At focal adhesions, Abl phosphorylates Ena/VASP proteins, thus regulating actin cytoskeleton (69). Phosphoryrosine 397 of FAK associate with the SH2 domain of p85 subunit of PI3-K (70). This direct interaction could activate PI3-K and thus promote cell survival. The same residue on FAK also mediated association with other proteins containing SH2 domain, including p130 Ras GAP, PLCγ, and GRB7 (71–73). In addition, FAK contains two proline-rich motifs at the C-terminal portion, which mediates interaction with various SH3-domain-containing proteins, such as CAS, Graf, ASAP1, and Endophilin A2 (74–77). N-terminal region of FAK has also been shown to associate with signaling proteins, such as N-WASP (78). Thus, FAK can relay the integrin signaling to affect a wide variety of pathways, which in turn regulate various cellular processes, including growth, survival, differentiation, and migration. In addition to the study on in vivo cell culture systems, the analysis of FAK knockout mice has provided important insight into the biological function of FAK in vivo. Constitutive as well as tissue-specific knockout of FAK have implicated it in many physiological and pathological processes, ranging from embryonic development, angiogenesis, and cortical basement membrane assembly or remodeling to tumorigenesis in skin, and heart hypertrophy (79–84).

ILK

ILK was identified by yeast two-hybrid screen for proteins that could bind to the cytoplasmic tail of integrin (85). The N-terminal domain of ILK contains three ankyrin repeats, which mediate protein interactions, and a putative fourth ankyrin repeat that lacks some conserved residues. The C-terminal portion shares significant sequence homology to Ser/Thr protein kinases. A pleckstrin homology (PH) domain is situated between these two domains. It is now widely accepted that ILK functions as the central component to organize a heterotrimeric protein complex named IPP (ILK, PINCH, and Parvin) complex (86, 87). ILK binds PINCH through the N-terminal ankyrin-repeat domain and parvins through the kinase domain. ILK may also link the IPP complex to the cytoplasmic tails of integrins. The IPP complex functions both as an adaptor between integrins and the actin cytoskeleton and as a hub that regulates various signaling pathways. It remains controversial whether ILK is a real protein kinase. The kinase domain of ILK shows significant homology to Ser/Thr protein kinases, except residues within the catalytic loop and the conserved DFG motif (88). Thus, ILK lacks a conventional catalytic base and Mg2+–chelating residues. However, recombinant, purified ILK has been shown to be able to phosphorylate several substrates in vitro (89–91), including GSK3β and AKT, which regulate many different signaling pathways. It is well established that AKT activation requires phosphorylation of Thr at position 308 by phosphatidylinositol 3-kinase (PI3-K) and this notion is further supported by immunoprecipitation assays showing that ILK directly binds to AKT (90). However, it is not clear whether ILK possesses sufficient activity to function as a physiologically relevant kinase in vivo. The function of the IPP complex as a signaling platform could be achieved mainly through its interaction with other proteins. Many IPP functions are consistent with a role for the IPP complex at focal adhesions, for example, the regulation of podocyte adhesion and spreading (92), platelet aggregation (93, 94), neuronal spreading and outgrowth (95, 96), and leukocyte recruitment (97) all support the notion that the IPP complex regulates actin–cytoskeleton dynamics and integrin activation in focal adhesions. As mentioned, ILK binds directly to the cytoplasmic tails of integrins (98), and it is connected to the actin
cytoskeleton through its interaction with parvins (98). Interactions with the cytoskeleton can also be mediated by the adaptor protein paxillin, which binds to ILK through a paxillin-binding site (PBS) within the kinase domain of ILK. Paxillin binds to F-actin via interactions with α-parvin and the actin-binding adaptor molecule vinculin (61, 98, 99). In addition, ILK binds to the LIM5 domain of PINCH1, but not PINCH2. In addition, PINCH1, but not PINCH2, associates with Thymosin-β1 through the LIM domains -4 and -5 of PINCH1 (106). This interaction can increase ILK activity and positively influences migration and survival of cardiac cells. PINCH1 also binds to NCK2, an adaptor protein in vitro through a LIM4-3H3-domain (Src-homology-3 domain) interaction (107, 108). However, the physiological relevance of this interaction is not clear. α-Parvin can bind to F-actin directly. It also associates with paxillin, which could further bridge it with actin cytoskeleton. HIC5, a paxillin-related protein, also associates with α-parvin (98). Interestingly, HIC5 shuts to the nucleus, where it modulates the expression of several genes (109, 110). Furthermore, α-parvin significantly binds to TESK1, a Ser/Thr kinase that phosphorylates coflin (111). β-Parvin can bind to the actin-cross-linking protein α-actinin and the guanine nucleotide-exchange factor α-Pix (112). It therefore provides a connection between the IPP complex and the Rho family GT-Pases, Rac1, and Cdc42. α-Pix, in turn, binds to PAK1 (114), a Rac/Cdc42 effector that regulates cytoskeletal dynamics. Furthermore, α-Pix can associate with the protease subunit calpain-4 (115). Calpain-4 has been shown to cleave talin, which serves as the rate-limiting step in the disassembly of focal adhesions (116).

Cytoskeleton and Rho Family Small GT-Pase

The initial study from Alan Hall's group described that addition of serum or LPA stimulates the formation of stress fibers and focal adhesion in serum-starved Swiss 3T3 cells, which retain only a few stress fibers and are devoid of focal adhesions (117-120). Later, it was found that the induction of cortical actin assemblies and formation of focal adhesions can be ascribed to the action of different Rho family proteins. Rho family proteins are Ras-related small GT-Pases consisting of Rho A, B, C, D, and E; Rac1, 2, 3, and 6; and Cdc42, Rho G, and TC10 (121). It is now well established that Rho is involved in the organization of focal adhesions and stress fibers; Rac is responsible for the membrane ruffling and extension of lamellipodia; and Cdc42 controls the formation of filopodia (121).

In addition to the growth factor receptors, Rho family members can also be activated by integrins. During adhesion and spreading on an ECM, cells develop filopodia and lamellipodia, which are regulated by Cdc42 and Rac, respectively. Integrin-mediated adhesion can activate Cdc42 and Rac (122). Like other small GT-Pases, Rho family protein is active when GDP-bound and inactive when GTP-bound. Activation of Rho proteins is catalyzed by GEFs and inactivation is induced by GAPs that stimulate the intrinsic GT-Pase activity of the Rho proteins. Vav2, a hematopoietic cell-specific GEFT, is activated upon integrin engagement (123). However, the closely related GEFT Vav3, which is widely distributed, is activated downstream from growth factor receptors but not from integrins (124, 125). Nevertheless, a dominant-negative mutant of Vav2 blocked lamellipodium formation and spreading on fibronectin, suggesting that Vav2 plays a role in Rac activation after integrin engagement (126). Furthermore, integrins may activate Rac through other pathways. P130cas and paxillin associate with FAK, and both of them have been linked to Rac activation. As mentioned above, tyrosine phosphorylation of p130cas promotes the formation of the focal complexes consisting of Crk, DOCK180, and ELMO (127). DOCK180 can function as a Rac GEF, even though it lacks the Dbl-homology/pleckstrin-homology tandem domains characteristic of conventional Rho family GEFTs (127, 128). Paxillin associates with another complex consisting of PKL/GIT and Pak-interacting exchange factor (PIX), the latter being a conventional Rac GEF (161). Interestingly, recent work demonstrated that, in addition to their effect on GTP loading, integrins independently control the translocation of active Rac to the plasma membrane (129). This step is required for Rac binding to its downstream effectors. Integrins can increase membrane affinity for Rac, leading to RhogD1 disassociation and effector coupling locally, in the vicinity of integrins. Furthermore, integrin-regulated Rac binding sites are within cholesterol-enriched membrane microdomains or lipid rafts. Integrins control Rac signaling by preventing the internalization of Rac-binding sites in lipid rafts. Regulation of Rho A activity by integrins is more complicated. It has been shown that integrin engagement leads to a transient depression in RhoA activity, followed by activation (130). The depression could play an essential role in lamellipodial extension during cell migration (131). The mechanism for this depression is not completely understood, but it may involve Src, FAK, paxillin, and p190RhoGAP (64, 65, 132, 133). However, different integrins may initiate different response of Rho A activity. Engagement of α6β4 resulted in stimulation of RhoA activity, in contrast to the depression induced by clustering of β1 integrins (134). Overexpression of β3 integrin in CHO cells resulted in a pronounced increase in Rho-GTP levels when the cells were plated on fibronectin or fibrinogen, whereas β1 integrin overexpression had no effect (135). In contrast, re-expression of β1 subunits in β1-deficient cells stimulated RhoA activity, whereas β3 had no effect (136). This controversy could be due to the differences of cell types used in these two studies. Rho family proteins serve as important mediators for integrin outside-in signaling, integrin clustering and focal complex

Regulation of Integrin Through Inside-Out Signaling, a Structural View

As the signals that are transduced by integrins from the outside of the cell to the inside were being elaborated, parallel investigations on the regulation of integrin affinity revealed that information also flowed in the opposite direction—from integrin cytoplasmic tails to the extracellular ligand-binding domain, usually named the “inside-out” signaling of integrin. This process was actually described even before the molecular definition of integrins. Bennett and Vilaire found that the binding of platelets to fibrinogen is subject to regulation by agonists (165). It was then shown that this regulation was not dependent on the recruitment of receptors to the surface, rather on an increase in the binding activity of the receptor, and that leukocyte adhesion receptors were subjected to a similar regulation of ligand-binding affinity (166, 167). After cloning of integrins, it became clear that most leukocyte and platelet integrins, including β₂-containing integrins, exist in a resting state until activated, and that a variety of agonists could regulate this process (4, 6). The physiological relevance of this regulation is obvious. It prevents the spontaneous adhesion of platelets and leukocytes within the circulation or to the blood vessel wall, but allows the rapid response upon injury.

Earlier studies using biophysical approaches and antibodies that specifically recognize the activated state of integrins demonstrated that their activation involves alterations in integrin conformation (168-172) and that the cytoplasmic tails of leukocyte adhesion receptors were subjected to a similar regulation of integrins. Bennett and Vilaire found that the binding of platelets to fibrinogen is subject to regulation by agonists (165). It was then shown that this regulation was not dependent on the recruitment of receptors to the surface, rather on an increase in the binding activity of the receptor, and that leukocyte adhesion receptors were subjected to a similar regulation of ligand-binding affinity (166, 167). After cloning of integrins, it became clear that most leukocyte and platelet integrins, including β₂-containing integrins, exist in a resting state until activated, and that a variety of agonists could regulate this process (4, 6). The physiological relevance of this regulation is obvious. Therefore, although 

conserved phosphotyrosine-binding domain (PTB)-like interac-
tion (176). Overexpression of talin fragments containing this
PTB-like domain activates integrins, whereas knocking down
talin expression with small interfering RNAs or sequestration of
talin blocks α1 and β3 integrin activation in different cells (175,
177). Furthermore, mutations in conserved residues in talin or
the integrin β tail that disrupt their interaction prevent activa-
tion (175). Thus, the binding of the talin PTB-like domain to the
integrin β tail serves as a common step in integrin activation.

The conserved membrane-proximal portions of integrin α and
β subunits and cytoplasmic tails control integrin activation. Mutation or trun-
cation of this region results in constitutive integrin activation
(178). Furthermore, replacement of the region by heterodimeric
coiled-coil peptides or a covalent cross-linking of the tails in-
activates integrins, whereas breaking the coiled-coil or the co-
valent bond activates them (179). It has been proposed that
the membrane-proximal regions of α and β cytoplasmic tails
associate through a salt bridge between a conserved Arg in
the α tail and an Asp in the β tail, thereby keeping the in-
tegrin heterodimer in an inactive state (178). The talin head
domain can disrupt the salt bridge formed between α1β1-Arg596
and β3-Asp723 (180) (Figure 3). Therefore, talin binding may
activate an integrin by disrupting a “clasp” between the α and
β cytoplasmic tails, leading to tail separation and integrin acti-
vation. However, this clasp has not been consistently observed
(179) in structural studies of isolated integrin cytoplasmic do-
 mains, and the interaction between tails was of low affinity.
Therefore, although α and β tail interactions may occur via a
salt bridge, the strength of this interaction appears to be modest.

In addition to the “clasp” model, a “piston” model has been
proposed. In this model, it is the displacement of the membrane-
proximal domain from the membrane that leads to integrin activation by shortening of the TM domain. Integrin cytoplasmic domains contain remarkably conserved sequences consisting of a Trp-Lys (Arg) doublet that is predicted to terminate the TM sequence. This doublet is followed by the membrane-proximal region, a hydrophobic stretch of four or five residues terminated by strongly polar residues, which are hotspots for mutations that activate integrins (181, 182). It has been shown that fragments of talin that activate integrins perturb NMR resonances in the membrane-proximal region, whereas a subdomain of talin that binds to the tail but fails to activate

ulib3 perturbs the NMR resonances to a much lesser extent. In
addition, the ulib cytoplasmic tail, which blocks talin interaction
with the membrane-proximal region of the β3 tail, prevents
ulib3 activation (183). Glycosylation mapping has indicated
that the membrane-proximal domains of the α and β subunits
can reside within the membrane and that certain activating
mutations in this region can displace them from the membrane,
thereby shortening the TM domains (184, 185). Various targeted
and random activating mutants of integrin ulib3 would be
predicted to shorten the TM domain in a similar manner (173,
181, 182, 186). However, studies with isolated ulib and β3
peptides and liposomes suggest that an upward movement
of membrane-proximal helices upon talin binding could contribute
to integrin activation (187). Resolution of this controversy will
require further structural analysis of integrin.

Propagation of the inside-out activation signal across the
plasma membrane is mediated by the TM helices. The TM he-
lies of the inactive, but not active, integrin show a periodic
disulfide cross-linking pattern (188), suggesting that the TM he-
lies specifically interact in the inactive state and that this inter-
action is disrupted upon activation. Many membrane-embedded
activating mutations identified by random and site-directed mu-
tagenesis studies further support this notion (181, 189, 191).
However, the molecular details of these interactions are not
fully understood. Furthermore, CFP and YFP fluorophores fused
to the C-terminus of α and β subunits showed decreased fluores-
cence resonance energy transfer (FRET) upon integrin activation
by a variety of stimuli (191), implying cytoplasmic domain sep-
oration during integrin activation. So the cytoplasmic domain
separation, and therefore TM separation, might be the critical
step in activation. However, another possibility cannot be ruled
out—that mutations of the TM domain might lead to altered ori-
teation of the TM domains instead of actual separation; such
an alteration of orientation is also consistent with the reported
FRET results (191).

A number of key questions concerning the integrin activa-
tion remain unresolved. Although we know that the membrane-
proximal region and TM region of integrins controls the acti-
vation, other mutagenesis results indicate that the C-terminus
membrane distal region of the α or β cytoplasmic tails is also
important in regulating integrin activation via a mechanism that
is yet unknown. Thus, the whole picture for the inside-out acti-
vation of integrins can be substantially more complicated. In addition, there
may exist other proteins besides talin that bind to the cytoplas-
mic tails and that regulate the conformational change required
for integrin activation. The current “clasp” or “piston” model
explains how the alterations of the cytoplasmic tail and TM
region of integrins relieve the structural constraint and allow
the unbending of the extracellular domain to attain the high
affinity ligand-binding state (192). However, a thorough molecu-
lar understanding of integrin inside-out signaling awaits further
structural analysis of the intact receptor in inactive and active
states.
Concluding Remarks

Recent years have witnessed exciting progress in understanding integrin signaling, owing to structural analyses and characterization of proteins that interact with integrins. The role of integrins in vivo has also been revealed by the functional studies of gene-targeted mice (193). Interestingly, despite the fact that the binding of integrin-binding proteins involves a loss of almost any integrin subunit to defects with varying severity in knockout mice, providing the strongest evidence for biological relevance of integrin signaling. However, many molecular details of integrin signaling remain elusive. A number of successful approaches have been carried out to study the integrin interactions at the molecular level. However, findings over the past two decades in this field have led to the development of clinically useful or promising integrin antagonists combating diseases such as cancer, cardiovascular defect, and inflammatory diseases (194). Therefore, a thorough understanding of integrin signaling is likely to lead to even greater opportunities for novel therapies.

The isoprostanes are a unique series of prostaglandin-like compounds formed in vivo via a nonenzymatic mechanism involving the free radical-initiated peroxidation of arachidonic acid. This article summarizes our current knowledge of these compounds. Herein, a historical account of their discovery and the mechanism of their formation are described. Methods by which these compounds can be analyzed and quantified are also discussed, and the use of these molecules as biomarkers of in vivo oxidant stress is summarized. In addition to being accurate indices of lipid peroxidation, some isoprostanes possess potent biological activity. This activity will be discussed in detail. Finally, in more recent years, isoprostane-like compounds have been shown to be formed from polyunsaturated fatty acids, including eicosapentaenoic acid and docosahexaenoic acid. These findings will be summarized as well.

Free radicals, largely derived from molecular oxygen, have been implicated in a variety of human conditions and diseases, including atherosclerosis and associated risk factors, cancer, neurodegenerative diseases, and aging. Damage to tissue biomolecules by free radicals is postulated to contribute significantly to the pathophysiology of oxidative stress. Measuring oxidative stress in humans requires accurate quantification of either free radicals or damaged biomolecules. The targets of free radical-mediated oxidant injury include lipids, proteins, and DNA. Several methods exist to quantify free radicals and their oxidation products, although many of these techniques suffer from lack of sensitivity and specificity, especially when used to assess oxidant stress status in vivo. In a recent multi-investigator study, termed the Biomarkers of Oxidative Stress Study (BOSS), sponsored by the National Institutes of Health, it was found that the most accurate method to assess in vivo oxidant stress is the quantification of plasma and urinary isoprostanes (IsoPs) (1). IsoPs, a series of prostaglandin (PG)-like compounds produced by the free radical-catalyzed peroxidation of arachidonic acid independent of the cyclooxygenase, were first discovered by our laboratory in 1990 (2). Since that time, we and others have shown that levels of IsoPs are increased in several human diseases. Furthermore, several of these compounds possess potent biological activity and thus may be mediators of oxidant injury. In recent years, additional related compounds, derived from various polyunsaturated fatty acids, such as eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), have been discovered to be formed as products of the IsoP pathway. It is the purpose herein to summarize our current knowledge regarding the IsoPs, including their discovery, the chemical biology of their formation, the utility of these compounds as markers of in vivo oxidant stress, and their bioactivity.

### Historical Aspects

In the 1960s and 1970s, it was shown that PG-like compounds could be formed by the autoxidation of purified polyunsaturated fatty acids. Seminal studies by Pryor, Porter, and others (see further reading) led to a proposed mechanism by which these compounds are generated via bicycloendoperoxide intermediates. However, this work was never carried beyond in vitro studies. Furthermore, it was not determined whether PG-like compounds could be formed in biological fluids containing unsaturated fatty acids.

In the 1980s, we showed that PGD_2_ derived from the cyclooxygenase is primarily metabolized in vivo in humans to form 9,11PGD_2_ by the enzyme 11-ketoreductase. In aqueous solutions, however, PGD_2_ is an unstable compound that undergoes isomerization of the lower side chain and these isomers can likewise be reduced by 11-ketoreductase to yield isomers of 9u,11u-PGF_2_. In studies undertaken to further characterize these compounds using gas chromatography (GC)/mass spectrometry (MS), we found that when plasma samples from normal volunteers were processed and analyzed immediately, a series of peaks was detected possessing characteristics of F-ring PGs. Interestingly, however, when plasma samples that had been stored at −20°C for several months were reanalyzed, identical chromatographic peaks were detected but levels of putative PGF_2-like compounds were up to 100-fold higher. Subsequent experiments led to the finding that these PGF_2-like compounds were generated in both freshly processed and stored plasma, not by a COX-derived mechanism, but nonenzymatically by autoxidation of arachidonic acid. Because these compounds contain F-type prostanate rings, they are referred to as F_2-IsoPs.
Formation of the F2-Isoprostanes

A mechanism to explain the formation of the F2-IsoPs from arachidonic acid is outlined in Fig. 1 and is based on that proposed by Pryor for the generation of bicycloendoperoxide intermediates. After abstraction of a bisallylic hydrogen atom and the addition of a molecule of oxygen to arachidonic acid, the peroxyl radical undergoes 5-exo cyclization and a second molecule of oxygen adds to the backbone of the compound to form PGG2-like compounds. These unstable bicycloendoperoxide intermediates are then reduced to the F2-IsoPs. Based on this mechanism of formation, four F2-IsoP regioisomers are generated. Compounds are denoted as 5-, 12-, 8-, or 15-series regioisomers depending on the carbon atom to which the side-chain hydroxyl is attached. An alternative nomenclature system for the IsoPs has been proposed by Rokach et al. in which the abbreviation iP is used for isoprostane and the regioisomers are denoted as III–VI based on the number of carbons between the omega carbon and the first double bond.

Although the initial abstraction of any bisallylic hydrogen atoms of arachidonic acid is equally likely, the different IsoP regioisomers are not formed in equal amounts. When arachidonic acid is oxidized, the 5- and 15-series regioisomers are formed in significantly higher amounts than the 8- and 12-series regioisomers. An explanation for this difference has been elucidated by Yin et al., who demonstrated that the arachidonyl hydroperoxides which give rise to the 8- and 12-series regioisomers readily undergo further oxidation to yield a newly discovered class of compounds that contain both bicycloendoperoxide and cyclic peroxide moieties termed dioxolane-IsoPs (Fig. 2). Overall, 5- and 15-series regioisomers cannot undergo this further oxidation but instead accumulate at higher concentrations in tissues and fluids. A method allowing the separation and quantification of each of the four classes of IsoP regioisomers, as well as their individual stereoisomers, has recently been developed in our laboratory.

An important structural distinction between IsoPs and cyclooxygenase-derived PGs is that the former contain side chains that are predominantly oriented cis to the prostane ring, whereas the latter possess exclusively trans side chains. A second important difference between IsoPs and PGs is that IsoPs are formed in situ esterified to phospholipids and are subsequently released by a phospholipase(s), whereas PGs are generated only from free arachidonic acid.

Quantification of F2-Isoprostanes

Several methods have been developed to quantify the F2-IsoPs. Our laboratory uses a gas chromatographic/negative ion chemical ionization–mass spectrometric (GC/NICI-MS) approach employing stable isotope dilution. For quantification purposes, we measure the F2-IsoP, 15-F2-IsoP, and other F2-IsoPs that coelute with this compound. Several internal standards are available from commercial sources to quantify the IsoPs. In our
Isoprostanes

assays, we typically use either $[^{2}H_4]$-15-F$_2$-IsoP ($[^{2}H_4]$-8-iso-PGF$_{2\alpha}$) or $[^{2}H_4]$-PGF$_{2\alpha}$ as internal standards. The advantages of mass spectrometry over other approaches include its high sensitivity and specificity, which yields quantitative results in the low picogram range. Its drawbacks are that it is labor intensive and requires considerable expenditures on equipment.

Several alternative mass spectrometric assays have been developed by different investigators, including Rokach et al. (4, 7, 8). Like our assay, these methods quantify F$_2$-IsoPs using stable isotope dilution GC/MS and require solid-phase extraction using a C18 column, thin layer chromatography (TLC) purification, and chemical derivatization. These assays, however, measure F$_2$-IsoP isomers other than 15-F$_2$-IsoP, but they are comparable with ours in terms of utility. In addition to these GC/MS assays, several liquid chromatographic (LC) MS methods for F$_2$-IsoPs have been developed. One advantage of LC/MS methods is that the sample preparation for analysis is simpler than that for GC/MS because no derivatization of the molecule is required. The method reported earlier this year by Taylor et al. is the first of these LC/MS methods to be validated for quantitation of 15-F$_2$-IsoPs in biological fluids (9). In this assay, a gradient reverse-phase LC tandem mass spectrometric approach is used to separate several 15-series IsoP stereoisomers for quantitation with $[^{2}H_4]$-PGF$_{2\alpha}$ as the internal standard. The outcomes of this assay correlated significantly with GC/MS results, and the coefficients of variation in the measurements were lower for their LC/MS assay than for their GC/MS assay. The authors thus suggest that this LC/MS method potentially offers greater precision than existing methods while allowing for the quantitation of more compounds with simpler sample preparation.

Alternative methods have also been developed to quantify IsoPs using immunological approaches (6, 10). A number of antibodies have been generated against 15-F$_2$-IsoP, and at least three immunoassay kits are commercially available. Although mass spectrometric methods of IsoP quantification are considered the best methods for analysis, immunoassays have expanded research in this area due to their low cost and relative ease of use. Only limited information is currently available regarding the precision and accuracy of immunoassays. In addition, little data exist comparing IsoP levels determined by immunoassay with MS, though Wang et al. offers one example of an MS-validated immunoassay (11) out laboratory’s experiments have not validated the commercial available kits. Analogous to immunological methods to quantify cyclooxygenase-derived PGs, immunoassays for IsoPs suffer from a lack of specificity. Furthermore, the sensitivity and/or specificity of these kits vary substantially between manufacturers.

**F$_2$-Isoprostanes as an Index of Oxidant Stress In Vivo**

The true utility of the F$_2$-IsoPs is in the quantification of lipid peroxidation and thus oxidant stress status in vivo. F$_2$-IsoPs are stable, robust molecules and are detectable in all human tissues and biological fluids analyzed, including plasma, urine, bronchoalveolar lavage fluid, cerebrospinal fluid, and bile (6). The quantification of F$_2$-IsoPs in urine and plasma, however, is most convenient and least invasive. And, based on available data, quantification of these compounds in either plasma or urine is representative of their endogenous production and thus gives a highly precise and accurate index of in vivo oxidant stress. Although measurement of F$_2$-IsoPs in plasma is indicative of their endogenous formation at a specific point in time, analysis of these compounds in urine is an index of systemic or “whole-body” oxidant stress integrated over time.
is important to note that the measurement of free F2-IsoPs in urine can be confounded by the potential contribution of local IsoP production in the kidney. In light of this issue, we have identified the primary urinary metabolite of 15-F2t-IsoP to be 2,3-dinor-5,6-dihydro-15-F2t-IsoP, and we have developed a highly sensitive and accurate mass spectrometric assay to quantify this molecule. However, the extent to which 15-F2t-IsoP is converted to the urinary metabolite remains unclear. Nevertheless, the quantification of 2,3-dinor-5,6-dihydro-15-F2t-IsoP may represent a truly noninvasive, time-integrated measurement of systemic oxidation status that can be applied to living subjects.

Normal levels of F2-IsoPs in healthy humans have been defined (6, 12, 13). Defining these levels is particularly important in that it allows for an assessment of the effects of diseases on endogenous oxidant tone and allows for the determination of the extent to which various therapeutic interventions affect levels of oxidant stress. Elevations of IsoPs in human body fluids and tissues have been found in a diverse array of human disorders, some of which include atherosclerosis, hypercholesterolemia, diabetes, obesity, cigarette smoking, neurodegenerative diseases, and rheumatoid arthritis. Furthermore treatments for some of these conditions, including antioxidant supplementation, treatments, cessation of smoking, and even weight loss, have been shown to decrease production of F2-IsoPs. Thus, the clinical utility of F2-IsoPs has been great and continues to grow. For manuscripts and comprehensive reviews on IsoP detection in human disease, please refer to the Further Reading Section.

**Biological Activities of the F2-IsoP Prostanoids**

In addition to being robust markers of tissue oxidant stress, F2-IsoPs can exert potent biological activity and potentially mediate some adverse effects of oxidant injury. As mentioned, IsoPs are initially formed in vivo esterified to glycerophospholipids. Molecular modeling of IsoP-containing phospholipids reveals them to be remarkably distorted molecules. Thus, the formation of these abnormal phospholipids would be expected to exert profound effects on membrane fluidity and integrity, well-known sequelae of oxidant injury. All studies exploring their bioactivity, however, have been performed using unesterified IsoPs. Recent studies by Stafforini et al. have shown that F2-IsoP hydrolysis from phospholipids is regulated, at least in part, by the platelet-activating factor (PAF) acylethanolamides I and II (14).

One particular F2-IsoP that is produced abundantly in vivo and has been extensively tested for biological activity is 15-F2t-IsoP (8-iso-PGF2α), which differs from cyclooxygenase-derived PGF2α, or in the inversion of the upper side-chain stereochemistry. This IsoP has been found to be a potent vasoconstrictor in a variety of vascular beds, including the kidney, lung, heart, and brain. In addition, 15-F2t-IsoP induces endothelin release and proliferation of vascular smooth muscle cells. There is also additional evidence that this molecule can increase resistance to aspirin inhibition of platelet aggregation in platelets as well as inhibit platelet aggregation in human whole blood. These vasoactive effects of 15-F2t-IsoP have been shown to result from interaction with the thromboxane receptor, a G-protein-coupled transmembrane eicosanoid receptor, based on the finding that these effects can be abrogated by thromboxane receptor antagonists.

The testing of other F2-IsoPs for biological activity has been limited. It has been shown, however, that 15-F2t-IsoP (12-iso-PGF2α) activates the PGF2α receptor and induces hypertropy in cardiac smooth muscle cells.

**Formation of Isoprostanes with Alternative Ring Structures**

Since the initial discovery of the F2-IsoPs, our laboratory has shown that the IsoP pathway provides a mechanism for the generation of various classes of IsoPs from arachidonic acid, which differ in regard to the functional groups on the prostane ring. In addition to undergoing reduction to yield F2-IsoPs, the arachidonyl endoperoxide intermediate can undergo isomerization to yield E- and D-ring IsoPs (Fig. 3), which are isomeric to PGE2 and PGD2, respectively. 15 E2/D2-IsoPs are formed competitively with F2-IsoPs, and recent studies have demonstrated that the depletion of cellular reducing agents, such as glutathione (GSH) or α-tocopherol, favors the formation of E2/D2-IsoPs over that of reduced F2-IsoPs. Importantly, depletion of GSH and α-tocopherol occurs in various human tissues under conditions of oxidant injury, including the brains of patients with Alzheimer’s disease (AD). Thus, the ratios of F-ring to E/D-ring IsoPs in postmortem brain tissues from patients with AD were examined, and not only were levels of both E2/D2- and F2-IsoPs significantly elevated, but also E2/D2-IsoPs were the favored products of the IsoP pathway in affected brain regions. This increased ratio of E2/D2-IsoPs to F2-IsoPs provides information not only about lipid peroxidation in a given organ but also about the reducing environment in that tissue.

E2/D2-IsoPs, however, are not terminal products of the IsoP pathway. These compounds readily dehydrate in vivo to yield A2J2-IsoPs (Fig. 3), which are also known as cyclopentenone IsoPs because they contain an α,β-unsaturated cyclopentenone ring structure (16, 17). A2J2-IsoPs are highly reactive electrophiles that readily form Michael adducts with cellular thiols, including those found on cysteine residues in proteins and glutathione. These cyclopentenone IsoPs are rapidly metabolized in vivo by glutathione transferase enzymes to water-soluble modified glutathione conjugates. The major urinary cyclopentenone IsoP metabolite in rats, a 15-A2J2-IsoP mercapturic acid sulfoxide conjugate, was recently identified in our laboratory 18.

The chemical reactivity of cyclopentenone IsoPs suggested that these compounds might be biologically active. The recent synthesis of two cyclopentenone IsoPs regioisomers, 15-A1-isoP and 15-J1-isoP, has allowed us to examine their bioactivity. Studies employing primary cortical neuronal cultures demonstrated that both 15-A1-isoP and 15-J1-isoP potently induce neuronal apoptosis and exacerbate neurodegeneration caused by other insults at concentrations as low as 100nM (19).
veal that 15-A2-IsoPs potently suppress lipopolysacharide (LPS)-induced inflammatory signaling via inhibition of the NF-κB pathway (20). 15-A2-IsoPs abrogate inducible nitric oxide synthase and cyclooxygenase-2 expression in response to LPS, as well as the elaboration of several pro-inflammatory cytokines. Similar anti-inflammatory effects were observed with 15-J2-IsoPs. However, 15-J2-IsoPs also activate the peroxisome proliferators activated receptor-gamma (PPARγ) with an EC50 of approximately 3 μM. This receptor modulates a wide variety of biological processes, including inflammatory signaling and fatty acid metabolism. 15-J2-IsoPs also induce macrophage apoptosis at low micromolar concentrations in a PPARγ-independent manner. Thus, there is a diversity of actions among cyclopentenone IsoP isomers. It seems that these compounds could act as negative-feedback regulators of the inflammatory response, because oxidative stress and lipid peroxidation often occur under conditions of chronic inflammation.

Formation of Isoprostanes from Other PUFAs

A rachidonic acid is not the only polyunsaturated fatty acid that can be oxidized to generate IsoPs. The basic requirement for cyclization to occur is the presence of at least three double bonds. F-ring IsoPs have been shown to be generated from the peroxidation of linolenic acid [C18:3, ω-3, F3-IsoPs] (21), EPA [C20:5, ω-3, F5-IsoPs] (22), and DHA [C22:6, ω-3, F6-IsoPs] or F4-neuroprostanes (NPs) (23). Similar to the distribution of F2-IsoP regioisomers, certain F3-IsoP and F4-NP regioisomers are more abundant than others (24). The 5-series and 18-series F3-IsoPs are the most abundant because the 8-, 12-, and 15-series compounds can further oxidize (unpublished data). Analogously, the 4-series and 20-series F4-NPs are formed in the largest amounts. In addition to F-ring compounds, E- and D-ring as well as A- and J-ring, or cyclopentenone, IsoPs are generated from the oxidation of EPA (unpublished data) and DHA.

In recent years, emerging evidence has implicated increased dietary intake of fish oil, which contains large amounts of EPA and DHA, as being beneficial in the prevention and treatment of several diseases, including atherosclerotic cardiovascular disease and sudden death, neurodegeneration, and various inflammatory disorders. Furthermore, recent data have suggested that the anti-inflammatory effects and other biologically relevant properties of ω-3 fatty acids are due, in part, to the generation of various bioactive oxidation products (25, 26). We thus hypothesized that EPA- and DHA-derived IsoPs could contribute to the beneficial biological effects of fish oil supplementation. Indeed, one report states that the EPA-derived IsoP, 15-F2t-IsoP, possesses activity that is different from 15-F2t-IsoP in that it does not affect human platelet shape change or aggregation. The lack of activity of 15-F2t-IsoP is consistent with observations regarding EPA-derived PGs in that these latter compounds exert either a weaker agonist or no effects in comparison with arachidonic acid-derived PGs.

Interestingly, our laboratory has recently shown that the levels of these compounds generated from the oxidation of EPA significantly exceeded those of F2t-IsoPs generated from arachidonic acid, perhaps because EPA contains more double bonds and is therefore more easily oxidizable. Additionally, in vivo in mice, levels of F2t-IsoPs in tissues such as heart were virtually undetectable at baseline but supplementation of animals with EPA markedly increased quantities up to 27.4 ± 5.6 ng/g heart. But, of particular note, we found that EPA supplementation markedly reduced levels of arachidonate-derived F2t-IsoPs by up to 64% (p < 0.05). Furthermore, in a recent small clinical trial, termed the K.A.N.W.U. study, of 162 healthy men and women, plasma F2t-IsoP levels significantly decreased (by as much as 29%) after 3 months of supplementation with 3.6-g/day fish oil (27). Together these observations are significant because F2t-IsoPs are generally considered to be pro-inflammatory molecules associated with the pathophysiological sequelae of oxidant stress (28–31). It is thus intriguing to propose that part of the mechanism by which EPA prevents certain diseases is its ability to decrease F2t-IsoP generation. In addition, it suggests that supplementation with fish oil may be of benefit to populations associated with increased levels of F2t-IsoPs.

Conclusions

The discovery of the IsoPs as products of nonenzymatic lipid peroxidation has been a major breakthrough in the field of free radical research. The quantification of these molecules has opened up new areas of investigation regarding the role of free...
radicals in human physiology and pathophysiology, and it seems to be the most useful tool currently available to explore the role of lipid peroxidation in the pathogenesis of human disease. Our understanding of the IsoP pathway continues to expand, providing new insights into the nature of lipid peroxidation in vivo, and revealing new molecules that exert potent biological actions and might serve as unique indices of disease. Basic research into the biochemistry and pharmacology of the IsoPs, coupled with clinical studies employing these molecules as biomarkers, should continue to provide important insights into the role of oxidant stress in human disease.

Large G-Proteins

David P. Siderovski, Adam J. Kimple and Francis S. Willard, University of North Carolina at Chapel Hill, North Carolina
doi: 10.1002/9780470048672.wecb219

Large G-proteins, also known as heterotrimeric G-proteins, cycle through inactive (GDP-bound) and active (GTP-bound) states, thereby coupling the activation of cell-surface receptors to the modulation of various second messengers and intracellular effector proteins. High-resolution structures of the constituent subunits of the heterotrimer (G\text{α}, G\text{β}, and G\text{γ}) have revealed the determinants involved in heterotrimer assembly and effector protein engagement as well as the mechanism of nucleotide hydrolysis by the G\text{α} subunit and its acceleration by “regulator of G-protein signaling” (RGS) proteins. Mechanistic details have also been gleaned from studies of G-protein modulation by pathogen toxins and chemicals such as aluminum tetrafluoride. Recent identification of peptide-binding “hotspots” on G-protein subunits should facilitate discovery and design of new chemical entities that can modulate nucleotide cycling and receptor/effector coupling at the level of the G-protein heterotrimer.

A wide variety of extracellular signaling molecules, such as hormones, neurotransmitters, growth factors, tastants, and odorants, communicate their information via binding and activating cell membrane-bound receptors and thus eliciting changes in various intracellular processes. The largest class of such receptors, the superfamily of seven-transmembrane, G protein-coupled receptors (GPCRs), has been an attractive target historically for discovery of small molecule therapeutics. GPCRs remain the largest single fraction of the druggable proteome, with GPCR-targeted drugs continuing to have annual sales in the tens of billions of dollars worldwide [1]. Thus considerable effort has been made over the past few decades to establish a complete mechanistic understanding of how GPCRs communicate extracellular signals into the cell, in the hopes of elucidating the mechanism of action of existing therapeutics as well as facilitating new modalities of GPCR-directed drug discovery/design (beyond the receptor/ligand binding interface per se). The precise structural determinants of GPCR-mediated G-protein activation on binding activating ligand remain enigmatic; however, the mechanisms by which heterotrimeric G-proteins couple receptor activation to modulation of intracellular processes are now known in great detail.

Background

As their name suggests, G protein-coupled receptors link ligand binding to intracellular changes functionally via their engagement of three distinct proteins (G\text{α}, G\text{β}, and G\text{γ}) known collectively as the G-protein heterotrimer [Fig. 3]. The G\text{α} subunit of the heterotrimer is the bona fide G-protein that binds guanine nucleotides in one of two states: guanosine 5′-diphosphate (GDP) when in the inactive, heterotrimeric state (i.e., complexed with G\text{β} and G\text{γ}) and guanosine 5′-triphosphate (GTP) when in the activated state. An activating ligand binds its respective GPCR and changes the conformation of the receptor’s transmembrane regions and intracytosolic loops to activate the receptor’s guanine nucleotide exchange factor (GEF) activity on the G\text{α} GDP/G\text{βγ} complex. Receptor-catalyzed exchange of GTP for the bound GDP within G\text{α} leads to release of bound G\text{βγ}, and subsequent, engagement of a- and bγ-effector proteins by GTP-bound G\text{α} and the now-freed G\text{βγ}-heterodimer.

Four general classes of G\text{α} subunits have been defined based on their functional couplings (in the GTP-bound state) to various effectors [Fig. 4]. G\text{α}-subfamily G\text{α} subunits are stimulatory to membrane-bound adenylyl cyclases that generate the second messenger 3′-5′-cyclic adenosine monophosphate (cAMP); cellular adenylyl cyclase activity can be stimulated directly (i.e., in the absence of G\text{βγ} heterotrimer activation) by forskolin, a plant-derived diterpene. Conversely, G\text{βγ}-subfamily G\text{α} subunits generally are inhibitory to adenylyl cyclases. G\text{βγ}-subfamily G\text{α} subunits are potent activators of phospholipase-C\text{β} enzymes that catalyze breakdown of the cell membrane lipid constituent phosphatidylinositol-4,5-bisphosphate into the second messengers diacylglycerol and inositol triphosphate, which leads to transient increases in intracellular calcium content. The G\text{βγ} subunits released by activated G\text{βγ} heterotrimers are also known to stimulate the activity of phospholipase-C\text{ζ} enzymes, as well as to modulate adenylyl cyclase activity, to activate phosphatidylinositol-3′ kinase and inward-rectifying potassium channels, and to inhibit calcium channel current (reviewed in...
Reference 2). G_{12/13}-subfamily G_{α} subunits activate the small G-protein RhoA through stimulation of RhoA-specific GEFs such as p115-RhoGEF, LARG, and PDZ-RhoGEF.

G_{α} subunits from all four subfamilies have the intrinsic ability to hydrolyze bound GTP to GDP and inorganic phosphate (Fig. 1). This intrinsic GTPase activity can be accelerated dramatically by the GTPase-accelerating proteins (GAPs) specific to G_{α} subunits: namely, the “regulator of G-protein signaling” (RGS) proteins (3). α–Effectors can also exhibit GAP activity [e.g., phospholipase-C_{β} activity in accelerating GTP hydrolysis by G_{α}q (4)]. GTP hydrolysis controls the timing of signal duration, as the loss of the third phosphate reverts the G_{α} back to the GDP-bound state with characteristic high affinity for G_{βγ} and low affinity for α–effectors. Hence, the root mechanism for coupling receptor activation to the modulation of intracellular processes is a cycle of GTP binding and GTP hydrolysis transacted by the G_{α} subunit of the G-protein heterotrimer.

Structures

X-ray diffraction crystallography has been the main technique employed to establish the structures of GDP-bound G-proteins (both as isolated G_{α} subunits and G_{αβγ} heterotrimeric complexes; Table 1), as well as activated states of G_{α} induced either by the binding of the nonhydrolyzable GTP analog guanosine 5'-γ-thiotriphosphate (GTPγS) or by the addition of aluminum tetrafluoride (AlF_{4}–) to GDP-bound G_{α} subunits. These efforts have unveiled the precise secondary and tertiary structures of both G_{α} and G_{βγ} (Figs. 2 and 3) (5), how the heterotrimeric complex is formed by these two binding partners, the conformational changes that are induced within G_{α} by the exchange of GDP for GTP (Fig. 2b), and the mechanisms of both intrinsic (Fig. 4) and RGS protein-accelerated GTP hydrolysis (6–8).

Large G-Proteins

G$\beta$ and G$\gamma$ subunits form tightly associated heterodimers (Fig. 3). G$\beta$ begins with an extended N-terminal $\alpha$-helix and is composed mainly of a $\beta$-propeller fold formed by seven individual segments of a ~40-amino-acid sequence known as the WD-40 repeat. G$\gamma$ is an extended stretch of two $\alpha$-helices joined by an intervening loop. Assuming no significant ter-

The particular conformations of these three switch regions are critical to the protein–protein interactions that $G_{\alpha}$ makes with its nucleotide-selective binding partners such as G$\beta$-$G_{\alpha}$ effectors, RGS proteins, and GoLoco motifs (6, 8). Mechanism of Guanine Nucleotide Hydrolysis

The mechanism of GTP hydrolysis by Gα, as well as RGS protein-mediated acceleration of this hydrolysis, has been discerned from x-ray diffraction crystallographic structures of the Gα transition state-mimetic form (Gα bound to GDP and AlF₄⁻), both in isolation and bound to the archetypal RGS protein RGS4 (7, 18), as well as hydrolysis reaction intermediates including Gα bound to guanosine 5′-(β,γ-imido)triphosphate (GppNHP) or GDP plus inorganic phosphate (19, 20). The GTP hydrolysis reaction is mediated by three conserved Gα amino acids (Fig. 4; residues numbered as found in Gαi1). Glutamine-204 in switch II coordinates the critical nucleophilic water molecule responsible for hydrolysis of the γ-phosphate, whereas arginine-178 and threonine-181 (both from switch I) help to stabilize the leaving group (as mimicked by the planar anion AlF₄⁻), with the latter coordinating a bound Mg²⁺ ion (18). These three residues within Gα are both necessary and sufficient for GTP hydrolysis to GDP and inorganic phosphate; thus, the mechanism of action of RGS proteins, the GTPase-accelerating proteins (GAPs) specific for Gα subunits, necessarily differs from those of the GAPs for small G-proteins that introduce an additional catalytic residue in trans (e.g., Reference 21). Instead, RGS protein binding to Gα stabilizes the transition state conformation, which lowers the activation energy required for the hydrolysis reaction (7, 22).
The γ subunit is subjected to posttranslational geranylgeranylation, which mimics the phosphate leaving group in the hydrolysis reaction, is highlighted in sticks configuration. The relative positioning of the N-terminal α-helix of the Gα subunit (often in the Gα-GDP/Gαi-heterotrimeric complex) is also highlighted. Coordinates are from PDB record 1OMW.

The causative agent of the Black Plague, Yersinia pestis, harbors several essential virulence determinants that it injects into host cells. One protein, the serine/threonine kinase YpkA, inactivates Gαi activation by phosphorylating serine-47, a residue located in the highly conserved diphosphate-binding loop of Gα (Fig. 4i, which impairs GTP binding (26). Although it is not a toxin, YM-254890, a cyclic depsipeptide identified from Chromobacterium sp. Q53666 culture broth that blocks ADP-induced platelet aggregation, is also an inhibitor of signaling from Gα11-containing heterotrimers, albeit with an unresolved mechanism of action potentially related to effects on receptor-catalyzed nucleotide exchange (27). Conversely, Pasteurella multocida, a common cause of animal infections, produces a toxin (PMT) that activates specifically Gα12 and not Gα11. Although the differential responsiveness of these two

**Figure 4** Residues within Gα that are critical to the GTP hydrolysis mechanism include arginine-178 and threonine-181 from switch I and glutamine-204 from switch II (colored as in Fig. 2 and numbered as in Gα11; coordinates are from PDB record 1GFI). Magnesium ion is highlighted in yellow. The planar anion aluminum tetrafluoride, which mimics the phosphate leaving group in the hydrolysis reaction, is depicted in metallic red. Note the position of serine-47, the target of ADP-ribosylation of arginine-178 within Gα. As mentioned previously, the planar anion aluminum tetrafluoride, which is used experimentally to activate Gα, is also an inhibitor of receptor-catalyzed nucleotide exchange (27).

**Figure 3** Overall structural fold of the Gαi heterodimer. The Gα subunit is colored to highlight the seven WD40 repeats that comprise the β-propeller (or "torus") fold: WD1, green; WD2, purple; WD3, cyan; WD4, orange; WD5, grey; WD6, red; WD7, blue. Residues within Gβ that contact the Gαiα2-binding peptide SIGK, which constitutes the Gβ-1 "hotspot" as defined by Bocaccio et al. (5), are highlighted in light green. The cysteine residue within Gγ (red) that is subjected to posttranslational geranylgeranylation is highlighted in sticks configuration. The relative positioning of the N-terminal α-helix of the Gα subunit (often in the Gα-GDP/Gαi-heterotrimeric complex) is also highlighted. Coordinates are from PDB record 1OMW.
particular mechanism of G\(\alpha_q\) activation by PMT has not yet been determined.

G protein-binding peptides reveal mechanistic insights and “hotspots” for chemical intervention

Using various random-peptide screening strategies, several groups have recently identified linear polypeptide sequences that bind to heterotrimeric G-protein subunits in unique and informative ways (5, 13, 29, 30). One example is KB-1753, a 10-amino acid peptide derived from bacteriophage screening (29) with selective binding affinity for G\(\alpha\)-subclass G\(\alpha\) subunits in their activated form (either GTP\(\gamma\)S or GDF AIF\(\gamma\)S-bound); KB-1753 can block \(\alpha\)-effector and RGS protein binding to these two activated G\(\alpha\) states. Its structural determination by X-ray crystallography (12) was instrumental in highlighting a universal site of effect/G\(\alpha\)-GTP engagement (as described above). A second peptide derived from the same screen, KB-752, has selective binding affinity for G\(\alpha\)-subclass G\(\alpha\) subunits in their inactive (GDP-bound) form. On binding, it enhances the rate of spontaneous GDP release; structural determination of a K\(B\)-752/G\(\alpha\) GDP complex by X-ray crystallography (29) provided strong support for a prevailing model of receptor-catalyzed nucleotide exchange in which the \(\alpha\)2 loop of G\(\alpha\), normally an occlusive barrier to GDP release, is remodeled by receptor-mediated binding of the G\(\alpha\) dimer (10).

The 36-amino acid GoLoco motif, a naturally occurring, G\(\alpha\) GDP-binding peptide sequence found in several G-protein regulators such as GoS12 and GoS14, exhibits the opposite biochemical activity to that of KB-752: namely, guanine nucleotide dissociation inhibitor (GDI) activity (i.e., reducing the rate of spontaneous GDP release) (12). Whole-cell electrophysiological studies of GPCR coupling to ion channel modulation have established that GoLoco motif-derived peptides are useful tools to uncouple heterotrimeric G-protein signaling, but they have no intrinsic ability to activate directly G\(\alpha\)-dependent signaling per se (31). By the use of mRNA display, Ja and Roberts (30) screened a set of semi-randomly permuted peptide sequences based on the GoLoco motif and identified a family of R\&A peptides (including a minimal 9-amino-acid sequence called R\&A-1) that interact with G\(\alpha\) bound GoS subunits in a manner competitive to G\(\alpha\) binding partners via engagement of switch II (13, 29, 32). Identifying this particular region of G\(\alpha\) as a “hotspot” potentially amenable to targeting by small molecules for future chemical modulation of G\(\alpha\) function. That peptides can define binding hotspots on G\(\alpha\) proteins targets has already been exploited successfully by Bonacci et al. (5) for the G\(\alpha\)phr heterodimer. Using bacteriophage display, this group identified four distinct groups of G\(\alpha\)phr-binding peptides that, despite divergent sequences, were found to bind the same site on G\(\alpha\)phr—a site identified previously in mutagenesis studies as critical to \(\alpha\)-effector interactions. A crystal structure of G\(\alpha\)phr bound to one of these peptides (SIGK) was determined by this group, which revealed a partial α helical conformation of the SIGK peptide reminiscent of that adopted by switch II of G\(\alpha\) within the G\(\gamma\)1b heterotrimer.

Small molecules that modulate the function of G-protein subunits and their regulators

Bonacci et al. (5) identified several G\(\alpha\)phr-binding compounds using the G\(\alpha\)phr/SIGK interface obtained by X-ray crystallography as the basis for computational docking screens of virtual compound libraries (5). One lead compound from this virtual screening, (S,S)-2-(3,4,5-trihydroxy-6-oxoxanthen-9-yl)cyclohexane-1-carboxylic acid (or “M119”; Fig. 5a), possesses several in vitro and in vivo activities consistent with sterol blockage of the G\(\gamma\)1b hotspot, which includes inhibition of G\(\gamma\)1b-mediated PLC\(\gamma\)2 activation and chemotactic-activated calcium signaling in immune cells, as well as sensitization of mice to the antinociceptive effects of morphine, an activator of the \(\mu\)-opioid GPCR. In a screen for compounds that can inhibit cholesterin-stimulated (but not forskolin-stimulated) cAMP accumulation in intact cells, Pelvod et al. (35) identified an imidazo-pyrazine derivative, 2-amino-1-(2-cyclohexyl)-8-(cyclohexylmethyl)-6,8-dihydro-5H-imidazo(2,1-c)pyrazin-7-yl-3-sulfanyl-propan-1-one or (“BIM-46174”) as a pan-inhibitor of heterotrimeric G-protein signaling that emanates from G\(\alpha\), G\(\beta\), and G\(\gamma\)-coupled GPCRs as well as Frizzled receptors (33). As this screen was conducted using a library of cysteine-related compounds designed originally as farnesyltransferase inhibitors, one likely mechanism of action of BIM-46174 is alteration of the G\(\gamma\)-isoprenylation that is critical to proper heterotrimeric membrane targeting and receptor coupling. Statin drugs are used clinically to reduce serum cholesterol; this class of compounds also exerts pleotropic, cholesterol-independent effects, which include the reduced production of isoprenoids because statins inhibit the rate-limiting enzyme (HMG-CoA reductase) in the mevalonate pathway. At least one statin, atorvastatin, has been found to affect β-adrenergic signaling in isolated cardiac myocytes by reducing G\(\gamma\) isoprenylation and thus decreasing the amount of functional G\(\alpha\)G\(\gamma\) heterotrimers at the cell membrane (34).

Another promising venue for developing chemical modulators of G-protein function is the G\(\gamma\)/RGs protein interface. With a chemical genetics approach that employs the egg-laying behavior of the nematode Caenorhabditis elegans, Fitzgerald et al. (35) identified two G\(\alpha\)-subunits (G\(\alpha\)-1/G\(\alpha\)-30/G\(\alpha\)-30/G\(\gamma\)-1) and an R\(\gamma\)-proteins (EAT-16) as the molecular targets for two related inhibitors of rat bladder muscle tone and spontaneous contractions [BMS-192364, BMS-195270; Fig. 5a]. A model of trapping a G\(\alpha\)-GTP/R\(\gamma\) protein pair in an unproductive complex, similar to the action of brefeldin A on the ARF1/G\(\gamma\)1/2/SIGK interface obtained by X-ray crystallography (36), has been proposed for the mechanism of action of BMS-192364 and BMS-195270 (33); however, no in vitro biochemistry has yet been published to support this model directly. Neubig et al. (37) used a flow-cytometry-based protein interaction assay to identify methyl-1-(4-chlorophenyl)sulfanyl)-1-nitrobenzene (MNS-
doate (CCG-4986) as a selective inhibitor of RGS4 (and not the related RGS protein RGS8). However, it has been shown subsequently that the selective nature of CCG-4986 lies in its mechanism of action—namely, covalent modification of surface-exposed cysteine-free thiols (Fig. 5b), which include cysteine-132 present in the Gα-interacting surface of RGS4, but not RGS8 (38). Placing this cysteine within RGS8 by site-directed mutagenesis engenders sensitivity to CCG-4986 inhibition. Along with earlier evidence that subtle changes in the Gα/RGS protein interface can lead to loss of RGS protein-mediated GAP activity (37), the precedence established by the early RGS protein inhibitors BMS-192364, BMS-195270, and CCG-4986 supports the notion that these particular G-protein regulators will be valuable drug discovery targets in the future (3). In addition, continued identification of peptide-binding “hotspots” on G-protein subunits, akin to recent Gβ1γ2/SIGK peptide and dopamine receptor loop/Gαi1 crystal structures (5, 39), should facilitate the rational design or discovery of direct chemical modulators of heterotrimeric G-protein action.

Mathematical Modeling of Biological Signaling Networks

Jason M. Haugh, North Carolina State University, Raleigh, North Carolina
doi: 10.1002/9780470048672.wecb646

Intracellular signaling networks, which are composed of interconnected biochemical pathways, regulate and actuate responses such as cell-cycle progression and cell migration, survival, and differentiation. Although our knowledge of the intricate biochemical mechanisms at the level of individual proteins and molecular interactions is ever expanding, those details leave us with an even murkier view of how the complex network operates as a whole. True understanding requires knowing not only what happens at the molecular level but also how these mechanisms influence the precise magnitude, timing, and spatial localization of signal transduction processes. Hence, mathematical modeling and analysis has emerged in recent years as a legitimate approach for interpreting experimental results and generating novel hypotheses for additional study and model refinement. Once conducted in isolation and scorned by most biologists, quantitative modeling has moved into the mainstream as a powerful tool for the analysis of cell signaling. In this article, the biological, chemical, and physical underpinnings of this approach are presented, as are its current applications and future challenges.

Biological research has been focused increasingly on the basis for cell regulation and function at the molecular level, and as a result, we now have a detailed map of how intracellular molecules are organized to form signal transduction pathways and cascades (Fig. 1). The “protein jungle,” as articulated by Bray a decade ago (1), is characterized by a wealth of qualitative information about the connectivity of pathways (the so-called interactome) but relatively little in the way of quantitative measurements. For example, one might wish to know how some meaningful quantity, such as the activity of a particular enzyme, changes as a function of time and stimulus in a given cell type. A quantitative assay could be developed for measuring that quantity. Understanding those kinetics fully, however, would require detailed knowledge of the underlying regulation mechanisms, of which several typically exist. Reconstructing those mechanisms in a test tube, in most cases, is prohibitively difficult, as is their systematic manipulation in the cell. Ultimately, the regulatory mechanisms would have to be characterized in terms of equilibrium and rate constants and intracellular concentrations. Finally, it would be useful to develop a correlation between the magnitude and timing of that pathway and the quality of cellular responses, such as rates of proliferation and probability of survival. Even if obtaining such a data set were feasible, it is not obvious how one would analyze it and extract useful insights and predictions from it.

This article deals with the mathematical modeling of signal transduction pathways and networks, which has emerged as a powerful tool that can aid in interpreting such quantitative data sets. In principle, quantitative models offer three advantages over the conceptual “arrow diagrams” that are encountered routinely in the signaling literature. First, a consequence of their mathematical construction is that they are precise, and the inherent assumptions may be laid out clearly. Second, to the extent that the underlying molecular biology is known, quantitative models can be mechanistic. Mechanistic models are based on established physico-chemical principles, in which case the form of the model equations is determined to a significant extent by the hypothetical mechanisms assumed. Thus, it is possible to evaluate the relative merits of different candidate mechanisms by comparison with experiment. In contrast with mechanistic models, phenomenological models are meant only to capture experimentally observed relationships in an empirical way. They naturally are less powerful, but they serve a definite and useful role and are appropriate in situations in which the underlying mechanisms are less certain. A prominent example is the sort of statistical, correlative models central to the field of bioinformatics; although such approaches
Receptor–ligand interactions and receptor dynamics

Receptors are responsible for transmitting information about the external environment to the cell interior, and therefore their mechanism of activation and action must be well characterized before the details of the intracellular networks can be analyzed and modeled mathematically. In most cases, receptor activation is induced by the noncovalent binding of a specific ligand. Expression of the cognate receptor, typically existing at copy numbers of 10^2–10^4 per cell, is tantamount to the ability of a cell to respond to the ligand, and thus chemical ligands signal specific cell types. Most ligands are soluble and diffusible, and such ligands are termed growth factors, cytokines, hormones, or agonists depending on the type of receptor engaged and/or the response elicited. Other ligands are associated with the extracellular matrix or other cells and mediate cell–matrix adhesion and cell–cell interactions, respectively, in addition to signaling functions. In many cases, ligation induces receptor dimerization or oligomerization as a prerequisite for signal transduction. For example, it is well established that receptor tyrosine kinases (RTKs), receptors that engage certain growth factors in a variety of cell types, must dimerize for their intrinsic enzymatic activity to phosphorylate specific tyrosine residues in the cytoplasmic portion of each receptor. The decoration of the receptor with phospho-tyrosine provides a scaffold for the recruitment of a host of signaling enzymes (4).

Receptors and receptor–ligand complexes on the cell surface are not static. Their lateral mobility in the plasma membrane enables receptor dimerization, as described above, but another critical aspect of receptor dynamics is receptor trafficking, whereby components of the plasma membrane are internalized, delivered to intracellular compartments called endosomes, and sorted either for recycling back to the cell surface or for enzymatic degradation (5). Thus, differential sorting of activated and inactive receptors provides a mechanism for regulating the number of cell surface receptors in response to chronic ligand exposure, a process called receptor downregulation, and can contribute to the clearance of external ligands over time. Typically, activated receptors are internalized at a faster rate and their intracellular sorting fate depends on the persistence of the receptor–ligand interaction in endosomes. Any realistic model of receptor-mediated signal transduction should take into consideration the processes of ligand binding, receptor dimerization or oligomerization, and receptor/ligand trafficking. Receptors that are well characterized, such as the epidermal growth factor receptor, therefore have attracted the most attention from modelers (6).

Modular functions of signaling proteins

Signaling proteins form complexes with other molecules using conserved motifs or domains, which are modular in the sense that the domain by itself typically is sufficient for its function (7, 8). Protein-protein interaction domains include those responsible for binding to phosphorylated receptors and other tyrosine-phosphorylated proteins (Src homology 2 and phospho-tyrosine binding domains) or to proline-rich protein...
sequences (Src homology 3 domains); other domains are responsible for interactions with lipids (pleckstrin homology, FYVE, C1, and C2 domains). Together, these domains mediate the formation of multimolecular complexes that regulate the activities and mediate the targeting of signaling enzymes. Many signaling enzymes have a handful of such domains, whereas other signaling proteins called adaptors have no enzymatic function but possess domains that mediate the binding of enzymes to signaling complexes. From the standpoint of modeling, this complexity presents a definite challenge.

Physical organization and compartmentalization of signaling processes

Cells are not simply well-mixed reaction vessels, and cell structure plays a critical role in signal transduction. Besides its obvious barrier function, the physical properties of the plasma membrane and other cell membranes are particularly important. In the inner leaflet of the plasma membrane, certain lipids such as phosphatidylinositol’s and phosphatidylcholine are substrates for signaling enzymes and can be hydrolyzed to form soluble and membrane-associated products or phosphorylated to yield other lipids with second-messenger functions. In signal transduction pathways that do not involve lipid modification reactions, typically a lipid-tethered protein is involved, such as small GTPases of the Ras and Rho families. Given the near ubiquity of biochemical reactions and interactions that occur at cell membranes, it is clear that aspects of both surface and solution chemistry should be considered when formulating models of signaling processes.

In modeling interactions at cell membranes, it is important to consider the mobility of the membrane-associated molecules, which is affected by the fluidity of the membrane bilayer. Often it is assumed that the membrane is isotropic and homogeneous in that respect, at least macroscopically; however, it has long been appreciated that the plasma membrane is organized into ordered and disordered subcompartments (9). Low-density microdomains, including lipid rafts and caveolae, have been found to be enriched with certain receptors, lipids, and lipid-tethered proteins that are involved in signaling, but their role in facilitating and/or regulating signal transduction remains controversial (10, 11). Even in the bulk, disordered plasma membrane, single-molecule imaging has revealed complex molecular mobility dynamics consistent with “hop” diffusion across corral-like barriers (12). These and other aspects of cell membrane organization increasingly have brought signal transduction into the realm of biophysics.

Beyond the distinctions between signaling processes that occur at the plasma membrane and in the cell cytoplasm, certain other intracellular compartments may need to be considered. As a prominent example, the signaling competency of internalized receptors has been studied for 2 decades (13, 14). Some receptor–ligand complexes remain active in endosomes and signal through certain pathways but not others, whereas other complexes dissociate and cease to signal after the delivery to the endosomes. Other intracellular compartments, such as the Golgi and endoplasmic reticulum, have been found more recently to serve as platforms for certain signaling interactions (15).

Signal Transduction Models: Chemical/Physical Foundations

The premise of molecular biology is that cellular processes are governed by physico-chemical principles, and accordingly, those principles may be used to translate known or hypothetical molecular mechanisms to mathematical equations. In this section, the general principles of chemical kinetics, mass transport, and fluid mechanics used to model chemical reaction systems are reviewed briefly.

Reaction and mass-action kinetics

In chemical kinetics, each molecule type in the system is considered a distinct species and a conservation equation is formulated to account for the change in the amount of each species per unit time. In this context, the system could be a single cell and the species could be cell-associated molecules; different states of a molecule, the simplest distinction being a two-state model (e.g., active versus inactive or phosphorylated versus dephosphorylated), are considered distinct species as are complexes of multiple molecules. The rate of each biochemical reaction or interaction is expressed in terms of the concentrations of the reacting/interacting species, defining the so-called rate law, which appears as a positive or negative term in the corresponding conservation equations depending on whether the transition generates or consumes the conserved species.

In formulating rate laws, it is common to invoke the law of mass action (Fig. 2a). In the biochemical context, this principle applies to only two types of processes: 1) the union of two species (complex formation), the rate defined as the product of both of their concentrations and a bimolecular rate constant, and 2) a spontaneous, unimolecular transition, such as the dissociation of two species from a complex or the covalent modification of a substrate in a complex with an enzyme, which occurs with a constant mean probability per unit time that defines its rate constant. A rate process that follows mass-action kinetics often is termed an elementary reaction, although that definition technically implies specific criteria that generally are not met for reactions in liquids much less for biomolecules. The advantage of mass action kinetics is that the mathematical form of the rate law is dictated by the mechanism, in which case one needs to specify only the values of the corresponding rate constants. For complicated rate processes, a notable example being the action of highly cooperative enzymes, a more abstract rate law that does not reflect the precise mechanism but nonetheless is in quantitative agreement with experimental measurements might be assumed.

Diffusion and mass transport

Biochemical rate processes depend on local species concentrations, which are not necessarily constant. When significant concentration gradients exist, it is appropriate to include a spatial dependence in the conservation equations, which then are
A. Consider the following mechanism for ligand/receptor dynamics: Cell surface receptors (R) are synthesized at a constant rate and bind reversibly with a ligand (L) to form a complex (C). Both free and bound receptors are internalized and later degraded, but they do so at different rates. Based on this mechanism, the law of mass action is used to construct the conservation equations for R and C.

B. Addition of transport effects. In the case of autocrine signaling, the cell is both the source of the secreted ligand and the responder. Spherical geometry is adopted, and a simple reaction/diffusion model is used to calculate the ligand concentration profile at steady state, assuming a dilute suspension of cells and the same receptor dynamics as in A. The profile is given by 

$$ [L] = \frac{[L]_s}{a/r} $$

where 

$$ [L]_s $$ is the value of 

$$ [L] $$ at the cell surface (r = a). It is shown readily that the maximum value of 

$$ [L]_s $$, achieved when no receptor binding exists, is equal to 

$$ \frac{V_L}{D_L} $$, where 

$$ V_L = \frac{V_R}{k_t} $$, and 

$$ D_L $$ are used here.

The actual value of 

$$ [L]_s $$ relative to the maximum is found to be a function of only two dimensionless variables: the ratio of receptor and ligand synthesis rates (equal to 1 for the plotted results) and a parameter that characterizes the efficiency of the receptor-mediated ligand capture (defined as 

$$ \frac{a k_f R_0}{D_L (k_t + k_e) } $$, where 

$$ R_0 = \frac{V_R}{k_t} $$; values of 100, 10, 1, and 0.1 were used here).

Solved in conjunction with appropriate boundary conditions that together specify the problem (Fig. 2b). For a species in solution present at a concentration 

$$ C_i (x, t) $$, where 

$$ x $$ is a spatial position vector (coordinates in 

$$ x, y, z $$) and 

$$ t $$ is time, the conservation equation is represented precisely as follows:

$$ \frac{\partial C_i}{\partial t} = - \nabla \cdot N_i + \sum_j v_{ij} r_j $$

Here, 

$$ N_i $$ is a vector that specifies the outward flux of species 

$$ i $$; thus, taking its gradient (\nabla = \partial/\partial x) and adding a minus sign gives the net rate of species 

$$ i $$ into location 

$$ x $$ by mass transport. The second term accounts for the net generation of species 

$$ i $$ by reactions 

$$ j $$, defined by the aforementioned rate laws 

$$ r_i $$ and stoichiometry coefficients 

$$ v_{ij} $$. Concentrations of species associated with membranes usually are expressed on a per unit area basis, and a planar geometry generally is adopted for the membrane.

For molecules in solution, the flux 

$$ N_i $$ is the sum of two contributions: a convection term that accounts for the bulk flow of the fluid, given by 

$$ v C_i $$ (v is the fluid velocity vector), and a diffusive flux term 

$$ J_i $$ that accounts for the tendency of molecules to disperse in solution. In the cellular context, it is important to note that the convective term also might include consideration of active transport processes, such as those actuated by motor proteins. To proceed, a semi-empirical constitutive equation that relates the form of 

$$ J_i $$ to macroscopic variables must be invoked. The only suitable theory that has been offered in that regard is attributed to Fick, who in 1855 asserted that the net diffusive flux of species 

$$ i $$ is proportional to its gradient in mole fraction; Einstein’s theory of Brownian motion, published 50 years later, is the microscopic analog of Fick’s Law. If species 

$$ i $$ is present in a dilute solution, Fick’s Law reduces to

$$ J_i = -D_i \nabla C_i $$

The diffusion coefficient 

$$ D_i $$ characterizes the mobility of species 

$$ i $$ in solution, determined by the thermal energy that promotes translational motion and the viscous drag force that opposes that motion. Substituting the expression above into the conservation
Fluid mechanics and mechanical forces

Mechanical stress and strain have not been given due consideration in the broad context of cell biochemistry, yet mechanical forces can affect intracellular signaling processes in at least two distinct ways. First, at the level of macroscopic fluid flow, the conservation of fluid momentum determines the velocity field \( \mathbf{v} \), which along with active transport considerations determines the contribution of convective mass transport to the conservation of species \( i \), as discussed in the previous section. Typically, this contribution to the reaction kinetics is neglected. Second, at the microscopic level, mechanical forces might alter directly the functions of macromolecules in prescribed ways, for example by exposing a cryptic binding pocket. This mode of regulation is thought to be at the core of mechanotransduction, which refers to the ability of cells to sense and respond to applied forces (17,18).

Mathematical Modeling Tools and Techniques

Armed with reasonably good knowledge or hypotheses of the underlying biochemistry and the ability to formulate models based on physico-chemical principles, the models must be implemented to obtain and analyze the quantitative results and to generate predictions. Except in very simple, idealized cases, this task requires the use of various numerical methods and tools. In this section, an overview of the various model types and associated methods is offered.

Continuum models

The most common approach in mechanism-based modeling is to model the system as a continuum. The underlying assumption is that the state variables of the system (e.g., species concentrations) vary continuously in time and space and that, therefore, they evolve in a deterministic fashion, according to the aforementioned conservation equations and their initial and boundary constraints. The implementation of such models involves the solution of ordinary and partial differential equations (ODEs and PDEs, respectively). ODEs are commonly encountered in kinetic models of cell signaling systems in which the species concentrations are assumed to be spatially homogeneous within the cell/cell compartment or are averaged over the domain in an appropriate way. In kinetic models of even modest complexity, the ODEs are nonlinear and therefore must be solved using numerical methods. With the advent of efficient, implicit solution algorithms and steadily increasing computing power, handling even large systems of ODEs is straightforward and the integration of these algorithms in various software packages is widespread.

Solution of PDEs, commonly encountered in spatial modeling, is more complicated and computationally intensive by comparison, but several approximate numerical methods are available for this purpose. These include the finite difference, finite volume, and finite element methods, which vary according to their ease of implementation and applicability. The finite element method is the most complicated but generally applicable method for complex domain geometries; numerous software packages that implement this method are available, although the most powerful commercial packages are quite expensive. The freely available and user-friendly virtual cell software environment, which uses the finite volume method, has been used extensively for spatial modeling of intracellular processes (19). Several challenges are encountered in spatial modeling, regardless of the method used. First, the method and the accuracy of its computed results need to be validated. This requirement typically is achieved by testing the method on a simple problem that has an analytical solution for comparison and by confirming that changes in the mesh size and time step do not affect the results significantly. Second, the accuracy of some models that need comprehensive, which is geometric complexity of the model increases from one to three spatial coordinates, and a temptation exists to oversimplify the domain geometry to reduce the dimensionality of the problem. Finally, certain cell biological processes, such as cell motility, demand advanced modeling features such as the coupling of cell mechanics and chemical kinetics and the handling of moving boundaries, which can make the problem computationally prohibitive without the introduction of simplifying assumptions.

Stochastic modeling techniques

By comparison with continuum models, stochastic models aim to account for the inherent fluctuations and discrete nature of chemically reacting molecular systems. In cell biology, this approach has been applied most prominently in the arena of gene regulation (20–22) because these systems tend to be characterized by relatively small numbers of molecules (<100) and nonlinear, switch-like transitions. For stochastic systems that vary in time only, the most commonly used method for computing probabilistic realizations of such a model is the Monte Carlo-based algorithm developed by Gillespie (23), wherein running totals of the numbers of molecules in each state are tracked and adjusted in each time step according...
to probabilities of the various rate processes. This method is easy to implement and exact, but it is computationally inefficient for so-called stiff problems that possess a broad range of characteristic time scales. Aproximate adaptations of the technique, using a method called tau leaping, allows more efficient computation of stiff systems albeit with a potential loss in accuracy (24, 25). A nother approximate approach, viable in the limit of large numbers of molecules, is the stochastic differential equation method, which also is referred to as the chemical master equation or chemical Langevin equation approach. In this method, the probabilities of the various states being populated by different numbers of molecules evolve in time according to ODEs. Although this method is not necessarily more efficient or applicable to stiff systems, it serves as the starting point for several powerful approximations that are valid in certain limiting cases (20).

Methods for modeling spatially fluctuating reaction-diffusion systems, wherein molecules are treated as discrete particles whose coordinates are tracked and moved with time, also are available. These methods account for stochastic transitions as motivated above and are appropriate when concentration gradients are expected, as in the case of diffusion-controlled reactions. They also allow one to generate movies of the simulations to visualize the constituent processes in action. In the lattice Monte Carlo method, particles occupy nodes on a regularly spaced grid and move to adjacent nodes according to probabilities determined by the diffusion coefficient (and by long-range intermolecular potentials, if applicable). Changes in state occur probabilistically, and intermolecular interactions are subject to specific rules. For example, when the molecules are treated as point particles, interactions might occur in the next time step if the two species occupy adjacent nodes. In this limit, the method is very efficient computationally but suffers in accuracy because of its inability to resolve off-lattice events, which is especially significant when concentration gradients are steep. The Brownian dynamics or dissipative particle dynamics method is similar to the lattice Monte Carlo except that the particles adopt coordinates that are continuous throughout the domain. Thus, this method is accurate but also more computationally intensive. Both methods have been used in the context of signal transduction, particularly to study processes at cell membranes (26, 27).

Construction of biochemical networks

The multiplicity of modifications and interactions that signaling molecules engage in constitutes a large number of potential activity states. For instance, a protein or protein complex with 10 phosphorylation sites has \(2^{10} = 1,024\) distinct combinations of modified or unmodified sites, and this number does not even include the binding status of each modified site. This issue, termed combinatorial complexity, presents a major challenge for detailed kinetic modeling, and hence rule-based modeling methods and accompanying software tools have been developed (28-30). In this approach, the individual interactions and reactions in the network are enumerated and the specific contexts in which they are allowed to occur (rules) are specified. The network of possible species, which could number in the hundreds or thousands, is generated automatically in the form of a system of ODEs; alternatively, the rules can be used in a stochastic simulation wherein the species of the network are formed spontaneously. Efforts are underway to extend this approach to the spatial domain as well.

Applications of Mathematical Modeling in Cell Signaling

With the availability of computational tools and, more importantly, the ability to judiciously apply physico-chemical principles to the biologic realm, what systems are and have been ripe for quantitative modeling? In this section, signal transduction processes that have been modeled successfully from the standpoint of yielding biologically meaningful insights are surveyed. Limitations on the number of references preclude a comprehensive coverage of this literature.

Models of specific signaling pathways and processes

For several reasons, no pathway has received more attention from modellers recently than the mitogen-activated protein kinase (MAPK) cascade, which involves the successive activation of three enzymes (Fig. 3). MAPKs are conserved in eukaryotes from yeast to man and are critical for cell functions that range from proliferation to differentiation to stress responses, among others. MAPKs are considered master integrators of upstream signals and master controllers of transcription factors and other downstream effectors. Aside from their obvious importance in cell biology, MAPK cascades have achieved “über-pathway” status among modellers because of their potentially interesting dynamical properties. Building on pioneering work by Goldbeter and Koshland (31), who examined a hypothetical sequence of reversible enzymatic steps, the first model of a MAPK cascade was offered by Huang and Ferrell (32), who showed that the pathway was capable of a sensitive, switch-like relationship between the input (upstream of the cascade) and output (activation of MAPK); the basis for this response was the assumed biochemical mechanism, whereby MAPK and the upstream kinase are each activated by dual phosphorylation steps in a nonprocessive fashion. Building on this finding, more recent modeling efforts have focused on the consequences of the negative feedback regulation of the cascade (33-35) and the possibility that MAPK cascades operate as bistable switches, wherein two stable states (low and high MAPK activation) can be achieved at the same input strength (36, 37). Because of these modeling efforts, a solid understanding exists of what the cascade is capable of and how it apparently is modulated. Other models have been used to study the dynamics of MAPK cascades in the context of a full pathway, initiated by the activation of a specific receptor (38, 39). This approach is equally insightful albeit less general.

A rather proving ground for mathematical modeling in cell signaling has been the dynamics of intracellular calcium. Spurred by the nonlinear nature of the calcium release mechanisms, which exhibit cooperativity and both positive and negative feedbacks, and by the availability of fluorescent dyes for
Pathway models related to specific cell responses

Signaling pathways drive phenotypic responses, but the precise details of how this occurs at the molecular level remain elusive. Consider cell migration. From the signaling literature, we know which receptor-mediated pathways are more or less important in controlling migration, and from the literature on cytoskeletal and adhesion dynamics we have a good understanding of how migration is coordinated, but currently the interface between those two fields is poorly understood by comparison. To move forward with a mathematical model capable of yielding mechanistic insights, the prudent course of action is to focus on the molecular details of the upstream signaling and use a coarse-grained, phenomenological model of the cell response or vice versa. In the context of cell migration and chemotaxis signaling, both approaches have been adopted in recent models (66–68). In other cell response-specific models, understandably more attention is paid to the execution of the response and less to the dynamics of the upstream regulation, as in the modeling of the cell cycle (69) and programmed cell death (70, 71). It is expected that such models will be refined as the details of how upstream signaling pathways regulate the execution of cell responses are revealed, and quantitative modeling and analysis could play a key role in elucidating those mechanisms.

Prospects and Challenges

Quantitative models of signal transduction processes, in conjunction with quantitative experimentation, are being used to evaluate biochemical mechanisms, predict the outcomes of novel experiments, and generate nonintuitive insights and hypotheses warranting additional study. One challenge we now face is how best to integrate such models to analyze complex intracellular and cell–cell communication systems. Although it is envisioned that quantitative models of cell physiology ultimately will progress in lock step with our knowledge of biochemical mechanisms, several hurdles loom on the horizon. Arguably the most important of these hurdles is the specification of parameter values and parameter estimation from data sets. With a few notable exceptions, mining the literature for “known” parameters is a dicey prospect, and this practice should be used only to provide reasonable, order-of-magnitude guesses for parameter values. Estimating parameters in their particular biochemical context would be ideal, and algorithms for doing so are applied readily, but a significant amount of quantitative data is needed. This exercise is only tractable for models with a modest number of parameters, and hence the challenge arises: a very detailed signaling network model might require hundreds of free parameters. At the pathway/network level, the formulation of simplified, coarse-grain models with lumped parameters offers a reasonable compromise. Even as experimental techniques for quantifying cellular processes become increasingly refined, the formulation of a useful model will continue to rely on biological and mathematical intuition, which, at its core, is the art of modeling.

Mitogen-activated protein kinases (MAPKs) are significant mediators in signal transduction pathways from the membrane to intracellular compartments including the nucleus. They regulate the functions of many gene products and therefore affect cell growth, differentiation, and death. Three main MAPK subfamilies have been identified and are studied widely. All function in cascades that include at least three tiers of protein kinases. Selective kinase inhibitors have been developed; they are powerful tools to study the physiologic functions of MAPKs and, in some cases, are promising and effective drugs. In this article, the regulation of the three main MAPK pathways is sketched, and the status of MAPK inhibitors and their inhibiting mechanisms are highlighted.

Signal transduction pathways play important roles in transducing environmental changes to the regulatory machinery in the cell, which allows cells to alter their behavior rapidly to respond appropriately to those changes. Protein kinases are major and critical components of signaling pathways. More than 500 genes that encode protein kinase domains have been identified in the human genome. They share conserved domains in sequence and in structure, but they have notable differences in regulatory mechanisms that are often similar within subfamilies (1). Mitogen-activated protein kinases (MAPKs) are protein Ser/Thr kinases that are involved in a broad range of cellular events, such as cell proliferation, cell death, homeostasis, acute hormonal responses, and the morphologic changes of embryogenesis and cell differentiation (2–9). Perturbation of these pathways results in diseases such as cancers, diabetes, inflammatory disorders, and autoimmune disorders. Therefore, MAPKs are important targets for drug development. The regulation of MAPK pathways has been studied widely. Several model systems have been established, including activating those pathways by various stimuli and identification of in vitro and possible in vivo substrates. However, novel strategies and tools for studying the physiologic functions of MAPKs are still needed. With the identification of the first inhibitors for the ERK1/2 MAPK pathway, PD098059 and U0126 (10, 11), pathway-specific inhibitors have proven indispensable in determining MAPK functions in biologic systems. The lack of absolute specificity is a well-known disadvantage of protein kinase inhibitors and will be discussed in the context of MAPK pathways. The advantages are many and include the possibility of investigating pathways in many cells and in whole animals. Moreover, these inhibitors may have therapeutic potential as anticancer or anti-inflammatory drugs, for example. Thus far, several dozen protein kinase inhibitors are in clinical development currently, and many more are in preclinical studies (12–14). In this article, the main MAPK subfamilies and their regulation are introduced and the status of selected small molecule inhibitors of MAPK pathways will be discussed with a focus on inhibitory mechanisms. For the sake of space, references are made to more extensive reviews that cite the primary literature.

Background
The MAPKs are protein kinases activated by growth factors, hormones, cytokines, and environmental stresses. One or more MAPKs are activated by almost every cell stimulus. The first MAPKs sequenced, Kss1p and Fus3p, are also the kinases most similar to mammalian ERK1/2 and were found in the pheromone response pathway of the budding yeast nearly 20 years ago (8). Subsequently, activities found in mammalian cells that favored Ser/Thr residues followed by Pro in substrates were purified and shown to be mammalian MAPKs. More than a dozen mammalian MAPKs have now been identified. The hallmark of the MAPK family is the tri-peptide motif (Thr-Xxx-Tyr) located within the activation loop (T-loop) of the kinase domain, which contains the two sites phosphorylated to activate the kinases (2–9). Based on the canonical TXY motif and other features of the primary sequence, MAPKs are classified even more into three major subgroups: the extracellular...
Mitogen-Activated Protein Kinases (MAPKs): ERKs, JNKs, and p38s

Figure 1

ERK pathways

To date, six MAPKs termed ERKs (ERKs 1, 2, 3, 4, 5, 7 also called ERK8 depending on species) have been identified (7-9). All but ERKs 3 and 4 contain the highly conserved TEY (Thr-Glu-Tyr) motif in the activation loop. The atypical ERKs 3 and 4 possess a SEG (Ser-Glu-Gly) activation loop sequence instead. ERK1/2 are the archetype MAPKs and also are the best-studied kinases in this subgroup. To some extent, ERK1/2 respond to most ligands and other cellular stimuli; nevertheless, the most pronounced responses are to growth factors, serum, phorbol esters, and cytokines (frequently reviewed, e.g., (8), and other articles in that volume). ERK1/2 are 43 and 41 kDa proteins with 83% sequence identity. The MAP3Ks that activate ERK1/2 include Raf-1 (or c-Raf) and B-Raf, most typically, A-Raf where it is expressed, and Mos and Tpl2 under very specific circumstances that have been reviewed in detail (2). Raf-1 is the best studied MAP3K for this pathway and is expressed ubiquitously. Once stimulated, it is phosphorylated and then activates the MAP2Ks MEK1/2, which in turn phosphorylate and activate ERK1/2. B-Raf can associate with and activate Raf-1, and this association can be involved in the transforming events caused by B-Raf in certain tumors (13).

ERK5, which is also well studied, is known as big MAP kinase 1 (B MK1) because it is twice the size of ERK1/2. Although ERK5 shares a TEY motif in its kinase domain, it contains a unique long C terminus that may have important regulatory functions (5). In the ERK5 pathway, the upstream kinase of ERK5 is MEK5 but not MEK1/2. MEK5 may be phosphorylated by the MAP3Ks MEKK2, MEKK3, Tpl2, and mixed-lineage kinases (MLKs). However, scaffolding is thought to distinguish settings in which these MAP3Ks act on ERK5 compared with other MAPKs discussed below (16). In common with ERK1/2, ERK5 is activated in response to serum and growth factors such as nerve growth factor and epidermal growth factor. ERK5 is more sensitive than ERK1/2 to many stress stimuli, such as oxidative stress and hyperosmolarity, although all three may be activated (5).

Compared with ERK1/2 and 5, the other ERKs are studied much less. Their regulatory mechanisms are less understood and may not involve dedicated MAP2Ks (7, 9).

JNK pathways

JNK (c-Jun N-terminal kinase) was first identified as the UV-induced activity responsible for phosphorylating, and thereby activating the proto-oncogene c-Jun (5). At the same time, they were found as SAPKs (stress-activated protein kinases), which are proline-directed kinases activated by growth factors and biosynthetic inhibitors such as anisomycin. Common stimuli that activate JNKS include inflammatory cytokines; fatty acids; and environmental stresses such as UV, osmotic shock, heat
Obesity results in JNK activation, which suggests that JNK inactivation and desensitization of insulin receptor substrate 1 (IRS-1) contribute to obesity (18). JNK inhibits insulin signaling through phosphorylation and dephosphorylation of IRS-1, and it is involved in JNK activation by different stimuli. JNK has important roles in determining cell fate during metazoan development, as well as in the regulation of tumor growth, inflammation, and obesity (18). JNK inhibits insulin signaling through phosphorylation and dephosphorylation of IRS-1, and it is involved in JNK activation by different stimuli. JNK has important roles in determining cell fate during metazoan development, as well as in the regulation of tumor growth, inflammation, and obesity (18).

Knockout studies have suggested that different MAP3Ks are involved in JNK activation by different stimuli. JNK has important roles in determining cell fate during metazoan development, as well as in the regulation of tumor growth, inflammation, and obesity (18). JNK inhibits insulin signaling through phosphorylation and dephosphorylation of IRS-1, and it is involved in JNK activation by different stimuli. JNK has important roles in determining cell fate during metazoan development, as well as in the regulation of tumor growth, inflammation, and obesity (18).

Many MAP3Ks have been reported to activate MEK4/7, including MEKK1-4, ASK1, TAK1, MLKs, and JNK3/SAPKγ. These proteins, which exist in 10 or more alternatively spliced forms, share more than 85% identity in the core kinase domain. JNK1 and JNK2 are ubiquitous, whereas JNK3 is expressed primarily in neuronal tissues and in the cardiac muscle. The JNKs are activated by dual phosphorylation on the activation loop (Thr-Pro-Tyr) motif by the MAP3Ks MEKK4 and MEK7. Interestingly, MEK4 displays a preference for tyrosine and MEK7 for threonine, which suggests that MEK4 and MEK7 activate JNKs synergistically (5). Many MAP3Ks have been reported to activate MEK4/7, including MEKK1-4, ASK1, TAK1, MLKs, and JNK3/SAPKγ. These proteins, which exist in 10 or more alternatively spliced forms, share more than 85% identity in the core kinase domain. JNK1 and JNK2 are ubiquitous, whereas JNK3 is expressed primarily in neuronal tissues and in the cardiac muscle. The JNKs are activated by dual phosphorylation on the activation loop (Thr-Pro-Tyr) motif by the MAP3Ks MEKK4 and MEK7. Interestingly, MEK4 displays a preference for tyrosine and MEK7 for threonine, which suggests that MEK4 and MEK7 activate JNKs synergistically (5).

Preferential effects on different p38 isoforms. p38α is stimulated by growth factors; stresses such as UV light, osmotic shock, and ionizing radiation; as well as inflammatory cytokines such as tumor necrosis factor (TNFα) and interleukin 1 (IL-1) and 2 (2-5). Once stimulated, p38α is activated by dual phosphorylation on the TGY (Thr-Gly-Tyr) motif by the upstream MAP2Ks MEK5 and 6. These upstream kinases have preferential effects on different p38 isoforms. p38α, p38β, and p38δ are phosphorylated by both MEK3 and MEK6, and p38β is phosphorylated by MEK6. MEK3 and 6 can be activated by the MAP3Ks MEKK1-4, MLKs, ASK1, TAK1, MLKs, and TAK1. It is well known that p38 is involved in inflammation, apoptosis, and cell differentiation.

### MAPK Inhibitors

The functions of MAPKs have been studied primarily using dominant negative mutants. Constitutively active point mutants of MAPKs are not available, and other constitutive forms involve fusions or mutations of multiple residues. A class of MAPKs and MAP2Ks have also been identified, but overexpressed MAP3Ks in particular often activate other pathways in addition to those intended (7). The development of specific inhibitors for each subfamily of MAPKs and inhibitors that act at different levels in these pathways would facilitate our understanding of the complex interactions of these signaling cascades greatly. Inhibitors for some MAPK, MAP2K, and MAP3K family members have been developed. These inhibitors have assisted in identifying physiologic substrates and cellular functions of these enzymes. Selected inhibitors of MAPKs are shown in Fig. 1.

### Chemistry

Protein kinases have two substrates: target proteins and ATP-Rg5. Kinases transfer the γ-phosphoryl group of ATP to hydroxy acceptor groups of Tyr, Ser, and Thr residues within target proteins. Phosphorylation may control the activation, inactivation, protein interactions, stability, and localization of the substrate. Crystallographic studies have shown that protein kinases consist of two folding domains: a smaller N-terminal domain composed largely of anti-parallel β-helices and a larger C-terminal domain composed primarily of α-helices. The nucleotide is bound in a cleft formed at the interface of the two C-terminal domain. The ATP binding pocket, together with less conserved surrounding pockets, has been the focus of inhibitor design. Most inhibitors target the ATP binding site itself and are competitive with ATP. Thus, the potential for any compound to inhibit multiple kinases is considerable. Inhibitor specificity cannot be deduced from primary sequence similarity among kinases, however, as should become clear in the discussion below. Most JNK and p38 pathways inhibitors fall into this group. A few inhibitors have been developed that inhibit protein kinases by noncompetitive mechanisms. Generally, these inhibitors are allosteric inhibitors that bind outside the ATP pocket to conformations other than the active one or bind in a mode that prevents transition to the active conformation. MEK1/2 inhibitors are good examples of this type of inhibition. Inhibitors that are not competitive with ATP may be more effective than those that are ATP competitive in the cellular milieu, with ATP concentrations in the millimolar range. A common binding site for several allosteric inhibitors exists in protein kinases that have a conformational state in which the active site segment containing the conserved DFG (Asp-Phe-Gly) motif is moved out of the active site. This conformation is known as the DFG out state. The aspartate in this motif coordinates Mg2+ bound to ATP and is important for positioning ATP for phosphoryl transfer. Inhibitors of the three major MAPK pathways will be discussed below.
Mitogen-Activated Protein Kinases (MAPKs): ERKs, JNKs, and p38s

ERK pathway inhibitors

Thus far, no potent ATP competitive inhibitors of ERK1/2 have been reported. Because of the likely cross-reactivity of ATP competitive inhibitors, compounds that inhibit through interactions outside the ATP binding pocket are attractive. Substrates bind to MAPKs on the opposite face from the active site in a region, which are sometimes called the common docking or CD site; this site can also influence kinase conformation (21). Small molecule inhibitors that bind to the CD site of ERK2 have been identified recently but have not received extensive testing (23).

Several inhibitors of upstream kinases Raf and MEK1/2 are used widely in elucidating the physiologic roles of the ERK pathways in a variety of biologic processes in cell culture systems (Figs. 1 and 2 (12, 13). The MEK1/2 inhibitors U0126, PD98059, and PD184352 (IC-1040) are noncompetitive with respect to both MEK substrates, ATP and ERK1/2, which is consistent with an allosteric mechanism of inhibition (24). They are effective largely by preventing the activation of MEK1/2, in addition to inhibiting MEK1/2 activity directly at higher concentrations. The recently solved crystal structure revealed that MEK1/2 have a unique inhibitor binding site located in an interior hydrophobic pocket near but not in the Mg-ATP-binding site. The binding of inhibitors induces several conformational changes in unphosphorylated MEK1/2 that may lock them into non-functional species (22). PD0325901 is a recently reported MEK inhibitor, which was modified from PD184352 with improvement of several pharmaceutical limitations. It has a 50-fold greater potency against MEK1 than PD184352, and suppresses ERK1/2 activity longer.

The catalytic domains of MEK5 and MEK1 have just less than 50% amino acid sequence identity and the MEK1/2 inhibitors PD98059, PD184352, and U0126 will inhibit the ERK5
Mitogen-Activated Protein Kinases (MAPKs): ERKs, JNKs, and p38s

Pathway through effects on MEK5. Inhibition of MEK5 occurs at roughly 5-fold greater concentrations (7). Recently, a benzimidazole derivative ARRY-142886 (AZD-6244) has been reported as a highly potent and selective inhibitor of MEK1/2. The IC50 was determined to be 14 nM against purified MEK1. This inhibitor is also not competitive with ATP, which is consistent with the high specificity of this compound for MEK1/2. It is currently in phase II clinical development (12). A novel compound XL518 was announced by Exelixis (South San Francisco, CA) as a potent and specific inhibitor of MEK1/2, which has highly optimized pharmacokinetic and pharmacodynamic properties.

BAY 43-9006 (Sorafenib; Bayer/Onyx Pharmaceuticals, Emeryville, CA) is a biaryl urea that inhibits Raf-1 kinase activity in vitro with IC50 value of 6 nM, and B-Raf with IC50 value of 22 nM (25). This compound also inhibits some receptor tyrosine kinases, which include VEGF receptor family members, PDGF receptor, FGF, and c-KIT, at close to the same potency.
and other protein Ser/Thr kinases including p38α, p38β, and RIP2 kinase (27, 14). The crystal structure of B-Raf with BAY 43-9006 shows that it binds in an allosteric site near to and partially overlapping the ATP pocket of B-Raf in a DFG out conformation, and it interacts with the residues of the kinase activation loop. The interaction prevents the activation loop and the catalytic residues from adopting a conformation that is competent to bind and phosphorylate substrates. Several other Raf inhibitors exist in different stages of clinical development including Chir-265, PLX-4032, GSK5074, and ZM 336372 (26).

JNK pathway inhibitors

SP600125 and CEP-1347 (KT-7515) are the two most commonly used inhibitors to probe JNK pathways (33). Both are ATP competitive and have demonstrated efficacy for use in vivo, with the successful intervention to decrease brain damage (CEP-1347) or to ameliorate some symptoms of arthritis (SP600125) in animal models (9). Both SP600125 and CEP-1374 inhibit the JNK pathway; however, their targets are different. SP600125 is an anthrapyrazolone that inhibits JNK1, 2, and 3 directly. The IC50 values are 40 nM for JNK1, 2, and 90 nM for JNK3. Testing against a broad panel of protein kinases has shown that SP-600125 inhibits at least 13 others with a similar potency as the JNKs, including p38 (27). Therefore, the activity of SP-600125 may not be attributed to the selective inhibition of JNKs. Despite this, SP-600125 has been useful to assess the role of JNK in cell culture and disease models, particularly in combination with p38 inhibitors described below. CEP-1347 inhibits MAP3Ks of the MLK group, which inhibits activation of the JNK pathway in those contexts in which MLKs are the MAP3Ks. The intra and cellular potentials are similar: Because of the role of JNK in diseases such as diabetes and obesity, it has been important to find additional novel small molecules that could inhibit the JNK pathway. At least two pan-JNK inhibitors have been reported. The Celgene (Summit, NJ) compound CC-401 has successfully completed a Phase I trial for acute myelogenous leukemia. The Merck compound A5602801 (Merck & Co., Whitehouse Station, NJ) may have therapeutic potential in multiple sclerosis and fibrosis.

p38 pathway inhibitors

Because the activation of p38 plays essential roles in the biosynthesis and release of proinflammatory cytokines such as TNF-α and interleukin-1β, blocking its activity may offer an effective therapy for treating many inflammatory diseases such as rheumatoid arthritis and inflammatory bowel disease (2, 5-7).

Many p38 kinase inhibitors have been developed and have been evaluated extensively in preclinical models of arthritis (12, 13). Among them, SB 203580, which is a pyridinyl imidazole compound, has been used as the template for many p38 inhibitors, and it has been extremely useful to delineate the function of p38. SB 203580 inhibits the catalytic activity of p38 by binding to the ATP-binding site, but it does not prevent its inhibition by MAP2Ks, based on ATP competitive experiments and crystallographic studies (30). SB 203580 inhibits only p38α and β isoforms, but not γ or δ isoforms. VX-745 (Vertex-745; Vertex, Cambridge, MA), another p38γ/δ inhibitor is a modified pyridinyl imidazole compound with better pharmacologic characteristics. Although it progressed to a Phase II trial for rheumatoid arthritis, additional development has ceased because it crossed into the central nervous system.

A diaryl urea compound BIRB796 is a potent and selective p38 α/β/γ/δ inhibitor that bears little structural similarity to SB 203580. Structural analysis shows that BIRB796 interacts with a DFG out conformation of p38 in which the activation loop has been reorganized exposing a critical binding site; this structure is incompatible with ATP binding (31, 32). The specific binding mode of BIRB796 suggests it will be a potent reagent in the treatment of chronic autoimmune diseases. In contrast to SB 203580, BIRB796 inhibits not only p38α and β, but also the γ and δ isoforms. Other p38 inhibitors in clinical phase II trials include VX-702 (Vertex), Socrs 469 (Socrs Inc., Mount View, CA), and PH-797804 (Pfizer Inc., New York, NY). These compounds hold promise for the treatment of rheumatoid arthritis and cardiovascular diseases.

Tg12 is a MAP3K that can lie upstream of all three MAPK pathways. It activates the translation of TNFα messenger RNA and TNFα production through activation of MAPK pathways. Therefore, Tg12 inhibitors could be of value for treatment of certain inflammatory diseases. A series of 1,7-naphthyridine-3-carbonitriles and the related quinoline-3-carbonitrile (cyano-quinoline) have been found to inhibit Tg2 activity and are promising for treatment of rheumatoid arthritis (33).

Key Experiments and Observations

X-ray crystallography is a powerful and direct tool to understand kinase inhibitory mechanisms. Key experiments demonstrate that inhibitors interact with multiple regions of kinases that lead to mechanisms that may or may not be competitive with substrates. As examples, p38 inhibitors fall into both groups.

Noncompetitive mechanism

All MEK1/2 inhibitors described above, U0126, PD098059, PD184352, and ARRY-142886 are noncompetitive inhibitors. From kinetic analysis, it was deduced that these inhibitors...
Mitogen-Activated Protein Kinases (MAPKs): ERKs, JNKs, and p38s

Competitive mechanism

Most kinase inhibitors compete with ATP. SB203580 is a pyridinyl imidazole with structure shown in Fig. 2c. Young et al. (35) first showed that SB203580 could bind to the inactive, unphosphorylated form of p38 with a Kd of about 40 µM. Binding in the active site was consistent with competitive inhibition of p38 by SB203580. They showed that SB203580 could also bind to activated, phosphorylated p38 and inhibit its activity. Inhibition was ATP competitive with a Kd of 21 nM. The KIC, ATP inhibition constant was determined as 2.100 ± 0.006, in the presence of 100 nM SB203580. Frantz et al. (36) compared the affinity of SB 203580 directly for both active and inactive p38 with a radioligand binding assay. They showed that the inhibitor could bind equally well to inactive and active p38, which demonstrates even more that binding of SB 203580 is independent of phosphorylation state. More direct evidence came from the crystal structure of unphosphorylated p38 that showed a pyridinyl-imidazole in the ATP pocket (37).

Ongoing and Future Research Efforts

Selective kinase inhibitors are invaluable tools to dissect the physiologic and pathophysiologic roles of protein kinases, to identify new substrates, to identify model systems that allow evaluation of potential clinical use, and importantly, to develop new therapeutic agents. Selectivity is critical for the use of protein kinase inhibitors in basic research. Protein kinases are a large class of enzymes related by sequence, all of which share the common capacity to bind ATP (1). Most inhibitors developed to date are competitive with ATP and bind in the active site. Thus, the potential for inhibitor cross-reactivity is great. Hence, establishing whether drug effects are caused by actions on the expected target or to previously unrecognized targets is an important step to validate their use.

We now understand that the entire kinase domain, not just the active site, may provide binding sites for inhibitory interactions. Inhibition may occur through selection of conformations that prevent a functional active state. Allosteric modifiers offer the possibility of high specificity and efficacy with reduced or different cross-reactivities relative to ATP competitive inhibitors. With more and more kinase structures solved, the inactive forms of kinases are becoming attractive targets for drug design, as the inactive kinases may have more distinct active sites compared with their active forms. Targeting the diverse inactive conformations might improve the inhibition specificity. A rather different approach may come from the development of nonphosphorylatable substrate analogs to interfere with the kinase-protein substrate association. These kinds of substrate-competitive inhibitors may also provide high specificity inhibitors with distinct cross-reactivities because of the varied binding modes of protein substrates.

Some MAPKs have several isoforms that may have different specific roles. Gene knockout studies have suggested isoform-specific roles. Thus, the development of inhibitors with the ability to interfere with one or a few isoforms as well as those that inhibit all isoforms will be desirable to understand the biology of these enzymes.

References

Nitric oxide (NO) is an essential signaling molecule for many eukaryotic organisms. NO is produced in vivo by the enzyme nitric oxide synthase (NOS) from the amino acid L-arginine. The apolar gas readily diffuses across cell membranes, where it binds to the heme of soluble guanylate cyclase (sGC), the principle NO receptor. Once activated, sGC converts GTP to cGMP at a rate that is several-hundred-fold above the basal level. This NO/cGMP signaling cascade modulates several physiologic processes including vasodilation, platelet aggregation, and neurotransmission. Although the cGMP-dependent affects of NO remain active areas of research, additional cGMP-independent responses to NO also are being investigated. Endogenous levels of NO can modulate protein function by S-nitrosation, a covalent modification that has been implicated in the transcriptional regulation of genes involved in the immune response and in apoptosis.

In biologic systems, nitric oxide (NO) functions as both a critical cytotoxic agent and an essential signaling molecule. The toxicity of the diatomic gas has long been accepted; however, nitric oxide was not known to be a physiologically relevant signaling molecule until it was identified as the endothelium-derived relaxing factor (EDRF) (reviewed in Reference 1). Since this discovery, the enzymatic synthesis of NO and the signaling pathways that it regulates have been the focus of many studies. In higher eukaryotes, nitric oxide synthase (NOS) produces NO from L-arginine (reviewed in References 2–4). Despite several years of research, the NOS catalytic mechanism remains a topic of investigation, but commonly it is accepted that NO is essential for several physiologic processes. Many signaling responses that NO modulates are mediated by the NO-induced activation of the heme protein soluble guanylate cyclase (sGC). NO binds to sGC at a diffusion-controlled rate and leads to a several-hundred-fold increase in the synthesis of the second messenger cGMP from GTP (5, 6). Other diatomic gases either do not bind (dioxygen) or do not activate sGC significantly (carbon monoxide). This characteristic provides selectivity and efficiency for NO even in an aerobic environment, which is critical because of the high reactivity of NO. The NOS/sGC pathway is important for maintaining homeostasis, and many diseases have been linked to the dysfunction in NO signaling (reviewed in Reference 7). Studies on NO-dependent NOS responses continue to expand, and other roles for the gas are emerging in both prokaryotic and eukaryotic organisms. In higher eukaryotes, protein S-nitrosation, an oxidative modification of cysteine residues, is implicated in an increasing number of cGMP-independent signaling systems (reviewed in Reference 8), whereas in bacteria, a class of potential heme-based NO sensors recently has been identified and proposed to participate in two-component signal transduction pathways (9).

Background and Significance

NOS is regulated highly to ensure that NO concentrations do not reach toxic levels and to control properly the processes that respond to the signaling molecule. At high concentrations (low mM), NO in an aerobic environment can damage DNA, oxidize critical heme proteins, and covalently modify essential biologic molecules (10–12). To deter these events, the expression, cellular localization, and activity of NOS is regulated highly (reviewed in Reference 3). All three isoforms, endothelial, neuronal, and inducible NOS (eNOS, nNOS, and iNOS), are regulated at the transcriptional level. Both eNOS and nNOS are expressed constitutively, and iNOS is induced with the appropriate immunostimulatory signals. The isoforms critical to signal transduction pathways (eNOS and iNOS) generate low nanomolar levels of NO and are regulated by the appropriate immunostimulatory signals. The isoforms critical to signal transduction pathways (eNOS and iNOS) generate low nanomolar levels of NO and are regulated in vivo by the binding of calcium and calmodulin. NO produced by NOS can diffuse rapidly across a cell membrane to activate sGC, a heme protein that has evolved to bind NO selectively even in the presence of oxygen (µM) (Fig. 3). In addition to NO, cGMP production by sGC is regulated by the nucleotides GTP and ATP.
Nitric Oxide signal transduction pathway. NO synthesized by NOS diffuses across cell membranes to a target cell. NO activates sGC, which leads to an increase in cGMP synthesis. The oxidation products of NO also can react with protein thiols, which leads to protein 5-nitrosation.

Figure 1  Nitric oxide signal transduction pathway. NO synthesized by NOS diffuses across cell membranes to a target cell. NO activates sGC, which leads to an increase in cGMP synthesis. The oxidation products of NO also can react with protein thiols, which leads to protein 5-nitrosation.

NO is important for the function of the cardiovascular system and is critical for blood pressure regulation. In vascular smooth muscle cells, cGMP can bind to and activate cGK, specifically the type Iα and Iβ isoforms. These isoforms are splice variants of the same gene that have different sensitivities to cGMP. During activation, cGK phosphorylates the large conductance Ca2+-activated K+ channel (23) and IRAK (IP), receptor-associated cGMP kinase substrate (24), which are involved in the regulation of extracellular Ca2+ entry and intracellular Ca2+ release, respectively. The release of Ca2+ into the cytosol leads to smooth muscle contraction by the activation of a myosin light chain kinase (MLCK) that phosphorylates the myosin light chain (MLC) (reviewed in Reference 25). Smooth muscle contraction also is regulated by myosin light chain phosphatase (MLCP), the protein that dephosphorylates MLC. cGKI phosphorylates and inhibits RhoA, a GTPase that activates Rho kinase. Rho kinase inhibits the activity of MLCP, and therefore the cGMP-dependent inhibition of RhoA contributes to smooth muscle relaxation (26). Vasodilation also is modulated by PDE5, a major cGMP-hydrolyzing PDE. This protein is important for inducing relaxation under low Ca2+ conditions and has become an important drug target because the inhibition of PDE5 leads to increased levels of cGMP after NO-induced sGC stimulation (19).

sGC activation also is important for the immune response. Human platelets generate cGMP after NO activation of sGC, which leads to the inhibition of platelet activation or aggregation. This effect is mediated primarily by cGMP activation of cGKI. Many targets for activated cGKI have been proposed, including the vasodilator stimulated phosphoprotein (VASPI). Phosphorylation of VASP correlates with the binding of NADPH oxidase to glycoprotein IIb/IIIa, expression of P-selectin, and platelet adhesion (reviewed in References 16 and 27). Small molecule sGC activators (28–30) have been shown to inhibit platelets and are potential antiplatelet agents that could be used to treat cardiovascular diseases.

cGMP-independent signaling

The oxidative addition of NO to a thiol, termed 5-nitrosation, is a posttranslational modification that can modulate protein function. With high concentrations of NO, this modification can alter protein function indiscriminately; however, only a limited number of proteins are 5-nitrosated in vivo (8). This selectivity of nitrosothiol formation suggests that a mechanism of regulation of SNO formation and/or decay exists; however, the details of this regulation are unknown.
Nitric Oxide, Biological Targets of

The S-nitrosation of proteins has been implicated in regulating apoptosis, protein expression, and tissue oxygenation (31–33). For example, low levels of NO can inhibit apoptosis via the S-nitrosation of caspase proteases, which contain a cysteine residue that is essential for catalytic activity (33). Furthermore, this process may be regulated by the protein thioredoxin, the primary intracellular oxidoreductase that may function as a nitrosotransferase (34). S-nitrosation also inhibits the DNA binding activity of NF-kB transcription factors, which effects protein expression (31), and S-nitrosohemoglobin has been implicated in the regulation of blood flow and tissue oxygenation (reviewed in References 32 and 35).

Interestingly, both NOS and sGC have been shown to be S-nitrosated by low levels of NO (36–38). In NOS, this nitrosation occurs at zinc tetrathiolate cysteines that are critical for maintaining a functional dimer. Modification of these cysteines leads to the formation of inactive monomers, which could be a means of regulating NO production in vivo (37). S-nitrosation of sGC results in the inhibition of NO-stimulated activity (38). This mechanism of desensitization may account for the clinical condition known as NO tolerance, which is an ongoing problem in the treatment of heart disease.

No Chemistry

NOS

Mammalian NOS is a P-450-like enzyme that catalyzes the oxidation of L-arginine to L-citrulline and NO. This process is a two-step reaction that leads to a five-electron oxidation of L-arginine. The enzyme requires NADPH and O2 as substrates for both reaction steps, and iron protoporphyrin IX (heme), FMN, FAD, and tetrahydrobiopterin (H4B) as protein-bound cofactors. NOS is active as a homodimer and contains an N-terminal oxygenase (or heme) domain, a C-terminal flavoprotein reductase domain, and a central calmodulin binding region (4) (Fig. 2a). The heme domain of NOS (NOS_heme) can be isolated, and it binds heme, H4B, and L-arginine. This domain is functional if provided with reducing equivalents such as sodium dithionite (39, 40). The crystal structures of eNOS_heme (41) and iNOS_heme (42) show how substrate and cofactors bind within the active site and identify residues that are important for H4B binding and dimerization, including a zinc tetrathiolate at the bottom of the dimer interface that stabilizes subunit binding and is involved in maintaining the integrity of the H4B binding site (43). The reductase domain binds to NADPH, FMN, and FAD and provides electrons to the heme active site for catalysis, a process that is controlled by Ca2+/calmodulin binding.

In the first step, L-arginine is hydroxylated to form N-ω-hydroxy-L-arginine (NHA) (Fig. 2b). This reaction mechanism is analogous to those catalyzed by cytochrome P-450s, which involves a proposed high-valent oxo-iron intermediate that could transfer an activated oxygen species to a substrate. In the second reaction step, the 3-electron oxidation of NHA produces L-citrulline and NO. It has been proposed that this step involves the attack of a ferric peroxide intermediate on the guanido carbon; however, experimental evidence is not sufficient to distinguish between this and other proposed mechanisms (reviewed in Reference 2). The most controversial questions about the NOS mechanism concern the source of the electrons in each reaction step and cofactor stoichiometry.

NO can have a short half-life in aqueous solution, which may seem problematic for it to reach its intracellular target. A second-order dependence exists on NO autoxidation shown in the rate law below (reviewed in Reference 44).

\[ v = k[N02][O2] \]

Consequently, at nanomolar signaling concentrations, the lifetime of NO is sufficient for it to reach sGC. The end-products of NO decomposition are nitrite (NO2−) and nitrate (NO3−). NO and reaction intermediates along the decomposition pathway can react with several intracellular molecules, but reactions

with heme cofactors and cysteines are the most relevant to its function as a signaling agent and also contribute to its toxicity.

Reactions with heme

Perhaps the best-characterized interactions are between NO and the heme proteins hemoglobin and myoglobin. NO binds to Fe\textsuperscript{II}-unligated globins on the order of 10\textsuperscript{7} M\textsuperscript{-1} \textsuperscript{-1} s\textsuperscript{-1} and leads to the formation of a stable 6-coordinate Fe\textsuperscript{II}-NO complex (45). These 6-coordinate complexes can be very stable and thereby inhibit the function of heme proteins by blocking the coordination site. NO also can react with Fe\textsuperscript{II}-O\textsubscript{2} complexes, which often leads to heme oxidation (Fe\textsuperscript{III}-heme) and the formation of NO\textsuperscript{3-}. With hemoglobin and myoglobin, this reaction occurs on the same order of magnitude as simple NO binding to the ferrous heme (30).

The affinity of NO for ferric heme is significantly lower than for the ferrous heme (46), but reductive nitrosylation of proteins has been observed (47). In this reaction, one equivalent of NO reduces the heme to Fe\textsuperscript{II}, and a second equivalent of NO rapidly binds to the unoccupied coordination site. This reaction also can generate the nitrosating agent NO\textsuperscript{2-}, which can react subsequently with free thiols. In fact, the 5-nitrosylation of hemoglobin and nitrophorin, a protein involved in NO storage and delivery in some bloodsucking insects, has been observed (48, 49). As the ferric heme is the physiologically relevant state for nitrophorins, it is likely that this reaction occurs in vivo.

It is evident from these reactions that O\textsubscript{2} binding to sGC would reduce the ability of the enzyme to function as a selective NO sensor. The mechanism of sGC activation by NO and the ability of NO to discriminate against O\textsubscript{2} currently are under investigation.

sGC activation and ligand discrimination

sGC is a heterodimeric protein that consists of two homologous subunits, \(\alpha\) and \(\beta\). The most commonly studied isofrom is the \(\alpha\)2\(\beta\)1 protein; however, the \(\alpha\)2 and \(\beta\)2 subunits also have been identified (50, 51). sGC contains an N-terminal heme binding region, a predicted PAS-like region, and a C-terminal catalytic domain (reviewed in Reference 52). The crystal structure of the sGC heme domain as well as sGC-like homologues discovered in bacteria (9) have facilitated the study of the heme environment and ligand binding (53–55).

NO binds to the heme of sGC at a diffusion-controlled rate to form an initial 6-coordinate complex, which rapidly converts to a 5-coordinate ferrous nitrosyl complex (Fig. 3a) (50). The breaking of the Fe-His bond is thought to be critical to the activation of sGC by NO; however, recent data has shown that the NO coordination to the heme is not sufficient for full activation (13, 56). A low-activity Fe\textsuperscript{II}-NO complex can be formed in the presence of stoichiometric amounts of NO, and this species is identical spectroscopically to the highly active form of the enzyme that is formed in the presence of substrate or excess NO. Based on these observations, two mechanisms of NO activation have been proposed. One proposal is that excess NO activates the ferrous nitrosyl complex by binding to nonheme sites on the protein (13). The second proposal involves excess NO binding to the heme to form a transient dinitrosyl complex, which then converts to a 5-coordinate complex with NO bound in the proximal heme pocket (56).

The ability of sGC to select against O\textsubscript{2} binding is important for it to function as a NO sensor because O\textsubscript{2} is present at much higher levels than NO in vivo and Fe\textsuperscript{II}-O\textsubscript{2} and Fe\textsuperscript{III}-O\textsubscript{2} proteins react rapidly with NO. Interestingly, some bacterial sGC-like homologues also bind O\textsubscript{2} and NO. These proteins were named heme nitric oxide/oxygen binding (H-NO\textsubscript{X}) proteins (reviewed in Reference 57). The crystal structure of the O\textsubscript{2}-binding H-NO\textsubscript{X} from Thermoaerobacter tengcongensis (TL) with O\textsubscript{2}...
bound was reported recently (54, 55). This structure shows that a distal pocket tyrosine interacts with bound O₂ though an H-bond. Whereas the crystal structure of the O₂-excluding H-NOX from Nostoc sp. shows that no hydrogen bond donor exists in the distal heme pocket (53), sequence analysis predicts that polar residues capable of interacting with O₂ are absent in sGC. Mutagenesis studies that introduced a Tyr into the distal pocket of the pL H-NOX domain produced a protein that was capable of binding O₂ (58); however, the same mutation in full-length sGC did not facilitate O₂ binding (59, 60). This finding indicates that the presence of a distal pocket Tyr may be involved in stabilizing Fe²⁺–O₂ complexes in H-NOX proteins, but other factors are involved in ligand discrimination in sGC. The size and overall polarity of the heme distal pocket and the strength of the proximal Fe-His bond have been proposed as mechanisms of discriminating against O₂ binding (57). The crystal structures of the H-NOX proteins also have facilitated the study of sGC activation. Specifically, the differential pivoting and bending in the H-NOX heme during NO or CO binding may account for the varying degree of activation induced by the two ligands (200-fold versus 4-fold, respectively) (53). However, details about how movement in the H-NOX domains affects the catalytic domain may remain unresolved until the full-length structure is elucidated.

Reactions with cysteine

Many pathways exist to generate a nitrosobrad in vitro by the 1-electron oxidation of NO. Nitrosothiols can be formed via the reaction of a thiol with N₂O₃, a nitrosating agent that is an inter- mediate in the decomposition of NO in aerobic solution, or via the reaction of NO with a thiol to form an addition complex (SNO⁻) followed by a 1-electron oxidation. S-nitrosation of a protein thiol also can occur by a trans-S-nitrosation reaction, from a low molecular weight nitrosothiol, such as S-nitrosoglutathione, or from a nitrosated protein thiol (8). Whereas the in vivo mechanism of protein S-nitrosation is unknown, a protein-mediated trans-S-nitrosation mechanism is an attractive possibility because of the specificity it could impart on the reaction. Additionally, the same protein could catalyze both the nitrosation and denitrosation of a specific cysteine. A report showing that the protein thiodexin can transnitrosate caspase 3 selectively and reversibly lends support to this proposal (34).

Chemical Tools and Techniques

Enzymology

The study of an enzyme requires a functional assay, or a quan- titative method for measuring the conversion of substrate to product. To develop this method the enzyme substrate(s) and product(s) must be identified. Isotopically or radiolabeled compounds can facilitate this identification. NO was identified first as an intermediate in the L-arginine to NO₂⁻/N₂O⁻ pathway by incubating macrophage cells with L-[guanido-¹⁵N₂]arginine (61). Similar experiments showed that L-arginine was the precursor in this pathway (62, 63), that L-citrulline was an additional product (63), and that L-arginine conversion to L-citrulline was coupled with NO formation (64). Chromato- graphic methods to separate substrate from product, radioim- munassays (RIA), or enzyme-linked immunosorbent assays (ELISA) can be used for the sensitive detection of reaction prod- ucts and/or substrate. Reaction stoichiometry, turnover number (kcat), and Kₘ for substrate can be determined. Additionally, reaction intermediates and possible transition states can be inves- tigated by rapid quench methods, design of rational based inhibitors, and isotope exchange experiments.

Spectroscopy of heme proteins

Iron porphyrin complexes, or heme, have diverse functions in biologic systems. Specifically the iron(III) complex of protopor- phyrin type IX is a cofactor critical to the production of NO by NOS and the subsequent activation of sGC by NO. The highly conjugated π-system of these porphyrins gives these proteins their characteristic color and facilitates the study of the biologic systems they regulate. Several methods can be used to study the ligation state and heme environment of these proteins. Briefly, electronic absorption, resonance Raman, and electron paramag- netic spectroscopy will be discussed; however, several useful techniques are used to investigate heme proteins (reviewed in Reference 65).

Electronic absorption spectroscopy can be determined to the general structure of porphyrins and their derivatives. The oxidation and coordination state of the iron and the identity of the amino acid that ligates the heme can be examined by com- paring the absorption spectrum of the protein of interest with the spectra of known heme proteins (45, 65). General charac- terization with electronic absorption spectroscopy indicated that NO and CO, but not O₂ bind to the sGC heme moiety (66). Dynamic studies of ligand binding and dissociation also can be examined with this technique on μsec-msec time scales with standard stopped-flow systems.

Heme proteins have been studied extensively with resonance Raman (RR) spectroscopy, a method that can be used to ex- aminate the environment around a heme cofactor and to confirm the atoms that coordinate to the metal center. A Raman spec- trum contains peaks of scattered light where the observed fre- quency shifts correspond to the various vibrational frequencies of the scattering molecules. Specifically, the oxidation state of the heme is indicated by the electron density marker, νₑ, in the 1350–1380 cm⁻¹ region, and ν₁, ν₂, and ν₃ are the spin and coordination state markers (65). Different ligation states of sGC (67) and NOS (68, 69) have been characterized with this technique. Interestingly, the resonance Raman spectra of sGC Fe²⁺-NO and Fe²⁺-CO complexes are influenced by the presence of GTP and known sGC allosteric activators (70, 71). This in- fluence indicates that conformational changes exist at the heme pocket during substrate and activator binding that may correlate with activation.

Nuclear hormone receptors are integral players in endocrine networks that lie at the interface between biology and chemistry. Unlike most other classes of transcription factors, these proteins are designed uniquely to bind small molecules and, thus, affect gene expression in response to the cellular and organismal chemical environment. After several decades of research, it is now appreciated that nuclear receptors bind very diverse lipophilic small molecules with a wide range of specificity and affinities. Recent nuclear receptor structures coupled with large-scale screening efforts challenge the dogma that all nuclear receptors, especially the large subset of constitutively active receptors, will have ligands and will represent tractable drug targets. As such, the "pharmacologic future" for such orphan nuclear receptors may reside outside of the ligand-binding pocket.

Nuclear hormone receptors are classically defined as ligand-regulated transcription factors. The transcriptional programs affected by these proteins are linked to metabolic pathways, endocrine homeostasis, and organ development; thus, both the loss and the gain of function of these receptors are associated closely with a variety of human diseases that include developmental and metabolic defects, cardiovascular disease, diabetes, reproductive failure, and cancer. Forty-eight nuclear receptors have been identified in the human genome and are subclassified into seven distinct subfamilies that consist of NR1, NR2, NR3, NR4, NR5, NR6, and NR0 based largely on sequence similarity in their two signature domains (1). These two domains are present in almost all nuclear receptors and consist of the N-terminal DNA-binding domain (DBD) and the C-terminal ligand-binding domain (LBD). The DBD interacts with specific DNA elements located in promoters of target genes, whereas the LBD binds hormones or other lipophilic molecules (2). Additionally, receptors include two highly variable domains: the N-terminal DNA-binding domain (DBD) and the C-terminal ligand-binding domain (LBD). The DBD interacts with specific DNA elements located in promoters of target genes, whereas the LBD binds hormones or other lipophilic molecules (2). Additionally, receptors include two highly variable domains: the N-terminal DNA-binding domain (DBD) and the C-terminal ligand-binding domain (LBD). The ligand-dependent feature of some nuclear receptors has been exploited successfully for therapeutic intervention against diseases such as breast cancer, type 2 diabetes, and hypertension (Table 1, 3–39).

Overview

Nuclear receptors are sophisticated homeostatic sensors that function in the endocrine network of vertebrate organisms and allow for communication between or within different tissues and organs, often over large distances. These receptors can detect a constantly changing environment by binding small lipophilic hormones and metabolic intermediates. The ligand dependent feature of some nuclear receptors has been exploited successfully for therapeutic intervention against diseases such as breast cancer, type 2 diabetes, and hypertension (Table 1, 3–39).

The use of nuclear receptors to mediate hormone signaling seems to have developed late during metazoan evolution. Indeed, genome-wide comparisons reveal that nuclear receptors are absent in some eukaryotic genomes. However, in those organisms, other signaling pathways have been adapted to meet their endocrine needs and respond to small lipophilic molecules. For instance, no nuclear receptors have been identified in the yeast genome. Interestingly, a protein fold similar to the nuclear receptor LBD was identified by structural prediction in the budding yeast S. pombe and by structural prediction in the budding yeast S. pombe.

Nuclear Receptors, Chemistry of

cerevisiae. These transcription factors heterodimerize and bind the fatty acid oleate, reminiscent of the mammalian retinoic X receptor (RXR, NR2B)/peroxisome proliferators-activated receptor (PPAR, NR1C) signaling pathway (40). Similarly, hormone signaling in multicellular plants is not mediated by nuclear receptors despite the fact that sterols mediate many analogous functions in plant biology. Instead, plants seem to use other ligand binding motifs. For example, the growth promoting plant phytohormone brassinosteroid binds a cell surface receptor that activates downstream kinases and ultimately Myc family transcription factors (41, 42). Another large family of homeodomain-START (star-related lipid-transfer) proteins is hypothesized to affect gene expression directly after binding sterols and lipids selectively via the START domain (43, 44). Collectively, these examples suggest conserved signaling by lipophilic molecules using evolutionarily distinct binding proteins.

Ligand Activation of Nuclear Receptors

To carry out the transcriptional programs that require both activation and repression of target genes, nuclear receptors interact with numerous coregulators, which nucleate the assembly of macromolecular protein complexes that remodel chromatin and modulate transcription initiation or silencing (45, 46). For ligand-dependent receptors, the presence or absence of ligand determines the nature of the assembled protein complex. Given the importance of the LBD in binding ligand and interacting with coregulators, collective efforts of academia and industry have now elucidated LBD crystal structures for nearly all seven subfamilies (47). The nuclear receptor LBD structure is conserved and consists of an α-helical bundle (α1-α12), one to five β-strands, with three to four antiparallel layers and a hydrophobic ligand-binding pocket that occupies the core of the bundle.
Nuclear Receptors, Chemistry of

The volume of this pocket varies greatly among the receptors, which enables these proteins to accommodate ligands of varying shapes and sizes (Fig. 1) (47, 48). In addition, the LBD contains a dimerization interface that allows receptors to bind DNA as homodimers or heterodimers (49). And, for some receptors, it is also a key site for interaction with the heat-shock proteins (50).

Based on the first crystal structures of liganded nuclear receptors, the “mouse trap model” was proposed to account for ligand-initiated activation (51). Ligand was proposed to complete and stabilize the hydrophobic core of the receptor in an active conformation of the LBD. Concomitant with binding of the ligand, helix H12 that contains the activation function 2 (AF2) undergoes a dramatic rearrangement, docking across the ligand-binding pocket and trapping the ligand inside (51). This repositioning of helix H12 creates a new hydrophobic surface that is bound by the LXXLL motif within coactivator proteins (Fig. 2a) (54, 55). Interestingly, corepressor proteins compete with coactivators for binding to the same hydrophobic groove but form a slightly extended surface that eliminates the need for ligand (56). This mechanism allows the ligand to dictate nuclear receptor action by repositioning AF2 and thus shifting the equilibrium between coactivator and corepressor binding (Fig. 2a) (57). However, many nuclear receptors, especially orphan receptors, are constitutively active in the apparent absence of a ligand. Moreover, structural studies point to seemingly small receptor-specific differences within the LBDs that must underlie the diversity of receptor action in controlling distinct biologic processes (47).

Thus far, about half of all nuclear receptors have been paired with physiologic ligands. The other half remain orphaned, and either await identification of their native ligands or alternatively will never be bound by a ligand. For the most part, matching ligands with their cognate receptors has followed traditional drug discovery approaches using both cell-based assays and biologic clues. Although nuclear receptors are found readily in tractable genetic model organisms, such as flies and worms (58), hunting for ligands by standard genetic screens has proven difficult and may reflect an overrepresentation of receptors that belong to the so-called “orphan receptor” subfamilies in these invertebrate species. Exceptions include the discovery of the ecdysone hormone receptors and heme receptors in Drosophila.
surprising that some of the first LBD crystal structures were those of the steroid receptors (52). The steroid receptors were also the first to be targeted by pharmaceutical compounds, even before the availability of the high-resolution LBD structures that paved the way for structure-based drug design. The estrogen receptor (ER, NR3A) is the best example of successful manipulation of a nuclear receptor with synthetic ligands. Crystal structures of the ER LBD bound by several distinct ligands reveal the exquisite specificity with which these ligands manipulate ER into active and inactive conformations. Each ER–ligand complex presents a distinct set of structural changes in the position of the AF2 relative to the core LBD, which suggests that standard approaches can be used to design specific agonists or antagonists for this receptor. When bound by the natural ligand estradiol (E2), ER possesses a relatively small and well-defined ligand-binding pocket, and multiple contacts between the receptor and the ligand result in high specificity of interaction (24). These features allow one to design ER modulatory ligands that range from selective ER modulators (SERMs) such as tamoxifen, which exhibit mixed agonist/antagonist properties depending on the tissue or promoter, to complete antagonists such as (ICI 164,384 (25, 26). In the latter case, the ER/ICI structure revealed how addition of bulky constituents to an agonist scaffold results in a protrusion from the ligand-binding pocket and movement of the AF2 helix into nonproductive conformation, which provides a paradigm for designing steroid nuclear receptor antagonists (Fig. 2c) (26). Regrettably, this approach has not worked for other ligand-dependent receptors. Indeed, in a search for a thyroid hormone receptor (TR, NR1A, Fig. 3a) antagonist for treatment of hyperthyroidism, adding bulky constituents onto the endogenous TR ligand triiodothyronine (T3) does not create a true antagonist as would be predicted from studies on synthetic ER ligands (3, 4). On the other hand, novel synthetic TR agonists have emerged based on the structure of T3 complexed with the LBD (5).

The existence of SERMs raises some intriguing questions: What does the inactive LBD structure mean at a cellular level? Do only active nuclear receptors interact with the genome? Based on the ER LBD structures with tamoxifen and relaxifene, no productive interactions with coactivator proteins are possible because the AF2 helix adopts an inactive conformation (24, 25); however, paradoxically, SERM-bound ER receptors retain transcriptional activity in certain tissues and on certain promoters. Thus, the small overlap in tamoxifen and relaxifene regulated genes when profiled in an osteosarcoma cell line (65) illustrates how diverse the transcriptional outcomes can be for different SERMs. Similarly, an extremely small overlap was noted between groups of genes regulated by tamoxifen and E2 in a uterine cell line, despite the fact that tamoxifen is thought to be a partial agonist in this tissue (66). Although additional studies are needed, these results illustrate how ligands can alter gene expression dramatically. With the advent of new genome-wide technologies, one can begin to examine how promoter occupancy is affected by ligands. Recent studies that use chromatin immunoprecipitation combined with microarray analyses (CNP/CHIP) reveal that many ER binding sites are located at a great distance from the proximal promoters and that some sites could be bound by the receptor even in the absence of ligand.
of E2 (67). For receptors fortunate enough to have high affinity ligands, as found for steroid receptors (NR3A, NR3C), the collective information gathered from these genome-wide approaches is likely to shed new insights into the physiologic consequences of drug and provide for additional refinement of drug structure.

**PPAR and LXR: Orphans Adopted by Pharmaceuticals**

Peroxisome Proliferator-Activated Receptor (PPAR, NR1C) and Liver X Receptor (LXR, NR1H3) represent two clear examples in which the lack of structural information did not hinder the development of efficacious high affinity pharmaceutical compounds. PPAR and LXR are responsive to glucose and lipid levels, and play important roles in inflammation, cholesterol and lipid metabolism, and energy balance (68–70). Despite the fact that natural ligands for PPAR remain controversial, with fatty acids and eicosanoids as the proposed low affinity endogenous ligands for PPARα (71), highly specific synthetic agonists and antagonists have been developed (Fig. 2a [6, 7]). Indeed, thiazolidinediones and the structurally related fibrates are used widely to treat diabetes and cardiovascular disease (8, 9).

Oxysterols are the proposed endogenous LXR ligands and can bind the ligand-binding pocket of LXR and activate its transcription in cellular assays (10, 72). Additionally, genetic disruption of oxysterol biosynthesis in mice attenuates LXR function greatly (73). Existing synthetic LXR agonists show potential to treat cardiovascular disease, although their collective role in controlling liver and gut metabolism may impose unwanted, off-target effects (10, 73). Oxysterols may not be the only endogenous ligands for LXR. Remarkably, a recent study reports that LXR also acts as a glucose sensor, in which high concentrations of glucose (2 mM) displace oxysterols from the ligand-binding pocket, bind directly to the LBD, and also seem to act synergistically with the synthetic LXR ligand to affect endogenous target gene expression in the liver (74). If true, LXR would be the first intracellular glucose sensor to be discovered and could provide a molecular explanation for the prominent linkages of diabetes with cardiovascular disease. Mechanistically, the authors suggest that glucose binds directly to the LXR LBD, perhaps in combination with oxysterol, or alternatively binds elsewhere in the pocket or on the solvent exposed surface of the LBD to modulate LXR activity allosterically (74, 75). If structural analysis upholds the latter, it would raise an interesting dilemma—how would a hydrophilic molecule, such as glucose or the cellular glucose-6-phosphate, bind tightly into the hydrophobic pocket of LXR? Nonetheless, this finding is provocative and potentially provides a new paradigm for targeting nuclear receptors.

**NR5A Receptors: Large Pockets in Search of Large Ligands**

The NR5A subfamily of nuclear hormone receptors includes LRH-1 and SF-1, as well as the Drosophila nuclear receptor Ftz-F1. SF-1, is required for endocrine tissue development and sexual differentiation, and it is a major regulator of steroid biosynthesis (76). LRH-1 is essential in embryonic development, and, in adults, it regulates bile acid production, cholesterol transport, and ovarian function (77). All LBD crystal structures of murine and human members of this subfamily revealed large ligand-binding pockets and structural inflexibility as evidenced by the minimal changes observed with or without ligand or coactivator peptide (31–3335, 78). The overall stability of the NR5A subfamily can be explained partially by the presence of an additional stabilizing layer caused by a well-formed and elongated helix H2.

Phosphatidyls were found in the ligand-binding pockets of mouse and human SF-1 and human LRH-1 and are relatively large (~750 Da) compared with other ligands such as steroid derivatives. The lipid tails fit exceptionally well into the ligand-binding pocket and make several specific contacts with helix H12 and the hydrophobic cavity (Fig. 3b [31, 32]). In addition to being integral membrane components, phospholipids also bind in the ligand pocket of START domain and in phosphatidyl inositol transport proteins (79). All NR5A receptors exhibit constitutive activity in cells, thus it is unclear whether these ligands serve simply to stabilize the LBD helical bundle or whether they act as regulatory ligands. Notably, filling the pocket with bulky residues diminishes ligand uptake in biochemical assays (31) and also attenuates transcriptional activity in cells (32, 33, 35). The challenge in designing synthetic ligands for NR5A receptors is two-fold. First, finding a ligand that recapitulates the positioning of the acyl chains and the phosphate head group might be problematic and, second, whereas the SF-1 LBD protein readily exchanges the bacterial phosphatidyl glycerol with PI3P or PI2P2 (HAI, unpublished data), and might be bound naturally by phosphatidic acid (80), displacing the endogenous phospholipid with a small molecule in a cellular environment might prove difficult. However, a recent report describes a small molecule that at nanomolar concentrations promotes coactivator peptide recruitment to SF-1 and LRH-1, displaces the phospholipid ligand, and evokes a modest increase in endogenous target gene activation in human hepatocytes (34). These studies suggest that, perhaps, this family of nuclear receptors is still tractable for drug discovery.

**PXR and CAR: Too Much Receptor for a Single Ligand**

Pregnane X receptor (PXR, NR12) and the constitutive androstane receptor (CAR, NR1I2) are highly promiscuous nuclear receptors that bind a variety of structurally diverse compounds. Thus, no difficulty exists in identifying ligands for these receptors—finding highly specific ligands seems to be the challenge, which is true especially for PXR and most likely reflects its role in the xenobiotic response. Several different compounds that range from small hydrophobic drugs to the large anti-epileptic rifampicin are accommodated in its ligand-binding pocket (12-14). Five expandable β-sheets, unique to PXR, allow for this dramatic increase in size of the ligand-binding pocket.
(12). Interestingly, a similar structural feature is also found in START domain proteins and may represent a critical structural arrangement for binding a wide variety of lipophilic molecules (79). CAR exhibits a large but empty ligand-binding pocket and high constitutive activity that results from two structural features: an α helix that precedes helix H12 that stabilizes AF-2 in an active conformation and an extended helix H2, similar to the NR5A receptors (15–18, 21). For an organism, the promiscuity of PXR and CAR activation is an indispensable feature because it assures protection from a variety of harmful xenobiotics and metabolites. However, this characteristic also presents a formidable challenge to rational drug design. Once again, and as found with TR, bulky constituents added onto existing PXR agonist scaffolds fail to yield suitable antagonists (81). For CAR, it appears that a significant mode of regulation occurs by shuttling between the nucleus and cytoplasm rather than by ligand activation (82). Interestingly, inverse agonists or ligands that reduce the constitutive activity of CAR have been reported (15, 19). Whether natural ligands exist for PXR and CAR remains unclear, and it may be more likely that these receptors are designed to sample their chemical environment constantly, and protect the organism from harmful cellular metabolites or from environmental toxins.

True Orphans Without Pockets

Finally, structural information on other receptor subfamilies reveals some receptors either to be complemented with “structural non-exchangeable ligands” or to simply have inadequate capacity in their pockets to accommodate the smallest of ligands. To date, hepatocyte nuclear factor 4 (HNF4, NR2A2) is an example of a receptor with a structural ligand. Structures of the rat HNF4α (NR2A1) and human HNF4γ (NR2A2) LBDs showed a mixture of bacterial fatty acids that occupy the ligand-binding pocket (22, 23). Although HNF4 is found complexed with only a small selection of fatty acids among an assortment of many, this fatty acid ligand is entrenched completely in the ligand-binding pocket and is dislodged only after complete denaturation of the protein, which suggests that in vitro approaches to ligand identification may not be feasible. Similar to this finding, the phosphorylpid ligand in human LRH-1 is also resistant to in vitro exchange with other phospholipids perhaps, presenting another case of a structural ligand for a nuclear receptor (35).

As mentioned above, the lack of a conventional hydrophobic cavity makes the ligand hunt extremely difficult. Two receptor subfamilies appear to be “pocketless,” including members of NR4A [(NGFI-B/Nur77, NR4A1; Nur1, NR4A2), (NOR1, NR4A3)] and their fly ortholog SHH-R8, and members of the NR0 subfamily including Dax-1 (NR0B1). All three structures of NR4 LBDs adopt a canonical protein fold but lack any ligand-binding pocket due to obstruction by bulky side chains (Fig. 3e). These LBDs also lack a hydrophobic coactivator cleft that is instead replaced with a charged surface (29, 30, 83). Another case of an empty pocket is the new structure of the atypical orphan nuclear receptor Dax-1 complexed with LRH-1. Both Dax-1 and SHP (NR0B2) lack a LBD altogether and thus rely on interactions with other NRs and transcription factors to be recruited to the DNA, but both are potent repressors in cellular reporter assays (36, 84). From the crystal structure, it is evident that the ligand-binding pocket of Dax-1 (80 Å³) cannot accommodate even the smallest ligand (E. Sablin and R. J. Fletterick, personal communication). Based on this structure and given the high identity with Dax-1, SHP is also predicted to be refractory to ligand regulation.

Finding pharmacological ligands for receptors with very small pockets still remains a feasible option as illustrated by recent discovery of a synthetic agonist for the estrogen-related receptor γ (ERRγ, NR3B3). ERRγ is a constitutively active nuclear receptor with no known natural ligand, and the crystal structure of the ERRγ LBD revealed an extremely small ligand-binding pocket (220 Å³) (27). Remarkably, in a new crystal structure of ERRγ-LBD with a synthetic agonist, GSK4716, the ligand-binding pocket expanded to a notable 610 Å³ (28). This result underscores the ability of the LBD to accommodate ligands of varying size, and suggests that continuing the hunt for ligands might yield some future surprises.

Alternative Surfaces for Regulation

Despite the fact that ligand discovery has focused historically on the LBD, emerging data suggest that alternative surfaces might be targeted to regulate receptor activity. Alternative binding surfaces have been suggested by structural studies on the NR4A subfamily member, Nur1. Nuclear magnetic resonance footprinting studies of Nur1 LBD with peptides derived from the nuclear receptor coactivator INO80 and a related coactivator SMRT identified a hydrophobic binding site on the surface of the LBD between helices H11 and H12 (85). Mutational disruption of this interaction surface abolished transcriptional activity of Nur1 underscoring its importance in Nur1 function. Because the canonical coactivator groove is absent in the NR4A subfamily, this additional LBD surface is possibly the major site for interaction with the coregulators. On that note, it is of interest that crystal structures of the rat farnesoid X receptor LBD (FXR, NR1H4) and the human LXR-1 LBD revealed two coactivator LXXLL peptides bound to the receptor (31, 33, 86); in these cases, the relevance of this additional bound peptide remains to be determined.

New pharmaceuticals might act by covalent modification of a key protein-protein interaction surface, by blocking an interaction surface, or by affecting the ligand-binding pocket allosterically, as suggested for glucose binding to LXR. Presumably, for most interactions, one would disrupt the assembly of receptor-coregulator complexes and in essence mimic conventional antagonists (87, 88). Rodriguez et al. (89) synthesized a small molecule inhibitor of coactivator binding that structurally mimics key contacts of a coactivator LXXLL motif with the hydrophobic binding groove of the nuclear receptor. The authors used a crystal structure of agonist-bound ERα in a complex with a coactivator peptide to guide small molecule design followed by a screen to identify molecules that abolish peptide recruitment but do not directly compete with ligand binding. A similar high-throughput approach was used to identify novel covalent inhibitors of TRβ (NR1A2), ß-arrestins. These inhibitors
invariably react with a cysteine residue located in the coactivator groove of TRβ-LBD thus disrupting the interaction between TRβ and an LXXLL-containing coactivator peptide (90). TRβ has multiple solvent-exposed cysteines on the LBD, yet these compounds show high selectivity towards a single residue, unique to the TR family of receptors. Additionally, some of the tested compounds appear to be isomor-specific, demonstrating vastly different affinities for TRα and TRβ. Similar to these findings, 4-hydroxylamidoxifen (OHT) was found to inhibit coactivator recruitment to ERα and surprisingly, the crystal structure of the ERα-LBD revealed two bound OHT molecules (91). One molecule was bound in the ligand-binding pocket, and another molecule was revealed in the coactivator groove, displacing the AF2 away from the LBD, into inactive conformation (25). While the exact contribution of this external OHT binding site to the antagonistic effects of OHT on ERβ function is unclear, this binding event could be uncovering a subtle structural difference between the two ER isoforms. Finally, another allosteric inhibitor compound has been identified for the structural difference between the two ER isoforms. It shows reversible binding at a novel hydrophobic LBD surface, conserved in other steroid receptors, and this binding allosterically moves the AF2 helix into an inactive conformation (E. Estévez-Pérfils and R. J. Flitterick, personal communication). Collectively, these studies raise the possibility that new drugs may emerge that target additional surfaces other than the hydrophobic ligand-binding pocket.

Summary and Future Directions

The ability of nuclear hormone receptors to bind small molecules with high affinity and high specificity places them squarely at the interface between biology and chemistry. As such, the nuclear receptor field has historically been focused primarily on the identification of regulatory ligands. Now, an alternative approach is needed for those receptors that fail to exhibit classic ligand dependency, but instead appear to be ligand-independent. Domains outside the DBD and the LBD, especially the Activation Function 1 (AF1) offer a regulatory platform for multiple posttranslational events and coregulator interactions (92, 93). Positioning of the AF1 varies among nuclear receptors, suggesting that it has hopped around throughout evolution, and can be found in the variable N-terminal extension preceding the DBD (NR4) for steroid receptors or in the hinge region close to the LBD for the NR4 and NR5 subfamilies (98-101). Both the N-terminal extension and the hinge region are highly variable in length and sequence, and most likely are disordered and flexible, thus making their structural determination elusive. Multiple sites of posttranslational modifications are found in these variable regions, such as phosphorylation, sumoylation, acetylation, and ubiquitination, and these sites of modification often cluster closely together. Additionally, the AF1 appears to be a major surface for interaction with numerous coregulator proteins (102-106). Considering the importance of AF1 in nuclear receptor activity, its structure, function, and interaction with the DBD and the LBD are still poorly understood, and there are no pharmacologicals available for direct manipulation of AF1 function. For the ligand-independent receptors, such as the NR4 subfamily, posttranslational modifications might be crucial in regulating their activity (107, 108).

The interplay between posttranslational modifications and the ligand potentially leads to a myriad of functional outcomes for the nuclear receptors. We are only beginning to map out the relationships between individual posttranslational events and to understand the specific effects of their combinations on receptor activity. Numerous studies highlight the importance of “the histone code” or how posttranslational modifications of histone proteins affect transcriptional state of the chromatin and dictate transcriptional competency of genes. The abundance of posttranslational modifications on nuclear receptors suggests a similar idea of regulation.

From the extensive cellular, biochemical and structural studies carried out on nuclear hormone receptors it is now appreciated that their ability to be “classically” regulated by ligands is no longer taken for granted. Indeed, we now know that over half of these receptors are not regulated by ligands as discovered for the steroid receptors many decades ago. In the last ten years, intensive research has focused on the “orphan receptors” with the goal of finding their high affinity ligands. Now, it is realized that many receptors cannot be bound by a ligand or have a non-exchangeable “structural” ligand embedded in their pockets. For ligand-dependent receptors, the challenge for the next decade will be to refine the specificity of the existing known ligands or identify allosteric modulatory ligands. For ligand-independent receptors, research will have to take a new direction to identify other regulatory sites that can then be targeted by small molecules. Given the importance of nuclear receptors in human biology and disease, they are likely to remain a primary focus for both academia and industry for years to come.

Introduction

Bacterial pathogenesis can cost in terms of loss of man-hours, loss of livestock, and damage to cash crops. Quorum sensing (QS) is a mechanism by which bacteria regulate the expression of their virulence factors and the resultant pathogenicity. It presents itself as an attractive target for the design of small-molecule inhibitors. An added advantage of targeting QS is that it does not threaten the viability of the bacteria as opposed to the traditional antibacterial agents. Thus, when compared with the traditional antibacterial agents, these small-molecule inhibitors promise to maintain their efficacy over a longer period of time. In this article, the mechanism of bacterial QS systems will be discussed along with a survey of the small molecules/strategies designed to combat them.

Mechanism of the luxIR System in Gram-Negative Bacteria

In the luxIR system (Fig. 1a), AI is an acylated homoserine lactone (AHL), and the family of AHL signal molecules is generally called A-I (Fig. 1a and Fig. 1b) (3). This name refers to the chronology of QS signals discovery. LuxI is the synthase of A-I, which is synthesized from S - adenosylmethionine (SAM) and acyl-acyl carrier protein (acyl-ACP) (Fig. 1a). Activation of the QS circuit(s) relies on the synthesis, accumulation, and subsequent sensing of A-I. The minimal concentration of A-I is constitutively synthesized by its cognate synthase in Vibrio fischeri, for instance, the chemical structure of A-I is...
Quorum Sensing

Figure 1  \( P.\ aeruginosa \) QS system. Its mechanism. (a) Biosynthesis of acyl-homoserine lactone (AHL). Abbreviations: SAM, S-adenosyl methionine; ACP, acyl carrier protein. (b) General chemical structure of AHL molecules, generally called autoinducer-1 (AI-1). (c) Chemical structure of \( V.\ fischeri \) AI-1. (d) Chemical structure of \( P.\ aeruginosa \) 3-oxo-C12-HSL and (e) C4-HSL. (f) Pseudomonas quinolone signal, PQS. 3-oxo-C6-HSL (Fig. 1c), which is synthesized by LuxI (4, 5). As the cell density increases (i.e., more bacteria are present) AI-1 accumulates in the area surrounding the bacteria. When the concentration of AI-1 reaches a critical threshold, AI-1 reenters the cells and is specifically sensed by its cognate transcription factor called LuxR. The LuxR–AI-1 complex binds to a region of DNA (lux box) causing the activation of downstream genes (6). In addition, the LuxR–AI-1 complex also causes an increase in the expression levels of LuxI, which results in more production of AI-1. Thus, the AI (autoinducer) is named after the function of “auto-induction” of its own synthesis. In \( V.\ fischeri \), activation of QS circuit results in activation of luminescence genes; thus, when \( V.\ fischeri \) exists at high cell densities, its colony becomes luminous.

Why can bacteria only sense exogenous the AI signal, not the endogenously existing AI signal? The most recent biochemical studies have suggested that LuxR associates with the cell membrane, and its AI receptor site is not likely exposed to the interior of the cell when it is in an unbound form. Thus, LuxR would not see the AI signal inside of the cell. Moreover, some bacteria actively transport AI signals via an efflux pump. Such mechanisms generally operate to sense the exogenous AI signal, and thus bacteria can monitor the surrounding environment for its own species or for other species of bacteria.

The QS system of \( Pseudomonas\ aeruginosa \) has been studied extensively because of its importance as a human pathogen. \( P.\ aeruginosa \) has a unique system of QS that consists of las, rhl, and \( Pseudomonas\ quinolone\ signal \) (PQS) circuits (Fig. 2a). The first two circuits, las and rhl, have a set of proteins (synthase and receptor) and AI-1 like the typical luxR circuit. The las circuit is composed of LasI and LasR along with 3-oxo-C12-HSL (Fig. 2a) as its cognate AI, whereas in the rhl circuit RhlI and RhlR exist with C4-HSL (Fig. 2c) as their cognate AI. The fundamental mechanism of the \( P.\ aeruginosa \) QS system is similar to that of \( V.\ fischeri \), but activation of the rhl circuit relies on activation of an upstream lasI circuit (7); for example, accumulation of LasR–3-oxo-C12-HSL activates the expression of the rhlI gene, which results in the activation of the rhl circuit. Significantly, activation of the rhl circuit is connected to the transcription of genes that express secondary metabolites and virulence factors, such as pyocyanin and elastase (8). Recently, more attention has been focused on the fact that the QS system controls biofilm formation/maturation (9).

AIs isolated from different Gram-negative bacteria differ in the N-acyl side-chain length (from C4 to C14) or degree of substitution (3-oxo, 3-hydroxy, saturated, or unsaturated). Generally, assumed to be freely diffusible in bacterial cells, radio-labeled \( V.\ fischeri \) AI (3-oxo-C6-HSL) (10) has been shown to be freely diffusible into and out of \( V.\ fischeri \) and \( Escherichia\ coli \) cells. However, in \( P.\ aeruginosa \), whereas C4-HSL can diffuse freely into and out of \( P.\ aeruginosa \) cells, 3-oxo-C12-HSL is actively transported by an efflux pump (MexAB-OprM) (11) outside the cell, which results in three times higher levels of 3-oxo-C12-HSL inside the cell, which suggests that the length and/or degree of substitution of the N-acyl chain determines whether it diffuses freely or is actively pumped out from the cells.

In the PQS circuit, it has been shown that PQS (12) is involved in controlling genes required for virulence factor expression and biofilm formation. PQS regulates the expression of lasI, encoding for elastase, an important virulence factor, and both the las and rhl QS systems of \( P.\ aeruginosa \) affect the synthesis and bioactivity of PQS. LasR positively regulates the synthesis of PQS, whereas RhlR represses it. Both
3-oxo-C₁₂-HSL and C₄-HSL compete for pqsABCDE (PQS operon) regulation, and the levels of expression are thus dependent on the ratio of the two autoinducers (13). Furthermore, PQS also induces the rhl circuit (14). PQS is hydrophobic and is conveyed between P. aeruginosa cells via a specialized vesicular transport mechanism (15). The vesicles package the PQS and other quinolones/quinolines and traffic them between P. aeruginosa cells that exist in biofilms in cystic fibrosis sputum. Mutants that do not produce these vesicles also do not show PQS-mediated QS. Interestingly, PQS behaves as an antibiotic against Gram-positive cells (16, 17), which suggests that mechanisms similar to those of other known quinolones/quinolines antibiotics are likely to be in place.

**Cross-Species Communication between Bacteria Using LUXR Signals**

P. aeruginosa is a soil bacterium and shares its habitat with antibiotic-producing bacteria such as Streptomyces tenebrarius (the source of tobramycin, an antibiotic used commonly against P. aeruginosa) (18) and the pathogenic filamentous yeast Candida albicans (19). It thus may use its AI molecules to restrain antipseudomonal compound(s) that produce environmental pathogens. Recently, it has been shown that the degradation product of 3-oxo-C₁₂-HSL resembles a class of antibacterial compounds called tetramic acids (Fig. 3) (20). Such a tetramic acid analog is produced through the enol form of the 3-oxo-carbonyl group on the fatty acid side chain undergoing intramolecular alkylation of the lactone ring of HSL, which gives rise to a HSL open-ring structure. This rearranged molecule turns out to resemble tetramic acid structurally. It has been shown that this tetramic acid-like molecule acts like an antibiotic toward several Gram-positive bacteria, while leaving the Gram-negative bacteria unaffected. Although the mechanism of bactericidal activity of this tetramic acid-like molecule derived from 3-oxo-C₁₂-HSL is as yet unclear, it has been postulated that it chelates metal ions such as Fe³⁺ and that this complex somehow may increase its bactericidal potency (Fig. 3) (20). Alternatively, it simply may exhibit the antibiotic activity via a mechanism similar to that of reutericyclin, which is known to act as a proton ionophore that dissipates the transmembrane change in pH and leads to the cell lysis of Gram-positive bacteria (21).

4-hydroxy-2-heptylquinoline-N-oxide (HQNO), a quinolone family member, similarly has antistaphylococcal activity, which suppresses the growth of many Gram-positive bacteria. Paradoxically, it also allows some Gram-positive bacteria to grow, albeit slowly, in the presence of aminoglycoside antibiotics like
Quorum Sensing

Why is Quorum Sensing Important as a Therapeutic Target?

Traditional antibacterial agents target processes crucial to the survival of a bacterium. These processes include cell wall biosynthesis, replication, and protein synthesis, which endanger its survival and thus lead to the development of drug resistance in bacteria. Bacteria eliminate drugs by exporting them out via multidrug pumps or by circumventing/degrading the drug molecule. QS inhibitors (QSI(s)), however, do not threaten bacterial survival, and therefore, in principle, bacteria would not be forced to evolve resistant strains if QSI(s) are used. Because QS regulates the production of virulence factors, QSI(s) potentially can attenuate the virulence of pathogenic bacteria (Fig. 3). Thus, QSI(s) may offer us a new class of antimicrobial agents that would not suffer from the emergence of resistant strains.

P. aeruginosa is an example of one such attractive target for therapeutic drug design. It is the leading cause of mortality among cystic fibrosis patients. It also affects immunocompromised individuals with HIV infections, cancer, burns, or organ transplants. Through knockout studies, it has been firmly established that P. aeruginosa, incapable of QS, is also incapable of virulence. For instance, analysis of a lasI mutant, rhlI mutant, and lasI-rhlI double mutant in a neonatal mouse model revealed markedly decreased virulence (24), with the most notable reduction in the double mutant. Other infection models studied (25, 26), firmly establish that it is the QS mechanism that enables P. aeruginosa to form biofilms and cause sustained infections in the host system (Fig. 3). Thus, strategies geared toward elimination of QS can aid in clearing the infection because they retard the formation of biofilm and the resulting sustained virulence, which makes the QS system an attractive therapeutic target.

Small Molecular QS Modulators

The discovery of AI antagonists is challenging and therapeutically significant. A potent antagonist was recently discovered by modification of natural AI antagonists, halogenated furanones (Fig. 4a), produced by a marine alga to prevent colonization by QS bacteria (27–31). These natural products disrupt the Serratia liquefaciens SwrR-C4-HSL (32) interaction and also inhibit the LasR-3-oxo-C12-HSL (33) and CarR-3-oxo-C6-HSL (27) interactions but have little activity against the LasR-3-oxo-C12-HSL interaction. Givkov et al. synthesized an analog that lacks the alkyl side chain of the natural furanones and found that this compound had considerable inhibitory activity against the P. aeruginosa QS system (Fig. 4b). They showed that the molecule inhibited QS-controlled reporter genes and virulence factors in a QS mutant with exogenous AIs but not in wild-type P. aeruginosa with natural levels of AI. This compound did not inhibit biofilm formation, but it affected biofilm architecture and enhanced the process of bacterial detachment. Interestingly, the same group recently reported that the QS inhibition by the synthetic furanone was not because of the interaction with LuxR demonstrated in V. cholerae; more likely, it accelerates the turnover, for example, degradation, of LuxR via an unknown mechanism(s). Although this finding might not be totally surprising because the synthetic furanone and natural furanones are structurally quite different from natural AIs, it is significant that the molecules somehow associating with QS inhibition can attenuate bacterial virulence.

Natural furanones are not alone in having anti-AI activity. They are joined in nature by garlic, vanilla, and phytochemicals present in dietary fruits and spices, and so forth. Garlic extracts have been shown to inhibit QS sensing in P. aeruginosa and also render it sensitive to tobramycin and phagocytosis by polymorphonuclear leukocytes (PMN) in a mice model of P. aeruginosa infection (34). However, the garlic-extract dose used to treat the mice equates to approximately 50 bulbs of garlic per day for an average human being. Thus, more work to identify and isolate the pure compounds responsible for inhibition of QS is awaited. Vanilla extract, however, mainly contains vanillin (85%). Vanillin, despite having no structural similarity to furanone derivatives or AIs, shows significant inhibition of QS in Chromobacterium violaceum (35). In Chromobacterium violaceum also is inhibited by phytochemicals in dietary fruits, herbs, and spices (36). These phytochemicals also affect the swarming mobility of P. aeruginosa through a possible impact on synthesis and activity of AI molecules. Macrolides like azithromycin also repress the las and rhl in P. aeruginosa albeit at sublethal concentrations (37).

Molecular insights into the LasR-3-oxo-C12-HSL interactions, available from crystal studies, may provide an important tool into the process of antagonist design. Over the past decade, tremendous efforts have been made to generate a soluble form of various LuxR family proteins and their cognate AIs. Three LuxR proteins, Erwinia chrysanthemi ExpR (38), Agrobacterium tumefaciens TraR (39), and Erwinia carotovora CarR (40) have been expressed successfully as a complex with the cognate AIs and purified for in vitro characterization. Particularly, the recent success in solving the crystal structure of the dimer of TraR-AI (3-oxo-C6-HSL) complex interacting with the target DNA (41, 42) has provided the first visual information regarding the molecular interactions between a LuxR family protein and its cognate AI. It should be noted that the dimerization of TraR (as well as ExpR and CarR) has been predicted by the in vitro biochemical studies, and thus the X-ray structure most likely represents the active form in vivo.

Despite the fact that many attempts to overexpress the full-length LasR failed, Bottommy et al. (43) have recently succeeded in crystallizing a construct of LasR consisting of only the N-terminal domain.
the predicted ligand binding domain (LasR-LBD), which consists of the amino acids from Met-1 to Ile-173) in a complex with 3-oxo-C12-HSL. The complex was observed as a symmetrical dimer of LasR-LBD, and 3-oxo-C12-HSL was buried deeply inside the binding site. The monomer exhibits structural features similar to TraR, which consists of an α-β-α sandwich structure with three α-helices flanking a five-stranded antiparallel β-sheet. 3-oxo-C12-HSL lies parallel to the β-sheet and lies buried in a pocket formed between the β-sheet and α3–α5 helices. Also, all the polar groups of 3-oxo-C12-HSL, except the oxygen of the lactone ring, make hydrogen bonds with the amino acid residues of LasR–LBD. The acyl chain extends into a hydrophobic residue-lined cavity. Some of these residues are observed only in LasR, thus providing high specificity and a minimum crosstalk between bacteria of different species. In silico, modeling of the interaction of available QS inhibitors with the LasR-LBD provides a clue to the mechanism of action of the inhibitors. This modeling also provides a scaffold for the de novo design of better inhibitor molecules.

Suga et al. (44, 45) have reported that the screening of a library of synthetic AI analogs with substituted HSL has yielded a novel class of QS inhibitors. Interestingly, two of these antagonists found in the screening, 3-oxo-C12-(S) 2 and 3-oxo-C12-(S,S) 1, are structurally related to the synthetic agonist 3-oxo-C12-(S,S) 1 and the antagonist 3-oxo-C12-(S) 2. Small structural changes of the agonist HSL substitute (1) altered activity dramatically from agonist to antagonist. In light of the strong agonist activity of 1, these antagonists most likely maintain binding to LasR but fail to activate it and hence act as potent inhibitors. These QS inhibitors inhibit expression of virulence factors, such as elastase B and pyocyanin. Moreover, 3-oxo-C12-(S) 2 inhibited biofilm formation in both QS mutant (in the presence of exogenous AIs) and wild-type P. aeruginosa under static conditions. The latter compound 3-oxo-C12-(S) 2 did not inhibit biofilm formation but significantly altered biofilm architecture. Thus, these antagonists are promising leads to derive more potent antagonists by the screening of focused libraries.

In fact, a resurvey of focused libraries based on the antagonists found in the initial screening has given several new strong antagonists. 3-oxo-C12-(S) 2 and its related molecule 3-oxo-C12-(S,S) 1 (which also is related to the 3-oxo-C12-(S) 2 ) have shown a strong inhibitory effect on las circuit and also show inhibition on the downstream rhl circuit (Fig. 4c). Likewise, 3-oxo-C12-(S) 2 exhibited a strong inhibitory effect on the QS circuits. Significantly, 3-oxo-C12-(S,S) 1 and 3-oxo-C12-(S,S) 6 showed remarkable abilities in the inhibition of biofilm formation of wild-type P. aeruginosa.
Quorum Sensing

In flow-cell experiments (Hiroaki Suga et al., unpublished data), these compounds to wild-type P. aeruginosa that had formed mature biofilms resulted in the detachment of biofilms and the removal of bacteria from the glass surface in a flow cell. Along similar lines, Greenberg et al. (46) reported two new substrates of HSL that can inhibit P. aeruginosa QS circuits (Fig. 4d). These QS inhibitors are promising candidates for drug development, and more results from in-depth studies in various models of infection are awaited.

A deletion of the fatty acid side-chain based on the structure of AHL is an obvious alternative approach to antagonist(s) discovery. Earlier works devoted to changing the length of the fatty acid or 3-functional group unfortunately did not yield notable antagonists. However, more recent investigations independently reported by Doutheau (47, 48) and Blackwell (49) successfully showed that more drastic derivatizations of the fatty acid side chain generated potent antagonists. Doutheau et al. has shown that AI analogs with C6-acyl, C7-sulfonyl, or C6-ureido chains (Fig. 4d, 7-10) bearing aromatic groups such as phenyl at the end of an alkyl chain antagonize the QS circuit of V. fischeri. Blackwell et al. later observed that substitution of the aromatic ring with an indole ring on the C6-acyl chain gave approximately two-orders of magnitude stronger inhibitory effect on P. aeruginosa QS system than the parental compounds reported by Doutheau. This molecule also could block the biofilm production under static conditions. It must be noted, however, that these AHL-based analogs likely suffer from an instability problem because of the hydrolysis of the lactone ring when the analogs are subjected to an in vivo environment (vide infra).

In conclusion, it is to be noted that although the current QSI candidates can disrupt the interaction of the A-HL molecule with its cognate receptor, they are not potent enough to halt the QS process and the resultant pathogenesis. Thus more studies geared toward the discovery of molecules that antagonize the QS system are awaited, in particular, those that target not only the receptors but also the AHL synthases.

Modulating the QS System Outside of Bacterial Cells

Because the QS system is triggered by the exogenous AI signal entering the cell, if the QS signals were to be degraded (50) so that the signaling function is lost, then the QS system could be modulated. In fact, some prokaryotes and eukaryotes do have such defense systems.

The aiiA gene (51) encoding an AHL lactonase, recently discovered in a Gram-positive bacillus bacterium isolated from soil, enables it to compete against Gram-negative bacteria in the soil. Expression of aiiA in a transformed Erwin carotovora strain reduced the release of AI significantly and attenuated the pathogenic effects on important crops like potato, eggplant, Chinese cabbage, carrot, celery, cauliflower, and tobacco. Such genetically engineered crops would be expected to fare better against bacterial infections.

Paraxonases (PONs) (52) are a family of mammalian lactone hydrolases, expressed in liver and various tissues, and they can deactivate 3-oxo-C12-HSL by the hydrolysis of the lactone ring. Similarly, arachidonic acid cells can inactivate 3-oxo-C12-HSL by an enzymatic mechanism. (53) The inactivation is selective for A-HLS with certain carbon chain lengths, and C6-HSL is reportedly immune to such inactivation. This inactivation activity is cell associated and not mediated by a secreted factor. Also, the inactivation is shown to occur in cell-free lysates, and the ability of the cell-free lysate to inactivate 3-oxo-C12-HSL depends on the amount of lysate used.

An alternative approach to the inhibition of QS is the use of antibodies directed toward the A-HL molecule. Recently, Kaufmann et al. (54) has reported the generation of anti-AHL monoclonal antibodies (mAbs). Their hapten design initially focused on the synthesis of A-HL analogs with a carboxylic acid functionality to facilitate the binding of BSA or KLH. Because of the instability of the hapten, a lactam moiety replaced the lactone ring. Three haptenes thus were synthesized, and after conjugation to KLH (18–23 hapten molecules per carrier protein), Balb/c mice were immunized for generation of hybridomas.

The monoclonal antibodies generated against the 3-oxo-hapten had a good affinity (Kd = 15 nM to 5 nM) for 3-oxo-C12-AHL and the lactam analog and high specificity because short-chain 3-oxo-AHLs were not recognized. Also, these antibodies, in particular RS2-1G9, demonstrated strong inhibition of QS signaling in both wild-type and mutant P. aeruginosa PAO cells concomitant with inhibition of pyocyanin production. The crystal structure of FabRS2-1G9 in complex with the lactam analog has revealed that the polar lactam moiety is encapsulated completely in the antibody-combining site (55). This study provides insight into the immune recognition of a quorum-sensing molecule by an antibody. Furthermore, this structure can be used for protein engineering that leads to an enhanced interaction of an antibody with the A-HL molecule. Lactonase activity could be added into the antibody through site-directed mutagenesis of the antibody. Lending additional credence to the antibody approach is the study on 3-oxo-C12-HSL-BSA conjugates (56). Mice immunized with 3-oxo-C12-HSL-BSA conjugate showed significant amounts of antibody in the serum. When challenged intranasally with P. aeruginosa, 36% of the mice survived for 4 days post challenge as compared with the control mice that died in 2 days. Interestingly, the bacterial numbers in the lungs were similar in the two groups. Thus, specific antibodies to 3-oxo-C12-HSL confer a protective advantage against acute P. aeruginosa infections.

Conclusion and Perspective

In this article we have seen how QS presents an alternate route to combating bacterial pathogenesis. Although more studies are awaited to develop efficient drug molecules to inhibit QS system, it nonetheless proves to be an attractive target for drug development. Also, the attenuation of virulence observed with the use of QSI is not accompanied with a loss in viability of the bacterial pathogens. In this respect, QSI are different from traditional antibacterial agents that act through affecting the viability of the bacteria in various ways. It is hoped that QSI will not suffer from the drawback of resistance development, which
tradiotional antibacterials have to battle against. Thus, more studies geared toward the design of QSIs, including both synthetic analogs of AI molecules and inhibitors of AI synthases, may lead to the availability of drug molecules capable of maintaining their efficacy over longer periods of time compared with the traditional antibacterial agents.

The Ras small GTPase is well known for its role in regulating normal cellular proliferation, as well as in promoting human oncogenesis when activated mutationally. In signal transduction, Ras functions as a guanine nucleotide-regulated on-off switch. Positioned at cellular membranes, Ras relays signals initiated by diverse extracellular stimuli to a complex network of cytoplasmic signaling cascades to affect changes in gene transcription, cell-cycle progression, survival, and differentiation. The intense research into the biologic and chemical nature of Ras has prompted the development of a variety of biologic, pharmacologic, and genetic tools to study Ras signaling. Also, Ras is the founding member of a superfamily of Ras-related and Ras-like proteins. The technical approaches and chemical concepts that have been generated from the study of Ras have aided greatly the studies of Ras superfamily proteins, which revealed the versatile and divergent biologic roles of small GTPases in cell physiology.

The connection between mutations in RAS genes and in human carcinogenesis was first established nearly 25 years ago (1). Research efforts since then have demonstrated that aberrant Ras signaling plays an integral role in the development and malignant growth of many types of human cancers. Ras proteins are simple binary switches that are controlled by a regulated GDP/GTP cycle (2) (see Fig. 1). A diverse spectrum of extracellular stimuli promotes the transient formation of active, GTP-bound Ras. Then, activated Ras interacts with downstream effectors that regulate cytoplasmic signaling cascades to promote changes in cell-cycle progression, actin cytoskeletal organization, cell survival, and gene transcription (3). Whereas wild-type Ras cycles between the GTP-bound and GDP-bound states in a regulated manner, cancer-associated mutations lock Ras in the “ON” position, which renders the protein constitutively activated. Given its role in oncogenesis, the biologic and chemical nature of Ras and the consequence of persistent Ras activation has been the subject of intensive biologic and pharmacetical research. This article will provide a brief overview of the chemistry, structure, and biology that underlie Ras signal and will summarize the key assays and reagents that have been developed and applied to study Ras signal transduction and biologic activity.

Biology

Ras proteins function as nodal points in signal transduction. Diverse extracellular stimuli act on plasma membrane-bound receptors (which include receptor tyrosine kinases and G protein-coupled receptors) and cause the activation of Ras (see Fig. 1). A accumulating evidence suggests that once activated, Ras may transit from the plasma membrane to endomembranes (4, 5). Alternatively, endomembrane-bound Ras may be activated by a discrete set of upstream activating proteins (4, 6, 7). Activated Ras then regulates myriad cytoplasmic signaling cascades to cause changes in normal cell physiology, which includes the regulation of cell morphology, growth, survival and differentiation, vesicular transport, and gene expression.

In addition to its role in promoting normal cellular growth and differentiation, Ras is perhaps best known as an oncogenic protein for its involvement in human carcinogenesis. Approximately 30% of all human cancers express a mutationally activated Ras protein (1, 8), with the highest incidence of somatic Ras mutation observed in pancreatic (90%), lung (50%), and colon (30%) cancers (9). An extensive body of research has implicated a strong causal role for mutated Ras in cancer development and growth. This relationship has prompted considerable
Ras Oncoproteins: Structure, Biochemistry, and Biology of Ras

The three human RAS genes encode four highly related 188-189 amino acid RAS proteins (H-Ras, N-Ras, and two K-Ras-encoded splice variants, K-Ras4A and K-Ras4B) that share significant sequence identity (90%) and common structural elements (see Fig. 2). RAS genes are conserved in vertebrate and invertebrate evolution, with homologous genes found in C. elegans, Drosophila, and yeast but not in plants or bacteria. RAS genes are the founding members of a greater than 150-member superfamily of RAS-related genes that encode small GTP-binding and hydrolyzing proteins (GTPases) (12, 13). RAS proteins are composed of two discrete sequence elements: a catalytic G domain and a hypervariable membrane-targeting domain (see Fig. 2). The amino-terminal 166 amino acids of RAS compose the G domain, which contains the consensus sequence motifs found in classic GTP-binding proteins. The carboxyl-terminal 23 to 24 amino acids compose the hypervariable region. The hypervariable region terminates in a consensus CAAX tetrapeptide motif that signals for posttranslational modifications that increase the hydrophobic nature of RAS. This region also contains additional sequences that promote membrane association and direct subcellular localization of Ras.

The three-dimensional structure of the G domain consists of five α-helices, six β-strands, and five loop regions (G1–G5) (see Fig. 3). The five loop regions are involved in protein–protein interaction and nucleotide binding (14). Within the G domain, two switch regions (switch I and II, residues 30–38 and 59–76, respectively) form exposed flexible loops that adopt different conformations depending on the identity of the bound guanine nucleotide. The effector loop or effector domain, which corresponds to G2, is embedded in switch I and forms critical contacts with effector molecules. Therefore, the stereochemical arrangement of the switch I and switch II regions translates Ras conformation into a downstream response by diminishing effector binding to GDP-bound Ras and favoring effector binding to GTP-bound Ras. The other G loops contact the guanine base, phosphate groups, and Mg2+ ion (15). In addition to mediating effector binding, the two switch regions of Ras interact with proteins that regulate the GDP/GTP cycle: guanine nucleotide exchange factors (GEFs) and GTPase activating proteins (GAPs).

Ras possesses a weak GDP/GTP exchange activity. Because the cellular levels of GTP are 20-fold greater than that of GDP, the dissociation of GDP from Ras favors the formation of Ras-GTP. Ras also possesses low intrinsic GTPase enzymatic activity, which stimulates hydrolysis of bound GTP to GDP to cycle Ras back to its inactive GDP-bound state. The intrinsic exchange and hydrolytic activity of Ras is not sufficient to promote rapid GDP/GTP cycling. Ras-specific GEFs and GAPs are critical to accelerate guanine nucleotide cycling and hence to promote a response to extracellular stimuli. RasGEFs (e.g., Sos, RasGRF, or RasGRP) promote the exchange of GDP for GTP and activate Ras signaling activity (16, 18). RasGAPs (e.g., p120 RasGAP, or NF1 neurofibromin) stimulate hydrolysis of GTP to GDP and terminate signaling activity (19). The activity of GEFs and GAPs enable Ras proteins to signal downstream to their effector molecules in a regulated manner.

Subcellular localization of Ras

In addition to nucleotide binding, the signaling activity of Ras is governed by subcellular localization. Ras proteins terminate in a tetrapeptide CAAX motif, where C is cysteine, A is any aliphatic amino acid, and X is serine or methionine. Ras proteins are synthesized initially as cytoplasmic pro- teins that have no signaling activity (see Fig. 3). Ras then undergoes a series of CAAX-directed posttranslational modifications. Farnesyltransferase (FTase) catalyzes a covalent addition of a 15-carbon farnesyl (isoprenyl) group to the cysteine of the CAAX motif, followed by Ras converting enzyme 1 (Rce1)-catalyzed proteolytic cleavage of the CAAX tetrapeptide motif, which signals for posttranslational modifications that increase the hydrophobic nature of Ras. This region also contains additional sequences that promote membrane association and direct subcellular localization of Ras.
Figure 2: Schematic of Ras small GTP binding and hydrolyzing proteins. The five G boxes (G1-G5, yellow) comprise the catalytic domain of Ras. The hypervariable region (red) at the carboxyl terminus contains the second signal that is critical for proper subcellular localization. The CAAX box (blue) is post-translationally modified by a 15-carbon isoprenyl lipid and is required for membrane association. The sequence of each motif for H-, N-, and K-Ras4B is given, as well as the consensus sequence found in all G domain-containing proteins. Mutation of residues highlighted in green (at G12, G13, or Q61) results in a constitutively activated protein. Conversely, mutation of the residue highlighted in red (S17) creates a dominant negative protein. Alternative names for some motifs, as well as their main function in Ras biochemistry, are listed as well.

residues (20), and isoprenyl/cysteine-directed carboxy methyltransferase (Icmt)-catalyzed carboxylmethylation of the now terminal prenylated cysteine residue. The prenyl residue inserts into cellular membranes, which bthers Ras to the cytosolic face of cellular membranes (21, 23). Point mutations engineered in the carboxyl terminus of Ras proteins (such as a cysteine to serine substitution in the CAAX box) as well as pharmacologic inhibitors (e.g., FTase inhibitors or FTIs) disrupt this posttranslational processing and cause mislocalization of Ras (24, 27).

The three CAAX-signaled modifications increase the overall hydrophobicity of the carboxyl terminus of Ras and are necessary to promote Ras membrane association. However, these modifications alone are not sufficient to direct full plasma membrane association and signaling activity. At least two additional motifs exist at the carboxyl terminus of Ras proteins, which serve to facilitate plasma membrane association and direct Ras proteins to discrete membrane subdomains. These motifs function as secondary signals and are composed either of a stretch of basic amino acids (K-Ras4B) or of cysteine(s) that are palmitoylated (H-Ras, N-Ras, K-Ras4A) and positioned immediately upstream of the CAAX motif (28, 30) (see Fig. 3). The addition of a palmitate fatty acid is catalyzed by a protein acyltransferase, which forms a reversible thioester bond between the cysteine and the palmitoyl group (31, 32).

Effector interaction

The biologic function of Ras is mediated by its ability to activate downstream cytoplasmic signaling networks through binding to a panel of effector proteins. The Ras-effector interaction is mediated through interactions between the core effector domain (amino acids 32–40) of Ras (see Fig. 2) and the specific residues within the Ras-binding domain (RBD) or Ras-association domain (RA) found in most Ras effectors. The RBDs and RA domains of effector proteins do not exhibit primary sequence homology, but instead they share a common tertiary structure that consists of an ubiquitin superfold, which forms critical contacts with Ras (33).

Figure 3: Ras membrane targeting is a multi-step process. A native Ras protein is found in the cytoplasm of the cell. The cysteine of the CAAX motif is posttranslationally covalently modified by a farnesyl (red) lipid in a reaction catalyzed by farnesyltransferase (FTase). A series of posttranslational processing steps catalyzed by the indicated enzymes at the endoplasmic reticulum cleave the AAX residues and modify the now terminal prenylated cysteine with a carboxymethyl group. A secondary signal, either lysine residues in the case of K-Ras4B or cysteine bound to palmitate in the case of N-Ras and H-Ras is required for final membrane location. Mutating the cysteine of the CAAX motif to a serine (Ras-SAAX) precludes the addition of an isoprenyl group and all subsequent modifications, resulting in a cytosolic, inactive mutant protein.

At least 10 distinct families of Ras effector proteins have been identified, with the Raf serine/threonine kinases, phosphatidylinositol 3-kinases (PI3K), and RasGEFs being the most extensively characterized (3) (see Fig. 4). Beyond their shared ability to bind preferentially to Ras-GTP, Ras effectors possess highly divergent biochemical and biologic functions.
members) can contribute to apoptosis (34).

RalBP1 RalGEF functions as an activator of the Ras-like (RalA and RalB) small proteins. The phosphatase and tensin homolog (PTEN) tumor suppressor promotes activation of the AKT serine/threonine kinase and other signaling proteins. The phosphoinositol 3,4,5-triphosphate (PIP3) second messenger regulates phosphoinositide metabolism and formation of the leading to subsequent phosphorylation and activation of the Elk-1 transcription factor and changes in gene expression. PI3K activation regulates phosphatidylinositol metabolism and formation of the phosphatidylinositol 3,4,5-triphosphate (PIP3) second messenger. PIP3 promotes activation of the AKT serine/threonine kinase and other signaling proteins. The phosphatase and tensin homolog (PTEN) tumor suppressor protein antagonizes the activity of PI3K by dephosphorylation of PIP3.

Ras proteins can be monitored through another fluorescence-based assay. The fluorescence of an N-methylanthraniloyl derivative of mant-GTP increases ∼20% when binding to small GTPases. The intrinsic and GAP-stimulated GTP hydrolysis can be measured with real-time fluorescence-based assays. The fluorescence of an N-methylanthraniloyl derivative of mant-GTP increases ∼20% when binding to small GTPases. The intrinsic and GAP-stimulated GTP hydrolysis can be measured with real-time fluorescence-based assays.

Various protein–protein interaction methods have been developed to study the GTP binding, exchange, and hydrolytic activities of Ras. The in vitro ultra rate of nucleotide exchange and GTP hydrolysis can be measured with real-time fluorescence-based assays. The fluorescence of an N-methylanthraniloyl derivative of GTP (mant-GTP) increases ∼20% when binding to small GTPases, and therefore can be used to monitor the rate of nucleotide exchange and incorporation of mant-GTP into Ras (38). The intrinsic and GAP-stimulated GTPase activities of Ras proteins can be monitored through another fluorescence-based technique.

### Ras structural mutants

The creation and application of Ras mutants that display gain- or loss-of-function phenotypes has provided the foundation for our knowledge of the basic function and regulation of Ras proteins (see Table 1). By analogy to Ras, similar mutations have been introduced in many Ras superfamily proteins as well as other unrelated GTPases. These mutant proteins, particularly mutants of the Rho family small GTPases, have proven to be powerful reagents for functional studies.

Constitutively active Ras proteins can be generated through substitutions of the preserved glycine at position 12 or glutamine at position 61, for example, with valine (G12V) or leucine (Q61L), respectively (see Fig. 2). Essentially, any amino acid substitution at these two positions impairs the intrinsic and GAP-stimulated GTP hydrolysis rate, which results in the formation of a constitutively GTP-bound and chronically active protein. These activated mutants can be used to determine the downstream signaling activities of Ras proteins.

Conversely, Ras with a substitution of serine at position 17 with asparagine (S17N) binds to and forms nonproductive complexes with RasGEFs (see Fig. 2). Because each RasGEF can activate several Ras proteins, Ras(S17N) acts as a dominant negative inhibitory protein that inhibits activation of all Ras proteins. This dominant negative reagent can be used to determine whether the biologic activity of a particular extracellular stimulus is mediated through RasGEF-dependent activation of Ras.

### Ras GEFS and downstream signaling

Figure 4 Ras activates multiple effector pathways. GTP-bound active Ras travels to and stimulates a myriad of cytoplasmic signaling cascades. The three most extensively characterized effector pathways (RalGEF, Raf, and PI3K) are shown. Signal propagation occurs via phosphorylation of Raf, leading to subsequent phosphorylation and activation of the ERK1/2 MAPK pathway. PI3K activation regulates phosphoinositide metabolism and formation of the phosphatidylinositol 3,4,5-triphosphate (PIP3) second messenger. PIP3 promotes activation of the AKT serine/threonine kinase and other signaling proteins. The phosphatase and tensin homolog (PTEN) tumor suppressor protein antagonizes the activity of PI3K by dephosphorylation of PIP3.

### Chemical Tools and Techniques

The research on Ras proteins has resulted in the development of an impressive collection of reagents, assays, and techniques to dissect the Ras function. These techniques include mutants of Ras proteins, biochemical assays to monitor Ras function in vitro and in vivo, pharmacologic and genetic tools to dissect Ras signaling, as well as more recent approaches that apply RNA interference (RNAi) and other gene silencing techniques, and fluorescence-based protein assays to monitor the spatial and the temporal activities of Ras. Tables 1–3 provide a comprehensive list of the tools and reagents available to study Ras biology.
Table 1. Genetic reagents for activation of Ras and Ras effector pathways

Analyses of Ras subcellular localization

When expressed in quiescent cells where Ras is inactive, the GFP-Raf-RBD probe is distributed homogeneously throughout the cell. When cells are stimulated with a growth factor or through a novel method that detects free thiol groups in proteins (50, 51). This assay involves blocking all available free thiol groups, presumably only at the sites of palmitate linkage. The thiol group can then be detected using a biotinylated thiol group, presumably only at the sites of palmitate linkage. The thiol group can then be detected using a biotinylated thiol reagent.

Analyses of Ras subcellular localization and posttranslational processing

Proper localization of Ras is essential for function, and several pharmacologic and genetic tools are available to study the posttranslational processing and subcellular localization of Ras. Note that epitope or fluorescent tags must be added at the amino terminus of Ras so as not to disrupt posttranslational processing of the carboxyl terminus. The localization of GFP-Ras can be monitored in live cells through confocal or widefield microscopy. Alternatively, anti-Ras antibodies can be applied to detect the location of endogenous protein in fixed cells. Similarly, antibodies that recognize epitope tags can be used to evaluate the subcellular localization of ectopically expressed, amino-terminal epitope-tagged Ras proteins. These antibodies include the commercially available antibodies that recognize peptide sequences found in the influenza hemagglutinin antigen (YPYDVPDYA), the human c-Myc transcription factor (LDEESILKQE), and the FLAG epitope (DYKDDDDK).

The treatment of cells that express GFP- or epitope-tagged Ras with various pharmacologic inhibitors is also useful to determine which posttranslational modifications are required for Ras membrane association. For example, treatment of cells that express GFP-H-Ras with FTIs causes GFP-H-Ras to mistarget to the cytoplasm, which indicates that farnesylation is required for membrane association. Compounds that block protein palmitoylation, such as 2-bromopalmmitate, can also be used to determine whether palmitoylation is required for Ras-related proteins to associate with the plasma membrane (46–48).

Various assays are available for direct analyses of the posttranslational modification of Ras by lipids. Recombinant FTase together with recombinant Ras can be used to evaluate the farnesylation of Ras. Rabbit reticulocyte lysate can be used for in vitro transcription/translation analyses of all CAAX-signaled modifications. Direct measurement of palmitoylation can be assessed by evaluating incorporation of a tritiated palmitate analog (49) or through a novel method that detects free thiol groups in proteins (50, 51). This assay involves blocking all available free cysteines in a protein and then chemically cleaving thiolester bonds that link palmitate to cysteine. Cleavage generates a free thiol group, presumably only at the sites of palmitate linkage. The thiol group can then be detected using a biotinylated thiol reagent.

Pharmacologic inhibitors of the enzymes involved in AAX proteolysis and carboxymethylation steps are available. However, as with all pharmacologic inhibitors, these compounds are likely to have off-target activities (52). Indeed, genetic approaches have provided more specific means to evaluate the role of these modifications in promoting Ras membrane association. In particular, mouse embryo fibroblast cell lines derived from mice that are deficient in Rce1 (RCE1−/−) or Icmt (ICMT−/−) are useful to determine the role of these two enzymatic modifications for Ras membrane association, signaling, and biologic activity. As mentioned, after protein prenylation, the AAX residues of Ras are cleaved by Rce1 (20). This step is critical for proper localization; exogenous H-, N-, and K-Ras are mislocalized in RCE1−/− mouse embryo fibroblasts (53). After proteolytic cleavage of the AAX residues, the prenylated cysteine residue is carboxymethylated by Icmt. As in RCE1−/− mouse embryo fibroblasts (53), after proteolytic cleavage of the AAX residues, the prenylated cysteine residue is carboxymethylated by Icmt. As in RCE1−/− mouse embryo fibroblasts (53), after proteolytic cleavage of the AAX residues, the prenylated cysteine residue is carboxymethylated by Icmt.

### Table 2: Reagents for biochemical detection of Ras and Ras effector pathway activation

cells, all three Ras proteins are mislocalized when expressed in ICMT−/− cells. Interestingly, a recent study suggests that the membrane association of CAAX-containing Ras family GT-Pases that are modified by geranylgeranylation do not require these modifications (S3).

Ras trafficking to cellular membranes can be measured by fluorescence recovery after photobleaching (FRAP) and fluorescence loss in photobleaching (FLIP) (S4). Both techniques rely on the expression of fluorescent-labeled Ras proteins to monitor different parameters of Ras movement across and between cellular membranes. FRAP involves photobleaching a membrane subdomain and measuring the kinetics of fluorescence recovery—and hence Ras trafficking—into the bleached area. With FLIP, a cellular membrane is photobleached repeatedly and the subsequent intercellular movement of the photobleached area is monitored.

**Analyses of Ras effector activation and function**

In addition to the use of Ras effector domain mutants, structural mutants of Ras effectors and pharmacologic inhibitors of effector signaling are valuable to study the role of specific effector signaling pathways in Ras function. Tumor-derived, constitutively activated mutants, as well as lab-designed and generated mutants, have been particularly useful reagents for these studies (see Tables 2 and 3). For example, the addition of the carboxyl-terminal CAAX-contiguous sequences that target K-Ras4B to the plasma membrane onto c-Raf-1, the Raf-1 GEF, Raf, and the p110α catalytic subunit of PI3K has created effector fusion proteins that are constitutively membrane-bound and active. Membrane localization activates effector function because Ras activates effectors, in part, by promoting their association with the plasma membrane. More recently, human disease-derived mutants have provided physiologically relevant activated versions of these effectors, with the identification of missense mutational activation of B-Raf and p110α in human tumors, and activated MEK1 and MEK2 in cardio-facio-cutaneous syndrome (S1). Novel activating mutations in Ras and B-Raf, as well as the Sos RasGEF, have also been identified in developmental syndromes. These genetic variants may also be useful reagents to study Ras signaling and function (S5, S6). Activated effectors can be used to determine whether the activation of a specific effector pathway alone is sufficient to mediate a specific Ras function.

Various approaches have been useful to block the function of a specific effector and to determine its necessity and role in Ras function. First, catalytically dead mutants of Ras effectors or their substrates function as dominant negative mutants that, when ectopically expressed, block the function of the endogenous effector (see Tables 2 and 3). These mutants include kinase-dead mutants of c-Raf-1, MEK, and ERK that block the Raf effector pathway. Second, selective pharmacologic inhibitors of the MEK (PD98059 and U0126) and PI3K (LY294002) kinase pathways have been useful to study Raf and PI3K effector signaling. Recently, RNAi has been applied to impair specific effector function selectively (S7, S8). However, this approach may be limited by the fact that a majority of effectors also have highly related isoforms that are expressed broadly and may have overlapping functions. Finally, the use of mice that are deficient in effector function, as well as cells derived from these animals, has been very effective to determine the role of specific effectors in Ras-mediated oncogenesis. For example, although genetic loss of Tiam1, PLC epsilon, or Raf-GEF does not impair mouse development, each knockout mouse has demonstrated elegantly that this specific PI3K isoform was necessary for Ras-mediated lung and skin oncogenesis (S2). Hence, the development of similar mouse models will be useful to evaluate the role of Ras effectors that are normally essential for development, because of their roles in oncogenesis.

**Conclusions**

The decades of research on Ras proteins have yielded impressive insight into the biologic and chemical properties of Ras, and they have established many important paradigms that have defined key concepts in signal transduction. Concurrent with these studies has been the development and application of an armamentarium of reagents, genetic and pharmacologic tools, and assays with which to study Ras. These technologic developments have also aided studies greatly to evaluate the biophysical, structural, and biologic properties of other Ras superfamily proteins. These studies reveal that despite a shared simple fundamental biochemical function as GDP/GTP-regulated binary switches, Ras family proteins display an incredible diversity in the mechanisms by which they are regulated and in how their subcellular localization is controlled. These tools have allowed additional delineation of Ras function and an appreciation of their involvement in virtually all facets of cell physiology and behavior. Our earlier depiction of Ras as a relay switch at the plasma membrane in a simple linear signaling pathway has been revised to reflect the current model: Ras is a central component of a highly complex and dynamic signaling network with discrete functions at several subcellular locations. In summary, whereas great strides have been made to understand Ras activation, localization, and signaling, much need still exists for focused research in each of these areas. New methodologies and technologies that are developed will undoubtedly facilitate additional advances. Because we have been surprised by many recent new discoveries regarding Ras, one must expect the unexpected in Ras signaling and biology.

Protein-Protein Interactions, Tools to Study
Ras-Like Proteins
Signal transduction in cells has been an area of intense study for many years. However, until recently, the focus was on interactions between individual components rather than on the global behavior of the cell signaling networks. New experimental technologies, such as protein and DNA microarrays, high-throughput screening instrumentation, and diverse compound libraries, allow for many interactions to be examined simultaneously. Along with new experimental methods, quantitative models with mathematical methods, such as deterministic, stochastic, and statistical analyses and graph theory, have been useful in the mapping and analysis of intracellular signaling networks. Here we describe current experimental and computational approaches that are used to develop a global understanding of the complex behavior of intracellular signaling networks. We also discuss important applications of signaling network analysis, including the discovery of new drug targets, the identification of the signaling components responsible for the side (off-target) effects of drugs, and the development of combination therapies.

Currently it is estimated that the human genome contains 25,000 protein-encoding genes (1), which correspond to several hundred thousand possible protein species resulting from alternative splicing and posttranslational modifications. Of these presumed protein species, the functions and interactions of only a fraction are well understood. Among the well-studied proteins, many interactions result in complex networks that often form the basis for the complex physiologic functions. Moreover, protein expression levels vary among individuals and different cell or tissue types, and the distribution of proteins varies in the subcellular regions of each cell. Therefore, it is important to develop tools to analyze these systems as a whole.

Despite the growing need for global analysis of signaling networks, mapping individual pathways has been the main approach in studying signal transduction. Studies focused on defining how these pathways interact to form networks are relatively new. By mapping out signaling networks within cells, we can get an initial description of the rules that are applied in the development of these networks and the discovery of new trends or network properties. This review article discusses the interactions that comprise intracellular networks, the mechanisms underlying them, their conserved trends, and the emerging tools being developed to understand networks as a whole.

### Cell Signaling Networks

When a cell receives stimuli, the signals are propagated from one component to another, eventually forming out to form a network of signals that produces physiologic responses (phenotypes). Interactions within a set of interconnected signaling pathways can be represented as a network composed of components and connections. Many natural and engineered systems can be described as networks. These systems include the World Wide Web (2), networks of coauthors of scientific papers (3), and other social networks (4).

Biochemical interactions within cells can also be described as networks (5-7), and in this review we consider two intracellular networks, one involved in the stimulation of cell proliferation by the epidermal growth factor (EGF) and the other involved in the initial immune response to pathogens through the toll-like receptor (TLR) (Fig. 1a and 1b, respectively).

---

*Both authors have contributed equally and share credit as first authors.*
Mechanisms of Cellular Signaling

Signal initiation

The initial stimulus for a signaling pathway can be intracellular or extracellular. Intracellular stimuli typically are the result of changes in the cellular environment, such as the formation of reactive oxygen species or DNA damage. For extracellular signaling events, the process is initiated by a ligand binding to a receptor, often transmembrane proteins, such as the EGF receptor (EGFR) or the TLR. (Fig. 1a and 1b). Ligands can either be small molecules (hormones and neurotransmitters), peptides (insulin), or small proteins (growth factors). The naturally occurring ligands that have an affinity for EGFR are EGF, transforming growth factor (TGF-α), and β-cellulin (βC), all of which are small proteins, whereas the natural ligand for TLR is a macromolecule, lipopolysaccharide (LPS). Extracellular ligands can be secreted by other cells or generated by the cleavage of a larger precursor protein within the signaling cell. For example, EGF is generated by the proteolytic cleavage of the membrane-bound precursor, heparin-binding EGF-like factor (HB-EGF), by a matrix metalloproteinase (MMP) (9).

Biochemical reactions involved with signal propagation

Signal propagation within cells occurs by binding and enzymatic interactions that involve proteins, ions, and small molecules. Binding interactions typically occur between two or more proteins, proteins and lipids, or proteins and small molecules. Enzymatic reactions involved in signal propagation include phosphorylation, dephosphorylation, ubiquitination and sumoylation, controlled protein cleavage, and the generation of small signaling molecules such as cyclic adenosine monophosphate (cAMP), diacylglycerol (DAG), and inositol triphosphate (IP3). Many signaling reactions in intracellular networks are reversible chemical reactions, catalyzed in the forward direction by the enzyme and in the reverse direction by a different enzyme. One example of a reversible signaling reaction is the phosphorylation of a protein by a kinase and the subsequent dephosphorylation by a phosphatase. For instance, in the TLR pathway (Fig. 1b), the activated kinase TAK1 (TGF-activated kinase 1), phosphorylates Iκκ (Iκκ kinase), whereas the protein phosphatase 2C (PP2C) dephosphorylates phospho-Iκκ. In nonenzymatic signaling reactions, adaptor proteins act as mediators between the activated receptor and signaling enzymes by recruiting other signaling molecules to form a complex, which increase the activity of the receptor by cross-linking it to other adaptors. For example, Grb2 (growth factor receptor bound protein 2) binds to the phosphorylated EGFR and, in turn, recruiting adaptor proteins Gab1 (growth factor receptor bound protein 2-associated protein), mediates the kinase Aki (a-akt murine thymoma viral oncogene homolog 1) that mediates cell survival signaling (5, 10).

Patterns of signal flow: propagation, amplification, and loops

Signal transduction from the membrane to the nucleus occurs via interactions between signaling components. For example, one TLR pathway (Fig. 1b) starts with the activation of TLR3 by the binding of viral dsRNA. Next, the adaptor protein, TRIF (Toll/IL-1 receptor domain-containing adapter inducing IFN-β), is recruited, and TRIF mediates the phosphorylation of TANK-binding protein kinase 1 (TBK1) by an unidentified kinase. Phospho-TBK1 in turn phosphorylates the transcription factor, IFN regulatory factor-3 (IRF3), at five distinct sites. The phosphorylated IRF3 homodimersizes and translocates to the nucleus to regulate transcription (11, 12).

Cellular signals generally are not propagated through single, linear pathways. Instead, the signals have the tendency to branch or fan out into several or many pathways, which lead to one or several possible outcomes. An activated protein may have more than one protein that it activates or interacts with, such as Grb2 (Fig. 1a and 1b) and TRAF6 (tumor necrosis factor receptor-associated factor 6) and Tak1 (Fig. 1b, 3b). Nonlinear increases the complexity of the network and introduces crosstalk between pathways or networks. Networks for the EGFR pathway (5) and the TLR pathway (6) have been constructed and have resulted in highly detailed, complicated schematics that represent the networks in their entirety, hence, a portion of each network is depicted in Fig. 1 to create a meaningful visual representation of the network. It is notable in complete networks that patterns of signal propagation and amplification exist.

Signal flow within networks often is controlled and/or amplified by regulatory loops (Fig. 1c). The connectivity within regulatory loops has multiple configurations. For example, consider an upstream protein A that activates downstream protein B that in turn activates protein C. In a feed forward loop (FFL), protein A activates protein C. In a positive feedback loop (PFBL), protein C in turn activates protein A. In a negative feedback loop (NFBL), protein C inhibits protein A. In the TLR pathway, a FFL is found within the MAPK cascade that activates ATF2 (activating transcription factor 2) through both

by facilitating Ras-mediated GTP hydrolysis to GDP (5). (Ras-GTPase activating protein), which inhibits Ras signaling example of a more distal NFBL is EGFR activation of Ras-GAP signaling by dephosphorylation of the receptor (5, 20). Another recruited to EGFR through Gab1 and Grb2 but inhibits EGFR signaling in cells under different conditions, such as stress, native ligand specificity. Some TLR ligands are involved in the TLR network; whereas, epithelial cells have relatively high expression level of TLRs, whereas epithelial cells have relatively high expression levels of growth factor receptors (25, 26).

Multiplicity in signaling pathways forms a complex network

Families of signaling receptor proteins most often include several isoforms that have varying affinities for ligands and adaptor proteins. Usually several to many ligands have affinity for one or more receptor. Once all possible ligand–receptor combinations and the multiplicity of recruited adaptor and signaling protein combinations are taken into account, the complexity of signaling networks becomes apparent. Take for example the ErbB signaling network. Four members exist: ErbB1 (EGFR), ErbB2 (Her-2/Neu), ErbB3, and ErbB4 (Fig. 1a). As depicted in Fig. 1a an abundance of adaptor proteins signal in the ErbB network. Ligand binding induces a conformational change that allows the ErbB receptors to homodimerize and crossphosphorylate at the C-terminal region of the intracellular domains (23, 24). The potential of heterodimerize and crossphosphorylate at the C-terminal region of the intracellular domains (23, 24). The potential of the receptors to homo- or heterodimerize with one another varies because of the expression level of the receptor, their affinities, and the amount and identity of ligand(s) present. The phosphorylated region provides a docking site for adaptor proteins, which have varying affinities for the different ErbB receptors. Specifically, the Src homology-2 (SH2) or phosphotyrosine binding (PTB) domains of adaptor proteins including Vav, Shc, Grb2, small heterodimeric partner (SHP), and phospholipase-Cγ (PLCγ), have affinity for the intracellular tyrosine-phosphorylated EGFR region (Fig. 1a). Many possible combinations of ligands, receptors, and recruited adaptor proteins can form the final signaling complex. Therefore, complexity in the signaling network is introduced early, at the level of the ligand. Further, the ligand governs the nature of the dimerized receptors which, in turn, modulate the mode and magnitude of the signal. At the ligand-receptor level, the TLR network (Fig. 1b) is similar to the EGFR network with respect to ligand specificity. Some TLR ligands are specific for one TLR, and others are not. In contrast to the EGFR network, one main adaptor protein MyD88 (myeloid differentiation primary response gene 88) has similar affinity for all TLR family members, with the exception of TLR3. Therefore, in the TLR pathway the nature and magnitude of the signal depends highly on the expression level of the receptors and the nature and relative amount of ligand(s) present. Because of the variation in the identity and level of expressed receptors across various cell types, different cells will respond differently to stimulation with particular ligands. The distribution of different receptors reflects the interplay of the signaling capacity of the receptor and its significance in the specialization of the cell type. For example, immune cells, such as dendritic cells, have a relatively high expression level of TLRs, whereas epithelial cells have relatively high expression levels of growth factor receptors (25, 26).

Experimental Approaches to Understanding Signaling Networks

The majority of published, reconstructed cellular signaling networks are built on the data that describe individual interactions and loops through classical biochemical techniques, such as immunoblot analysis, coimmunoprecipitation, binding, and enzymatic assays. However, to obtain global perspectives on interaction networks, new experimental approaches to obtain high-content data sets on interactions that make up cellular signaling networks recently have been developed. These fields serve two distinct but complementary purposes: First, to catalog and inventory genes, mRNAs, and proteins and their functions; and second and more pertinent, to develop signaling networks, to parse, on a global scale, the properties of signaling networks in cells under different conditions, such as stress, native ligand treatment, non-native agonist/antagonist treatment, or other. Also, to observe differences in different cell types, including healthy and normal cells and those in a disease state. Often, because of the heightened possibility of false positive or negative results because of their high-content nature, results from these high-content experiments are validated by single experiments that use more classical techniques. The experimental methodologies and examples of experiments in these fields will be discussed here; whereas, the mathematical and computational approaches including the analyses of the resultant large data sets will be discussed in the section entitled “Computational approaches that facilitate the understanding of intracellular networks.”
Genomic and proteomic methods

Genomics entails cataloging genes and genetic mutations and observing changes in gene expression levels under various conditions. Genomics can be used to catalog genetic mutations, polymorphisms, or amplifications that may play a role in disease by comparing gene sequences or levels from disease and normal genetic samples. The overall changes in gene expression or genetic mutations in a disease can help identify a critical signaling protein or pathway as a therapeutic target. Genetic analysis of cells that have undergone treatment to activate a specific signaling pathway can lead to signaling information, which provides a basis for the construction and analysis of the cell signaling network. For example, after treatment with an agent known to affect exclusively a pathway of interest, all the genes that are upregulated or downregulated by the pathway can be analyzed by genomics. This type of analysis may lead to information on the genetic programs that are outcomes of signaling pathways.

The technology to detect gene expression, coined DNA microarrays or DNA chips, was developed over the past decade (27). Recently, methods such as ChIP-chip (chromatin immunoprecipitation-microarray) (28), DamID (DNA adenine methyltransferase ID) (29), and PBMs (protein binding microarrays) (30), allow for a more mechanistic understanding of gene regulation (and chromosome structure). With transcription factor microarrays, one can detect transcription factors that are activated or inhibited under various conditions and/or different cell types.

Proteomics focuses on obtaining an inventory of proteins and their functions, as well as unfolding interaction networks and posttranslational modifications, such as phosphorylation (phospho-proteomics). Further, proteomic experiments can yield quantitative information such as rates and relative concentrations. A range of methodologies are used to generate proteomic data, ranging from low-throughput methods such as Western blotting and immunoprecipitation to high-throughput methods such as protein microarrays, yeast two-hybrid screens (31), and SILAC (stable isotope labeling by amino acids in culture) combined with quantitative tandem mass spectrometry (32). Important advances in the technologies involved in proteomic studies allow for a more detailed, global understanding of interaction networks.

A protein microarray study by Jones et al. (33) was designed to test the affinity of all proteins that contain SH2 and PTB domains, which specify binding to the phosphorylated domains of all four ErbB family members. The study uncovered that some ErbB family members were more promiscuous than others, which has important implications for the ErbB signaling network in general and specifically in that the promiscuous ErbB family members are much more commonly overexpressed in several cancer cell types. Furthermore, 116 new ErbB interaction partners were discovered. A further study by Schürr et al. (34) was also designed to identify all interaction partners for the phosphorylated ErbB family members but using a novel methodology that combines SILAC and LC-MS/MS. This study defined the specific ErbB sites where the interaction partners bind.

Many of these studies have resolved the temporal and spatial aspects of signaling networks. The dynamics of EGF stimulation was examined by Blagoev et al. (35) in a phospho-proteomics study by examining the phosphorylation pattern of EGFR after different periods of EGF treatment. The spatial aspects of signaling can be captured by analyzing different fractions of the cell such as the nucleus, organelles, vesicles, membrane-bound proteins, or cytoplasmic proteins. Several recent studies have analyzed holistically the signaling components of purified cellular organelles, such as synaptic vesicles (36) and the ER-Golgi apparatus (37).

Chemical genetic approaches

Chemical genetics (38, 39) can be considered a combination of chemistry and genetics or proteomics because it is based on the use of small molecules to modulate protein or gene function. This method is similar to pharmacology, except that the experiments are designed in a similar fashion to "omics" experiments, in which an entire set of genes, proteins, or phenotypes is examined simultaneously. The effects of modulating protein function with a small molecule or library of small molecules are examined either phenotypically or at the signaling level. Chemical genetic experiments are instrumental in understanding how signaling networks are affected by the down- or upregulation of one or more signaling proteins by a drug or other small molecule(s).

The two types of chemical genetic methods, "forward" and "reverse," lead to different results. In a "forward" experiment, small molecules are used to probe for a desired phenotype, and the protein that binds the small molecule and induces the phenotype can be subsequently identified. In an example of a "forward" chemical genetic experiment, the small molecule necrostatin-1 was discovered by screening a 15,000-compound library for an inhibitor of a novel type of cell death that is unique from apoptosis or necrosis, coined "necroptosis" (40). Other forward chemical genetic experiments have led to information on the genetic basis of neural stem cells (41) and on the role of copper and lysyl oxidase in notochord morphogenesis during development (42). Furthermore, forward chemical genetic experiments have been used to identify unknown targets of clinically approved drugs and can lead to the identification of new potential drug targets (38, 39, 43).

In a "reverse" chemical genetic experiment, a protein with a known function is modulated with small molecules, either to simply discover a small molecule modulator of the protein or to examine the downstream effects of modulating the protein to further dissect the mechanism of its function. In an example of a "reverse" chemical genetic experiment, a protein kinase of interest is mutated to be specifically inhibited by a bulky, synthetic ATP analog, which cannot bind all other protein kinases. These "reverse" chemical genetic experiments have led to the elucidation of numerous signaling pathways including the cell cycle pathway by inhibiting CDK-activating kinase 7 (cdk7) (44), c-Jun N-terminal kinase (JNK) signal transduction pathway (45, 46), G protein-coupled receptor kinases (GRKs)-regulated receptor regulation pathway (47), the actin assembly process by inhibiting vinculin (48), and mitosis and cell division by inhibiting Plk-1 (49). The consequences or potential off-targets of modulating a protein with a small molecule or drug can be elucidated by using reverse chemical genetics.
Collaborative research initiatives for the use of chemical genetics to facilitate discovery of potential cancer (or other) therapeutics by the Initiative for Chemical Genetics at the National Cancer Institute (50) and to facilitate the discovery of new targets and drug candidates by the Chemical Genomics Center at the National Institutes of Health (51) have been initiated. These initiatives will result in databases that contain information that most likely will be valuable to the study of cellular signaling networks.

The design and synthesis of chemical compound libraries

The synthesis, collection, and development of chemical libraries are essential for the global analysis of intracellular signaling networks, chemical genetics, and drug discovery. Commercial sources of compound libraries are available and often categorized by the type of compounds they contain. Library categories include natural product, drug-like, various molecular weight ranges, various inhibitor classes, and peptide or peptide-like (38, 52). Many institutions have a screening facility where purchased libraries and/or libraries obtained from archives of compounds synthesized in-house are available for assaying.

Most commonly, a commercial library, containing a subset of compounds that matches a desired set of properties (if known), is screened in an initial study. Once hits are obtained and verified, a small library of compounds is synthesized to produce a set of compounds that are chemically different from the original hit structure. This process allows for hits with higher potency and elucidates information of the structure-activity relationship within the system of interest. Such synthetic libraries of chemically diverse compounds have been made possible through combinatorial chemistry (52-56) and diversity-oriented synthesis (52).

There continues to be a strong motivation in the chemical biology field to synthesize new libraries and build on existing ones, as well as to improve combinatorial chemistry approaches. The data collected from chemical genetic experiments adds to the delineation of the proteome and a complete cell signaling network and promotes the discovery of new therapeutic targets. To make a compilation of the data generated, Chembank (affiliated with the Initiative for Chemical Genetics by the NCI) was created. Chembank is an initiative to create a public database containing all data obtained from screening compound libraries for various purposes.

Computational Approaches that Facilitate the Understanding of Intracellular Networks

In the past decade, computational analyses, based on mathematical methods and experimental data, have been recognized as powerful tools to understand the complexity that is inherent to biological systems. The integration of computational and experimental approaches to construct and analyze cell signaling networks generally is a multistep process involving collaborative efforts between the two fields. The major steps involved in the development of mathematical models that yield systems-level insights are outlined in Fig. 2.

The first step in constructing a cell signaling network model is to generate an in silico interaction network. Signaling components of interest are identified, and data on binary interactions are extracted from the experimental literature. Often times, the creation of an entire interaction map for a large network is beyond the scope of one laboratory; therefore, public databases have been created in which newly discovered proteins and/or protein interactions are deposited (57-63). However, often data are included from studies that cover a broad range of protein interactions, such as proteomic studies or yeast two-hybrid screens, and frequently contain many potential false positives or negatives. Thus, it becomes necessary to critically examine each reference to verify the interaction data reported, as this is in silico network is the basis of further study.

Once the reaction network is created, an appropriate mathematical approach is identified according to the information available and the biological question(s) to be addressed. In this section, some mathematical approaches that have been applied successfully in the analysis of biological signaling networks will be discussed. These methods are summarized in Table 1 (64-85).

Statistical approaches

High-throughput experiments such as those involved with genomic and proteomic studies (e.g., microarray studies and SILAC-mass spectrometry studies, discussed in the section entitled “Experimental approaches to understanding signaling networks”) are useful for understanding the interdependence of signaling components in the network. However, these types of experiments generally yield large-scale data sets that often are analyzed by computational algorithms, based on statistics. The basic concept behind this computational statistical analysis is to identify clusters or groups of signaling components that show similar trends. This analysis is used to extract the relationships between different signaling components in a network from these large-scale data sets. These kinds of analyses have been used for analyzing microarray data to identify patterns that correlate with distinct physiologic and pathophysiologic states. For example, an hierarchical algorithm has been used to identify different types of cancers in human soft tissue tumors (86), and K-mean clustering has been used to identify molecular subtypes of brain tumors (87). However, these types of statistical clustering analysis do not exclude the noise or artifacts induced by the experimental techniques. To overcome this limitation, singular value decomposition (a modified type of principal component analysis) has been used to identify which clusters of signaling components have a significant amount of influence in changing patterns of biological behaviors (88-91). Another statistical technique, partial least square regression analysis on multidimensional experiments (signaling components, time, and ligands), has been used to predict new interactions between components in a network, regulating apoptosis (92).
Signaling Networks in Biology

New systems level understanding

Graph theory

Statistical analysis is a powerful tool for understanding interdependence between groups of self-similar behaviors, especially when a large data set is being analyzed. However, it does not yield information about the topology of the interaction network. Graph theory-based approaches have been developed to study the topological properties of a large biological network. In graph theory, each signaling component in the network is represented as a node and identified by its degree, which represents the number of interacting partners. Within the context of the entire signaling network, the relationship between the degree of individual nodes and the degree of distribution of the whole network can be characterized. This kind of analysis has shown many intrinsic topological properties, such as scale-free configuration, small world configuration, and modular organization of networks across different cell types and species (2, 7, 22, 93, 94).

Boolean analysis

Although it is possible to analyze the topological properties of the network using graph theory, the states of the signaling components (phosphorylated/dephosphorylated, bound/unbound) often are not accounted for in such analyses. Boolean analysis can be used to understand such dynamics. In Boolean analysis, the signaling components in the network are identified by strings of 0’s and 1’s. The activated state of the protein is denoted by ‘1’, and the inactivated state is denoted by ‘0’. Changes in states of components can be computed as a function of various perturbations to the network.

To illustrate the concept of Boolean analysis in a biological context, an example is taken from the TLR pathway (Fig. 1c). To initiate the induction of the IFNβ gene in TLR signaling pathway, it is necessary for three transcription factor complexes, ATF2-c-jun heterodimer, two IRF3 homodimers, and NF-κB, to bind simultaneously at the promoter region. This biological condition can be represented in the Boolean form in the following way: Each of the four transcription factor complexes, ATF2-c-jun, two IRF3 homodimers and NF-κB, and the gene IFNβ is expressed as strings of five 0s and 1s that lead to 2^5 (or 32) combinations. For instance, the representation ‘11111’ denotes that all transcription factor complexes are bound to the promoter region and IFNβ gene expression occurs; ‘01000’ denotes that only one of two IRF3 homodimers are bound to the promoter region and, hence, IFNβ gene expression does not occur. A simulation is performed to analyze the effect of the change of state of an upstream signaling component on the downstream component in the signaling network, and rules, based on Boolean operators, are applied (95, 96).

Boolean analysis has been used to understand the effect of different states of signaling components on their downstream signaling components under various conditions. For example, Albert and Othmer (64) used Boolean analysis of a Drosophila melanogaster network to validate results from previously published microarray data and predicted the crucial role of the two genes, wingless and sloppy paired, in segment polarity. Gonzales et al. (65) mutated different genes in silico and used Boolean analysis to predict that the delay in the activation of two genes, Apterous and Notch, is essential to maintain the dorsal-ventral boundary of Drosophila melanogaster. Sarkar and Franz (97) predicted that the costimulation of T-cell receptors (TCR) and CD28 in T cells influences cell proliferation by providing a greater diversity of paths in the network. Maayan et al. (67) has used a combination of graph theory and Boolean analysis to obtain a distribution of redundant pathways in a cell signaling network.

  - Network analysis based on probabilities (Markov chain and Bayesian) to identify paths and relationships between different nodes in the network. | (75–81)     |
| Statistical analysis  | Clustering based on correlations to identify group relationships.
  - Partial least square regression analysis to track pathways of signal flow.
  - Principal component analysis to identify significant signaling components. | (82–85)     |

Deterministic analysis

Although large-scale network analysis using graph theory or Boolean analysis can be very powerful in understanding the overall topological properties of the network, these tools do not take into consideration the rate of change of states of the signaling components with respect to time, explicitly. To understand the dynamics of activation or deactivation of a component in a signaling network, the most commonly used approach is deterministic analysis, which involves solving ordinary differential equations (ODEs). For deterministic analysis of biological systems, the initial concentrations and the kinetic parameters (K_m, K_d, and V_max) for enzymatic reactions and binding reactions (K_a or K_d) are required and need to be determined experimentally. Numerous examples exist in which deterministic analysis has provided critical insights into the dynamic behavior of a protein in a network under various conditions. One early effort in computational modeling, which uses a system of ODEs, is the EGF-EGFR reaction kinetics and internalization of the receptors (98–102). Bhalla and Iyengar (103) predicted the importance of feedback loops in a signaling network by illustrating bistable behavior of output proteins. Moreover, the sensitivity of the MAPK activity in response to a stimulus has been studied in detail by using systems of ODEs (104, 105). Bentele et al. (106) have studied apoptosis induced by the CD95 receptor by using deterministic analysis.

Stochastic analysis

The deterministic analysis provides the average behavior of signaling components in a network but does not include the results of fluctuations in the activation states of the signaling components (noise). Such analysis becomes essential when the volume of interest becomes in the scale of femtoliters because of the limitingly small number of molecules contained in such a small volume (1 fL of a 0.1 µM solution is equivalent to 60 molecules). Small volumes such as these are biologically relevant and present in cellular systems quite often, for example, in the spines of dendrites and endosomal regions. Moreover,
stochastic analysis becomes important in studying gene regulation where many genes have less than 10 copy numbers. Stochastic analyses, based on Monte Carlo theory and probabilities, have been used to capture the effects of fluctuations of an upstream signaling component on the kinetics of a downstream signaling component in the network. The most popular method for stochastic analysis is the Gillespie method (107), which is based on the probability of which reaction will take place within a defined time period. This type of simulation can give insights into the characteristics of signaling events at the single-molecule level. For example, in the analysis of an individual cell, noise introduced in enzymatic futile cycles can be strong enough to switch the system from one state of the cell to another (108). This technique has not gained much popularity over deterministic approaches, even though it is the only appropriate mathematical representation for certain cellular phenomena. This lack of popularity primarily is because of the following reasons: 1) Stochastic models need information at the molecular level as building blocks to construct the model properly and to validate simulation results obtained from the model. Experimental methods that yield molecular-level data have not been developed for biological systems, and 2) Stochastic simulations of a relatively small model, which contains less than 10 signaling components and their interactions, can pose large computational demands. However, application of the Gillespie method in small volume can reduce computation time to be comparable to that of deterministic simulation.

The Importance of Signaling Networks in Understanding Mechanisms that Underlie Disease and Drug Discovery

Cellular signaling networks are useful for drug discovery in three ways: 1) to develop an understanding of the biochemical mechanisms that underlie disease, which aids the discovery of novel drug targets, 2) to examine how current drugs affect the on-target (leading to therapeutic effect) and off-target (causing side effects and/or drug resistance) signaling pathways, which may lead to more informed prescribing methods and improved therapies, and 3) to lay out the interplay between signaling pathways in such a way that explains or facilitates the success of combination therapies. A dynamic relationship exists between the understanding of the biochemical mechanisms that underlie disease and drug discovery (Fig. 3). The compilation of data into a detailed signaling network is central in properly choosing a drug target (109). Many network models are in place, such as those described for the EGFR and TLR networks in this review, which can be applied to drug discovery (110). Before pursuing a drug target, it is important to understand as thoroughly as possible the consequences of regulating the target of choice because of the sheer expense involved with drug development and clinical trials. This understanding may be gained by analyzing a computational model of the signaling network involved, generating a knockout mouse, examining the chemical genetics of the target, and critically examining the current data on the drug target in the literature and databases (i.e., Chembank).

Of the total number of proteins that have a function we currently understand, only a small fraction is drug targets. The pool of drug targets is evolving with the introduction of new drug discovery technologies, such as the cell signaling network analyses described in this review, combinatorial chemistry, chemical genetics, molecular informatics, and advanced high-throughput screening technologies. With a new direction in the medical field toward personalized therapy regiments, it is increasingly important to expand the “druggable” network, and the enhanced global knowledge of signaling networks and the new drug discovery technology are indispensable in achieving this goal.

A thorough understanding of signaling analysis is essential to uncover new drug targets and aid in subsequently validating their potential, it also plays a role in studying roadblocks for approved pipeline drugs, such as developed drug resistance or off-target effects. Network analysis combined with carefully designed proteomic experiments aid in understanding the mechanisms of resistance and in developing methods to overcome the resistance. For example, a study by Chen et al. (111) combined signaling network analysis and a carefully designed proteomic experiment to illuminate the signaling network involved with the resistance of ovarian cancer cells to cisplatin treatment.

In the light of the abundant data on drug resistance in disease, many therapies are dosed in combinations to affect several pathways at once and/or gain a therapeutic advantage that stems from synergistic effects between drugs (112). An assembly of the data on the pathophysiology and biochemistry of cancer will allow treatment regimens to evolve toward targeting a network rather than a single protein (113). Efforts are currently underway to use a network analysis approach in understanding the effects of treatment with more than one drug (114). Alternatively, the combination of effects of two or more drugs can be used to uncover information about how the networks that each drug targets are connected (114). Combined with advances in high-throughput screening technologies, these approaches will be the powerhouse in the discovery of numerous novel therapeutic drug combinations and the most effective dosing schedules.

Perspective and Future Directions

Cell signaling networks are a rich source of targets for drug. A vast majority of drugs today are targeted to receptors or signaling components inside the cell such as protein kinases. The understanding that individual signaling pathways come together to form networks is very useful in looking for new drug targets not solely as individual components but also as pairs and triplets in interacting pathways for combination therapy for complex diseases. The convergence of computational approaches with high-throughput experimental analyses and chemical libraries offers substantial new opportunities not only to understand in depth the regulatory complexities within cells but also to design
and identify drugs that can be used as therapeutic agents for diseases that arise from alterations in the regulatory capabilities of cell signaling networks.

doi: 10.1002/9780470048672.wecb030

Bacteria use a variety of strategies to regulate transcription elongation in response to changes in their environment. Several of these regulatory events are classified as transcription attenuation mechanisms, which involve regulated transcription termination to control expression of downstream genes. In most cases, two alternative RNA secondary structures, an antiterminator and an intrinsic terminator, share nucleotides in common such that their formation is mutually exclusive. Thus, the level of expression of the downstream genes depends on the frequency that the antiterminator forms in the nascent transcript. Transcription attenuation mechanisms in general are divided into two categories. The first category involves situations in which the action of a regulatory molecule promotes transcription termination, with the default situation being transcription readthrough. The second category involves situations in which the action of the regulatory molecule promotes transcription readthrough (antitermination), with the default situation being transcription termination. Transcription attenuation controls the expression of several amino acid biosynthetic and catabolic operons. These mechanisms are often controlled by the efficiency of leader peptide synthesis in Gram-negative bacteria, whereas Gram-positive organisms often use RNA binding proteins or tRNA molecules to determine whether the RNA will fold into the antiterminator or terminator structures. Several examples of transcription attenuation also exist in which an antisense RNA is responsible for controlling plasmid copy number. In addition, small metabolites participate in transcription attenuation mechanisms of a wide variety of bacterial genes by binding directly to the nascent transcript.

The ability of organisms to regulate gene expression in response to environmental signals is vital for their survival. Virtually every step involved in the synthesis, function, and degradation of macromolecules is a potential target for one or more regulatory events (reviewed in References 1–3). Several regulatory events that occur after transcription initiates are categorized as transcription attenuation mechanisms in which the extent of transcription termination is modulated to control the expression of downstream genes. Transcription attenuation allows the organism to modulate the extent of transcription readthrough past the terminator in response to changing environmental signals, thereby regulating expression of the downstream genes. Transcription attenuation mechanisms in general are divided into two categories. In one case, the default situation is transcription readthrough; the action of a regulatory (effector) molecule promotes termination. The default situation for the second category is transcription termination. In this case, the action of an effector molecule promotes transcription readthrough (antitermination) (1, 2). In each case, the genetic information required for transcription attenuation is encoded within a leader region located between the transcription start site and the first structural gene of the operon or between two genes within an operon (reviewed in Reference 4). This article is organized around the class of effector molecule that is used to sense environmental changes. These regulatory factors can be translating ribosomes, proteins, RNA molecules, or metabolites (Fig. 1). Examples are known in which each class of effector molecule promotes transcription termination or antitermination. One example of each of these
The discovery of transcription attenuation was the first demonstration that organisms can exploit an RNA structure to modulate gene expression. The first examples of transcription attenuation were discovered for the Escherichia coli trp (tryptophan biosynthetic) and Salmonella typhimurium his (histidine biosynthetic) operons, although many other amino acid biosynthetic operons in Gram-negative bacteria are regulated in a similar fashion. Together, these discoveries established an important paradigm for regulation of gene expression after transcription initiation. It is now apparent that translating ribosomes can serve as the effector molecule for both mechanistic categories of transcription attenuation.

Transcription Termination Mediated by a Translating Ribosome

TrpR, which is a DNA binding repressor protein, regulates transcription initiation of the E. coli trpEDCBA operon. Under tryptophan-limiting conditions, TrpR represses transcription initiation, whereas repression is relieved in the presence of excess tryptophan. Once transcription initiates the elongating transcription complex is subject to control by transcription attenuation (reviewed in References 5 and 6). The leader transcript can form three RNA secondary structures that are referred to as the pause hairpin, the antiterminator structure, and an intrinsic terminator hairpin. Because the antiterminator shares nucleotides in common with the terminator, their formation is mutually exclusive. The pause hairpin has two additional roles in this transcription attenuation mechanism; it serves as an anti-antiterminator structure that prevents antiterminator formation, and it codes for a leader peptide. A model of the E. coli trp operon transcription attenuation mechanism is presented in Fig. 2a.

Soon after transcription of the trp operon is initiated, the pause hairpin forms in the nascent transcript, which signals RNA to pause. The paused RNA complex allows sufficient time for a ribosome to initiate translation of a short open reading frame that encodes a 14-amino-acid leader peptide. The translating ribosome disrupts the paused RNA complex such that transcription resumes, which thereby couples transcription and translation. At this point two different outcomes can occur depending on the level of tryptophan in the cell. Under tryptophan-limiting conditions, the aminoaacylation of RNA is inefficient such that the level of tryptophanyl-tRNA (also called charged tRNA) is low. As a consequence, the translating ribosome stalls at either of two tandem Trp codons within the leader peptide coding sequence. Ribosome stalling at either Trp codon uncouples transcription from translation. As transcription proceeds, the antiterminator structure forms, which prevents formation of the overlapping terminator hairpin, resulting in transcription readthrough into the trp operon structural genes (Fig. 2a). Under tryptophan excess conditions, the concentration of tryptophanyl-tRNA is sufficient to allow efficient translation of the Trp codons within the leader peptide coding sequence. As a consequence, the ribosome continues translation to the end of the leader peptide unaltered and dissociates from the mRNA. In this situation, the anti-antiterminator forms and prevents formation of the overlapping antiterminator. Because formation of the antiterminator is prevented, the overlapping terminator hairpin can form, which results in termination of transcription before RNA reaches the trp operon structural genes. Thus, expression of the trp operon is decreased when the cell has an adequate supply of tryptophan.

Figure 1 Generalized model for sensing regulatory effectors by nascent mRNA leader transcripts. Transcription attenuation mechanisms have been identified in which the nascent transcript interacts with a translating 70S ribosome, a protein, an RNA molecule or a small metabolite. (a) Binding of the effector molecule promotes transcription termination. (b) Binding of the effector molecule promotes transcription readthrough (antitermination). See text for details.
Figure 2 (a) Transcription attenuation model of the E. coli trpEDCBA operon. RNAP pauses after formation of the pause hairpin (stem-loop 1:2). RNAP pausing provides time for a ribosome to initiate translation of the leader peptide. In tryptophan-limiting conditions, the ribosome stalls at one of the tandem Trp codons, which thereby allows formation of the antiterminator structure (stem-loop 2:3), which results in transcription readthrough. In conditions of tryptophan excess, the ribosome reaches the leader peptide stop codon and dissociates. In this instance, formation of the anti-antiterminator blocks formation of the antiterminator, which thereby allows formation of the terminator hairpin (stem-loop 3:4), which causes transcription to terminate upstream from the trp operon structural genes. See text for details. [Adapted from the Encyclopedia of Molecular Biology (1999) with permission (1).] (b) Antitermination model of E. coli tnaCAB operon. RNAP pauses after formation of the pause hairpin. RNAP pausing provides time for a ribosome to initiate translation of the leader peptide. Under noninducing conditions (free tryptophan is not in excess), dissociation of the 70 S ribosome at the tnaC stop codon exposes a rut site allowing Rho binding. Rho translocates to paused RNAP leading to transcription termination. Under inducing conditions (excess tryptophan), the combination of tryptophan binding and nascent peptide interaction with the ribosome exit channel causes the ribosome to stall at the tnaC stop codon because the nascent peptide cannot be cleaved from the peptidyl-tRNA. The stalled ribosome prevents Rho from binding to the nascent transcript that leads to transcription readthrough. Tryptophan is represented by a star. See text for details. [Adapted from the Encyclopedia of Molecular Biology (1999) with permission (2).]
Transcription Antitermination Mediated by a Translating Ribosome

E. coli and several other microorganisms have the capacity to degrade tryptophan to serve as a carbon and nitrogen source. The degradative tryptophanase operon (tnaCAB) of E. coli is regulated by catabolite repression and by an antitermination mechanism (reviewed in Reference 4). This antitermination mechanism involves translation of a 24-amino-acid leader peptide (TnaC) containing a crucial Trp codon (7, 8). RNAP pause sites(s) between tnaC and tnaA (9), and Rho termination factor (10). A model that illustrates the tna antitermination mechanism is shown in Fig. 2b.

Under non-catabolite-repressing conditions, RNAP initiates transcription and continues until it reaches a pause site downstream of tnaC. Paused RNAP provides time for a ribosome to initiate translation of the leader peptide. Under tryptophan-limiting conditions, the translating ribosome reaches the UGA stop codon and is released, thereby exposing a rut (Rho utilization) site that immediately follows the stop codon. Rho binds to the rut site in the nascent tna transcript and translocates along the RNA in a 5′ to 3′ direction until it encounters paused RNAP, which ultimately leads to transcription termination upstream of tnaA. When cells are growing with inducing levels of tryptophan, the nascent TnaC peptide and a free molecule of tryptophan interact with the translating ribosome, which inhibits ribosomal peptidyl transferase activity such that peptidyl-tRNA remains bound to the ribosome (11–13). The stalled ribosome masks the rut site, which thereby prevents Rho interaction with the transcript. Eventually RNAP resumes transcription such that the structural genes encoding tryptophanase (tnaA) and a tryptophan permease (tnaB) are expressed (Fig. 2b).

The mechanism of ribosome stalling during translation of tnaC has been investigated in considerable detail. The nascent leader peptide (TnaC) interacts with ribosomal protein L22 and 23S rRNA in the narrow region of the ribosome exit channel (14). Ribosome recognition of the TnaC peptide results in specific binding of free tryptophan in the ribosome, which inhibits cleavage and the subsequent release of the nascent leader peptide (15, 16).

Transcription Attenuation Mediated by Proteins

Although the transcription attenuation mechanism of the E. coli trp operon served as a paradigm for several years, it is now apparent that several classes of effector molecules can be responsible for sensing and responding to environmental signals. Numerous examples exist in which RNA binding proteins perform this important task. In some instances, the presence of a specific metabolite leads to activation of the RNA binding protein such that it can bind to its RNA targets. In other examples, the metabolite leads to inactivation of the RNA binding protein. Despite this fundamental difference, several features of the corresponding mechanisms are remarkably similar to those described above. One clear distinction that is worthy of particular mention is that the mechanisms that rely on RNA binding proteins do not require coupling of transcription and translation. As a consequence, this general regulatory strategy has been identified in several eukaryotic organisms in which transcription and translation occur in separate cellular compartments (reviewed in Reference 3).

Transcription Termination Mediated by an RNA Binding Protein

The transcription attenuation mechanism for the trpEDCFBA operon in the Gram-positive organism Bacillus subtilis differs dramatically from that described for E. coli. Most notably, translation of a leader peptide is not involved in the B. subtilis mechanism. Instead, an RNA binding protein called TRAP (trp RNA-binding attenuation protein) is responsible for sensing the level of tryptophan in the cell and for the decision of whether to terminate transcription in the 5′ leader region, or to readthrough into the trp operon structural genes (reviewed in References 17 and 18). Transcription initiation of the trp operon seems to be constitutive, which suggests that the >1000-fold regulation in response to tryptophan occurs after transcription initiates. A transcription attenuation model for the B. subtilis trp operon is depicted in Fig. 3a.

The B. subtilis trp leader transcript contains inverted repeats that can form mutually exclusive antiterminator and intrinsic terminator structures. Soon after transcription initiates, RNAP can pause at the nucleotide just preceding the critical overlap between these two alternative structures, presumably to provide additional time for TRAP binding (19, 20). Under tryptophan excess conditions, tryptophan-activated TRAP binds to 11 closely spaced (G/U)AG repeats in the nascent transcript. As transcription proceeds, the RNA wraps around the protein ring with each triplet repeat interacting with several amino acids on adjacent subunits in the protein (21). Bound TRAP prevents formation of the antiterminator, which allows formation of the overlapping terminator structure. Thus, transcription halts in the leader region before RNAP reaches the trp operon structural genes. An RNA hairpin called the 5′ stem-loop (5′SL) also interacts with TRAP; however, the mechanism of TRAP binding to this structure is distinct from TRAP interaction with the (G/U)AG repeats (22–24). It seems that TRAP-5′SL RNA interaction increases the rate in which TRAP binds to the nascent leader transcript, which thereby increases the efficiency of termination (24). Under tryptophan-limiting conditions, TRAP is not activated and does not bind to the nascent trp operon transcript. As a consequence, formation of the antiterminator prevents formation of the terminator, which results in transcription readthrough into the trp operon structural genes (Fig. 3b).

The crystal structure of B. subtilis TRAP in complex with tryptophan shows that this protein consists of 11 identical subunits arranged in a ring (25). The TRAP oligomer is composed of 11 seven-stranded antiparallel β-sheets, with each β-sheet
Attenuation, Control of Gene Expression by Limiting β-glucosides

**Figure 3** (a) Transcription attenuation model for the *B. subtilis* trpEDCFBA operon. RNAP pauses after formation of the pause hairpin. RNAP pausing may provide additional time for tryptophan-activated TRAP to bind to the nascent transcript. In tryptophan-limiting conditions, TRAP does not bind to the 5′ SL and the (G/U)AG repeats (small black rectangles). Thus, formation of the antiterminator (stem-loop 2:3) results in transcription readthrough. In conditions of tryptophan excess, tryptophan-activated TRAP binds to the 5′ SL and the triplet repeats. Bound TRAP blocks or disrupts formation of the antiterminator structure, which thereby allows formation of the terminator hairpin (stem-loop 2:3), which causes transcription to terminate upstream from the trp operon structural genes. See text for details. (b) Antitermination model for the *E. coli* bglGFB operon. Under noninducing conditions (limiting β-glucosides), the phospho-BglG monomers cannot bind to the nascent transcript. Thus, formation of a terminator hairpin (stem-loop 2:3) causes transcription to terminate. In the presence of β-glucosides, the BglG monomers are dephosphorylated, which allows them to dimerize. BglG dimers bind and stabilize the antiterminator structure (stem-loop 1:2), which prevents formation of the overlapping terminator, and transcription continues into the structural genes. Note that overlapping antiterminator and terminator hairpins are found in the leader region and between the bglG and the bglF coding sequences. See text for details.

Four amino acid residues within each TRAP subunit (E36, K37, K56, and K58) are critical for RNA binding (29). Three of these residues form KKR motifs that are aligned on the perimeter of the *B. subtilis* and the homologous *B. stearothermophilus* TRAP ring. Several crystal structures of *B. stearothermophilus* TRAP–RNA complexes show that the RNA wraps around the TRAP protein ring with the bases pointing toward the protein, such that the majority of the hydrogen bond interactions are with the RNA bases and there are no contacts to phosphates (21, 30). The only direct hydrogen bond to the RNA backbone is to the 2′ OH of the ribose of the third G in each repeat. K37 forms a hydrogen bond with the A of each GAG repeat, whereas K56, R58, and E36 hydrogen bond with the G in the third position of each repeat. The side chain of K37 also forms hydrophobic interactions with the base in the first residue of each repeat. The spacer bases do not make specific contacts with TRAP, which is consistent with the lack of sequence conservation in spacers of natural TRAP binding sites and with findings that indicate that their composition in general is not critical for TRAP binding.
A model of TRAP-trp leader RNA interaction that encompasses several recent findings is as follows. Once a sufficient number of triplet repeats emerge from RNAP (e.g., three or four repeats), TRAP binds to the nascent trp leader transcript by contacting the 5′SL and the emerging triplet repeats. The nature of these contacts orients the protein so the RNA easily can wrap around TRAP’s periphery as transcription continues. TRAP sequencesthe remaining repeats in a 5′ to 3′ directionality as they emerge from RNAP (31, 32). As the tenth and eleventh repeats bind, the 5′SL is displaced as a consequence of the geometry of the TRAP-RNA complex in which TRAP completely is encircled by RNA (24). In conjunction with RNAP pausing, this RNA binding mechanism ensures that TRAP binds in time to block formation of the antiterminator structure.

Transcription Antitermination Mediated by an RNA Binding Protein

RNA binding proteins are responsible for mediating antitermination of several catabolic operons in bacteria. BglG, SacT, SacY, and LicT belong to a family of more than 50 proteins that regulate gene expression by a common antitermination mechanism; antitermination is mediated by the RNA binding proteins SacT and SacY, respectively (33). The structure of the RNA binding domain of SacT has been solved by both NMR (36) and X-ray crystallography (37). The domain exists as a dimer with each monomer consisting of a four-stranded antiparallel β-sheet. The structure of the RNA-binding domain from the LicT antiterminator protein in complex with a 29 base RNA shows that LicT binds mostly through hydrophobic and stacking interactions with the RNA and that binding “clamps” the RNA so as to stabilize the antitermination structure (38).

Transcription Antitermination

Mediated by an RNA Molecule

Antiserine RNA- mediated transcription attenuation controls the copy number of several Gram-positive plasmids (reviewed in References 39 and 40). In the case of the Streptococcus agalactiae plasmid, pIPS01, the antiserine RNA (RNA III) inhibits expression of repR, which is the gene encoding the essential RepR inhibitor protein, by binding to the nascent repR leader transcript (RNA II) (Fig. 4a). This interaction promotes formation of an intrinsic terminator upstream of the repR coding sequence. In the absence of RNA III-RNA II interaction, an alternative structure forms in the nascent RNA II transcript that blocks formation of the terminator. Although this alternative structure is more complex, it is functionally analogous to the antiterminator structures described above.

Interaction of RNA III with RNA II is initiated by the formation of a so-called kissing complex between single-stranded loops of both molecules, followed by propagation of the intermolecular RNA helix (41). The kissing interaction involves base pairing between loops III and IV from RNA III with loops subsequently to β-glucosides. It seems that BglF recruits BglG to the cell membrane in the absence of β-glucosides such that the system can respond rapidly to the presence of the stimulating sugar (35).

Expression of two sucrose utilization operons in B. subtilis, sacPA and sacB, is induced by sucrose by similar transcription antitermination mechanisms; antitermination is mediated by the RNA binding proteins SacT and SacY, respectively (33). The structure of the RNA binding domain of SacY has been solved by both NMR (36) and X-ray crystallography (37). The domain exists as a dimer with each monomer consisting of a four-stranded antiparallel β-sheet. The structure of the RNA-binding domain from the LicT antiterminator protein in complex with a 29 base RNA shows that LicT binds mostly through hydrophobic and stacking interactions with the RNA and that binding “clamps” the RNA so as to stabilize the antitermination structure (38).
Attenuation, Control of Gene Expression by RNAP

Figure 4. (a) Transcription attenuation model of S. agalactiae plasmid pIP501-encoded repR. When the concentration of RNA III is low, the absence of RNA III interaction allows formation of the antiterminator structure (stem-loop 1:2), which blocks formation of the terminator that leads to transcription readthrough. When RNA III is abundant, the kissing loop interaction between loops L III and L IV of RNA III with loops L I and L II within the nascent RNA II (repR) transcript blocks formation of the antiterminator, which promotes formation of the terminator hairpin (stem-loop 2:3) and transcription termination in the repR leader region. The positions of the residues that correspond to L II of RNA II (stem-loop A:B) are included in each structure for clarity. See text for details. [Adapted from the Encyclopedia of Molecular Biology (1999) with permission (1).] (b) General T-box model of tRNA-mediated antitermination. Under excess amino acid conditions, the amino acid on charged tRNA does not allow interaction of the tRNA with the discriminator sequence in the nascent transcript. As a consequence, formation of the terminator (stem-loop 2:3) halts transcription in the leader region. Under limiting amino acid conditions, uncharged tRNA binds to the nascent transcript via anticodon-specifying sequence base pairing as well as by base pairing between the 3' end of tRNA and the discriminator region. This second interaction stabilizes the antiterminator structure (stem-loop 1:2), which results in transcription readthrough. The tRNA is shown as a cloverleaf structure, and a boxed A.A. attached to the tRNA indicates it is aminoacylated. See text for details. (Adapted from Reference 45 with permission.)

II and I of RNA II, respectively (42). Moreover, loop L1 of RNA II contains a YUNR (Y = C or U; N = A, C, G or U; R = A or G) “U-turn” motif that is important for the kissing interaction; mutations that disrupt the U-turn motif result in higher plasmid copy number (43). Although RNA III and RNA II share extensive sequence complementarity, complete pairing is not necessary to promote transcription termination of RNA II. The finding that inhibition of transcription readthrough is considerably faster than stable complex formation suggests that inhibition precedes stable pairing (41). Furthermore, complete pairing only occurs at a low frequency because pairing of complementary folded RNAs often arrests at the stage of stable binding intermediates (41).

Transcription Antitermination Mediated by an RNA Molecule

In several bacterial species, uncharged tRNA serves as the effector molecule in controlling expression of several aminoacyl-tRNA synthetase genes and a few amino acid biosynthetic operons by a common mechanism termed T-box antitermination.
Most of these genes are from Gram-positive bacteria, although a few examples have been identified in Gram-negative organisms as well (reviewed in References 44 and 45). Expression of these genes is induced specifically by starvation for the cognate amino acid. A generalized model of the T-box antitermination mechanism is shown in Fig. 4b.

The untranslated leader region of each operon contains several conserved structural elements preceding an intrinsic transcription terminator. When the amino acid pool in the cell is sufficiently high, transcription terminates prematurely in the leader region upstream from the coding sequences. In addition to the conserved secondary structures, a critical 21-nt sequence called the T box is present in each leader region. A more structure of the leader region, which forms when the T-box base pairs with the 5' terminus of the terminator stem, functions as an antiterminator, which allows transcription to read through to the structural genes (46).

A critical feature is that the region of T-box control is a trinucleotide sequence that corresponds to a codon for the appropriate amino acid involved in regulating the structural genes. For example, in tyrS, which encodes tyrosyl-tRNA synthetase, the leader contains a UAC tyrosine codon (46). This coden-like sequence is always present within an internal loop of a conserved RNA structure. This triplet is designated the "specifier sequence" because it specifically interacts with the antiterminator, which allows transcription to read through to the structural genes (46).

A second base pairing interaction between the acceptor end of uncharged tRNA and the complementary sequence in the T box leads to stabilization of the antiterminator structure. The antiterminator side bulges contain a UGGN sequence, where N corresponds to a variable T-box position that covaries with the residue preceding the CCA acceptor end of the cognate tRNA (47, 48). The presence of the amino acid on charged tRNA prevents this second interaction from taking place (49). Although tRNA interaction with the specifier and UGGN sequences is firmly established, substantial genetic data suggest that additional RNA–mRNA contacts take place (44).

Reconstitution of the B. subtilis gleQ5 T-box mechanism in vitro with purified components suggests that additional protein factors are not required for RNA-mediated antitermination (50). Furthermore, the finding that charged tRNA can compete with uncharged tRNA for mRNAs binding indicates that the ratio of uncharged:charged tRNA is monitored by the nascent transcript, rather than simply the concentration of uncharged tRNA (49).

Although codon–anticodon interaction takes place at least 100 nt upstream from the terminator, nascent transcripts that extend just upstream of the terminator are still competent for RNA binding and antitermination (49). Thus, it is possible that RNA-P pausing participates in this regulatory mechanism by providing additional time for RNA binding, although a regulatory pausing event has not been firmly established (51).

Under starvation conditions for the corresponding amino acid, the ratio of uncharged-to-charged tRNA is relatively high. In this case, efficient interaction of uncharged tRNA with both the specifier and the discriminator sequence elements of the nascent leader transcript promotes formation of the antiterminator structure, which allows transcription to proceed into the coding region. The resulting increase in the level of RNA synthetase presumably allows more efficient charging of the scarce amino acid. As the concentration of the amino acid increases, an increasing proportion of nascent transcripts will interact with charged tRNA. In this case, the terminator hairpin will cause RNA-P to terminate transcription in the leader region.

Transcription Attenuation Mediated by Metabolites

The most recently identified class of transcription attenuation mechanism involves direct sensing of the effector molecule by the nascent transcript (52–54). These RNA sensors control metabolically diverse pathways. As for the other attenuation and antitermination mechanisms discussed thus far, recognition of the particular effector molecule occurs with the appropriate affinity and high specificity required for precise control of gene expression.

Transcription Termination Mediated by a Small Metabolite

In B. subtilis, 26 genes grouped into 11 operons constitute the S-box regulon. These genes are involved in sulfur metabolism as well as in the biosynthesis of methionine, cysteine, and S-adenosylmethionine (SAM) (55–57). SAM, the effector of the S-box regulon, binds to the nascent transcript with exquisite specificity; the closely related SAM analog S-adenosylhomocysteine binds with much lower affinity to the RNA targets and does not promote transcription termination in vitro (54, 58, 59). A simplified model of SAM-mediated attenuation is presented in Fig. 5a. Under limiting SAM concentrations, the nascent S-box transcript adopts an antiterminator structure that allows transcription to proceed into the structural gene(s). However, under conditions of SAM excess, SAM binds to the nascent transcript and stabilizes the antiterminator structure, which blocks formation of the antiterminator. As a consequence, the terminator hairpin forms and transcription halted in the leader region.

High-resolution structural information has been obtained for several RNA sensors (56, 60–63). A common feature of the leader RNAs is that they form tertiary structures in which single-stranded loops base pair with another (pseudoknot). For example, the tertiary structure of the SAM-sensing RNA contains a pseudoknot that occurs between the loop of an RNA hairpin and the single-stranded junction between two other helices (64). This pseudoknot seems to stabilize the global architecture of the structure and probably facilitates SAM recognition (56). A more common characteristic of these structures is engulfment of the ligand by the binding pocket of the folded RNA (63).
Transcription Antitermination Mediated by a Small Metabolite

Adenine sensing by the nascent *B. subtilis* pbuE (*ydhL*) transcript constitutes the most recently described antitermination mechanism (63–65). Although this is the only reported example of this type of antitermination mechanism, it is likely that additional examples will be identified. A model that depicts this antitermination mechanism is shown in Fig. 5a. Under limiting adenine conditions, an intrinsic terminator hairpin forms in the nascent pbuE transcript, which causes RNAP to terminate transcription in the leader region. In the presence of excess adenine, adenine binds to the nascent transcript and stabilizes formation of an alternative antiterminator structure, which thereby allows transcription to continue into the pbuE structural gene (65). Adenine-mediated activation of pbuE expression makes biologic sense as it encodes an apparent purine efflux pump (66). Deletions of the adenine-binding domain of the leader RNA caused constitutive expression of pbuE and conferred resistance to 2-fluoroadenine, which suggests that PbUE can pump this adenine analog out of the cell (65, 66). Analog binding studies demonstrated that the binding affinity of adenine and 2-aminopurine are similar, whereas the affinity of 2,6-diaminopurine is considerably higher. However, the association rate was faster for adenine compared with the two purine analogs. This finding supports a model in which regulation depends on the kinetics of ligand binding and the rate of transcription, rather than simple binding affinity (67).

The structure of the pbuE leader RNA is similar to the guanine-dependent RNA sensor in the xpt leader transcript (65). It was shown that a single C to U substitution in the loop of a triple helical junction swapped the xpt aptamer specificity from guanine to adenine. Importantly, the pbuE leader contains a U in the identical position. These results led to the hypothesis that this U residue in the pbuE transcript paired with adenine, whereas the C residue in the xpt transcript paired with guanine. This hypothesis was verified by NMR structural studies. Moreover, it was determined that adenine binding to pbuE leader RNA involved a base triple with two U residues, which includes the previously proposed uridine (68).

Concluding Remarks

The discovery of transcription attenuation over 30 years ago led to the realization that mRNAs serve a purpose beyond simply functioning as a conduit of information from DNA to protein. Indeed, the discovery of transcription attenuation established for the first time that RNA structure can modulate gene expression. It is now abundantly clear that expression of many genes is controlled by several different mechanisms after transcription.
initiates. Furthermore, it is apparent that transcription attenuation occurs by a variety of mechanisms that differ in the nature of the effector molecule (translating ribosome, RNA binding protein, RNA molecule, small metabolite), whether the effector promotes transcription termination (attenuation) or transcription readthrough (antitermination), as well as the structure of the RNA target in the nascent transcript. Although each mechanism described in this review contains key differences, it is also apparent that all but one of these mechanisms share an important feature: the presence of mutually exclusive terminator and terminator structures. One point of view is that these RNA-based regulatory mechanisms are relics of an RNA world in which both the storage of genetic information and the metabolic function were carried out by RNA molecules. Conversely, it is conceivable that these regulatory mechanisms have evolved more recently. In either case, it is apparent that what was once viewed as a biologic quirk is widespread and has been adapted to suit the physiologic needs of perhaps every organism.

doi: 10.1002/9780470048672.wecb161

Epigenetic modifications play a fundamental role in chromatin structure and function. Histone modifications and DNA methylation regulate important biologic processes such as heterochromatin formation, genomic imprinting, X-chromosome inactivation, and transcriptional activation and silencing. Epigenetic mechanisms are responsible for a considerable part of the phenotype of complex organisms. The understanding of epigenetic modifications in chromatin may offer some clues to solve the mechanisms of cellular identity, tumorigenesis, stem cell plasticity, regeneration, and aging. These processes are of interest in the fields of human biology and human diseases. Here, we describe the principal components involved in epigenetic modifications, such as the enzymes that modify chromatin, the protein domains that recognize modified chromatin, some best-characterized downstream effectors, and the tools and techniques for studying epigenetics. However, the biological mechanism of the majority of components is still poorly understood, and the analysis of these components is fundamental to our understanding of epigenetics.

The identity of cells within an organism is determined by its heritable information, which is encoded by genetic and epigenetic information. Genetic information is the ordered sequence of nucleotides present in the genome of all cells of a given organism. Epigenetic information is based on epigenetic modifications, which are chromatin covalent modifications responsible for maintaining stable states of gene expression through mitotic divisions without alterations in DNA sequence. Although genetic information is homogenous throughout all cells within an organism, epigenetic modifications vary according to developmental programs that define the transcriptome of each cell type and ultimately determine the identity of cells (1). The epigenetic information of cells is stored as covalent modifications of DNA and histones. The most common epigenetic modification of DNA is the methylation of the 5' position of cytosines in the context of CpG dinucleotide (2). In addition, epigenetic modifications of histones include a variety of complex post-translational modifications, of which lysine acetylation and methylation and serine phosphorylation are the best characterized.

In the last decade, remarkable progress has been made to characterize epigenetic modifications and to associate specific patterns of modification with chromatin functionality. In this review, we will discuss the nature of DNA and histone epigenetic modifications. We will describe the modifying enzymes responsible for creating or eliminating each modification and the proteins that read such epigenetic modifications and recruit functional protein complexes. These are the downstream effectors that regulate chromatin structure and DNA accessibility.

The functionality of some chromatin modification patterns is well established; however, the vast majority remains poorly understood. Given that histones are subject to more than 100 post-translational modifications, considerable efforts to characterize the mammalian epigenome are ongoing.

Biological Background

Studies of a wide range of systems have contributed to our understanding of epigenetic processes in various model organisms. The majority of epigenetic processes are associated with gene silencing, for example, heterochromatin formation (3), genomic imprinting (4), X-chromosome inactivation (5), and Polycomb repression (6). In addition, the activation of transcription by the Trithorax group of genes is also an epigenetic mechanism (7).

Constitutive heterochromatin

The DNA within the cell exists as a nucleoprotein complex termed chromatin. Chromatin allows the packaging of DNA within the nucleus while at the same time is flexible...
epigenetic machinery (5). Gene silencing of the whole chromosome by recruitment of the Xist coats the entire inactive X chromosome, which leads to the X chromosome that will become silenced. This RNA transcript is likely that only a subset will have epigenetic inheritance. Whether the entire repertoire of histone modifications is heritable remains to be established. In fact, whether they are “epigenetic” in this sense or not is a matter of semantics, and the term may need to be redefined. Indeed Allis, Jenuwein, and Reinberg have proposed (10, 11) that epigenetics be defined as “the sum of the alterations to the chromatin template that collectively establish and propagate different patterns of gene expression (transcription) and silencing from the same genome.”

This definition includes transient chromatin modifications, which are associated with DNA repair or cell-cycle stages, and stable chromatin modifications that are maintained across multiple cell generations.

DNA methylation and the Polycomb/Trithorax system are the paradigms of epigenetic heritable systems. Cavalli and Paro (12) have shown that an activated state of the Fab-7 element, incorporated in transgenic flies, is inheritable mitotically through development and can be transmitted to the subsequent generations through female meiosis. This finding means that the Polycomb/Trithorax system can memorize gene expression patterns that have been set up by other cellular mechanisms.

The evidence that DNA methylation is heritable is self-sustaining. Maintenance DNA methylases recognize hemi-methylated DNA, the product of replication of the fully methylated DNA, and add methyl groups to the unmethylated DNA strand.

The study of epigenetic modifications is of great interest. Perturbations of chromatin structure can cause inappropriate gene expression and genomic instability that results in cellular transformation and malignant outgrowth. Proteins that control chromatin organization therefore constitute key players in cancer pathogenesis.

**Histone Modifications**

The DNA within the cell exists in the form of chromatin. The basic repeating unit of chromatin is the nucleosome, a structure consisting of 147 bp of DNA wrapped around an octamer of the core histones H2A, H2B, H3, and H4. The histone proteins are composed of a globular domain and unstructured and protruding N- and C-terminal tails. A striking feature of the tail histones is that they are subjected to several posttranslational modifications, which are associated with DNA repair or cell-cycle stages, and stable chromatin modifications that are maintained across multiple cell generations.

Histone modifications affect the organization of the chromatin to modulate its involvement in important nuclear functions such as DNA transcription, repair, and replication. The possibility that such combinations could modify chromatin behavior led to the hypothesis that they might constitute a molecular “histone code” (13) that is read by other proteins to mediate unique cellular responses.

A cetylation of the lysine residues of histones H3 and H4 was one of the first modifications of chromatin to be described (Fig. 1) (14). It is associated with the establishment of an open chromatin state that is active transcriptionally. This modification contrasts with hypoacetylation, which is associated with a compacted chromatin structure that is inaccessible to transcription machinery. The majority of all lysine residues of the N-terminal tails of histones H3, H4, H2A, and H2B have the ability to be...

![Histone modifications diagram](image_url)
Thus, SirT2 is a major contributor to the inheritance of epigenetic marks through mitosis (21). The methylation of histones can occur in various lysines of histone H3, such as K4, K9, K27, K36, and K79, and at lysine 20 of histone H4. Lysines can be mono-, di-, or trimethylated at all these sites. This modification could be associated with either the repression or activation of DNA transcription, depending on the site and methylation status (mono-, di-, or tri-) of the histone lysine residues. Chromatin immunoprecipitation (ChIP) experiments have shown that three methylation sites on histones are involved in transcriptional activation: methylation at lysine 4 (H3K4), at lysine 36 (H3K36), and at lysine 79 (H3K79) (22, 23). Three lysine methylation sites are connected with transcriptional repression: methylation of lysine 9 (H3K9) and lysine 27 (H3K27) of histone H3 and methylation of lysine 20 of histone H4 (H4K20). These modifications are epigenetic modifications of a repressed chromatin state (24).

Histone arginine methylation can be either mono- or dimethylated at residues R2, R8, R17, and R26 of histone H3 and at R3 of histone H4. It plays a role in transcriptional activation and repression. The biological mechanism of each histone arginine modification is mainly unknown; however some data implicates H4R3, H3R17, and H3R26 modifications with transcriptional activation. In contrast, H3R8 and H3R2 are associated with repression (25, 26). Furthermore, two different groups have recently provided the first mechanistic insight into the function of arginine methylation on chromatin (27, 28). They have shown that H3R2 is enriched throughout all silenced loci in budding yeast and that in all cases the pattern of H3R2me2 is mutually exclusive with the trimethylation of H3K4 (27), which marks active genes. The role of H3R2me2 in controlling H3K4me3 also is conserved in humans (28).

The phosphorylation of histones can occur at serine and threonine residues. The function of histone phosphorylation is related largely to either chromosome condensation and/or DNA repair of double-stranded breaks (DSBs). Phosphorylation at serine 10 of histone 3 (H3S10) plays a key role in chromosome condensation during mitosis (29). Phosphorylation at threonine 3 of histone 3 (H3T3) is required for normal metaphase chromosome alignment (30). Other lesser-known residues, such as phosphorylation at serine 1 of histone 4 (H4S1) and at serine 14 of histone H2B (H2BS14), also regulate chromosome condensation in budding yeast (31). Serine 139 of the histone variant H2A.X is phosphorylated in response to DNA DSBs and seems to be an early step in the response to DNA damage (32). Phosphorylation at other sites, such as serine 1 of histone H4 (H4S1), serine 129 of histone H2A (H2AS129), and serine 14 of histone H2B (H2BS14), also contribute to sense DSBs during DNA repair (33). In addition, the phosphorylation of histone H3 is involved in transcriptional activation through H3S10 or H3S28 (34).

**Histone-modifying enzymes**

The modification of histones is a dynamic process with contributing enzymes that can either direct or remove the modification. In the last 10 years, enzymes that play a role in both directions have been identified (Table 2).

**Epigenetic Modifications**

Histone acetyltransferases (HATs) form an extended family of enzymes that can be grouped into three families on the basis of sequence homology. The first of these families is the GNAT family (Gcn5-related N-acetyltransferase), which includes HAT1, the yeast Gcn5, and its human ortholog, PCAF. The second family is p300/CBP, which includes the two human paralogs p300 and CBP. The third family is the MYST family, which includes MOZ, Ybf2/Sas3, Sas2, and Tip60. Although HATs in general acetylate more than one lysine, some specificity has been detected. Structural comparison between the three families has shown that HATs contain a conserved core for Ac-CoA binding and that different domains fold around this core to facilitate substrate specificity (35). However, more analyses are necessary to elucidate the possible specificity of HATs for lysine residues.

Histone deacetylases (HDACs) are divided into four families on the basis of phylogenetic analysis. The class I family includes human HDAC1, HDAC3, and HDAC8, which are homologous to the yeast Rpd3. The class II family is homologous to the yeast Hda1 and is subdivided into the Iia (HDAC4, HDAC5, HDAC7, and HDAC9) and Iib (HDAC6 and HDAC10) subfamilies on the basis of their sequence homology. The class III family includes the NAD⁺-dependent enzymes of the Sir (or sirtein) family. Its components are yeast Hist proteins 1-4 and human Sirtuins 1-7. The class IV family contains the human HDAC 11. In general, HDACs are not specific for a particular acetyl group, but the sirtein family seems to prefer deacetylating the lysine 16 of histone H4 (36). The catalytic mechanism of the Sirtein family differs from those of other families in its use of NAD⁺ as a cofactor.

One important feature of HAT and HDAC enzymes is that they are integrated frequently within multiprotein complexes in which the noncatalytic subunits tend to regulate the substrate specificity that contributes to the molecular functionality in a cellular context.

Histone methyltransferases (HMTs) of lysines contain a catalytic SET domain of about 130 amino acids, with the exception of those of the Dot family. SET owes its name to the shared domain of the first three HMTs to be identified in Drosophila: Suppressor of position-effect variegation Su(var)3-9, Enhancer of Zeste E(z)2, and Trithorax (Trx). The HMTs can be classified into several families on the basis of the sequence homology within the SET domain and adjacent sequences (24, 37). The SET1 family includes the MLL family of proteins, which are homologous to the TRX proteins of Drosophila, and the Set1 protein of yeast. They specifically methylate lysine 4 of histone H3 linked to the activation of transcription. The SMYD family proteins also methylate H3K4 but include an MYND domain that binds to specific DNA sequences. The SUV39 family includes the SUV39H1 and SUV39H2 histone methyltransferases, SETDB1, and G9A, which specifically methylate lysine 9 of histone H3. The PRDM family contains a PR SET domain that is considered a subclass of the SET domain. The catalytic activity of the PRDM family is controversial. However, it includes crucial proteins such as RIZ1 and BLIMP1 that are associated with the methylation of lysine 9 of histone H3, which is important in regulating the gene transcription of many biological processes. The EZH family includes the two homologs of Enhancer of

Histone deacetylases (HDACs), histone acetyltransferases (HMTs), histone demethylases (HDMTs), protein arginine methyltransferases (PRMTs), histone arginine demethylases (HADs), and DNA methyltransferases (DNMTs).
Histone demethylases can remove all three histone lysine methylation states (mono-, di-, and trimethylation). The family is divided into several subfamilies, including JHDM1, JHDM2, JHDM3, JHDM4, JHDM5, JHDM6, and JHDM7. These demethylases have been associated with important roles in chromatin structure and development. For example, JHDM3 and JHDM4 demethylate H3K9 and H3K36, which antagonizes HP1 recruitment to chromatin and regulates gene expression. Moreover, very recent studies have confirmed the important role of histone demethylases in histone modification dynamics. It has been shown that four proteins of the JARID family possess the demethylase activity specific to H3K27 and contribute to cell-fate determination (39). Two more studies have established that members of the UTX/UTY family possess demethylase activity specific to H3K27 and are involved in HOX gene regulation and development (40, 41).

Histone arginine methylation is achieved by protein arginine methyltransferases (PRMTs), which are evolutionarily conserved from yeasts to humans. PRMTs are classified as Type I and II based on the nature of the methylation introduced. Type I catalyzes symmetric demethylation of arginine, and type II catalyzes the asymmetric one. Eleven PRMTs have been identified in humans based on sequence homology; however, their substrate specificity and their biologic functions still remain unknown. PRMTs catalyze many cellular proteins, and some of them also can methylate histones, such as PRMT1, PRMT4, PRMT5, and PRMT7 (26). PRMT1 methylates H4R3 contributing to transcriptional activation. PRMT4 or CARM1 can methylate H3R327 and H3R26, which are marks linked to gene activation. PRMT4 also can methylate H3R32 in vitro with low efficiency. PRMT5 methylates H3R38 and H4R3, and it has been copurified with chromatin remodeling complexes such as HSW1/SNF and NURD. It has been implicated also in transcriptional repression of cell cycle regulator and tumor suppressor genes. PRMT7 mediates H4R3 methylation at the imprinting loci in embryonic stem cells. Very recently, it has been shown that PRMT6 catalyzes asymmetric H3R2 dimethylation in human cells thereby preventing the recruitment of MLL histone acetyltransferase complexes and H3K4 methylation. Reciprocally, H3K4me3 prevents H3R2 methylation by PRMT6 (26).

Of special interest is the finding of the first histone arginine demethylase, the Jumonji domain-containing 9 protein (JMJD9). It shares homology with the jmjC domains found in the histone lysine demethylases. JMJD6 can demethylate H3R2 and H4R3 in biochemical and cell-based assays (42). The recent data that are emerging place histone arginine methylation as a key player of cell growth and cell proliferation processes.

Reading the histone modifications

Histone modifications generate two types of downstream effects on chromatin organization. The first type is produced mainly by the acetylation of lysine residues, which neutralize positive charges of lysine and allow the unfolding of the chromatin through an electrostatic mechanism. The DNA then is more accessible to the transcription machinery. The second effect arises from the generation of docking sites that are read by specific proteins with the purpose of tethering enzymatic activities to the chromatin.

The acetylation of lysines is recognized by the bromodomains, which are small domains included in an extensive family of proteins. The first bromodomain was identified in the Drosophila Brahma protein. Bromodomains were later found widely distributed among different enzymes that acetylate, methylate, or remodel chromatin (43). The bromodomain is present in the members of different families of histone acetyltransferases, such as the Gcn5/PCAF and p300/CBP families. They also are part of some histone methyltransferase enzymes such as Ash1, RIZ, and MLL. Bromodomains are important components of the remodeling enzymes that use ATP to remodel chromatin structure, such as BRM or members of the SWI/SNF complexes. Sequence-specific lysine acetylation recognition by a bromodomain is dependent on how the bromodomain recognizes residues flanking the acetylated lysine, but currently the exact specificity is poorly understood.

Different protein domains recognize the methylation of lysine: the chromodomains, the Tudor domain, the WD-40 repeat, and the PDZ domain. The chromodomain of HP1 within heterochromatin, HP1 can recruit other heterochromatins as the histone methyltransferases Suvar3-9 and deacetylases. Methylation of lysine 27 of histone H3 is recognized specifically by the chromodomain of HP1 within heterochromatin. HP1 can recruit other heterochromatins as the histone methyltransferases Suvar3-9 and deacetylases. Methylation of lysine 27 of histone H3 is recognized specifically by the chromodomain of HP1 within heterochromatin. HP1 can recruit other heterochromatins as the histone methyltransferases Suvar3-9 and deacetylases. Methylation of lysine 27 of histone H3 is recognized specifically by the chromodomain of HP1 within heterochromatin. HP1 can recruit other heterochromatins as the histone methyltransferases Suvar3-9 and deacetylases. Methylation of lysine 27 of histone H3 is recognized specifically by the chromodomain of HP1 within heterochromatin. Methylation of lysine 27 of histone H3 is recognized specifically by the chromodomain of HP1 within heterochromatin. HP1 can recruit other heterochromatins as the histone methyltransferases Suvar3-9
chromatin unfolding. Secondly, histone modification can create a docking site that can be read by a protein domain. This protein may act as an independent effector or alternatively tether other complexes with different enzymatic activities that collectively modify the chromatin environment in response to histone modification. In this section, we will discuss some best-characterized biologic processes that involve specific histone modifications. Histone modification is of paramount importance to the establishment of constitutive heterochromatin at centromeres.

**Figure 2**  Constitutive heterochromatin at centromeres. a) Mammalian centromere model. SUV39H1/2 produces H3K9me3 residues, which are recognized by the chromodomain protein HP1α and HP1β. Both proteins interact with other HMTs, such as SUV420H1/2, that methylate adjacent histones that lead to the spreading of heterochromatin. Mammalian heterochromatin is enriched in H3K9me3 and H4K20me3 residues.
b) S. pombe centromere model. The assembly of centromeric heterochromatin in S. pombe is very well established. The components of the RNAi machinery play an essential role. Dicer produces siRNA from the centromeric dsRNA transcripts. siRNA are loaded within the RITS (RNA-induced transcriptional gene silencing) complex to target heterochromatin by recruiting Clr4, which methylates lysine 9 of histone H3. H3K9me2 will be recognized by Swi6 and Chp1. Chp1 is part of the RITS complex that also includes Ago1 and with the RDRC complex (which contains Rdp1, an RNA-dependent RNA polymerase) and dicer process nascent transcripts into siRNA. Clr4 will be recruited in a positive feedback loop that propagates the heterochromatin. Methylation of lysine 9 is accomplished after recruiting histone deacetylases (HDAC) complexes to heterochromatin to deacetylate lysine 9 residues.
Epigenetic Modifications

(Fig. 2) The histone methyltransferase SUV39H1/2 trimethylates lysine 9 of histone H3, which generates targets for the chromodomain-containing proteins HP1α and HP1β. HP1 molecules recruit other histone methyltransferases, like SUV39H1/2 and SUV420H1/2, that di- and trimethylate histones of adjacent sequences spreading the heterochromatin (44) (Fig. 2a). The initial targeting of SUV39H1/2 to heterochromatin involves components of the RNAi silencing machinery, as has been shown in the centromeres (Fig. 2b) of Schizosaccharomyces pombe. Centromeric transcripts can generate siRNA that are loaded within the RITS (RNA-induced initiation of transcriptional gene silencing) complex to target heterochromatin, probably by base-pairing homology with centromeric transcripts. The RITS recruit Clr4, the S. pombe homolog of Clr4, that will methylate lysine 9 of histone H3, acting as recognition sites of the S. pombe homolog of HP1, Swi6, and favoring heterochromatin spreading (45).

DNA methylation also is present within tandem-repetitive DNA sequences in the heterochromatin. They also are thought to inhibit recombination between homologous repeats, which could lead to genomic instability (46). In fact, mutations of the DNMT3b cause centromeric instability. In addition, HDACs lie at the heart of heterochromatin pathways and can be recruited by transcriptional repressor or by methyl–DNA binding proteins.

The epigenetic gene silencing by Polycomb protein complexes is one of the best examples of how epigenetics modulate gene transcription across generations. When the Polycomb repressive complex 2 (PRC2) is recruited to the Polycomb target genes, its histone methyltransferase component, EZH2, trimethylates lysine 27 residues of histone H3 (Fig. 3). The Polycomb repressive complex 1 (PRC1) can recognize trimethylated H3K27 through the chromodomains of the Polycomb protein, a component of the PRC1. This interaction might bring adjacent nucleosomes into the proximity of the PRC2 complex to facilitate widespread methylation over extended chromosomal regions. PRC1 mediates recruitment of DNA methyltransferases, chromatin compaction, and ubiquitylation of the lysine 119 of histone H2A, which is thought to contribute to transcriptional inhibition, but the precise mechanism of gene silencing is unknown (46). Very important contributions to this biologic process have been made recently. The proteins UTX and JMJD3 can demethylate H3K27me3 within the HOX genes, which leads to transcriptional activation. Moreover, UTX can associate with the H3K4me3 histone methyltransferase MLL2. This association is consistent with a model in which the coordinated removal of repressive marks, the polycomb group displacement, and the deposition of activating marks are important for the stringent regulation of the transcription during cellular differentiation (40, 41).

Figure 3  Epigenetic gene regulation of HOX genes by Polycomb complexes and H3K27 demethylases. The HMT EZH2 is a component of the PRC2 complex, and its binding to the HOX genes leads to H3K27me3, which is recognized by the PRC1 complex through its Polycomb member. The polycomb binding produces chromatin compaction and transcriptional repression. The mechanism of transcriptional repression is unknown but might be achieved either by the ubiquitylation of the H2AK119 by the ubiquitin E3 ligase activity present in the PRC1 complex or by the recruitment of DNA methyltransferases by the PRC2 complex. Recently, two H3K27 demethylases associated with MLL2 have been identified. Moreover, UTX associates with MLL2, an H3K4me3 HMT. These results suggest a model in which H3K27 demethylases associated with MLL2 can reverse the transcriptional silencing mediated by Polycomb. The complex would remove H3K27me3 residues and create H3K4me3 marks that lead to the activation of transcription. In this model, the hypothetical association of the PRC2 complex with H3K4me3 demethylases facilitates transcriptional silencing.
The best-characterized model that describes the activation of transcription at a molecular level has been developed in Saccharomyces cerevisiae (47). Activator factors recruit the Rad6–Bre1 complex, which is loaded into RNA polymerase II (RPNII) and catalyzes the ubiquitylation of lysine 123 of histone H2B (Fig. 4). This ubiquitylation favors the recruitment of the histone methyltransferases Set1, Set2, and probably Dot1. Ubiquitylation is necessary for methylation of H3K4 and H3K79 by Set1 and Dot1, respectively. During elongation, the C-terminal domain of RNP II is phosphorylated at serine 2 and Set1 dissociates from RNP II, whereas Set2 methylates H3K36. H3K4 serves as a binding site for the recruitment of histone acetyltransferase SAGA complex through a specific interaction between methyl H3K4 and the chromodomain of its component Chd1. Histone acetylation by the SAGA complex leads to transcription activation. An important contribution has been made recently regarding the implication of histone arginine methylation in transcription. The activity of the Set 1 complex is regulated by the asymmetric dimethylation of H3R2. The patterns of H3R2me2a and H3K4me3 are mutually exclusive because H3 R2 methylation can prevent Spp1, a component of the Set1 complex, from binding H3K4me3 (27).

DNA Methyltransferases are responsible for maintaining the methylation patterns following DNA replication. DNMT1 exhibits a 5- to 30-fold preference for hemimethylated substrates. This property led to the identification of DNMT1 as the enzyme responsible for maintaining the methylation patterns following DNA replication. DNMT3a and DNMT3b were identified by EST database searches and were proposed as the enzymes responsible for de novo methylation. DNMTs originally were classified as either maintenance or de novo DNA methyltransferases, but several lines of evidence indicate that all three DNMTs cooperate and possess both these functions in vivo (49).

The cell reads the DNA methylaction code by the methyl-CpG binding proteins (MBDs). This family of proteins consists of five members, MeCP2, MBD1, MBD2, MBD3, and MBD4. They target the transcriptional repressive chromatin machinery to hypermethylated CpG islands (50). The first finding connecting DNA methylation and chromatin modification involved MeCP2, which can repress the transcription of methylated DNA through the recruitment of a histone deactylase complex, HDAC. Other evidences that connect DNA methylation with histone modifications are that DNMTs and MBDs recruit repressive HM Ts and HDACs complexes (51).
